- “You could deal with problems beforehand. I had already seen what has been discussed, what she herself has said, and then you could just go from there. That then ultimately leads to shorter, more concise consultation times.” [HCP interviewee #19]

Textbox 2. Quotes from three health care professionals (HCPs) to emphasize improvements in quality of patient care from using the digital patient monitoring and management tool.

- “It became evident that we can use it for a more structured follow-up of the side effects of the treatments and symptoms of the patients.” [HCP interviewee #15]
- “For the data quality, for the care, it is a benefit. Undoubtedly. And they all felt really well cared-for, no doubt about it.” [HCP interviewee #13]
- “Perhaps some points are red [high severity] or newly yellow [medium severity], then you can say, ‘They must come to therapy earlier so that the doctor can talk to them directly and decide whether they would need only/either treatment or perhaps even hospitalization.’” [HCP interviewee #14]

Use of the DPMM Tool’s Individual Functions

Among HCPs who responded to the end-of-study survey, the most commonly appreciated functions of the tool were the patient symptom alerts (26/27, 96%) and the direct message communication function between patients and HCPs (19/27, 70%; see Table 7). Other important features for HCPs were the ability to use the tool during patient consultations (15/27, 56%), the facilitation of more effective conversations and referrals between nurses and physicians through the triage function

(13/27, 48%), the ability to use the tool during telephone consultations (13/27, 48%), and the onboarding of patients (13/27, 48%) (see Table 7).

Results from the end-of-study survey showed that patients had a similar preference with regard to the tool's functions; the most commonly appreciated functions were the symptoms questionnaire (20/21, 95%) and the direct message communication function between HCPs and patients (9/21, 43%). The patient card content—a PDF that could be completed digitally—offered to patients treated with atezolizumab was also appreciated; 2 of the 4 (50%) patients responding to the survey used the function (see Table 7). The median time to fill out the symptom questionnaire ranged from 2 minutes and 18 seconds (Clinic D, Germany) to 9 minutes and 56 seconds (Clinic J, Germany); the mean median time for questionnaire completion was 4 minutes and 14 seconds (see Multimedia Appendix 7).

Table 7. Functions of the digital patient monitoring and management (DPMM) tool most commonly appreciated by end-of-study survey respondents.

Functions of the DPMM tool	Nurses (n=19), n (%)	Physicians (n=8), n (%)	Patients (n=21), n (%)
Monitor the patient's symptoms	18 (95)	8 (100)	N/A[a]
Analyze the collected patient information	2 (11)	4 (50)	N/A
Draw patient reports	2 (11)	1 (13)	N/A
Directly communicate with the patients	14 (74)	5 (63)	N/A
Have more effective conversations and referrals between nurses and physicians	8 (42)	5 (63)	N/A
Use the tool during patient consultations	9 (47)	6 (75)	N/A
Use the tool during telephone consultations	7 (37)	6 (75)	N/A
Onboard patients to the tool	10 (53)	3 (38)	N/A
Symptoms questionnaire	N/A	N/A	20 (95)
Chat function	N/A	N/A	9 (43)
Patient card (n=4)[b]	N/A	N/A	2 (50)
Educational material[c]	N/A	N/A	3 (14)

[a] N/A: not applicable. This function was not relevant to this user group.

[b] Patient cards were part of the atezolizumab-specific material and were only relevant to patients treated with atezolizumab, of whom 4 responded to the survey.

[c] Educational material was offered to all 21 patients, although atezolizumab-specific educational material was offered only to atezolizumab-treated patients.

Impact of Individual Functions of the DPMM Tool on Users

Ratings from the end-of-study survey respondents demonstrated that the tool empowered patients, helping them to feel more in control (patient mean rating 3.9, SD 1.2), increasing their feelings of safety during their treatment (patient mean rating 3.9, SD 1.2), and helping them to feel more secure in evaluating their symptoms (patient mean rating 3.8, SD 1.3) (see Multimedia Appendix 8). HCPs appreciated the compact overview of patient development offered by the dashboard (HCP mean rating 4.25, SD 0.70) (see Multimedia Appendix 8).

Overall, according to in-module activities, the drug- and indication-specific educational material within the tool was engaged by, based on the number of downloads, 80% of patients (36/45) (see Multimedia Appendix 9), with two of the three atezolizumab-specific material items engaged by all 4 of the patients treated with atezolizumab who responded to the survey. Total median article viewing time across all clinics for the drug- and indication-specific educational material was approximately 3.5 hours; the longest viewing time was observed for the breathing exercises video, which was 1 hour, 28 minutes, and 56 seconds (see Multimedia Appendix 10). According to the end-of-study survey, the educational material was found by all users to be very helpful and informative, especially the lung cancer material (mean user rating 4.30, SD 0.73), the breathing exercises video (mean user rating 4.20, SD 0.93), and the CIT video (mean user rating 4.1, SD 0.7) (see Multimedia Appendix 8). The atezolizumab-specific material (ie, patient card, information on preparing for first infusion and treatment, and medication-specific material) received the highest rating of any of the materials offered; all 4 atezolizumab-treated patients who responded to the survey rated it as 5 (see Multimedia Appendix 8).

Discussion

Principal Findings

The CIT+ module that we co-developed with HCPs and patients was tested by physicians, nurses, and patients who considered themselves competent, proficient, or expert users. Most of them used the tool weekly (patients) or multiple times per week

(HCPs), and most used the tool for 10 minutes or less per session. As this was a pilot study, a population sample representative of the general cancer population was not its purpose.

Overall, the results of our proof-of-concept pilot study demonstrate that user acceptance of the tool was high, with usefulness and communication being the most appreciated attributes. Mean ratings were consistently over 3.5, which, similar to previous studies, were assumed to indicate high agreement [60]. A pilot study assessing the Diabetes Family Teamwork Online intervention in patients with type 1 diabetes also used a Likert scale, but a 7-point scale rather than a 5-point scale [61]. However, similarly, the study deemed approximately 70% of the maximum score to equal high feasibility [61]. In this study, the symptom questionnaire and symptom alerts were the most commonly used functions of the DPMM tool among patients and HCPs, respectively, followed by the direct message communication function and the drug- and indication-specific educational material. The symptom alert function was a key element, enabling HCPs to define alerts for particular symptoms and severity. HCPs stated that this enabled them to detect and manage critical symptoms earlier and personalize treatment plans, a result aligned with findings from other similar studies [24,62,63]. Our results highlight the essential features that a DPMM tool should include to better serve the needs of both patients and HCPs in clinical practice. Currently, few available tools combine all these features [20].

All survey respondents agreed that the attributes of the DPMM tool enabled more efficient and focused communication between patients and HCPs; this positive impact on communication has also been reported in previous studies [38,51,62]. Furthermore, the tool empowered patients, which has been shown to be correlated with an improved QoL [64,65], and helped them to evaluate and monitor their symptom progression.

In general, HCPs believed that the standalone tool was well integrated in their daily clinical workflow and improved efficiency within the health care team. This is based on positive insights from interviews (see Table 6), where HCPs reported improvements in quality of care and communications with the care team as well as time savings in patient visits with tool use, allowing for more clinically meaningful time with patients. Such positive insights are consistent with previous similar studies [66-68]. However, in this study, time savings were sometimes compromised by interoperability issues, such as lack of tool integration into the information technology (IT) system of the clinic and, consequently, data having to be gathered from both the web-based Kaiku Health platform and the clinic IT system. This challenge has been demonstrated in numerous other studies [38,40,69-71]. However, it should be resolved once the interoperability and system integration are incorporated beyond the pilot study as participating clinics and hospitals undertake complete rollout.

Notably, in addition to the time savings reported per patient visit by some HCPs, the tool also has the potential to free up time by decreasing the need for unscheduled outpatient appointments and telephone consultations, as reported by some patients (see Table 5). This is consistent with a possible reduction of scheduled visits in lung cancer patients following use of a DPMM tool that enables early detection of critical symptoms [23]. Considering most HCPs invested up to 30 minutes in introducing patients to the tool, and half of them saved 5 minutes or more per consultation, the time invested in patient onboarding was repaid within a few visits. The time saved through use of the DPMM tool can be invested in addressing other patient needs or serving more patients, highlighting the health-economic benefits of the tool.

Compared with studies of other ePRO-based tools, the CIT+ tool studied here showed similar high feasibility, patient engagement, and patient satisfaction [62,72-74]. However, the CIT+ module also harnesses features not commonly seen in other tools. For example, a 2019 systematic review of existing electronic symptom reporting systems developed for patients during cancer treatment found that fewer than half included a feature for delivering advice to patients in symptom self-management, and fewer than a third gave patients access to general educational information [20]. An even less common feature was the facility to support patient-HCP communication (15%) [20]. The CIT+ tool currently harnesses all these features, which is pertinent considering that previous research has indicated communication features, in particular, to be highly valued and utilized by patients [75-77].

Based on the results of this pilot study and insights from other studies, we propose several recommendations for future use in clinical practice or in study settings. For both, a positive and easy user experience is essential (eg, via optimization of the user interface), thereby enabling a choice of symptoms to be reported, as is providing automated contextual information according to user needs. In a clinical practice setting, a higher workflow efficiency and a much earlier detection of critical symptoms could be achieved with a seamless integration into the clinical workflow. Hence, integration into the local electronic health record system would be beneficial but may require substantial initial investments, given the complexities of existing systems. Such an integration may also enable local integration of patient self-management information and materials; these materials have been shown to be critical in supporting patient self-monitoring [77-79]. Integration may further enable connections to local resources and services, such as mental health or other supportive services, which can improve personalization of treatment according to patient needs and local standards. An enhanced local integration and tailoring to patient needs may improve adherence and allow patients to review and monitor their own data, which is the case for barely half of current ePRO systems [20].

In a clinical study setting, where assessment standards can be defined centrally and where stratified randomization of patients into standard-of-care control cohorts is possible, it is of interest to assess impact of the DPMM tool on patient outcomes and health care resource utilization and subsequently optimize for these elements. Regarding patient outcomes, assessment of QoL [22,23], in particular time to deterioration of symptoms and symptom development or adverse event intensity and duration over time, are important. Patients' abilities to work, their mental well-being, their self-care needs, and their self-efficacy are also important to assess. In regard to health care resource utilization, assessment of hospitalization days and emergency room visits [22], duration and adherence of treatment, co-medication use, and supportive care costs could yield valuable insights into the impact of a DPMM tool on clinical practice.

Limitations of the Study

A key limitation of this pilot study was its small sample size and single-arm design. Also, due to disease severity, the study was only able to recruit one participant for the patient advisory board. Further to this, DPMM tools are currently rarely used in routine clinical practice; as a result, there could be a bias for inclusion of sites, HCPs, and patients who are more accepting of these tools from the outset and are, therefore, more positive about their use. There are also several limitations associated with the chosen methods of data collection in this pilot study, namely surveys and interviews. Both rely on memory for answering questions, which may affect accuracy of the information received; furthermore, some bias may be created as participants who chose not to respond to survey questions or to participate in HCP interviews may have had different opinions from those who did so. Closed-ended questions, like those in our surveys, may have lower validity than open-ended questions, and answer options may be subject to the interpretation of different respondents. Finally, as discussed above, our DPMM tool was not integrated into the local electronic health record and patient management IT systems but was used as a standalone tool, which led to patient information needing to be gathered and recorded twice, causing additional workload for HCPs. This may have impeded HCPs from having an even more positive experience with the DPMM tool, thereby hampering their positive perceptions of the impact of the tool on clinical workflow efficiency. Hence, integration of the DPMM tool into the clinical IT data flow will be an important aspect of efficient routine clinical practice in the future. These limitations will be addressed in planned studies to evaluate the impact of the DPMM tool on patient health and health-economic benefits in a broader, better implemented, and more comprehensive approach.

Conclusions

Our results demonstrate high user satisfaction and acceptance of DPMM tools by HCPs and patients and highlight the contributions that DPMM tools can make to clinical care of patients with advanced or metastatic NSCLC treated with CIT monotherapy. Findings here will offer an incentive for continuous improvement and development of our tool, so that a platform can be provided that best serves the needs of HCPs and patients in this and other indications. The results add to the growing evidence base that DPMM tools can improve management of patients with cancer, empower patients, and have a health-economic impact by saving time in visits and reducing the need for patient telephone consultations [21,22]. Improvements in patient care have also been observed following the introduction of DPMM tools in other disease areas, such as multiple sclerosis [80-82]. Further studies or registries that allow investigation of the use of our DPMM tool may provide insights into whether its use would have any significant effect on other outcome measures, such as patient survival or QoL, or on health-economic benefits.

Acknowledgments

We would like to thank all the patients, HCPs, and investigators involved in this study. We would also like to thank Dr Sepiede Azghandi, Roche Pharma AG, Germany; Alexandra Schmid and Dr Flurina Pletscher, Roche Pharma AG, Switzerland; and Dr Anssi Linnankivi, Roche Oy, Finland, for their support with study setup and conduct. We would also like to thank Taina Hintikka, Roche Oy, Finland, and Claudia Hanselmann, Roche Pharma AG, Switzerland, for operational study support. This study was sponsored by F Hoffmann-La Roche Ltd, Basel, Switzerland. The study sponsor was involved in the study design, analysis and interpretation of data, writing of the article, and the decision to submit the manuscript for publication. Support for third-party writing assistance for this manuscript, furnished by Katie Wilson, PhD, and Stephen Salem, BSc, of Health Interactions, was provided by F Hoffmann-La Roche Ltd.

Authors' Contributions

OS contributed to the study concept and design; acquisition, analysis, or interpretation of data; and drafting of the manuscript. CJ is an external consultant for F Hoffmann-La Roche Ltd; CJ led the study design, was responsible for reporting, and contributed to the study concept; acquisition, analysis, or interpretation of data; drafting of the manuscript; and statistical analysis. JA contributed to acquisition, analysis, or interpretation of data and drafting of the manuscript. BL contributed to acquisition, analysis, or interpretation of data. SI contributed to the study concept and design; acquisition, analysis, or interpretation of data; and drafting of the manuscript. MK served as an external consultant for F Hoffmann-La Roche Ltd; MK was involved in the study operations, data collection, and reporting and contributed to the study concept and design; acquisition, analysis, or interpretation of data; drafting of the manuscript; and statistical analysis. JK contributed to acquisition, analysis, or interpretation of data and drafting of the manuscript. AK contributed to the study concept and design and the acquisition, analysis, or interpretation of data. RP contributed to acquisition, analysis, or interpretation of data. All authors contributed to critical revision of the manuscript for important intellectual content.

Conflicts of Interest

All authors received support for third-party writing assistance for this manuscript, provided by F Hoffmann-La Roche Ltd, Basel, Switzerland. OS and BL have acted in an advisory and consultancy role for F Hoffmann-La Roche Ltd (payment planned). CJ and MK have received honoraria from, and have acted as external consultants for, F Hoffmann-La Roche Ltd. JA and AK are employees of, and hold shares and stocks in, F Hoffmann-La Roche Ltd. SI has acted in a consultancy and advisory role for Bristol-Myers Squibb, Roche, and Merck Sharp & Dohme; has participated in a speaker bureau or provided expert testimony for Boehringer Ingelheim; is an employee at an institution that has received a research grant or funding from Roche; and has received travel and accommodation expenses from Boehringer Ingelheim, Merck Sharp & Dohme, Roche, Novartis, and Kaiku Health. MK is a part-time contractor for F Hoffmann-La Roche Ltd. JK has received honoraria from AstraZeneca, Bristol-Myers Squibb, Boehringer Ingelheim, Merck Sharp & Dohme, Novartis, Pfizer, Pierre Fabre, Roche, and Takeda; has acted in a consultancy and advisory role for AstraZeneca, Bristol-Myers Squibb, Boehringer Ingelheim, Faron, Kaiku Health, Merck Sharp & Dohme, Novartis, Pfizer, Pierre Fabre, Roche, and Takeda; has received a research grant or funding from Roche; and has received travel and accommodation expenses from AstraZeneca, Bristol-Myers Squibb, Boehringer Ingelheim, Faron, Kaiku Health, Merck Sharp & Dohme, Novartis, Pfizer, Pierre Fabre, Roche, and Takeda. MG is an employee at an institution that has received honoraria from F Hoffmann-La Roche Ltd. RP has acted in a consultancy and advisory role for Roche, Novartis, Merck Sharp & Dohme, Merck, Lilly, Bristol-Myers Squibb, AstraZeneca, Vifor Pharma, and Nutricia (all payments received by the institution) and is an employee at an institution that has received a research grant or funding from Roche, Novartis, Sanofi, and AbbVie.

Abstract

Background: Consumer-oriented mobile self-diagnosis apps have been developed using undisclosed algorithms, presumably based on machine learning and other artificial intelligence (AI) technologies. The US Food and Drug Administration now discerns apps with learning AI algorithms from those with stable ones and treats the former as medical devices. To the author's knowledge, no self-diagnosis app testing has been performed in the field of ophthalmology so far.

Objective: The objective of this study was to test apps that were previously mentioned in the scientific literature on a set of diagnoses in a deliberate time interval, comparing the results and looking for differences that hint at "nonlocked" learning algorithms.

Methods: Four apps from the literature were chosen (Ada, Babylon, Buoy, and Your.MD). A set of three ophthalmology diagnoses (glaucoma, retinal tear, dry eye syndrome) representing three levels of urgency was used to simultaneously test the apps' diagnostic efficiency and treatment recommendations in this specialty. Two years was the chosen time interval between the tests (2018 and 2020). Scores were awarded by one evaluating physician using a defined scheme.

Results: Two apps (Ada and Your.MD) received significantly higher scores than the other two. All apps either worsened in their results between 2018 and 2020 or remained unchanged at a low level. The variation in the results over time indicates "nonlocked" learning algorithms using AI technologies. None of the apps provided correct diagnoses and treatment recommendations for all three diagnoses in 2020. Two apps (Babylon and Your.MD) asked significantly fewer questions than the other two ($P<.001$).

Conclusions: "Nonlocked" algorithms are used by self-diagnosis apps. The diagnostic efficiency of the tested apps seems to worsen over time, with some apps being more capable than others. Systematic studies on a wider scale are necessary for health care providers and patients to correctly assess the safety and efficacy of such apps and for correct classification by health care regulating authorities.

KEYWORDS

artificial intelligence; machine learning; mobile apps; medical diagnosis; mHealth

Introduction

Algorithms and machine learning (ML) have conquered, transformed, and essentially revolutionized people's everyday lives in many aspects (eg, with personalized Google searches, self-driving cars, or convenient smartphone apps) [1,2]. In recent years, self-diagnosis apps have emerged that allow patients to look for a diagnosis based on entered symptoms [3,4]. ML is already being standardly used in various applications like estimating diagnoses from radiology images [5], but the adoption and acceptance of new technologies in health care in general is curbed by trust issues, strict regulations, and lack of thorough investigation [3,6]. Little testing of the aforementioned apps has been previously performed; Semigran et al tested self-diagnosis apps in general in 2015 but did not mention ML as an underlying technology [7]. A recent scoping review by Aboueid et al in 2019 named several apps of this type [3], but only two have been tested in their diagnostic functionality so far [8-10]. The US Food and Drug Administration (FDA) had previously excluded "symptom checker" apps from the enforcement of the strict rules that are usually applied to medical devices [11] but has lately released a white paper with a proposal for possible changes in the regulation of self-diagnosis apps, introducing a new discrimination between "locked" and artificial intelligence (AI)–based/ML-based learning algorithms, with the latter falling under a stricter set of rules [12]. However, the provided definitions of the two categories are still vague and rely on the manufacturer admitting the use of AI-based technologies rather than on hard criteria. Repeated examinations of such apps would offer insight into whether the results they offer are stable over time or change, which would also indicate actual use of "learning" AI technologies by the manufacturers, rendering the apps more than plain symptom checkers. Thus, the first aim of this study was to test apps that have previously been mentioned in the scientific literature on a set of diagnoses and to subsequently follow up on the results after a deliberate time interval to determine whether the algorithms change over time. A significant change in the results might indicate that learning algorithms are used by the manufacturers.

None of the aforementioned studies had tested self-diagnosis apps in the field of ophthalmology, the author's primary specialty with over 12 years of clinical experience. Thus, the second aim of the study was to test the efficacy of self-diagnosis apps by presenting them with three common diagnoses representing three levels of urgency in this field to see if their results and treatment recommendations match those of someone familiar with the topic.

Methods

Overview

The mobile apps were tested on Android 9 and Android 10, and the web app was tested on Google Chrome for OSX. All tests took place in Germany, and in all cases the English user interfaces were used. For all apps, up-to-date versions in the Google Play Store or on the internet were used; they correspond to the dates noted for each of the diagnostic walk-throughs (see Multimedia Appendix 1). The programs that were included in the testing were those that have been mentioned in the scientific literature: Ada [3,8,13], Babylon Health or Babylon Check [3,9,13], Buoy Health [14], and Your.MD [13]. Excluded from testing were Baidu Doctor [15], which is available only in Chinese, and K Health [3], which could not be downloaded onto the devices due to regional unavailability on iOS and unresolvable compatibility issues on Android, which may also stem from regional restriction without explicit notification. While there are reports about Buoy that claim that an Android-based app is in development, at the time of testing it could only be used as a web app [16]. The basic functional principles as understood by the author or described by the software developers themselves and recent literature, including gray literature where scientific literature was unavailable, were summarized. There is no consensus on broad testing of AI-based apps yet, but in the past, symptom checker apps have been tested using a randomized set of virtual diagnoses combined with gathered patient information in sets called vignettes [7]. The same setup has been used recently in a 2018 study by Razzaki et al to test Babylon Health [10] and in a 2019 study by Jungmann et al to test Ada Health in the field of mental disorders [8]. Only one physician creating one virtual patient per diagnosis was involved in this work; thus, an abbreviated and simplified version of this procedure was performed as follows. Three defined diagnoses from the ophthalmology branch of medicine were entered via the apps' given user interfaces: representing an absolute emergency (immediate treatment recommended), a glaucoma attack in one eye with the typical combination of a painful red eye for about two hours, blurred vision, a headache, and other symptoms depending on how each app asked its questions (see Multimedia Appendix 1 for the walk-through of all diagnoses as experienced); as a relative emergency (same-day treatment recommended), a retinal tear; and as a diagnosis that does not need immediate treatment and may also be self-treated first, dry eyes. For all three diagnoses, there are no strict general clinical therapy guidelines available, but some regional societies offer general recommendations [17-19]. The symptoms of all three diagnoses are common knowledge in ophthalmology and are thoroughly examined in the American Academy of Ophthalmology's Basic and Clinical Science Course, congruent with the author's applied knowledge on the cases [20]. As no clear guidelines exist, a minimum requirement for the apps was to not underestimate the urgency of the patient's situation, regardless of whether a diagnosis was found or not. The foremost diagnoses and treatment recommendations given by the apps were assessed by the author and a score was awarded: for a correct diagnosis/treatment, 1 point; for a partially correct diagnosis or treatment, half a point, which was awarded if a correct diagnosis or treatment was not provided, but the answer would not mislead the user or underestimate the urgency (eg, if no diagnosis was found, and the app recommended visiting a real physician); for all diagnoses/treatments that did not meet these requirements, 0 points. More specifically, for glaucoma, anything less than emergency treatment would result in 0 points; for the retinal tear diagnosis, 1 point was awarded to treatment recommendation ranges of "instantly" to very few days; and for dry eyes, 0 points were awarded if treatment was deemed urgent, and half a point was awarded if trying self-treatment was not recommended before seeing a physician. A virtual anonymous patient was created to be diagnosed to prevent the potential influence of phone-based data (phone type, GPS coordinates, country, etc). Roughly two years was chosen as a deliberate time interval between tests, based on the assumption of a slow but continuous rise of the apps' user count, and thus a slow but continuous buildup of internal data to process for possible improvements of presumed learning algorithms used by the apps. Other than the author, there were no human subjects involved in the process of this research. *P* values were calculated with a Student *t* test for independent variables using SPSS (version 16.0; IBM Corp).

Ada

Ada is a Berlin-based app that was first tested and gained popularity on the New Zealand market in 2016 and was released more broadly afterward [21,22]. It uses a chat bot to collect data from the user, selecting symptoms from a list generated in response to the user's free text input and subsequently asking questions that adapt to previously entered information. The resulting report may then be sent to a physician on behalf of the user.

Babylon

Babylon is a London-based app that primarily focuses on the UK market. It started out in 2013 as a service provider for online consultations with real-life physicians, and since 2016 it has added a chat bot that presents the user with simple or multiple-choice questions for symptom assessment [23]. An explicit description of the ML algorithms that are used is not available, but judging by the publicly available information from gray literature, the use of recurrent neural networks (RNNs) for deep learning may be involved, and Python may be used as the primary programming language [24]. Ni et al mentioned the use of Bayesian networks, although a source was not given [25].

Buoy Health

Buoy has been developed at Harvard Medical School since 2014 as a smart symptom checker with an undisclosed algorithm, supposedly relying on natural language processing (NLP)–extracted data from 18,000 clinical papers [26]. As stated by its chief executive officer and founder, Buoy Health specifically does not use decision trees but "dynamically picks" 1 of 30,000 questions based on the principle of greatest reduction of diagnostic uncertainty, which does not necessarily imply the use of neural networks. By his accounts, its diagnostic certainty is within a range of 90.9%-98%, without a detailed explanation [27].

Your.MD

Your.MD was founded in 2012 in Oslo, Norway, and is now based in London [28,29]. Users ask free questions via its chat bot and it in turn presents simple or multiple-choice questions. The algorithms that are used are undisclosed, but judging by the publicly available information, Python may be used as a primary programming language and, according to its CEO, Bayesian networks may also be used [30].

Results

Ada

Ada diagnosed the angle closure glaucoma correctly in 2018 but misdiagnosed it as cluster headache in 2020 without mentioning glaucoma (this result and all following are shown in Table 1 and Table 2; for the walk-throughs with raw output data for all apps, see Multimedia Appendix 1; for an overview of the relevant results and awarded scores, see Multimedia Appendix 2).

Table 1. Testing of all four apps in three virtual patients with different diagnoses in 2018. Points awarded for diagnosis/treatment: (-)=0, (*)=0.5, (•)=1.

Diagnosis	Glaucoma	Retinal tear	Dry eyes
Ada	(•)/(•)	(•)/(•)	(•)/(-)
Babylon	(-)/(•)	(-)/(-)	(-)/(-)
Buoy	(-)/(•)	(-)/(-)	(-)/(*)
Your.MD	(•)/(•)	(•)/(•)	(•)/(•)

Table 2. Testing of all four apps in three virtual patients with different diagnoses in 2020. Points awarded for diagnosis/treatment: (-)=0, (*)=0.5, (•)=1.

Diagnosis	Glaucoma	Retinal tear	Dry eyes
Ada	(-)/(-)	(•)/(•)	(•)/(*)
Babylon	(-)/(•)	(-)/(-)	(-)/(-)
Buoy	(-)/(-)	(-)/(•)	(-)/(*)
Your.MD	(•)/(•)	(-)/(•)	(*)/(-)

Babylon

In the glaucoma attack case, in both years Babylon recommended seeking emergency treatment after five questions when the user classified the pain as "severe," with no further statement about a diagnosis. The retinal tear was not diagnosed due to "insufficient information," and Babylon recommended referral to an online physician or real-life general practitioner. In the dry eyes case, Babylon did not state a diagnosis either and classified this as a relative emergency (same-day medical treatment recommended). There was no change in 2020.

Buoy Health

Buoy yielded a correct diagnosis neither in 2018—although its second suggestion of "Blepharitis" could be interpreted as partly correct in the dry eyes case [31]—nor in 2020; the result for the retinal tear inquiry was far off in 2018 with "Cataract" or "Bone disease" given as possible causes. The efficiency and accuracy did not improve in 2020.

Your.MD

Your.MD was able to output the correct diagnosis in all three tests in 2018, requiring distinctly fewer questions. In contrast to Ada, the treatment priorities were categorized correctly in all three, recognizing dry eyes as self-treatable. It was the only app to correctly identify the angle closure glaucoma, which it did in 2020; in 2018, it had only stated "Glaucoma". In case of the retinal tear, however, it was unable to correctly identify it in 2020, while it had done so in 2018. In the dry eyes case, it changed the advice from self-treatment in 2018, which is correct, to an emergency in 2020, which is not.

Technologies

All tested apps require an online connection to use the diagnosis function. All rely on a chat bot that is likely based on NLP and subsequently on discrete answers to questions to process user input, but they significantly differ on how the information is treated, which questions are asked, and which conclusions are drawn from the information (see Multimedia Appendix 1). There is no substantial information available on the algorithms used by the apps.

Summary of Comparison Between Performances in 2018 and 2020

The average number of questions changed from 27.3 for Ada, 11 for Babylon, 31.3 for Buoy, and 10 for Your.MD in 2018 to 31 for Ada (*P*=.38), 9 for Babylon (*P*=.64), 30.3 for Buoy (*P*=.63), and 10.3 for Your.MD (*P*=.84) in 2020 (see Multimedia Appendix 3). In the average number of questions asked in both time periods, no difference could be found between Ada and Buoy (*P*=.41) and between Babylon and Your.MD (*P*=.93), but significant differences were found between Ada and Babylon (*P*<.001), Ada and Your.MD (*P*<.001), Babylon and Buoy (*P*<.001), and Buoy and Your.MD (*P*<.001). The scores from 2018 to 2020 changed in Ada from 3/2 to 2/1.5 (*P*=.37/.73) and in Your.MD from 3/3 to 1.5/2 (*P*=.16/.37), while Babylon and Buoy remained unchanged at 0/1 and 0/1.5, respectively (Table 1 and Table 2).

The average scores were 2.5/1.75 for Ada, 0/1 for Babylon, 0/1.5 for Buoy, and 2.25/2.5 for Your.MD, and the sums over both years were 5/3.5 for Ada, 0/2 for Babylon, 0/3 for Buoy, and 4.5/5 for Your.MD. In the sum of all points, Ada and Your.MD (*P*=.70) and Babylon and Buoy (*P*=.56) did not differ significantly, while Ada and Babylon (*P*=.02), Ada and Buoy (*P*=.03), Babylon and Your.MD (*P*=.01) and Buoy and Your.MD (*P*=.01) did.

Discussion

During testing of the apps, some notable observations could be made about their behaviors. Ada seemed to ask redundant questions in the end, (eg, asking about eye pain when this was the primary symptom entered at the beginning). It could be speculated that this functionality serves to add input for the diagnosis to the database. Ada circumvents the common “black box” problem in ML [32] by offering a pictorial description of how many patients in 10 with the given symptoms have the suggested diagnosis. This additional information seems to indicate that by Ada’s accounts, the provided symptoms for dry eyes seemed to correspond less with the diagnosis in 2020 (“8 in 10” vs “5 in 10 people”). Here, one could speculate that there are problems incorporating the data the app accumulates over the years. Generally, the provided statistics indicate that either Bayesian probabilities are used in some way, as artificial neural network (ANN) output activities are not linked to statistical values, or the offered values are interpolated from ANN outputs. The former assumption seems to be backed up by information published by Ada Health itself, where the use of Bayesian networks is mentioned [33]. Buoy asked several questions that seemed off topic (eg, for the user’s health insurance), and in 2018 it presented users with pictures of medical conditions for comparison that may not be suitable for laymen, like testing a patellar reflex in the dry eye case or comparing one’s cornea with a microscopy picture to identify Horner-Trantas dots. In 2020, no pictures were offered for the same set of symptoms. In both years, both Babylon and Buoy failed to produce a useful diagnosis and also gave out very few treatment recommendations, with some results being very far off, such as “Bone issue” or “Non-bacterial brain inflammation” diagnoses by Buoy for the retinal tear patient, contributing to the overall result that Ada and Your.MD fared significantly better in the test than the other two. The variety of treatment recommendations given by the apps for the same starting sets of symptoms is also remarkable. Ada made it simple by generally recommending emergency care for virtually every diagnosis, which may help the manufacturers shift responsibility to the patient but counteracts the possible value of good medical advice. Babylon seemed to send any patient who chooses “severe pain” as a symptom to the emergency department, which is a good outcome for the glaucoma patient, but no diagnosis was given, and its other recommendations were very general. In 2020, Buoy gave the glaucoma patient the advice to seek medical advice within three days as its first option, followed up by “emergency treatment” as second and third options, which would confuse a real patient. Your.MD provided the most valid recommendations in this study, but also worsened on the dry eyes diagnosis from 2018 to 2020, now unnecessarily transitioning from self-treatment to emergency care.

While the number of questions the apps asked did not significantly change between the years, the temporal variances in diagnoses and treatment recommendations indicate the use of learning algorithms in all four, suggesting that the algorithms used for history-taking and diagnosis calculation are changing over time and would thus fall under the FDA’s proposed regulations for learning or “nonlocked” algorithms. In terms of their effectiveness in diagnosing ophthalmic diseases, the results were mixed with a tendency to worsening. It is noteworthy that no trend to improvement of history-taking and results could be observed at all. On the contrary, Ada and Your.MD worsened in their diagnostic outputs, while Babylon and Buoy were stable at a low level. This deterioration of diagnostic performance seems to contradict the very purpose of using “learning” algorithms in the first place and certainly justifies further inquiry. It is also notable that while two of the apps ask more questions than the other two, there seems to be no correlation between the number of questions asked and the quality of the results. On the contrary, the app with the highest overall score had the second-lowest total of questions asked. This indicates high variation in their diagnostic approaches and efficiencies, all worthy of subsequent systematic evaluation. Their algorithms are undisclosed; judging by the apps’ workflows, they all basically resemble the adaptive feedforward neural network–based mobile diagnosis engine that the author conceptualized in 2016 [34], which in its framework resembles the classic AI game “20 Questions” [35]. In both frameworks, two separate neural networks (or similar algorithms) separately calculate the current diagnosis based on the available information and the next best question based on the input up to that point. Where these examples used simple ANNs, the apps may also utilize the previously mentioned RNNs, Bayesian networks, or convolutional neural networks [15], accessed through the chat bot.

There are several limitations to this study. First, the cases that were entered included information that seemed irrelevant to the author for deciding on a suspicion of a potentially dangerous diagnosis; this includes, for example, the prevalence of diabetes, a history of smoking, and seemingly unrelated questions. It is possible, however, that to a large database that collects and sorts information without bias, answering the questions from a biased physician's point of view might in fact mislead the algorithms. Second, the evaluation of the results is as subjective as entering the symptoms, which ultimately might test the apps' ability to imitate a potentially flawed physician rather than whether they can correctly identify diagnoses. This could be improved by introducing systematic evaluations in the framework of a randomized controlled trial. Semigran et al had used human input and output on a randomized stack of diagnoses to assess self-diagnosis apps [7]. New methods may be necessary to investigate AI-driven apps in the future, possibly including some degree of automation considering the superhuman data storage capacities such systems can house and taking into consideration the dynamic of the algorithms. A simpler but also less systematic approach would be to include more physicians in the evaluation of the apps and average their assessments as has been done before [10]. The possibility of the manufacturers adapting to known sets of questions (eg, from this study) should also be considered upon further investigation. Third, the sample size is low. In future investigations, large-sample investigations should be preferred. Other authors like Fraser et al in 2018 have already demanded standardized and transparent procedures for examining such devices [36]. In 2019, Kelly et al advocated for a focus on peer-reviewed studies in order to increase trust in AI devices and added that the introduction of consumer-oriented technology offers the opportunity for vast prospective studies with the new collected data, provided that a sufficient level of data transparency is reached [37]. They also mentioned that an extension to the existing TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis) statement, which has defined recommendations for the evaluation of diagnosis prediction since 2015 [38], is being developed to include ML algorithms [39]. In addition, the World Health Organization and the International Telecommunication Union are working on benchmarking frameworks for AI tools in health care [40]. All of these could act as guidelines for future scientific exploration of the topic, but they will require funding and manpower. The four enterprises mentioned in this paper are employing physicians, mostly with an additional formal or informal education in medical informatics or similar, at high ranks within their hierarchy, in two of them even as cofounders [41-44]. Now that this Pandora's box of AI in the hands of patients and corporations has been opened, the question is whether this novel type of physician that supervises and administrates an automated diagnostic system will be mirrored by scientific counterparts who publicly evaluate the apps' performances, or whether these essential data will remain undisclosed—a common practice in the commercial sector due to conflicts of interest. Considering the apps' possible leverage and impact on public health [4], this should be in the public interest. The prospect of AI support for physicians provided by simple and accessible apps in the hands of layman users could be a golden one, as long as they actually learn and improve. Most importantly, they need to satisfy the crucial premises within the field of health care: to be efficient and safe.

Abstract

Background: In December 2019, COVID-19 broke out in Wuhan, China, leading to national and international disruptions in health care, business, education, transportation, and nearly every aspect of our daily lives. Artificial intelligence (AI) has been leveraged amid the COVID-19 pandemic; however, little is known about its use for supporting public health efforts.

Objective: This scoping review aims to explore how AI technology is being used during the COVID-19 pandemic, as reported in the literature. Thus, it is the first review that describes and summarizes features of the identified AI techniques and data sets used for their development and validation.

Methods: A scoping review was conducted following the guidelines of PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews). We searched the most commonly used electronic databases (eg, MEDLINE, EMBASE, and PsycInfo) between April 10 and 12, 2020. These terms were selected based on the target intervention (ie, AI) and the target disease (ie, COVID-19). Two reviewers independently conducted study selection and data extraction. A narrative approach was used to synthesize the extracted data.

Results: We considered 82 studies out of the 435 retrieved studies. The most common use of AI was diagnosing COVID-19 cases based on various indicators. AI was also employed in drug and vaccine discovery or repurposing and for assessing their safety. Further, the included studies used AI for forecasting the epidemic development of COVID-19 and predicting its potential hosts and reservoirs. Researchers used AI for patient outcome–related tasks such as assessing the severity of COVID-19, predicting mortality risk, its associated factors, and the length of hospital stay. AI was used for infodemiology to raise awareness to use water, sanitation, and hygiene. The most prominent AI technique used was convolutional neural network, followed by support vector machine.

Conclusions: The included studies showed that AI has the potential to fight against COVID-19. However, many of the proposed methods are not yet clinically accepted. Thus, the most rewarding research will be on methods promising value beyond COVID-19. More efforts are needed for developing standardized reporting protocols or guidelines for studies on AI.

artificial intelligence; machine learning; deep learning; natural language processing; coronavirus; COVID-19; 2019-nCoV; SARS-CoV-2

Introduction

Background

COVID-19 broke out in Wuhan, Hubei Province, China in December 2019 [1], spreading across the world and, as of May 2020, claiming the lives of more than 330,000 people [2]. Caused by SARS-CoV-2, COVID-19 was declared a global pandemic by the World Health Organization in March 2020 [3]. Many individuals infected with COVID-19 experienced fever, dry cough, and fatigue; some faced a severe course of the medical condition, often requiring intensive care, including mechanical ventilation [4]. The contagious COVID-19 and its unprecedented volume of cases around the world have caused national and international disruptions to business, health care, education, transportation, and nearly every aspect of our daily lives [5]. Prompt and effective countermeasures are necessary to cap off the effects of this pandemic; comprehensive public health strategies that involve surveillance, diagnostics, clinical treatment, and research are required [6].

Leveraging digital tools and technologies to combat COVID-19 can augment public health strategies [7], for example, by using chatbots to address public inquiries about COVID-19. Additionally, using digital tools, public health professionals can track in real time the incidence of COVID-19 infections and potentially model their projection. Among such tools is artificial intelligence (AI)—a branch of computer science concerned with intelligently analyzing and handling complex information [8,9]—amplifying public health efforts against COVID-19. Despite the enthusiasm for AI applications since the 1950s, only recently have we witnessed interest in AI due to the availability of high-performance computing and vast amounts of data being generated every second [10].

AI enables machines to become intelligent, understand queries, sift through and connect mountains of data points, and draw actionable conclusions [11]. Although defining the taxonomy of AI is not trivial, its methods can be categorized based on the objective pursued: learn from knowledge, explore and discover knowledge, extract conclusions, and reason from knowledge [8].

Soon after the COVID-19 pandemic spread across the world, several governments, research institutes, and technology companies have issued calls to action urging researchers to develop AI applications to assist with COVID-19–related research [12]. From a hierarchical perspective, AI can support COVID-19 at different levels: the molecular level (eg, drug and vaccine discovery), patient level (eg, patient diagnosis), and population level (eg, epidemiological surveillance) [13].

A full review of the AI field is beyond the scope of this review, and we refer the reader to some surveys (eg, [14]) and lectures (eg, [15,16]). However, we provide a compact overview of the AI-based techniques occurring most frequently in included studies in Multimedia Appendix 1.

Research Problem

AI has the ability to analyze big data sets through aggregating and sifting through mountains of health care data (including patient data) to generate insights that can enable predictive analysis. The quick ability to obtain these insights helps clinicians as well as other stakeholders in the health care ecosystem to make effective, safe, and timely decisions to better serve patients and public health policy. There has been a steady rise in the number of studies regarding the use of AI techniques to resolve or address the COVID-19 pandemic [13]. Much of the AI research effort during the COVID-19 pandemic has been scattered, and a need to explore and summarize how AI technologies are being used to resolve or address the many challenges relating to COVID-19 can help us plan on how to leverage AI technologies in the current or a future pandemic. Several reviews have been conducted on AI techniques used to address the COVID-19 pandemic [12,13,17-20]. However, much of the work has been in the form of literature reviews [12,13,17-19] or systematic reviews focusing on one application of AI (eg, diagnosis and prognosis of COVID-19) [20]. Therefore, it is necessary to conduct a more systematic and comprehensive review that focuses on all applications of AI used amid the COVID-19 pandemic. Accordingly, this review aims to explore how AI technology is being used during the COVID-19 pandemic as reported in the literature. The results can be useful for health care professionals and policy makers considering leveraging AI to complement public health efforts in response to COVID-19.

Methods

To achieve the objective of this study while ensuring both replicable and transparent methods, we conducted a scoping review following the guidelines of PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [21]. Methods used in this review are detailed in the following subsections.

Search Strategy

Search Sources

In this review, we performed search queries between April 10 and 12, 2020, on the following online databases: MEDLINE (via Ovid), EMBASE (via Ovid), PsycInfo (via Ovid), IEEE Xplore, ACM Digital Library, arXiv, medRxiv, bioRxiv, Scopus, and Google Scholar. In the case of Google Scholar and due to the volume of returned hits, only the first 100 results were considered, as we found that, beyond this, results quickly lose relevance and applicability. In addition to searching bibliographic databases, we screened the reference list of the included studies and relevant reviews to look for other relevant studies that could be added to this review (ie, backward reference list checking).

Search Terms

The search terms we used to identify relevant studies were specified from the available literature and by referring to subject matter experts. These terms were selected based on the target intervention (eg, AI, machine learning, and deep learning) and the target disease (eg, coronavirus, COVID-19, and 2019-nCoV). Details about the exact search strings used in this study are provided in Multimedia Appendix 2.

Study Eligibility Criteria

In this review, we focused on any AI-based technology or approach used for any purpose related to the COVID-19 pandemic, such as diagnosis, epidemiological predictions, treatment and vaccine discovery, and prediction of patient outcomes. However, we excluded studies providing an overview or proposing a potential AI technique for COVID-19, or studies that were purely discussed from a research perspective.

We considered studies published in English between December 25, 2019, and April 12, 2020, such as peer-reviewed articles, theses, dissertations, conference proceedings, and preprints, while excluding other publications such as reviews, conference abstracts, proposals, editorials, and commentaries. We did not enforce any restrictions on the country of publication, study design, comparator, and outcomes.

Study Selection

Two reviewers, namely, authors AAA and MA, independently screened the titles and abstracts of the identified studies. They independently read the full text of studies that passed the *title and abstract* screening. We then investigated any disagreement between AAA and MA and resolved them through discussion and consensus. We calculated Cohen kappa [22] to measure the reviewer's agreement and found it to be 0.83 for the *title and abstract* screening and 0.94 for the full-text reading, indicating a very good agreement [23]. Multimedia Appendix 3 shows a matrix of interrater agreement in each step.

Data Extraction

Multimedia Appendix 4 shows a purpose-built data extraction form, which was pilot-tested using 7 relevant studies to accurately extract data. The two reviewers (AAA and MA) independently extracted data related to characteristics of the included studies, AI techniques, and data sets used for the development and validation of AI models. Like the study selection process, any disagreement between the reviewers was resolved through consensus. We calculated Cohen kappa [22] and found it to be 0.88, meaning a very good agreement [23].

Data Synthesis

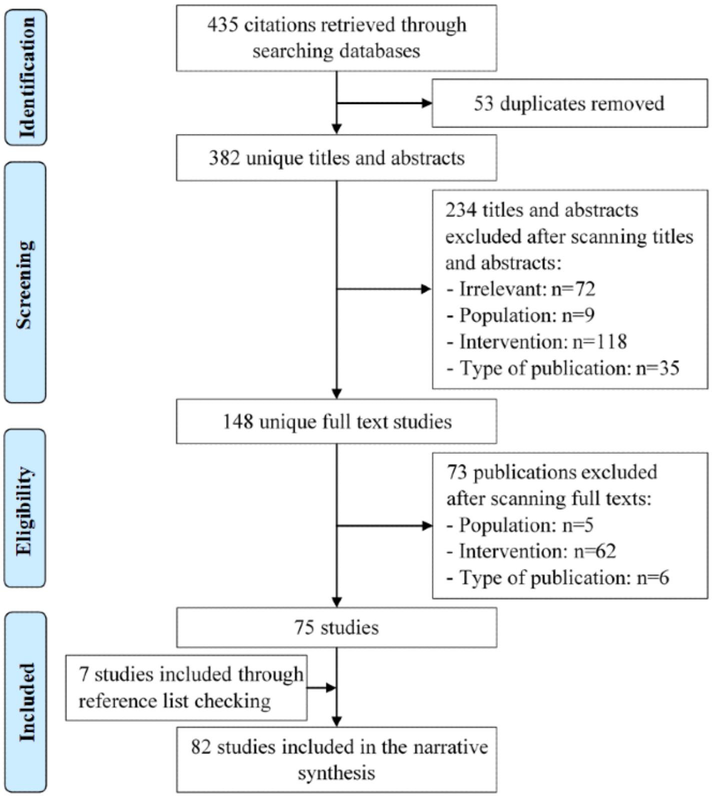
After extracting the data from the identified studies, we used a narrative approach to synthesize it. Specifically, we classified and described AI techniques used in the included studies in terms of their purposes (eg, diagnosis and drug and vaccine development), AI area or branch (eg, traditional machine learning and deep learning), AI models and algorithms (eg, decision tree, random forest, and naive Bayes), and platform (ie, computer and mobile). Further, we described the data sets used for development and validation of AI models in terms of data sources (eg, public databases and clinical settings); type of data (eg, radiology images, biological data, and laboratory data); size of the data set; type of validation; and proportion of training, validation, and test data sets. We used Microsoft Excel (Microsoft Corporation) to manage data synthesis.

Results

Search Results

We retrieved 435 studies through searching the identified bibliographic databases (Figure 1). Of those studies, we removed 53 duplicates; we then screened the titles and abstracts of the remaining 382 studies. The screening process led to the exclusion of 234 studies for reasons detailed in Figure 1. After reading the full texts of the remaining 148 studies, we excluded 73 studies, as they did not meet all eligibility criteria. Thus, we included the remaining 75 studies. We identified 7 additional studies by checking reference lists of the included studies and relevant literature reviews. Overall, 82 studies were included in this review.

Figure 1. Flowchart of the study selection process.



Characteristics of the Included Studies

Among the included studies, 72 were preprints and 10 were published articles in peer-reviewed journals (Table 1 and Figure 2). About two-thirds (n=53) of the included studies were submitted in March 2020, and the remaining studies were published in February and April 2020. However, no studies were published during the first 2 months of the COVID-19 outbreak. The included studies were conducted in 19 countries; however, half of the studies (n=41) were published in China. Multimedia Appendix 5 shows the characteristics of each included study.

AI-Based Techniques Used for COVID-19

Purposes or Uses of AI Against COVID-19

As shown in Table 2, AI techniques have been used for five purposes amid the pandemic. In 31 studies [24-54], AI was used for diagnosing COVID-19 cases or identifying suspected COVID-19 cases based on various indicators, including computed tomography (CT) images [24-38], x-ray images [39-50], laboratory tests [51,52], genome sequences [53], and respiratory patterns [54].

[a] CT: computed tomography.

In 20 studies [55-74], AI was also harnessed for treatment and vaccines for COVID-19. Specifically, 9 studies used AI for discovering drugs suitable for combating COVID-19 [55-63], and 2 studies used AI for repurposing commercially available drugs that could be used for treating COVID-19 [64,65]. There was 1 study that employed AI to predict the safety of using traditional Chinese medicine for COVID-19 [66]. In 4 studies [67-70], AI was used for discovering COVID-19 vaccines. Another 4 studies used AI for predicting the protein structure of SARS-CoV-2, thereby aiding researchers and pharmaceutical companies to discover drugs for COVID-19 [71-74].

There were 17 studies that used AI for epidemiological modeling tasks [75-91]. In particular, 14 of these studies employed AI for forecasting the epidemic development (eg, numbers of confirmed, recovered, death, suspected, asymptomatic, and critical cases, and lengths and ending time) [75-88], and 3 studies [89-91] used AI for predicting the potential hosts or reservoirs of SARS-CoV-2.

In 14 studies [33,92-104], AI was used for patient outcome–related tasks. In particular, 6 studies used AI for segmentation and quantification of infected regions in the lungs due to COVID-19, thereby assessing the severity of the disease [92-97]. AI was also used in 4 studies for identifying cases at high risk of progression to severe COVID-19 [33,98-100]. Furthermore, AI was also used for predicting mortality risk [101,102], its associated factors [103], and the length of hospital stay in patients with COVID-19 [104].

AI has also been used for infodemiology [105]. Specifically, AI was used for raising awareness to use water, sanitation, and hygiene through combining authentic sources of information with daily news [105]. Multimedia Appendix 5 presents the purposes or uses of AI techniques in each included study.

Features of AI-Based Techniques Used for COVID-19

In 29 studies [24,31,47, 51,52,58, 63,68,70, 74,79,83-86,88,90,91,95-105], AI techniques used against COVID-19 were based on traditional machine learning models and algorithms (Table 3). The most commonly used machine learning models and algorithms were support vector machine (SVM) [24, 31, 47,58, 68, 70,79,91,98,101], random forest [31,58,68,74,90,96,101,103,104], decision tree [52,58,68,74,79,97,99,101,102], and logistic regression [31,51,52,58,68,99-101,104].

[a] AI: artificial intelligence.

[b] Numbers do not add up as AI techniques in some studies were based on more than one AI branch.

[c] Numbers do not add up as several studies used more than one AI model or algorithm.

In 60 studies, AI techniques used against COVID-19 were based on deep learning models and algorithms [25-50,53-57,59-67,69,71-73,75-82,87,89,92-95,98,101]. The most commonly used learning models and algorithms in the included studies were convolutional neural network (CNN) [25-50,53,62,64,72,73,82,89,92-95] and recurrent neural network (RNN) [54,55,57,59,71,73,77,98].

In 2 studies [64,105], AI techniques used against COVID-19 were based on models related to natural language processing (NLP), such as the continuous bag of words model, skip-gram models, and porter stemming. Although AI techniques were implemented in mobile phones for 1 study [105], computers were the platform for AI techniques in the remaining studies. Multimedia Appendix 5 shows features of AI-based techniques used in each included study.

Features of Data Sets Used for Development and Validation of AI Models

As shown in Table 4, public resources (eg, National Center for Biotechnology Information [NCBI], GitHub, and Kaggle) were the most commonly used data source for development and validation of AI models [24,27, 29,36,39-50,53, 55-65,67-75,77, 80-85,87-89,91-93,103,105]. Other data sources used by the included studies were as follows: clinical settings (eg, databases in hospitals and medical centers) [25-35,37,38,51,52,63,94-98,100, 102,104], government sources (eg, Chinese Center for Disease Control and Prevention) [53,76,78, 79, 84,86, 90, 99,101], literature (eg, previous studies and books) [36,40,42,61,66,101], news websites [101,105], and participants recruited by the study [54].

[a] Numbers do not add up as several studies collected their data from more than one data source.

[b] Numbers do not add up as several studies collected more than one type of data.

[c] Data set size was reported in 50 studies.

[d] Type of validation was reported in 53 studies.

[e] Numbers do not add up as 1 study used two different types of validation.

[f] Proportion of the training set was reported in 49 studies.

[g] Proportion of the validation set was reported in 11 studies.

[h] Proportion of the test set was reported in 49 studies.

The types of data collected from these data sources were as follows: radiology images (eg, CT and x-ray) [24-50,54,92-96,98,104], biological data (eg, protein and genome sequences) [53,55-65,67-74,89-91], epidemiological data (eg, number of infected and recovered cases) [75-85,87,88,97,102], clinical data (eg, signs, symptoms, physician notes, and patients' history) [25,51,52,66,97-103], laboratory data (blood and polymerase chain reaction test results) [25,51,52,86,97,98,100,102], demographic data (eg, age, gender, and ethnicity) [52,99-102], guidelines [105], and news articles [105].

The data set size was reported by 50 studies, ranging from 31 to 3,000,000. The data set size was less than 1000 samples in half of these studies [24,27,32,34, 36,37,39, 41,44,45, 47,51-53,69,86,92,94-98,100,102-104], and only 8 studies reported a size of 10,000 samples or more [25,26,54,59,61,87,99,101].

Validation of models was reported in 53 studies. Three types of validation were used in the included studies: train-test split [25,29, 30, 34-39, 41, 43, 44, 47-50, 59, 75,87,88, 93,94,99,100,103], K-fold cross-validation [24,31,40, 42,45,46, 52,53, 58, 66,68,90-92,96,98, 101,104], and external validation [26,27,29,32,33,38,51,54,82,95,102].

The training set proportion of the total data set was reported in 49 studies. The proportion of the training set ranged from ≤25% in 3 studies [25,27,28], 26%-50% in 2 studies [26,95], 51%-75% in 16 studies [32,33,35,36, 38, 39,47, 51, 59,75,87,88,96,100,102,103], and >75% in 28 studies [24,29-31,34,37,40-46,48,50, 52-54,58, 66,90-92, 94,98,99,101,104]. The mean of the proportions of the training set in the 49 studies was 72.7%.

The validation set proportion of the total data set was reported in 11 studies; it ranged from ≤25% in 8 studies [26,28, 35, 36,38, 47, 48,53] and 26%-50% in 3 studies [25,100,102]. The mean of the validation set proportions in the 11 studies was 18.7%.

The test set proportion of the total data set was reported in 49 studies, ranging from ≤25% in 35 studies [24,29-31,34,36,37,40-48,50,52-54,58,59,66,75,87,90-92,94,98-102,104], 26%-50% in 10 studies [26,32,33,35,38,39,51,88,96,103], 51%-75% in 3 studies [25,28,95], and >75% in 1 study [27]. The mean of the test set proportions in the 49 studies was 22.9%. Multimedia Appendix 6 presents features of the data sets used for development and validation of AI models in each included study.

Discussion

Principal Results

In this study, we conducted a scoping review of the use of AI against COVID-19. We found a lack of publications in December 2019 and January 2020. This is not surprising, given that SARS-CoV-2 was only identified on January 7 [106]; insufficient data was not available to back scientific publications, in particular internationally; and the contagiousness and aggressiveness of the virus were underestimated (first lockdown in China was January 23 [106]). Half of the studies in this report were published in China. Since SARS-CoV-2 originated in China and affected it the most during the first 3 months of the pandemic, it had the most data related to COVID-19. Considering lengthy publication processes and the vast number of COVID-19–related manuscript submissions, it is also not surprising that most of the included studies were preprints.

In the included studies, AI was used for five purposes: diagnosis, treatment and vaccine discovery, epidemiological modeling, patient outcome–related tasks, and infodemiology. None of the included studies used AI for other purposes such as contact tracing of the individuals, providing training to students and health care professionals, or robotics to deal with suspected and quarantined cases.

Most of the AI techniques used in the included studies were based on deep learning approaches such as CNN and RNN. All but 1 study used desktop machines, workstations, and clusters as opposed to mobile platforms. This can be explained by the computational demand in training AIs. Although all major mobile phone manufacturers equip their flagship models with AI coprocessors, these coprocessors accelerate inference, a computationally much lighter task. In addition, *federated* learning [107] (a machine learning privacy-preserving technique usually used in mobile phones) is still in its infancy and raises issues such as data sovereignty, scalability, and performance.

Data sources used in the included studies usually came from the public domain (eg, NCBI, GitHub, Kaggle) and proprietary databases (less common). Radiology images were the most commonly used type of data, followed by biological data. The number of samples was still comparably small (less than 1000 in half of the studies). The diversity and size of data indicate a lack of publicly available data despite COVID-19 cases having surpassed 5 million at the time of writing. We, therefore, second Wynants et al [20] call "for immediate sharing of the individual participant data from COVID-19 studies worldwide."

Practical and Research Implications

Although this review explores the use of AI against COVID-19, some applications could prove useful far beyond this pandemic. For instance, Kiwibot designs autonomous medical delivery robots to minimize interpersonal contact [108]. Whiteboard Coordinator developed a high precision thermal screening device eliminating individual measurements, leading to higher throughput and larger social distances [109]. Although mobile phones are not yet the AI platform of choice, the first apps to track interpersonal contact using mobile phones have been published to prioritize COVID-19 testing [110]. Finally, whereas a real-time reverse transcription polymerase chain reaction test takes around 25 minutes and requires stocks of chemical reagents, AI can inspect chest CTs to provide preliminary diagnoses in seconds. We believe that increasing social distance and providing fully autonomous checkups will be the most valuable use of AI beyond the current pandemic.

In the past, fundamental AI research was focused mainly on faster (or even feasible) training. We believe that, in the future, this must be complemented with public education. AI mistrust, because of our still lacking understanding of how AI works at the deepest level, further raises ethical questions that need to be answered before AI will be uniformly accepted. We also found that AI features and results were reported in an inconsistent manner, potentially fueling AI mistrust and making a direct comparison between studies difficult. Of the 82 studies, we found that only 64.6% (n=53) of the studies included in this review disclosed the type of validation, 61% (n=50) mentioned the data size, and more than 7% (n=6) did not even specify the type of AI used. It is therefore important that we as a community develop a standardized reporting protocol to slow down the barrage of poorly conducted COVID-19 studies that threaten to overwhelm serious scientists (1916 related papers were retrieved before April 5, 2020 by Wynants et al [20]), strengthen properly conducted studies, and improve reproducibility.

We found that, explicably, the landscape of studies is still dominated by Chinese institutions, which bears the potential for cultural, technological, and geospatial biases. However, we see a recent move toward a more balanced landscape (see Figure 2). Although we identified more than 100 models developed in the included studies, we did not assess their quality as it was out of this review's scope. Therefore, further reviews are needed to assess the quality of AI models used in the fight against COVID-19.

Given the current "infodemic" [13], we find it surprising that NLP is not used more often. We see AI-based analysis of effective advertisement for nonpharmaceutical interventions as one research opportunity to answer questions like what manner of speech results in maximum public acceptance.

Strengths and Limitations

Strengths

Given that this review includes all AI techniques used for the COVID-19 pandemic regardless of their characteristics, study design, study setting, and country of publication, it may be considered the most comprehensive review in this research area. This helps readers to speculate how AI is being leveraged amid the COVID-19 pandemic. In comparison with similar reviews [12,13,17-20], our review is the only one that describes and summarizes features of the identified AI techniques and data sets used for their development and validation. Furthermore, unlike previous reviews [12,13,17-19], this review follows the full scientific rigor of PRISMA-ScR [21].

In contrast to other reviews, we searched the most commonly used databases in health and information technology fields to identify as many relevant studies as possible. Thus, the number of studies included in this review was much higher than in other reviews [12,13,17-20]. Additionally, we strove to retrieve gray literature and minimized the risk of publication bias by searching Google Scholar and conducting backward reference list checking. Furthermore, we minimized selection bias by having two independent reviewers conducting study selection and data extraction, with a very high agreement in both processes.

Limitations

Given that our review excludes proposals of AI techniques, it is likely that we missed other applications of AI for COVID-19. This review, therefore, might not identify all potential uses of AI for the current pandemic. Owing to practical constraints, the search was restricted to English studies. Therefore, we probably missed several studies written in other languages, especially Chinese. The search query did not include terms related to specific types of models or algorithms such as CNN, RNN, and SVM. Thus, it is likely that we missed some studies that used such terms in their title and abstract instead of the terms that we used (ie, AI, machine learning, and deep learning). The findings of this review are mostly based on preprints, which are more likely to have inaccurate or missing information. Therefore, the accuracy of the information in the included studies may affect the accuracy of our findings.

Conclusions

In this study, we provide a scoping review of 82 studies on AI against COVID-19. Given that many of the proposed methods are not yet clinically accepted, we remark that the most rewarding research will be on methods promising value beyond COVID-19. We believe that mobile phones offer unexploited potential, but more research in the direction of energy-efficient and federated learning is needed. We also believe that the use of NLP to assess effective communication of nonpharmaceutical interventions is a largely unexplored research direction, especially since data driving this research is available in the public domain, unlike much of the data produced by clinical studies. For AI to gain broad acceptance, standardized reporting protocols to be followed by studies on AI are needed. Likewise, more research on AI ethics and explainable AI is needed, paired with public education initiatives.

Abstract

Background: Despite excellent prediction performance, noninterpretability has undermined the value of applying deep-learning algorithms in clinical practice. To overcome this limitation, attention mechanism has been introduced to clinical research as an explanatory modeling method. However, potential limitations of using this attractive method have not been clarified to clinical researchers. Furthermore, there has been a lack of introductory information explaining attention mechanisms to clinical researchers.

Objective: The aim of this study was to introduce the basic concepts and design approaches of attention mechanisms. In addition, we aimed to empirically assess the potential limitations of current attention mechanisms in terms of prediction and interpretability performance.

Methods: First, the basic concepts and several key considerations regarding attention mechanisms were identified. Second, four approaches to attention mechanisms were suggested according to a two-dimensional framework based on the degrees of freedom and uncertainty awareness. Third, the prediction performance, probability reliability, concentration of variable importance, consistency of attention results, and generalizability of attention results to conventional statistics were assessed in the diabetic classification modeling setting. Fourth, the potential limitations of attention mechanisms were considered.

Results: Prediction performance was very high for all models. Probability reliability was high in models with uncertainty awareness. Variable importance was concentrated in several variables when uncertainty awareness was not considered. The consistency of attention results was high when uncertainty awareness was considered. The generalizability of attention results to conventional statistics was poor regardless of the modeling approach.

Conclusions: The attention mechanism is an attractive technique with potential to be very promising in the future. However, it may not yet be desirable to rely on this method to assess variable importance in clinical settings. Therefore, along with theoretical studies enhancing attention mechanisms, more empirical studies investigating potential limitations should be encouraged.

Introduction

In recent years, there has been significant evidence that deep-learning algorithms can outperform other machine-learning algorithms and conventional statistics in the medical field [1,2]. Despite the better prediction accuracy than conventional algorithms, the implications of using deep learning have been limited owing to the inability to explain the models [3,4]. Particularly in the medical environment, where the association between a disease and symptoms must be identified to provide adequate treatments, the interpretability of models is very important [3-5]. To overcome these limitations, interpretable deep-learning algorithms such as Shapley Additive Explanations (SHAP), Local Interpretable Model-agnostic Explanations (LIME), and attention mechanisms have been introduced [6-8]. The commonality of these three methodologies provides interpretability in the form of variable importance [6-8]. The difference between the methodologies is that with SHAP or LIME, variable importance is measured through simulations that change the data after model training is completed [6,7], whereas under attention mechanisms, variable importance is inferred during model training, which improves model performance by weighting several important variables [8,9].

Based on this advantage, attention mechanisms have starting to gain appeal in the clinical research field [10-17]. However, there is a gap between the application of attention mechanisms in clinical research and up-to-date attention algorithms in development. Specifically, most of the recent attention studies have focused on improving the theoretical robustness, design approach, and model accuracy with attention mechanisms [10-17]. However, clinical researchers are more interested in potential limitations that may arise when attention mechanisms are applied, and how they may differ from conventional statistics, than in the details as to how robust and sophisticated attention mechanisms are being developed. A few studies have introduced the potential limitations of attention mechanisms [18,19]. However, these studies have been theoretical, making it difficult for clinical researchers to understand and accept the results. Thus, it is increasingly necessary to provide a discussion of what clinical researchers should be aware of when applying the new concept of attention mechanisms in their research.

With the goal of reducing this gap, the aim of this study was to evaluate attention mechanisms in terms of prediction performance and interpretability. In addition, there remains a lack of guidance for clinical researchers in the implementation of attention mechanisms; therefore, to facilitate understanding for clinical researchers, this study preemptively provides basic concepts, key considerations, and codes for attention mechanisms. Finally, a case analysis was performed in a cross-sectional and structured data environment, which is the simplest data setting possible for clinical researchers.

This study was conducted according to the following procedure. First, the scope of the study was established in terms of the data structure. Then, a brief introduction and several important considerations regarding attention mechanisms were considered. Second, based on previous research, a two-dimensional framework was established to guide the four modeling approaches to attention mechanisms. Third, five empirical tests with attention mechanisms were performed using the four models: prediction performance, probability reliability, concentration of variable importance, consistency of attention results, and generalizability of attention results to conventional statistics. Finally, potential limitations that may arise when using attention mechanisms were identified.

Methods

Research Scope

Since the design approaches of attention mechanisms differ greatly depending on the data structure, the scope of this study was established in terms of data structure. Specifically, attention mechanism research in the medical field can be divided into two main categories from a data point of view. The first category is an unstructured data area where data containing natural language and images cannot be stored in a row and column table structure [20,21]. In the field of natural language processing, attention mechanisms have been applied to determine the relationship between words or between words and diseases in clinical notes [13,14,22]. In the image area, attention mechanisms have been used to highlight which parts of clinical images were related to clinical events, or to annotate the images [15-17]. The second category is a structured data area where data can be organized in table formats with a row and column structure [21]. In this area, attention mechanisms have been applied to electronic health records to determine variables that are strongly associated with clinical events [9,12,23].

Structured data familiar to clinical researchers are widely applicable to most statistical analyses, including linear regression analysis and analysis of variance (ANOVA). Since one purpose of this study was to compare the results of attention mechanisms and conventional statistical methods, the scope of the study was limited to structured data. Furthermore, most previous attention mechanism studies using structured data have been conducted in time-series settings [9,12,23]. However, this study was conducted in a cross-sectional data setting, which is simpler and easier than a time-series data setting, and can therefore help readers less familiar with attention mechanisms to better understand the results of the case study.

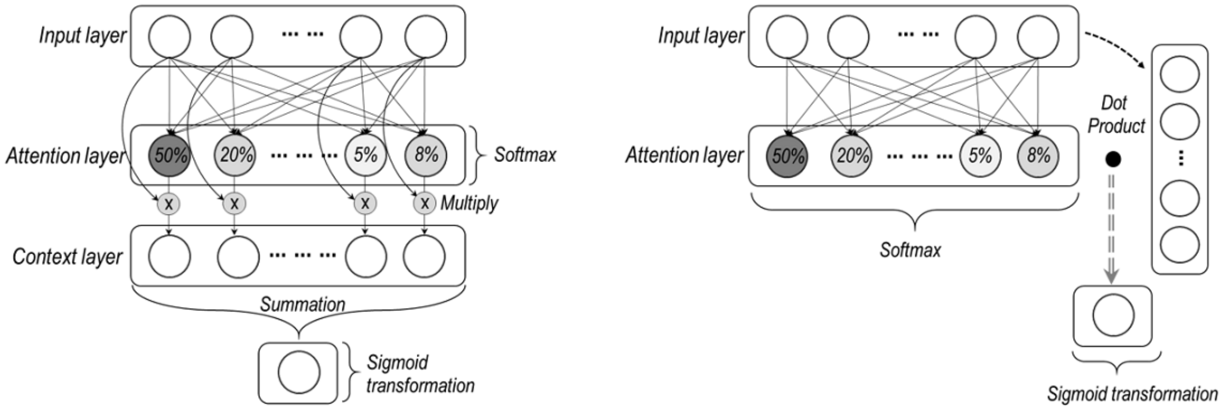
Introduction to Attention

Concepts of Attention Mechanisms

Attention, one of the layers in a neural network model, quantifies the importance of input variables in terms of their impact on outcomes (Figure 1) [8,24,25]. Attention is mostly calculated based on the Softmax function (Notation A1 in Multimedia Appendix 1), such that each node in the layer has a value between 0 and 1 and the sum of all node values must be 1

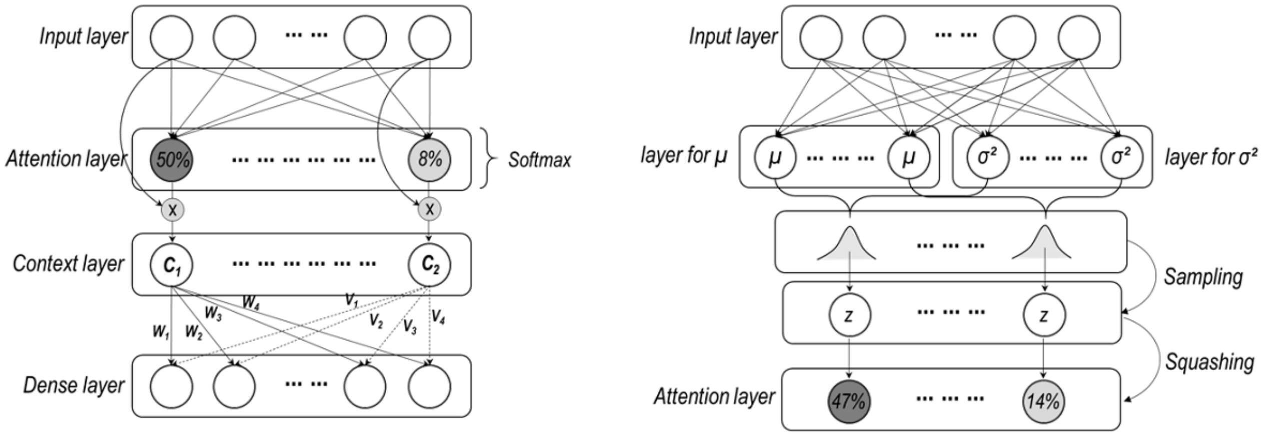
[8,24,25]. When the node size of attention is equal to the number of input variables, the influence of the input variables can be transferred toward the model outcome by multiplying the attention values with the corresponding input variables (Context layer in Figure 1A) [8,24,25]. Accordingly, in the case of binary classification, all values in the context layer are summed together to produce a single value (Summation in Figure 1A). The efficient model design without context layers is possible through the dot product between the input and attention values (Figure 1B). Finally, the single value may be converted to a value between 0 and 1 through the sigmoid function (Sigmoid transformation in Figure 1A and B).

Figure 1. Model structures for attention implementation. (A) Basic architecture of an attention mechanism model. (B) Model architecture where the dot product is employed for transferring the influence of input variables toward the outcome. (C) Model architecture where the importance of input variables may be decayed. (D) Model architecture that is aware of uncertainty. The percentages in the circles show examples of attention values.



(A) Basic architecture

(B) Dot product architecture



(C) Importance decayed architecture

(D) Uncertainty awareness architecture

The attention value of a certain variable indicates the relative importance of that variable compared with that of other variables. If the attention value of a particular variable is large, the large influence of that variable is transmitted when predicting the outcome variable. As an extreme example, when the attention value of a variable is 1, only that variable is used to predict the outcome variable, whereas if the attention value of a variable is 0, that variable is not used to predict the outcome variable. Figure 1A shows the basic architecture of a model with attention mechanisms; the code for the model implemented in Keras is provided in Codes A1 of Multimedia Appendix 2.

Consideration in Attention Modeling

Attention mechanisms can be implemented in various ways, because the key feature of deep-learning modeling is that users can freely design the structure [8,9,23-25]. However, there is a primary important consideration in implementing attention mechanisms. In some cases, the influence of variable importance in the context layer can be distorted. For instance, if all w_i values are close to 0, the value of C_1 has a minor effect on the next layer even if that value is the highest in the context layer (Figure 1C). Moreover, even if the value of C_2 is the lowest, if all v_is have very large positive values, the large influence of C_2 can be passed to the next layer (Figure 1C). As such, context values can be skewed as they are computed through a weight matrix in the process of being passed to the next layer (ie, Dense layer in Figure 1C). As a result, the skewed effects can be propagated to the model output if the output is inferred from the layer. Therefore, it is very important to design a structure where the outputs are not computed through weight matrices [9,23].

Modeling Approaches

Although deep-learning models can be developed in various ways depending on the tendency of developers, two approaches have been commonly applied in recent attention studies: increasing the degrees of freedom and uncertainty awareness (UA).

Increase in the Degrees of Freedom

The mechanism for increasing the degrees of freedom is to design multi-attention layers; representative algorithms that reflect such a mechanism include transformer and bidirectional transformer (BERT) [8,26]. Our intuition regarding the effectiveness of the mechanism relies on the idea that models can learn the importance of input variables from various perspectives [8,26]. Given the randomness feature of deep-learning training, the result from one attention layer can be unreliable. However, the multi-attention model offers multiple result sets with variable importance so that a reliable set of results may compensate for an unreliable set. Consequently, models in which multi-attention layers are applied have recently shown better performance than other models [8,26-28].

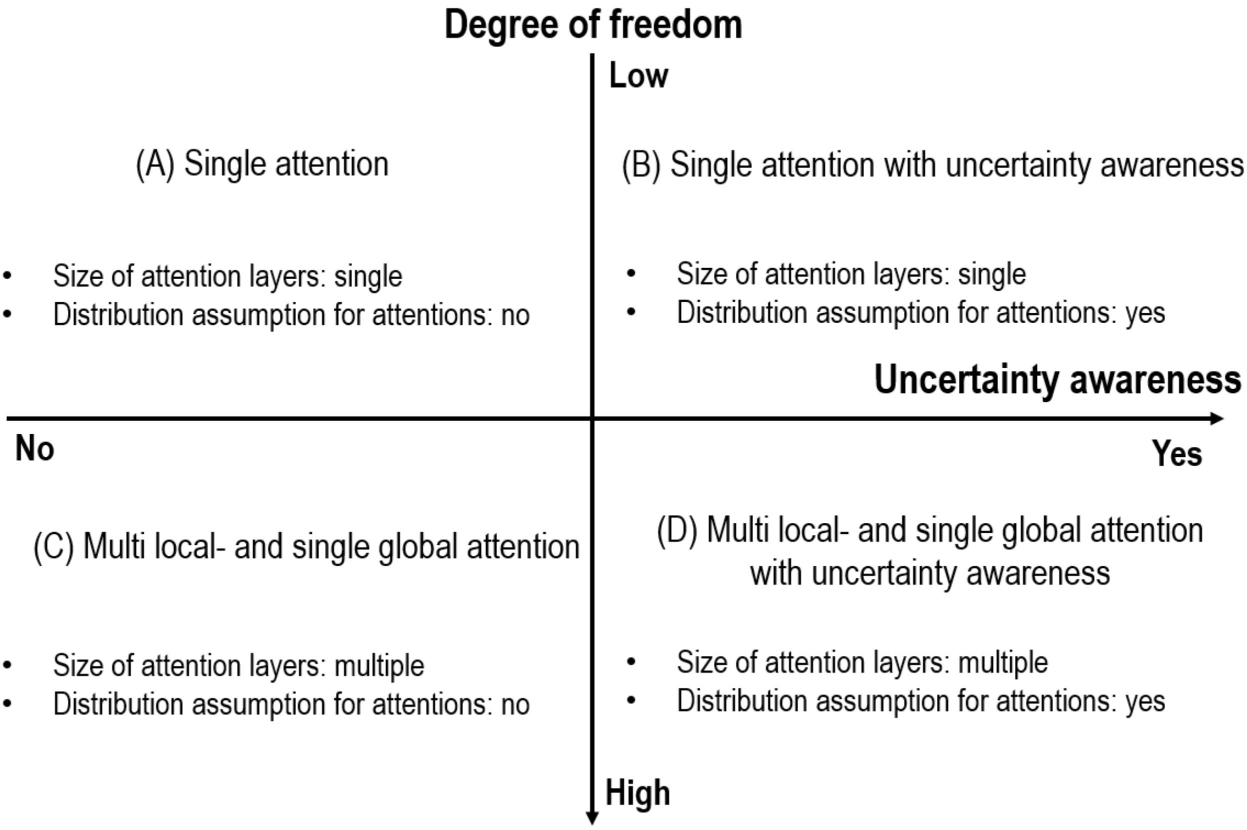
UA

Deep-learning algorithms are not free from the uncertainty issue, which concerns the fact that prediction results have the potential to be incomplete in terms of accuracy and consistency [9,29-33]. The major sources of uncertainty include data with noise and omissions, the complexity of the model associated with the parameters (ie, number of weights and type of activation functions), and the structures (ie, degree of depth) [30,31]. One way to alleviate this issue is to consider the presence of uncertainty in modeling [9,29,32,33]. Specifically, we may assume that node values (ie, attention values) in a certain layer come from a distribution with a mean (μ) and a variance (σ^2; Figure 1D) [9,29,32,33]. A normal distribution (ie, a Gaussian distribution) that is theoretically clear and can be computed efficiently is often assumed [9,29,32,33]. Based on this assumption, certain values with high probability are estimated, which may mitigate the random nature of deep-learning training [9,29-33]. A representative model designed under these assumptions is the variational auto-encoder [32,33].

Framework for Empirical Tests

Based on the discussion above, two directions (ie, degree of freedom and UA) were considered for attention modeling (Figure 2). In this two-dimensional framework, four cases were suggested for empirical tests (Figure 2). Degree of freedom is related to model structures and UA is related to the estimation approach.

Figure 2. Framework for empirical tests.



Empirical test entries for the four models in the framework were categorized into two broad categories: outcome and attention (Table 1). In terms of model outcome, a receiver operating characteristic (ROC) test, which expresses model accuracy based on the relationship between sensitivity and specificity, was employed for prediction performance [34]. In addition, the performance of probability reliability, which measures the degree of agreement between predicted and actual probability, was assessed using a reliability diagram and Brier scores [35-37].

In terms of attention, the degree of how concentrated the variable importance was in particular variables was measured (ie, Concentration in Table 1). The Herfindahl index, which represents the degree of concentration with values ranging from near 0 (least concentrated) to 1 (most concentrated), was employed for this measure [38]. Furthermore, correlation analysis was conducted to evaluate the consistency of attention results between multiple instances. Lastly, the generalizability of attention results was tested in two ways. First, the variable effect sizes obtained from conventional statistical methods (*t* test, Cohen *d*; chi-square test, Cramer *V*) were compared with variable importance (ie, attention values) [39,40]. For clear comparison from a clinical point of view, only the top 5% of the variables in terms of effect size (ie, conventional methods) and variable importance (ie, attention) were compared. Second, regression analysis was used to determine the overall relationship between attention values and effect sizes from conventional methods.

Table 1. Empirical test entries for measuring the performance of four models.

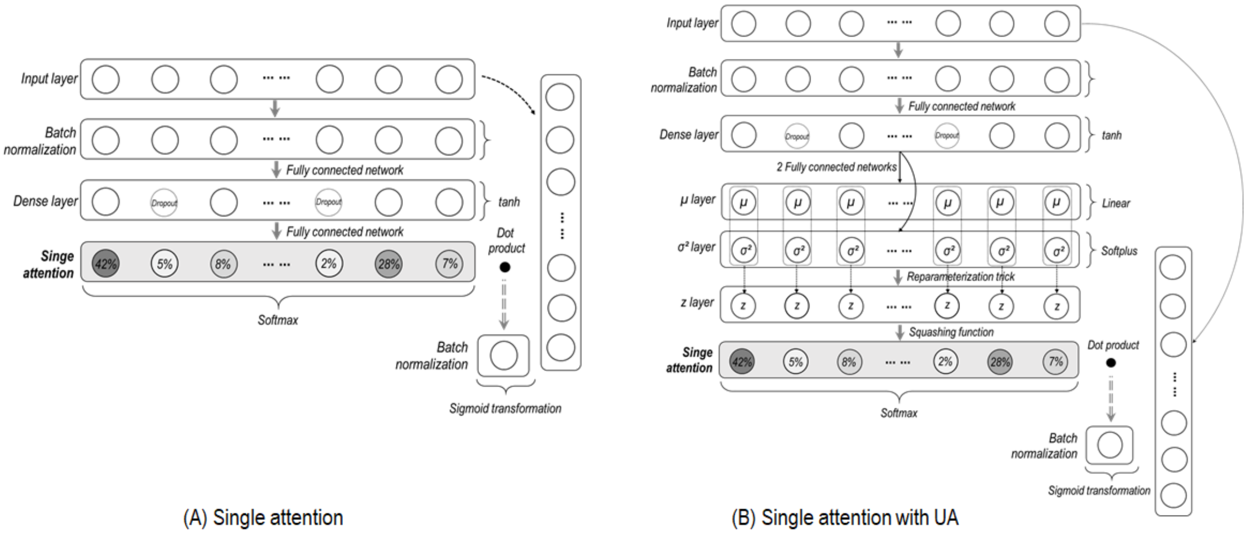
Entries (measures)	Methods
Outcome	
Prediction performance	- Receiver operating characteristic
Probability reliability	- Reliability diagrams
Attention	
Concentration	- Herfindahl index (near 0, least concentrated; 1, most concentrated)
Consistency	- Correlation
Generalizability	- Effect size: Cohen *d* (*t* test), Cramer *V* (chi-square test) - Regression analysis (dependent variable, effect size obtained from conventional methods; independent variable, attention values)

Model Specifications

Model Designs

Four models were developed according to the framework presented in Figure 2. The letters A, B, C, and D represent quadrants on the framework that correspond to the letters representing the model designs in Figure 3 and Figure 4. Model A (without any uncertainty considerations) has only a single attention layer (Figure 3A). The basic design of model B is the same as that of model A; however, it differs in that it has additional layers for UA (see layers with μ, σ^2, and z in Figure 3B). Thus, attention values in model B were estimated from the Gaussian distribution [9,33].

Figure 3. Model designs for single attention mechanisms. UA: uncertainty awareness. The concept of "reparameterization trick" is described in Concept A1 of Multimedia Appendix 1.



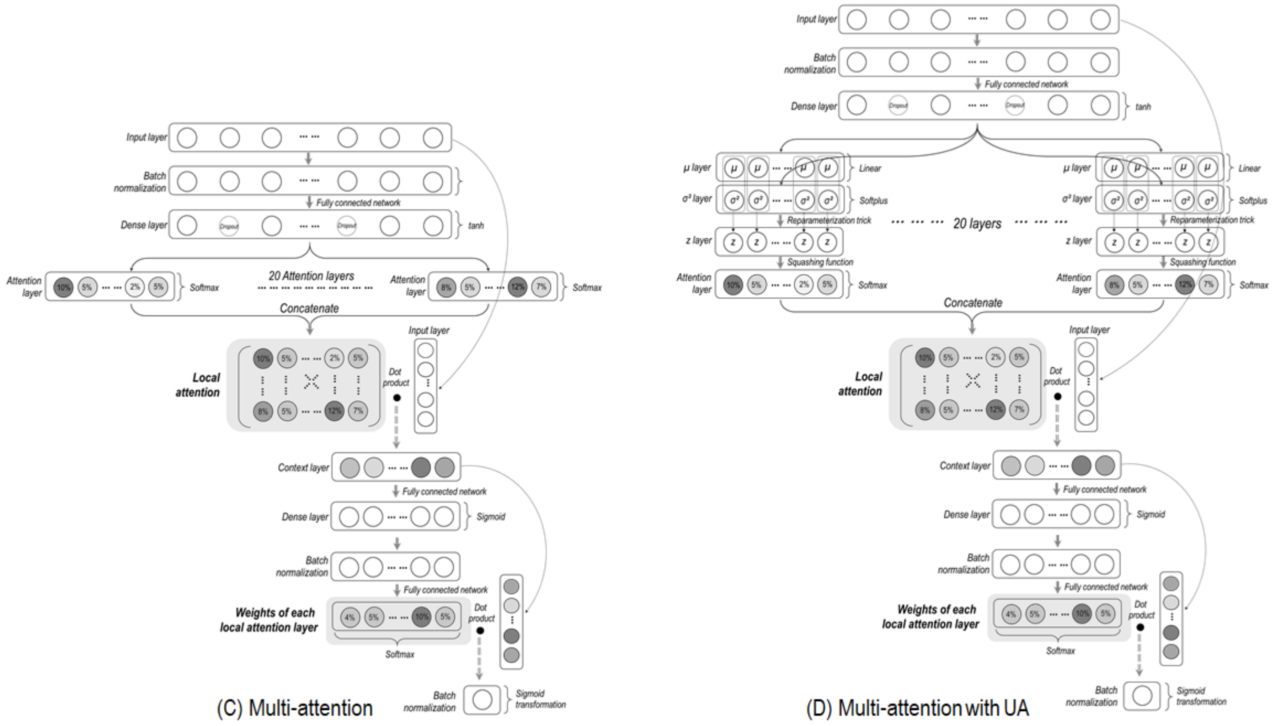
(A) Single attention

(B) Single attention with UA

The two models in which the degree of freedom is considered are presented in Figure 4. The difference between models C and D is that uncertainty in attention estimation is considered in model D (see layers with μ, σ^2, and z in Figure 4D).

Since these models have multi-attention layers (ie, Local attention in Figure 4) with a heuristic size of 20, multiple attentions are estimated. Thus, a novel structure was designed to convey the multiple values in the direction of model outcomes. Specifically, a context layer was created as the dot product of the local attention layer and the input layer (see Context layer in Figure 4). Each value on the context layer represents the summed impact of each corresponding local attention layer. Next, a “Weights of each local attention layer” was formed, whose role is to weigh (with weights between 0 and 1) the summed impact values in the context layer (Figure 4). Lastly, the outcome layer was created as the dot product of the weights of each local attention layer and the context layer.

Figure 4. Model designs for multi-attention mechanisms. UA: uncertainty awareness. The concept of "reparameterization trick" is described in Concept A1 of Multimedia Appendix 1.



(C) Multi-attention

(D) Multi-attention with UA

This somewhat complex structure ensures that the influence of one variable is passed only once to the model outcome, even if attention values are inferred multiple times (20 times in this case). Furthermore, using both the local attention layer and the weights corresponding to each vector, a unique attention value for each variable can be obtained, which facilitates interpretation.

Graphical and mathematical notations are provided for obtaining a set of unique values (global attention in Figure A1 of Multimedia Appendix 1). In addition, details of the four models are provided as Keras codes in Codes A2-A5 of Multimedia Appendix 2.

Settings for Rigorous Analysis

A 10-fold test was performed to assess the empirical test entries. The dataset was divided into 10 test sets (10% of total sets) and 10 training sets (90% of total sets). The training sets were then subdivided with 80% used directly for model training and 20% for validation.

Entries related to the model outcome (Table 1) were evaluated using all predicted probabilities of the entire sample. In other words, all of the values estimated from the 10 test sets were combined into one total set, which was then used for testing. Entries related to model attention were assessed based on the level of fold sets. Specifically, all of the estimated attention values were aggregated so that each set of 10 folds had a representative value. For rigorous estimation, both outcome and attention were estimated through Monte Carlo simulations with 100 trials [5,25]. Detailed procedures for estimating outcome and attention values are provided in the form of pseudoalgorithms (Algorithms A1-A3) in Multimedia Appendix 2.

Cost Functions

The binary cross-entropy function, which is generally used in binary outcome settings [41,42], was employed for models A and C where UA was not considered. However, the loss functions for models B and D, given their UA, were specified differently.

The UA models assume that the model outcome is dependent on the normal distribution (ie, layers with μ, σ^2, and z), which infers the attention value [9,32,33]. Therefore, the distribution associated with attention should be considered in the cost function. The cost function under these assumptions was derived through Bayesian inference theory [9,32,33,43]. According to this theory, the network weights should be learned so that the distributions in the *z* layer generated by the weights (see *z* layer in Figure 3B) become similar to the true distributions in the *z* layer [9,32,33,43]. Therefore, the cost function for uncertainty awareness models consists of two terms: the loss associated with the model outcome and the degree of similarity associated with the *z* distribution [9,32,33,43]. The cost function, with its description, is presented in Notation A2 of Multimedia Appendix 1.

Learning Environments and Parameters

Attention models were developed, learned, and tested on Keras 2.3.1, tensorflow 2.1.0, and Python 3.7.6. Adam with a learning rate of 0.001 was employed as an optimizer to train all models. A training dataset with a batch size of 5000 was provided to the model. The early-stop rule was applied to stop training the models at the optimal epoch. Thus, model training was terminated when the loss value of the validation set did not improve further during the last 1200 epochs. Other details about activation functions and the structure of nodes and layers are provided in Code A2 to Code A5 of Multimedia Appendix 2. For the effect sizes of conventional statistical methods, the values for Cohen *d* and Cramer *V* were obtained from researchpy 0.2.3, a third-party Python library. Additionally, regression analysis was performed on Stata 13, a commercial statistical analysis software.

Data

The case analysis was performed in a setting where the relationship between a disease and other variables is well established: an 8-year (2010 to 2017 inclusive) cumulative Korea National Health and Nutrition Examination Survey dataset, which assesses the nutrition and health status of Koreans and collects information about major chronic diseases such as metabolic syndrome and diabetes [44]. Since the association between diabetes and other variables has been well established through prior studies using these data, this selection facilitated a clear assessment of the empirical test results of this study [45-49]. Thus, a diabetes diagnosis (1=diabetes, 0=no diabetes) was set as the outcome variable for the four attention models. The subjects were classified as having or not having diabetes based on whether they were diagnosed by a doctor, or received diabetes medication or insulin injections. Fasting blood glucose levels, which are a very strong indicator for diagnosing diabetes, were intentionally used as an input variable to evaluate the power of the attention mechanism for determining important variables.

In the 8-year cumulative data, only variables with consistent labels during that period were included. Variables with no change in value, containing more than a 50% omission rate and subject identification information were excluded from the study set. Categorical variables of both nominal and ordinal types were integerized using integer encoding [50]. In other words, class labels of each categorical variable were converted into integers. Missing values were encoded as the extreme value 99,999. Since deep-learning algorithms can learn the nonlinear relations among variables [51], these encoding approaches can be workable and are efficient in settings where preprocessing is demanding owing to many variables. All values in input variables except for a missing value indicator (ie, 99,999) were normalized to be between 0 and 1, and were then fed into the deep-learning models.

Results

Data Preprocessing

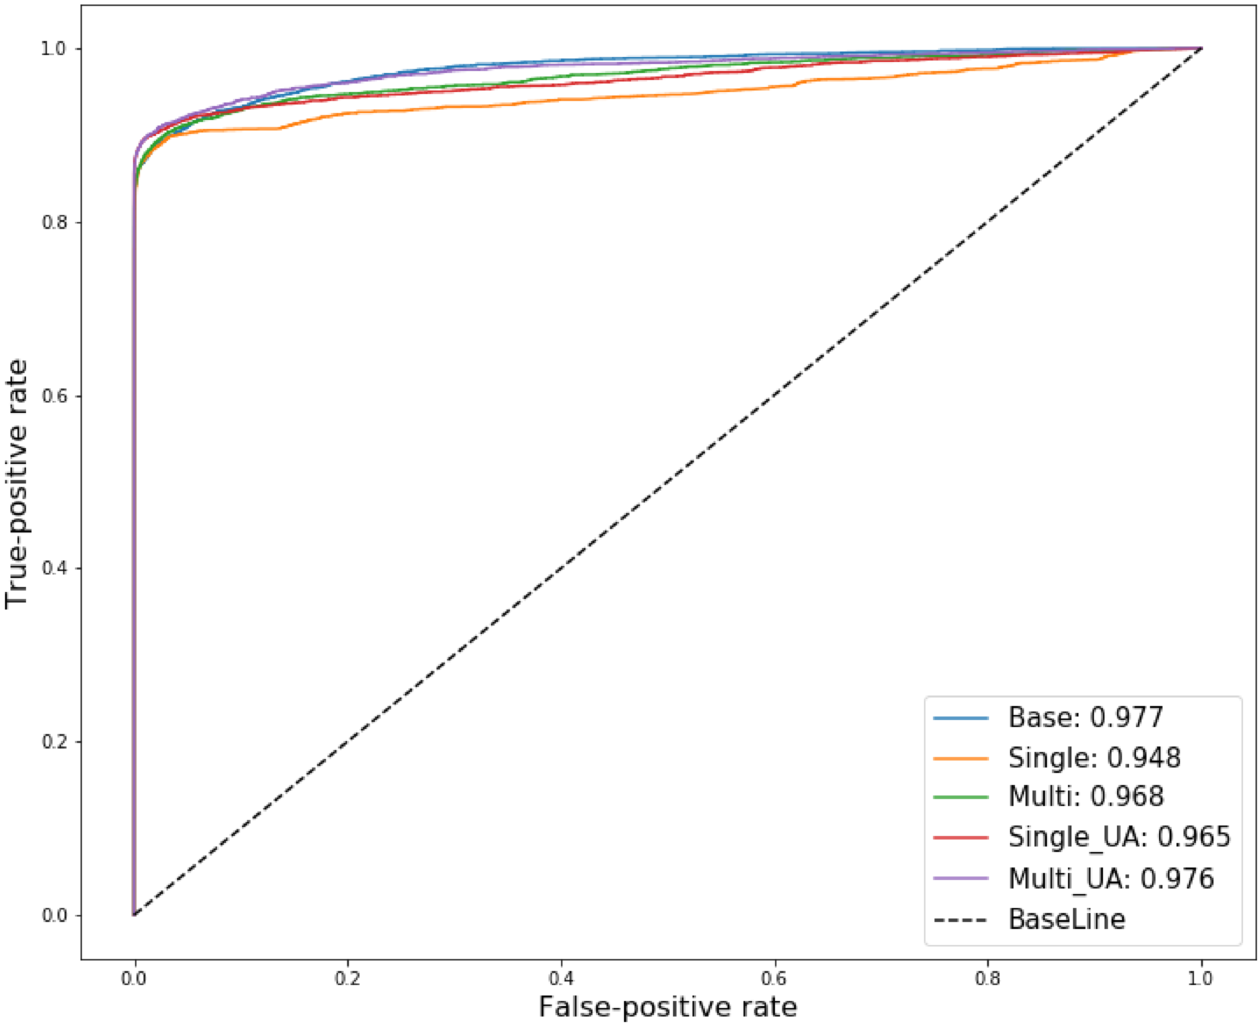
There were 238 variables with consistent labels in the 8-year cumulative dataset. Only 128 variables were selected by preprocessing. There were 22 variables with no change in value, 84 variables with more than 50% missing values, and 4 variables containing identification information that were excluded from the analysis. The total number of observations (ie, the number of subjects) was 33,065, with an average age of 48.89 years and with men accounting for 40.41% (n=13,361) of the sample. Only 6 variables had no omissions, and the average missing rate of variables with omissions was 10.38%

Outcome

Prediction Performance

Figure 5 represents the results for the ROC test and area under the curve (AUC) values of the five models. The results are based on the combined sets of predicted probabilities of 10 test sets of each model. According to the AUC results, the accuracy of the five models in terms of sensitivity and specificity was excellent overall. The AUCs of the base model without the attention mechanism, the single attention model, multi-attention model, single attention model with UA, and multi-attention model with UA were 0.977, 0.948, 0.968, 0.965, and 0.976, respectively.

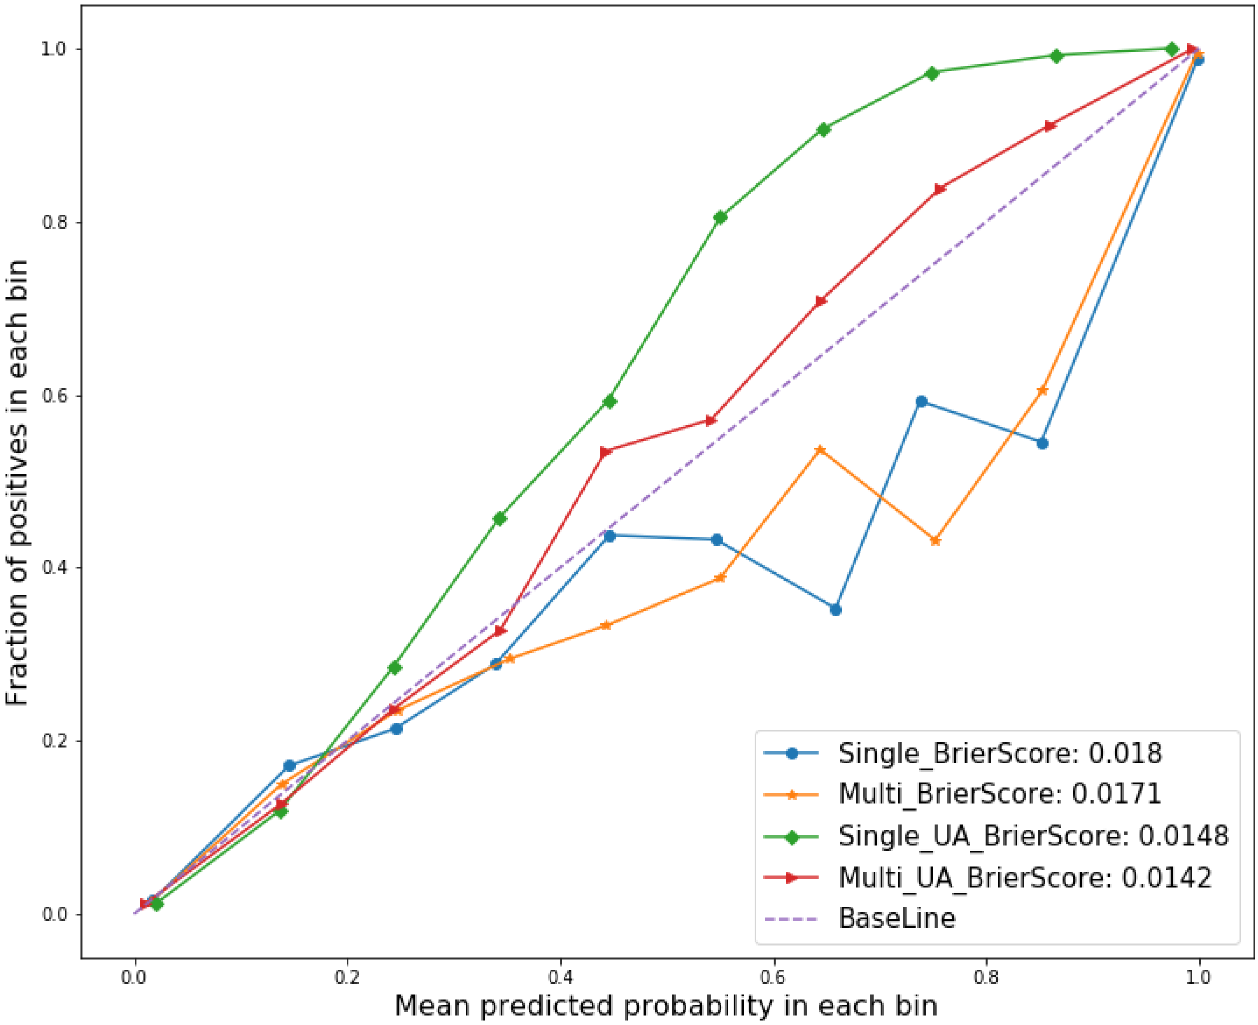
Figure 5. Receiver operating characteristic (ROC) test for the four models. All values estimated from 10 test sets are combined into one set for each model. The base indicates the deep-learning model without attention mechanisms. UA: uncertainty awareness.



Probability Reliability

Figure 6 shows the performance of probability reliability for the four models in the form of a reliability diagram. A characteristic of the UA models is that most fractions of positives were plotted above the diagonal. By contrast, models without UA showed more fractions of positives below the diagonal than the other models. The fraction of positives of the multi-attention with UA model was the closest to the diagonal. The Brier scores of the single attention, multi-attention, single attention with UA, and multi-attention with UA models were 0.018, 0.0171, 0.0148, and 0.0142, respectively.

Figure 6. Reliability diagrams for four models. The Brier score measures the overall reliability of probabilistic predictions. UA: uncertainty awareness.

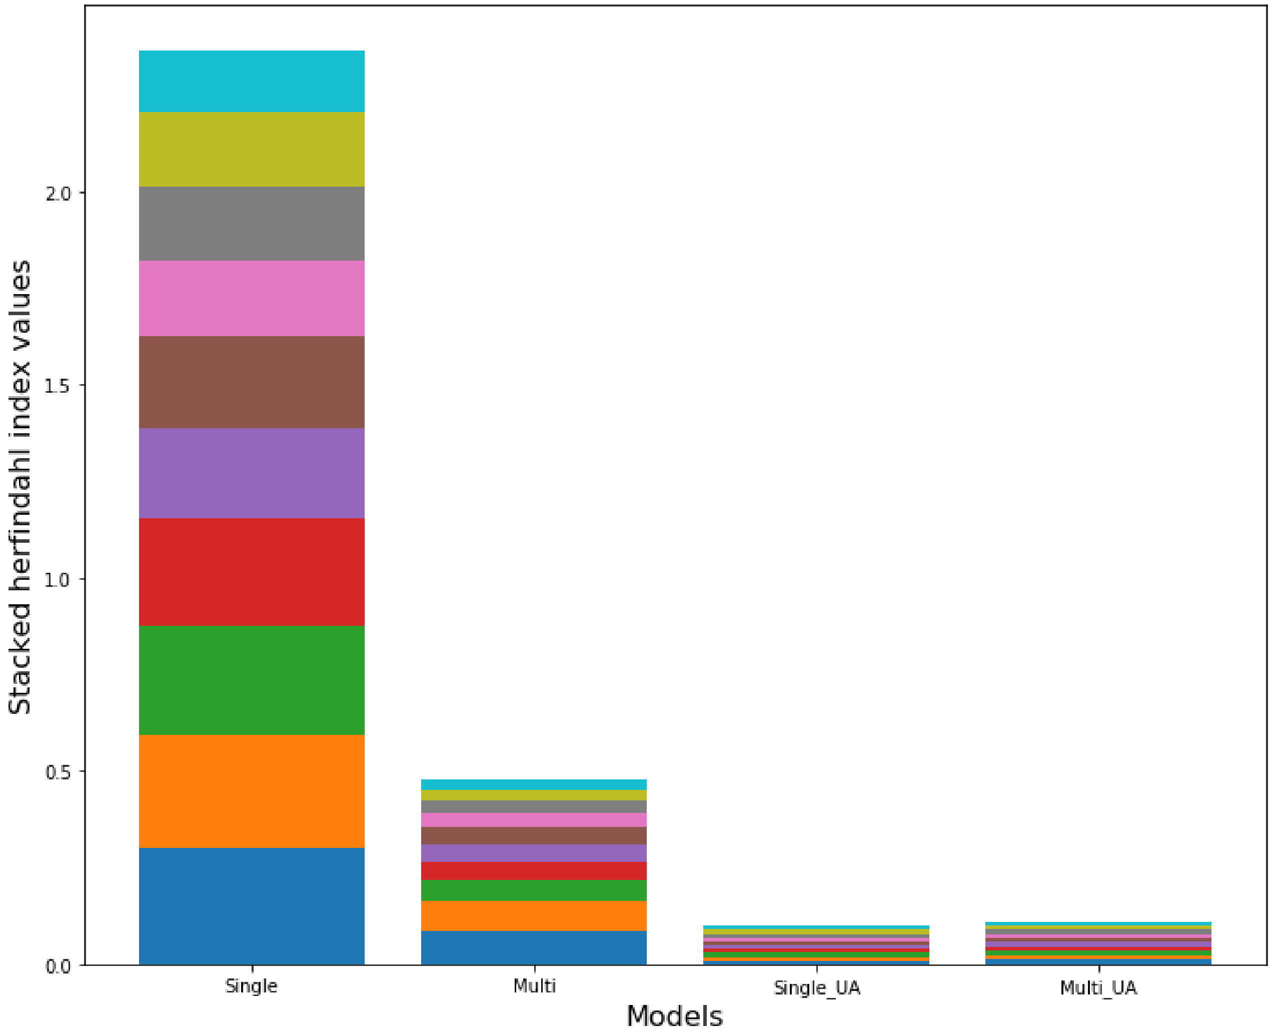


Attention

Concentration

Figure 7 shows stacked Herfindahl indices sorted by value size for the 10-fold sets in each model. The values for each fold are presented in Table A1 of Multimedia Appendix 1. In general, models without UA showed relatively large Herfindahl indices. The average Herfindahl index values for the single attention and multi-attention models were 0.236 and 0.048, respectively. However, models with UA had very small values, regardless of the degree of freedom. The average Herfindahl index values for the single attention with UA and multi-attention with UA models were 0.01 and 0.01, respectively. These results indicate that influence is more concentrated on several variables in models where uncertainty is not considered than in those where uncertainty is considered.

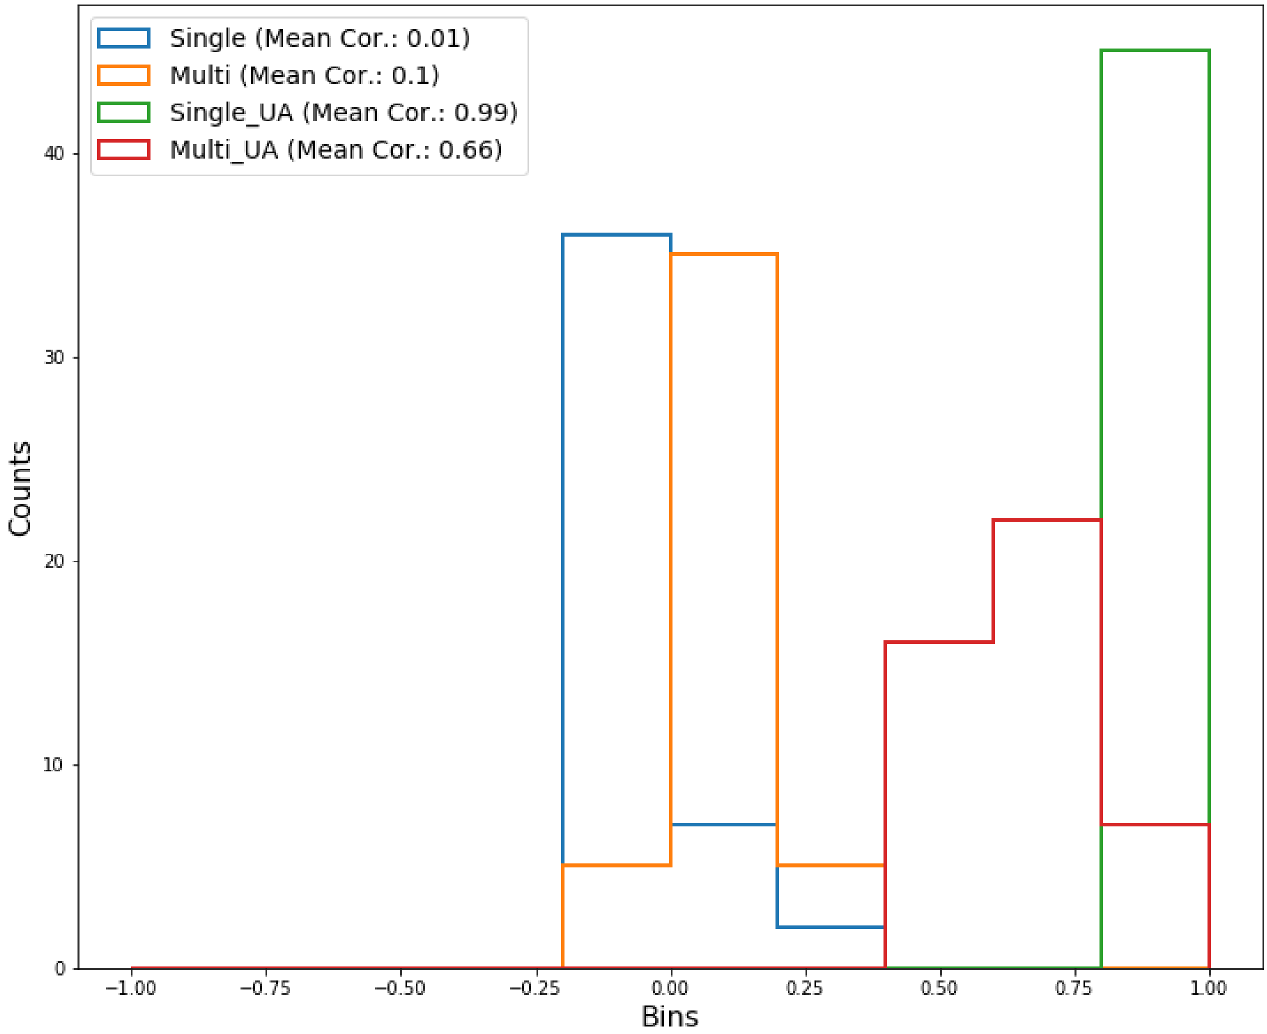
Figure 7. Herfindahl index values of 10-fold sets for each model. UA: uncertainty awareness.



Consistency

Figure 8 shows histograms for the 45 correlations ({[10×10]–10}/2) among the 10-fold sets for each model. In general, the correlations of the fold sets from the models with UA were higher than those of the models without UA. The average correlations of the fold sets from both models without UA were calculated to be close to zero (ie, 0.01 and 0.1). Moreover, the average correlations from the two models with UA were calculated as 0.99 and 0.66, respectively.

Figure 8. Histograms for correlations among 10-fold sets for each model. UA: uncertainty awareness.



Generalizability

Table 2 shows the results of the variable importance learned by the attention models and the effect sizes measured by conventional statistical methods. Definitions of each variable are provided in Table A2 of Multimedia Appendix 1. The top 5% (127×0.05=6) of variables, sorted by the magnitude of values obtained from each method, are reported. Since Cohen *d* from conventional methods may take on negative values, the absolute value was applied when sorting. Overall, models in which uncertainty was not considered were trained to have high attention values. Furthermore, variables such as “allownc” (whether to receive a basic living allowance) and “house” (whether to have own house) that bear little relation to health status were included in the results.

Table 2. Top 5% variable importance results estimated by different methods.

Variable[a]	Attention value[b]/Effect size[c]
Single attention model	
sm_presnt	0.0615
BD1	0.0519
pa_walk	0.0479
HE_Upro	0.0468
HE_alt	0.0430
Npins	0.0413
Multi-attention model	
HE_HB	0.041
Sex	0.033
Pa_walk	0.032
HE_HBsAg	0.027
Allownc	0.026
HE_sbp	0.026
Single attention model with UA[d]	
pa_walk	0.050
BH9_11	0.017
HE_THfh2	0.011
HE_THfh1	0.010
HE_THfh3	0.010
DI5_dg	0.010
Multi-attention model with UA	
pa_walk	0.050
HE_THfh2	0.019
BH9_11	0.015
HE_THfh1	0.013
HE_ast	0.010
house	0.010
Conventional statistics[e]	
age	1.536
HE_glu	1.214
HE_HbA1c	–1.014
Wt_pool_1	–0.516
Wt_itvex	–0.516
HE_Uglu	0.319

[a] See Table A2 in Multimedia Appendix 1 for variable label descriptions.

[b] Average from the 10 fold sets.

[c] Effect size is presented only for the conventional statistics.

[d] UA: uncertainty awareness.

[e] Null hypothesis of categorical variables=no relationships between diabetes and a categorical variable; null hypothesis of continuous variables=no difference in variables between the diabetes and no diabetes groups.

Table 3 shows the overall relationship between the effect sizes of variables and variable importance. Since attention values from both single attention and multi-attention models with UA had a high correlation (0.943), two regression models in which the two variables did not overlap were specified. The regression results showed no association between the variable importance from attention models and the effect size of variables from conventional methods.

Table 3. Regression analysis results for assessing an association between attention values and effect sizes.

Regression model variables[a]	Regression 1		Regression 2	
	Coefficient	$P > t$	Coefficient	$P > t$
Single attention	−0.696	0.635	−0.668	0.652
Multi-attention	1.897	0.487	2.019	0.476
Single attention with UA[b]	−1.351	0.797	—[c]	—
Multi-attention with UA	—	—	−1.541	0.772
Intercept	0.075	0.09	0.075	0.075

[a] The dependent variable is the absolute value of effect size, calculated by Cohen *d* for continuous variables and Cramer *V* for categorical variables. The total number of observations is equal to the number of variables.

[b] UA: uncertainty awareness.

[c] —: variable not included in the regression model.

Discussion

Principal Findings

Reliability

A difference in performance according to the degree of freedom was prominent in the probability reliability diagram (Figure 6). The fraction of positives located above the diagonal indicates that probabilities are predicted to be larger than expected, while the fraction of positives located below the diagonal means that probabilities are estimated to be smaller than expected [35,36]. In this regard, overall probabilities from the two attention models without UA tended to be underestimated, whereas the attention models with UA tended to overestimate probabilities. Although no clear causal relationship has been identified, several lines of empirical evidence suggest that the over- and underestimation is associated with data noise, estimation methods, and parameter settings [30,52-54].

Since the difference appeared to be based on the UA axis, the over- or underestimation tendency of the models may be related to UA. Furthermore, the Brier scores of the two models with UA were smaller than those of the two models without UA, indicating that models with UA tend to estimate more reliable probabilities than models without UA. These findings are consistent with the results of recent research that estimated reliable outcomes with an emphasis on UA [9,55-57]. Theoretically, the most probabilistic values are inferred from a distribution that takes means and variances into account under UA [9,55-57]. Thus, the awareness of uncertainty may bring reliability to the prediction results of deep-learning models, which are vulnerable to randomness during the learning process.

Consistency

UA produced noticeable differences in results consistency and the concentration of variable importance. Specifically, in UA models with low Herfindahl indices, variable importance appeared to be distributed over many variables in contrast to models that did not consider uncertainty (Figure 7). In addition, high correlations between 10-fold sets were found in the attention results from the UA models, whereas no correlations were found in the results from UA models (Figure 8). Furthermore, the attention values in the models with UA were generally smaller than those of models without UA.

These results suggest that the consistency of results from the UA models is high because the variable importance with overall low values is distributed evenly over most variables. This result is closely associated with the assumption that attention values were estimated based on a normal distribution within the cost function (see equation for the Kullback–Leibler divergence D_{KL} in Notation A2 of Multimedia Appendix 1). According to this equation, as both μ and σ^2 approach zero, model parameters for forming the normal distribution approximate the true theoretical distribution, indicating that the models are well learned [32,33]. Consequently, the overall attention values were small since the overall values of μ were small.

Spurious Correlations

As with conventional statistical methods, the attention models were unable to control spurious correlations during attention learning. Specifically, of the top 5% of variables obtained from conventional statistics, wt_pool_1 (interview weight combined years) and wt_itvex (interview weight for a single year) have little to do with health status (Table 2). These variables are weights for compensating errors due to differences in the number of households and populations between the sample design time and the survey time. In addition, the variables “allownc” (whether to receive basic living allowance) and “house” (whether to have own house) were obtained from the attention models (Table 2). These results may suggest spurious correlations in the dataset itself [58]. In other words, these variables, with little relation to diabetes, have a relatively close relationship with diabetes only by chance.

Generalizability to Conventional Statistics

In terms of clinically relevant variables, no significant association between the results of conventional statistics and attention models was found. Specifically, the variables age, HE_glu (fasting blood sugar), HE_HbA1c (hemoglobin AIC), and HE_Uglu (urine glucose) selected by conventional methods are well known to have a direct association with diabetes [59-61]. In addition, several variables, including pa_walk (amount of walking) and BH9_11 (vaccination status against influenza virus), obtained by the attention models are less directly related to diabetes. These variables may represent behavioral characteristics of patients with diabetes who are trying to manage their health.

Furthermore, there was no intersection of variables selected by both attention models and conventional statistical methods (Table 2). In particular, HE_glu, which was intentionally used as an input variable for testing purposes, was not determined as a major variable in the attention mechanism models in contrast to the conventional statistical methods. Additionally, no variable was statistically significant in the regression analysis that evaluated the positive association between attention values and effect sizes (Table 3). Comprehensively, these results suggest that the variable importance obtained from attention mechanisms may not be generalized to the effect size of conventional statistics.

Lessons from the Findings

Hyperparameters

The model structure and weight of terms in the cost function are hyperparameters to be adjusted. In terms of the model structure, the degree of freedom of attention layers was evaluated by comparing two extreme cases of 1 attention layer and 20 attention layers. Although the size of attention layers does not make a significant difference, the results can be significantly different if the number of attention layers is different under other conditions.

Furthermore, by taking uncertainty into account in the models, a term (ie, the degree of similarity associated with the normal distribution) was added to the cost function. However, as discussed previously, this term may interfere with the assignment of great importance values to variables by making all μ values small. To alleviate this issue, the weight of the term may be lowered, so that the term is less reflected during model training [9,29,33].

However, hyperparameter tuning is not conducted based on a theoretical basis but rather on a heuristic basis. In other words, there is no standard of how many attention layers should be specified and how much the weight should be adjusted for better results. If the goal of building models aims to maximize accuracy, various hyperparameter settings can be tested in the direction of increasing model accuracy. However, there is no clear criterion to maximize the performance of interpretability. In other words, although various hyperparameter settings are tested, finding the best-optimized hyperparameter setting based on the statistical point of view is challenging. Therefore, the variable importance should be understood in a limited way only within the framework of this experiment.

Potential Limitations of Interpretability

There was no significant association between the variable importance obtained from the attention mechanism and the effect size obtained from conventional statistics. One of the most probable reasons for this result is that the assumption of the association among input variables is different between conventional methods and deep-learning algorithms. Specifically, conventional statistical methodologies such as linear regression analysis and ANOVA basically estimate effect sizes based on the assumption of independence between input variables [62,63]. Thus, if a particular input variable has nothing to do with an outcome variable, the variable has little effect on the outcome. In contrast, neural network–based algorithms, including deep learning, infer outcome variables by taking into account the dependencies between the input variables [41,42]. Therefore, a variable that is not directly related to an outcome variable but is associated with others that are related to the outcome variable may have a somewhat greater effect on the outcome variable. Owing to these differences, attention results must not be considered to have similar meanings and tendency to the variable effect size from conventional methodologies.

Recent new technologies such as sensors (ie, wearable devices or facilities in operating rooms) have produced new types of data. Since the associations between variables have not yet been fully explored, relying solely on attention mechanisms may lead to a false judgment that variables that have minimal association with the outcome variable are important. Hence, it is advisable to consider the results of attention and conventional statistics together.

Furthermore, in situations where there is a spurious correlation, neither method provides good explanatory power. Spurious correlations can only be eliminated through data preprocessing based on domain knowledge. Hence, care must be taken when implementing both attention models and conventional statistical methods in environments with manifold variables that cannot be preprocessed (ie, included or excluded) using definite knowledge. In particular, finding new features using attention mechanisms may not be adequate in environments where the data are susceptible to spurious correlations owing to a large number of variables but few observations such as in the field of genetic engineering [64,65]. In this case, it may be appropriate to employ results of attention mechanisms for reaffirming existing findings in previous research or supporting informed knowledge.

Future Direction for Medical Informatics

The results of this study provide several points of guidance for future research in the medical field. First, more empirical evidence should be secured based on various structures in terms of the degree of freedom. It may be desirable to test what attention results are produced when different values of degree of freedom are employed. Particularly, given that the medical field has various data types such as images, natural languages, and numerical values, attention results should be assessed according to the degree of freedom with consideration of the data characteristics [66-69].

Second, attention models with more sophisticated UA should be tested. In this study, the model outcome variable was assumed to depend on the distribution of the attention layer; that is, $P(diabetes|z)$. However, current state-of-the-art Bayesian estimation assumes that the model outcomes depend on all network weights and data; that is, $P(outcome|z, weight, data)$ [9,29]. Thus, it is necessary to evaluate how the variable importance is formed when more up-to-date estimation methods are applied.

Third, more research that strictly evaluates variable importance based on attention mechanisms over diverse disease domains is needed. As found in this study, attention has its limitations in terms of generalizability to conventional statistics and control of spurious correlations. However, since this case study was conducted with a single cohort of Korean patients with diabetes, more empirical evidence from various cohorts or diseases should be tested to confirm that attention mechanisms may not provide any significant meaning. Importantly, for elaborate empirical research, a greater in-depth understanding of the association between covariates and health outcomes is needed. Hence, more domain experts on a specific disease along with data scientists should be actively involved in these studies.

Fourth, methods for controlling the distribution of variable importance should be studied. As revealed in this analysis, the variable importance can be distributed over many variables or concentrated on a few variables depending on the model structure (Figure 7). When examining the overall relationships between covariates and health outcomes such as a comprehensive review of national health status [45-49], it may be desirable to detect many potentially important variables. By contrast, when the relationship between a small number of key variables and outcome is important, such as in the generation of targeted therapy [70,71], the importance should be focused on a few variables. However, to the best of our knowledge, most existing attention studies have not considered the control of the variable importance distribution [8,10-12,24,25,32,33,66,68]. Therefore, more studies on this subject are needed.

Limitations

There are several limitations to be aware of when assessing the academic value of this study. First, well-behaved data with excellent predictive performance owing to the data characteristics were employed for the analysis. For this reason, the overall AUC performance (see ROC test in Figure 5) might have been good for all approaches (ie, the degree of freedom and UA). When the attention mechanisms are applied to ill-behaved data without manipulation, such as the intentional use of a variable HE_glu as an input variable, the model accuracy may be reduced. If the accuracy of the model is moderate and domain expertise exists for the disease, it is still advisable to attempt a variable importance interpretation. However, if the model accuracy becomes too poor, it may not be worthwhile to interpret the variable importance. Furthermore, categorical variables of both nominal and ordinal types were integerized, and missing values were encoded as the extreme value in this study. Although this operationalization can be efficient in deep-learning algorithms that can learn nonlinear relationships, it is not a robust approach. Thus, it is necessary to identify problems with the approach and to discuss how to deal with them when ill-behaved data with robust operationalization are employed. Furthermore, since data from a single cohort were used, the results of this study, which point out the limitations of the interpretable power of attention mechanisms, should not be generalized. Rather, it should be recognized that accuracy performance and interpretable power may vary depending on the modeling approaches and data.

Second, this study does not guarantee that state-of-the-art estimation methods for UA were applied. Specifically, the models' outcomes do not depend on network weights. In addition, research on estimation methodologies in deep learning is in progress, and therefore new methodologies are still being developed. Accordingly, the value of this study lies in the framework proposals that suggest the research direction of attention modeling rather than in the details of attention estimation methods.

Third, the design of weights of each local attention layer is not as sophisticated as the design of local attention layers (Figure 4). Specifically, uncertainty considerations are not assumed in the weights layer. Moreover, this layer does not have to be dependent on the local attention layer. In other words, the weights layer may be designed as an independent layer that does not come from the local attention layer. We plan to perform various investigations in this area.

Conclusions

Attention mechanisms have the potential to make a significant contribution to the medical field, where explanatory power is important, by overcoming the limitations of the noninterpretability of deep-learning algorithms. However, potential problems that may arise when attention mechanisms are applied in practice have not been well studied. Thus, we hope that this study will serve as a cornerstone to raise potential issues, and that many similar studies will be conducted in the future. The cohesive awareness of potential problems arising from attention mechanisms in the field of application will provide theoretical researchers with new goals for problem-solving.

Abstract

Background: COVID-19, which is accompanied by acute respiratory distress, multiple organ failure, and death, has spread worldwide much faster than previously thought. However, at present, it has limited treatments.

Objective: To overcome this issue, we developed an artificial intelligence (AI) model of COVID-19, named EDRnet (ensemble learning model based on deep neural network and random forest models), to predict in-hospital mortality using a routine blood sample at the time of hospital admission.

Methods: We selected 28 blood biomarkers and used the age and gender information of patients as model inputs. To improve the mortality prediction, we adopted an ensemble approach combining deep neural network and random forest models. We trained our model with a database of blood samples from 361 COVID-19 patients in Wuhan, China, and applied it to 106 COVID-19 patients in three Korean medical institutions.

Results: In the testing data sets, EDRnet provided high sensitivity (100%), specificity (91%), and accuracy (92%). To extend the number of patient data points, we developed a web application (BeatCOVID19) where anyone can access the model to predict mortality and can register his or her own blood laboratory results.

Conclusions: Our new AI model, EDRnet, accurately predicts the mortality rate for COVID-19. It is publicly available and aims to help health care providers fight COVID-19 and improve patients' outcomes.

KEYWORDS

COVID-19; artificial intelligence; blood samples; mortality prediction

Introduction

COVID-19 is a highly contagious infection caused by SARS-CoV2. In severe cases, COVID-19 causes acute respiratory distress, multiple organ failure, and, eventually, death [1]. As of November 2020, COVID-19 cases and deaths are approaching 60 million and 1.5 million, respectively, worldwide.

In a pandemic situation, the most important issue in the management of patients diagnosed with COVID-19 is to select patients at risk of high mortality in the early period of disease and to provide appropriate treatments [2]. Particularly, the condition of patients at high risk can rapidly deteriorate. Some papers reported that deceased COVID-19 patients initially had mild symptoms but suddenly transitioned to a critical stage, leading to death [3-5]. In Italy, 75% of deceased patients showed mild symptoms, such as fever, dyspnea, and cough, at admission to the hospital [1]. Thus, the development of a prognostic model to predict mortality as early as possible is very critical.

In this pandemic crisis, the shortage of resources and medical staff causes big problems in the health care system. Accordingly, artificial intelligence (AI) can aid in the management of COVID-19 patients. A recent research study has developed an AI prediction model of mortality based on blood test results [6]. In this study, Yan et al initially considered 73 blood-borne markers for the mortality prediction model; finally, three blood biomarkers were selected, including lactate dehydrogenase (LDH), lymphocyte, and high-sensitivity C-reactive protein (hs-CRP). This model predicted mortality with 90% accuracy based on a decision tree using an XGBoost classifier [7] to analyze feature importance.

However, Yan et al's study has drawbacks. First, the three biomarkers derived from the XGBoost-based feature selection may not be the best choices. Feature importance provides a score indicating how each feature contributes in the construction of decision trees within the model. However, due to the stochastic nature of machine learning algorithms, each feature's importance score may vary. Moreover, in decision tree algorithms, such as an XGBoost and a random forest (RF), when multiple features have the same gain during the split, a branch in a tree is made by randomly selecting features among them. Second, numerous studies have shown that the disease progression of COVID-19 is not only associated with LDH [2,8-11], lymphocyte [12,13], and hs-CRP [2,10,14-17] but also with other blood-based biomarkers, such as neutrophil counts [16,18,19], albumin [18,20,21], and prothrombin activity [18,22-24]. In our study, we developed an AI model using 28 biomarkers for predicting the mortality of COVID-19 patients. Third, the three biomarker-based AI models [6] predicted mortality 10 days before a patient's recovery or death. These limitations show that the model may not work for COVID-19 patients who have just been diagnosed and hospitalized.

Therefore, in this study, we aimed to develop an AI model based on a blood test for mortality prediction at the early stage of hospital admission. We deployed the developed AI model on a public website so that all patients and medical staff could predict mortality using individual patient blood test results.

Methods

Data Sets

This study was approved by Wonkwang University Hospital (WKUH), Chonnam National University Hospital (CNUH), and Samsung Medical Center (SMC) in Korea. Informed consent was waived. For training data, we used the blood test results obtained from 375 COVID-19 patients collected between January 10, 2020, and February 24, 2020, in Tongji Hospital, Wuhan, China [6]. Of these, 14 patients without a blood test within 1 day after the hospital admission were excluded, and 361 patients—212 males (58.7%) and 149 females (41.3%); mean age 58.9 years (SD 16.5)—were included. As presented in Multimedia Appendix 1, the training data set of 361 patients included the admission date and time, discharge date and time, age, gender, mortality outcome, and results of blood tests obtained within 24 hours after hospital admission. For testing data, we collected medical records on COVID-19 patients (N=106) from three medical institutions: CNUH (85/106, 80.2%), WKUH (11/106, 10.4%), and SMC (10/106, 9.4%). The blood laboratory results from these 106 COVID-19 patients were collected between February 2020 and July 2020. Similar to the training data, we used the blood test data obtained within 24 hours after hospital admission (see Multimedia Appendix 2). For summarizing the statistics of the training and testing data sets, the patients were classified into a survivor group and a deceased group in the training and testing data sets. The number of blood tests differed across patients and institutions. The mean numbers of blood tests per patient were 61.21 (range 24-73) in the training data set and 35.36 (range 30-55) in the testing data set. The mean numbers of hospitalization days were 13.82 (survivor group) and 8.16 (deceased group) in the training data set and 18.21 (survivor group) and 17.98 (deceased group) in the testing data set (see Table 1).

Table 1. Statistical summary of the training and testing data sets.

Patient data	Training data set (N=361)	Testing data set (N=106)			
	Tongji Hospital	CNUH[a] (n=85)	WKUH[b] (n=11)	SMC[c] (n=10)	Total (N=106)
Number of patients, n (%)					
Total	361 (100)	85 (100)	11 (100)	10 (100)	106 (100)
Survived	195 (54.0)	85 (100)	9 (82)	10 (100)	104 (98.1)
Deceased	212 (58.7)	0 (0)	2 (18)	0 (0)	2 (1.9)
Gender, n (%)					
Male	212 (58.7)	34 (40)	5 (45)	3 (30)	42 (39.6)
Female	149 (41.3)	51 (60)	6 (55)	7 (70)	64 (60.4)
Number of hospitalization days, mean (SD)					
Survived	13.82 (6.38)	15.06 (7.90)	28.16 (11.13)	30.95 (23.03)	18.21 (11.46)
Deceased	8.16 (7.38)	N/A[d]	17.98 (11.83)	N/A	17.98 (11.83)
Age in years, mean (SD)	58.91 (16.49)	44.14 (21.81)	56.27 (23.00)	58.20 (21.05)	46.73 (22.28)
Number of blood biomarkers collected					
Min-max	24-73	32-55	30-52	30-40	30-55
Mean (SD)	61.21 (6.92)	36.89 (4.11)	35.00 (5.31)	34.20 (3.16)	35.36 (4.19)

[a] CNUH: Chonnam National University Hospital.

[b] WKUH: Wonkwang University Hospital.

[c] SMC: Samsung Medical Center.

[d] N/A: not applicable; there were no deceased patients in the testing data set at this institution.

Feature Selection

Given the total 73 blood biomarkers from the training data, we performed an analysis of variance (ANOVA), which uses an F test to check for any significant difference between the two groups (ie, deceased vs survivor) according to each blood biomarker. For the feature selection, we also considered the available data rate (ADR), which refers to how much blood biomarker data were available for training the AI model. This is calculated as

where $N_{patients}$ is the total number of patients (N=361) and $N_{biomarker}$ is the number of patients having each of the specific biomarker data.

Based on the ANOVA, we first selected the top 32 biomarkers corresponding to P values less than 10^{-5}. Subsequently, we excluded four biomarkers with ADR values of less than 90%. Table 2 summarizes the final selection of 28 biomarkers with the corresponding ANOVA P values and ADR values. The ANOVA P values and ADR values for all 73 biomarkers in the training data set are summarized in Multimedia Appendix 3, Table S1. The sample distributions of the selected 28 biomarkers in the survivor and deceased groups are presented in Multimedia Appendix 3, Figure S1.

Table 2. List of 28 blood biomarkers selected for the artificial intelligence model training.

Biomarker index No.	Blood biomarker	ANOVA[a] *P* value	ADR[b], %
1	Lymphocytes	2.44×10^{-46}	96.95
2	Neutrophils	5.65×10^{-43}	96.68
3	Albumin	2.90×10^{-37}	96.12
4	Lactate dehydrogenase	4.18×10^{-36}	96.12
5	Neutrophil count	3.54×10^{-35}	96.68
6	Hypersensitive C-reactive protein	8.38×10^{-35}	94.74
7	Prothrombin activity	3.20×10^{-26}	94.18
8	Calcium	2.24×10^{-19}	95.29
9	Urea	3.29×10^{-17}	96.12
10	Estimated glomerular filtration rate	5.05×10^{-17}	96.12
11	Monocytes	1.09×10^{-14}	96.95
12	Globulin	6.06×10^{-13}	96.12
13	Eosinophils	2.07×10^{-12}	96.68
14	Glucose	2.39×10^{-11}	93.63
15	Red blood cell distribution width (RDW)	8.43×10^{-10}	92.24
16	HCO_3^- (bicarbonate)	2.68×10^{-9}	96.12
17	RDW standard deviation	3.06×10^{-9}	92.24
18	Platelet count	1.46×10^{-8}	96.68
19	Mean platelet volume	1.92×10^{-7}	92.24
20	Platelet large-cell ratio	2.02×10^{-7}	92.24
21	Prothrombin time	3.42×10^{-7}	94.18
22	Total protein	5.29×10^{-7}	96.12
23	Platelet distribution width	6.98×10^{-7}	92.24
24	Aspartate aminotransferase	1.01×10^{-6}	96.12
25	Thrombocytocrit	1.49×10^{-6}	92.24
26	Eosinophil count	2.90×10^{-6}	92.24
27	Alkaline phosphatase	8.27×10^{-6}	96.12
28	International standard ratio	2.65×10^{-5}	92.24

[a] ANOVA: analysis of variance.

[b] ADR: available data rate.

Preprocessing

Given the selected 28 biomarkers, the mean number of available biomarkers per patient was 27.22 (SD 2.33) for the training data and 16.86 (SD 1.58) for the testing data, as summarized in Table 3. To handle the missing data, we calculated the mean value from the training data for each biomarker and replaced the missing data with the mean value for the training and testing data sets. We then added two more features (ie, age and gender) to the 28 biomarkers and trained our AI model using 30 features.

Table 3. Number of available blood biomarkers per patient for the artificial intelligence model training.

Data sets and sources	Number of blood biomarkers	
	Mean (SD)	Min-max
Training data: Tongji Hospital	27.22 (2.33)	13-28
Testing data		
Chonnam National University Hospital	20.39 (1.13)	19-24
Wonkwang University Hospital	15.82 (1.94)	14-19
Samsung Medical Center	14.40 (1.58)	14-17
Total	16.86 (1.58)	14-24

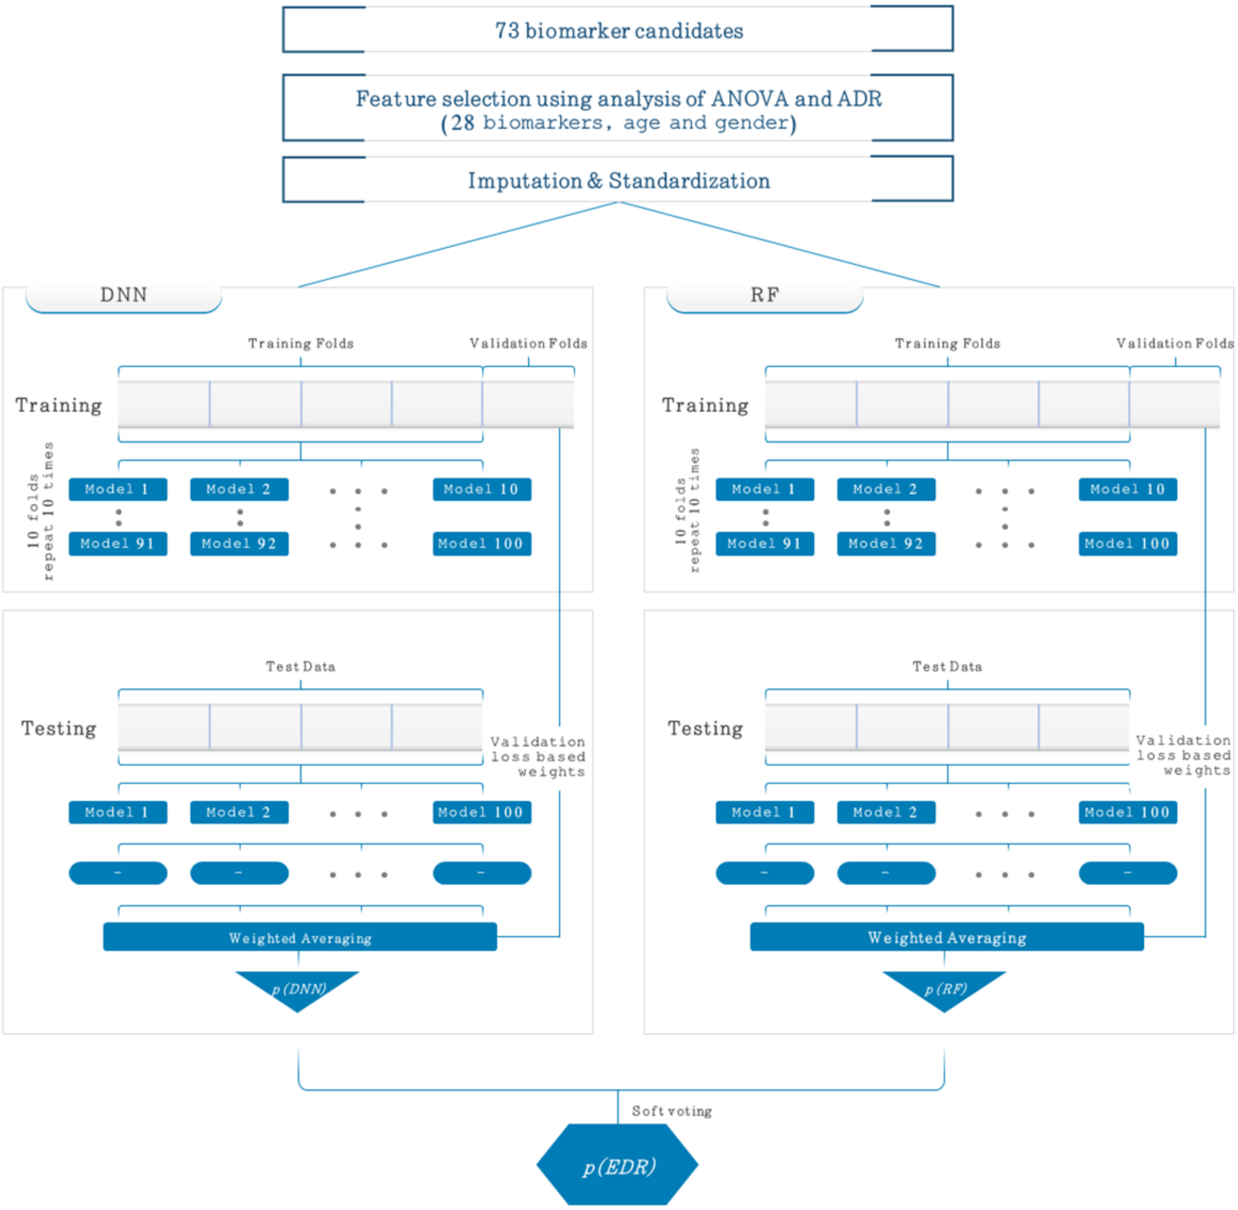
With the 30 features, we performed data set standardization, which is a common requirement for machine learning estimators. The standardization changes the data distribution of each feature with zero mean and standard deviation of 1 as

where *mean(train)* and *SD(train)* are the mean and standard deviation values, respectively, for each feature from the training data. The standardization was applied to the training and testing data sets.

Development of an Ensemble AI Model

As illustrated in Figure 1, the new ensemble AI model is composed of a 5-layer deep neural network (DNN) and RF model. Our ensemble AI model was named as EDRnet (ensemble learning model based on DNN and RF models). The 5-layer DNN was comprised of an input layer, three fully connected (FC) layers, and an output layer. The input layer contained 30 features, including 28 biomarkers, age, and gender. The input layer was fed into three FC layers in a series, each of which consisted of 30, 16, and 8 nodes. To alleviate the overfitting issue, we applied a dropout rate of 0.3. Then, the last FC layer was fed into a softmax layer, which is an output layer providing the probabilities for the patient mortality. Figure S2 in Multimedia Appendix 3 shows our DNN model and its printed textual summary run on Keras, where the total number of parameters (ie, weights and biases) was 1571.

Figure 1. Proposed ensemble model (EDRnet) composed of a 5-layer deep neural network (DNN) and random forest (RF) model for the mortality prediction. In the training of both models, a 10-time-repetition 10-fold stratified cross-validation was separately performed, and the predicted mortality probabilities of the DNN model, p(DNN), and the RF model, p(RF), were calculated. The final predicted mortality probability of the ensemble model, p(EDR), was obtained by soft voting based on the p(DNN) and the p(RF). ADR: available data rate; ANOVA: analysis of variance; EDRnet: ensemble learning model based on DNN and RF models.



For the 5-layer DNN, a 10-time-repetition 10-fold stratified cross-validation was performed to confirm the model's generalization ability. The training data (N=361) were randomly shuffled and partitioned into 10 equal subgroups in a stratified manner. Of the 10 subgroups, a single subgroup was retained as the validation data set for testing the model, and the remaining nine subgroups were used as the training data set. The process was then repeated 10 times, with each of the 10 subgroups used exactly once as the validation data set. By repeating this stratified 10-fold cross-validation process 10 times, a total of 100 models from the 5-layer DNN were derived. Then, we ensembled the models with the weighted average as

where $p_m(DNN)$ is the predicted mortality probability value from the m^{th} model of the DNN, $p(DNN)$ is the ensemble result corresponding to the predicted mortality prediction probability, and ${}_m(DNN)$ is the normalized weight value for the m^{th} model. We obtained the normalized weight value ${}_m(DNN)$ as

where the weight $w_m(DNN)$ was obtained using the validation loss from the m^{th} model, $l_m(DNN)$, as

Along with the 5-layer DNN, we separately trained an RF model. For the RF model, 100 decision trees were trained with a maximum depth of 4 and maximum feature number of 5. Similar to the 5-layer DNN, we performed a 10-time-repetition 10-fold stratified cross-validation and ensembled the 100 models with the weighted average as

where $p_m(RF)$ is the predicted mortality probability value from the m^{th} model of the RF, $p(RF)$ is the ensemble result corresponding to the predicted mortality prediction probability, and $_m(RF)$ is the normalized weight value for the m^{th} model. We obtained the normalized weight value $_m$ as

where the weight $w_m(RF)$ was obtained using the validation loss from the m^{th} model, $l_m(RF)$, as

Given the two ensemble results $p(DNN)$ and $p(RF)$, we finally obtained the final predicted mortality probability value using soft voting. Based on the average of the two probability values $p(DNN)$ and $p(RF)$, if the value is greater than or equal to 0.5, then the prediction result represents death; otherwise, it represents survival.

Implementation

We implemented and trained EDRnet using TensorFlow, version 1.13.1 for graphics processing unit (GPU), and Keras, version 2.2.4 for GPU. NumPy, version 1.16.4; Pandas, version: 0.25.3; Matplotlib, version 3.1.2; and scikit-learn, version 0.22.1, were used to build the model and analyze the results. We trained the models with the Adam optimizer and a binary cross-entropy cost function in equation 9 with a learning rate of 0.0001 and a batch size of 64 on the NVIDIA GeForce GTX 1080 Ti GPU as

where y_i is the label (ie, 1 for deceased and 0 for survived) and $p(y_i)$ is the predicted probability of each patient being deceased for the batch size N number of patients.

Performance Evaluation of AI Models

To evaluate the performance of the AI models in predicting mortality, we used the sensitivity, specificity, accuracy, and balanced accuracy metrics, defined as

where TP, TN, FP, and FN represent the true positive, true negative, false positive, and false negative, respectively.

In the training data set, the prediction performance of the AI models was evaluated based on a 10-time-repetition 10-fold stratified cross-validation. In the testing data set, the prediction performance of the AI models was independently evaluated.

To compare the performance of our proposed EDRnet model with those of other external AI models, we separately trained the models of XGBoost and AdaBoost (AB), each of which was evaluated as a single model and as an ensemble model combined with DNN, resulting in four models: XGBoost, AB, ensemble with DNN and XGBoost (EDX), and ensemble with DNN and AB (EDA). For the training of these models, we searched the optimal hyperparameters providing the highest validation accuracy value, as presented in Multimedia Appendix 3, Table S2. In addition, we adopted a recently published AI model by Li et al [6] using a decision tree via an XGBoost-based feature selection for performance comparison. All five external AI models were evaluated using our testing data set of 106 patients.

Results

The cross-validation of RF, DNN, and our ensemble model EDRnet showed that the accuracy on the validation data set is 89% for RF, 92% for DNN, and 93% for EDRnet. Thus, EDRnet provides the highest sensitivity, specificity, accuracy, and balanced accuracy values (see Table 4).

Table 4. Cross-validation accuracy comparison.

Model	Cross-validation results (N=361), mean (SD)			
	Sensitivity	Specificity	Accuracy	Balanced accuracy
Random forest	0.89 (0.06)	0.89 (0.07)	0.89 (0.04)	0.89 (0.04)
Deep neural network	0.91 (0.06)	0.93 (0.04)	0.92 (0.04)	0.92 (0.06)
EDRnet[a]	0.92 (0.05)	0.93 (0.03)	0.93 (0.03)	0.93 (0.05)

[a] EDRnet: ensemble learning model based on deep neural network and random forest models.

Moreover, we applied EDRnet to 106 Korean patients as an independent testing data set to check the TP, TN, FP, FN, sensitivity, specificity, accuracy, and balanced accuracy. The results show a sensitivity of 100%, specificity of 91%, accuracy of 92%, and balanced accuracy of 96%, indicating that the model trained and validated on Chinese patient data can be applied to Korean patients for mortality prediction (see Table 5). The computational times of DNN and RF in EDRnet for the training were 796 and 126 seconds, respectively. The overall computational time for the testing of EDRnet was 72 seconds.

Next, we summarized the performance comparison results between XGBoost, AB, RF, DNN, EDX, EDA, Li et al's model [6], and EDRnet. Considering all variables, EDRnet provided the highest prediction performance. Indeed, the balanced accuracy was 88% with XGBoost, 89% with AB, 92% with RF, 71% with DNN, 88% with EDX, 71% with EDA, 67% with Li et al's model [6], and 96% with EDRnet. Notably, the accuracy of Li et al's model was only 36%, indicating that a few blood markers may not be sufficient to predict patient mortality (see Table 6).

Table 6. Comparison of the performance of various methods.

Model	True negative, %	False positive, %	False negative, %	True positive, %	Sensitivity	Specificity	Accuracy	Balanced accuracy
XGBoost	80	24	0	2	1.00	0.77	0.77	0.88

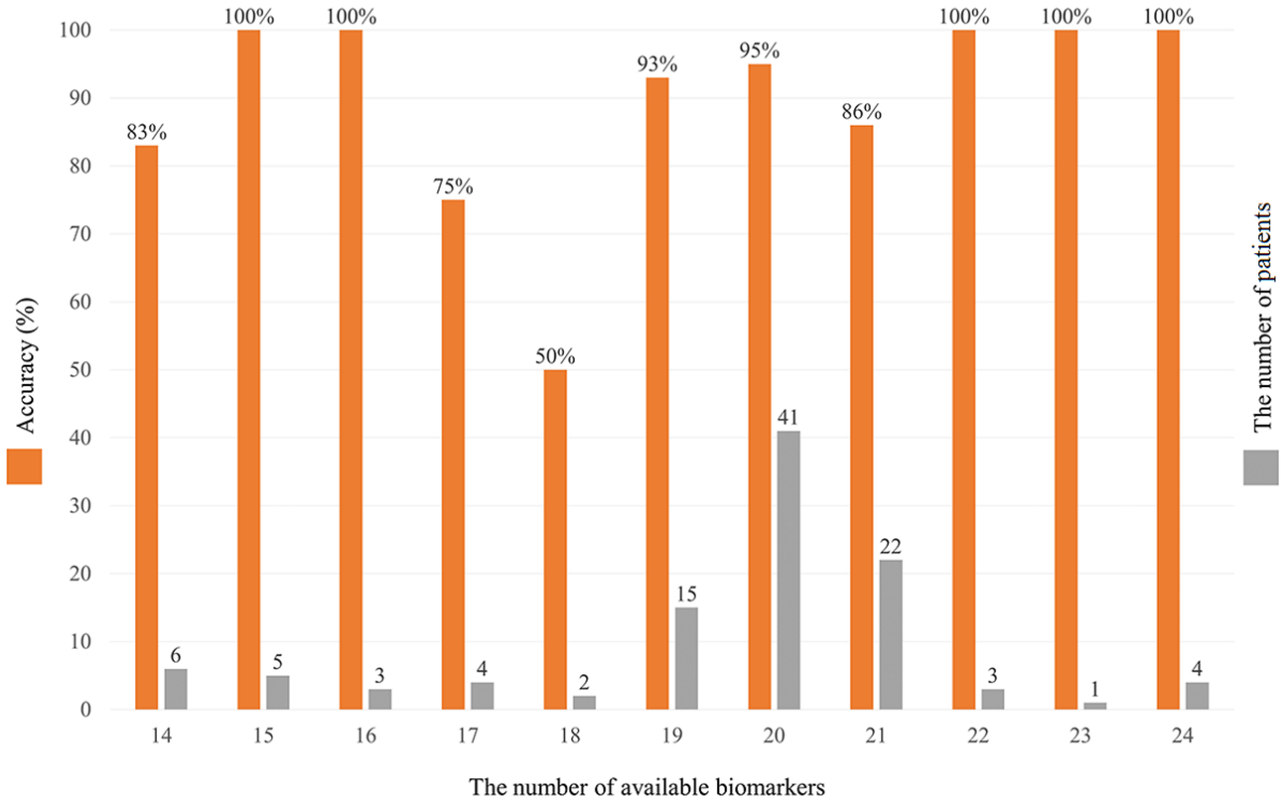
[a] EDRnet: ensemble learning model based on DNN and random forest models.

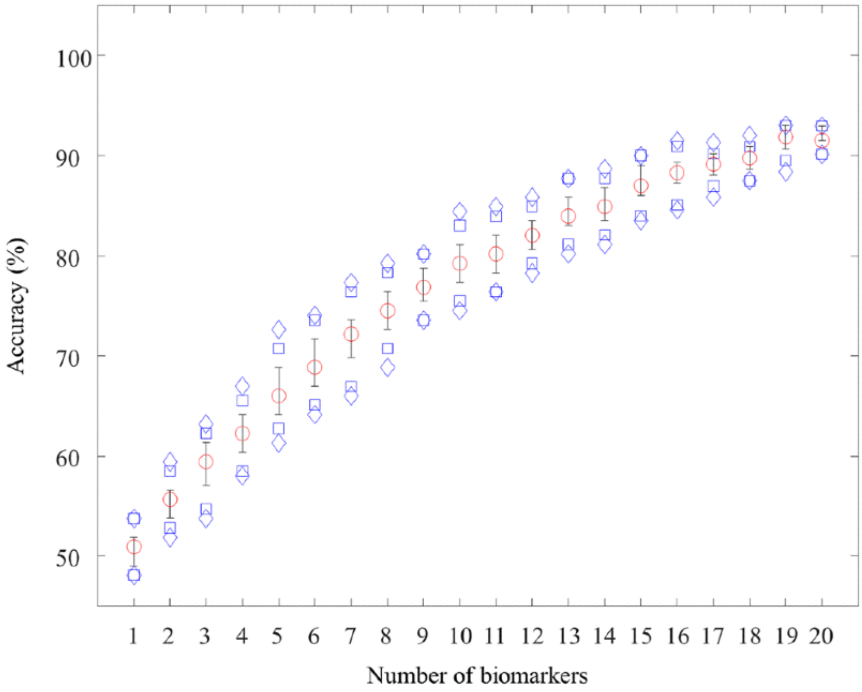
Our proposed EDRnet model used 28 blood biomarkers for prediction, but it does not require all 28 blood biomarkers. In our testing data sets, EDRnet training was validated using available biomarkers, ranging from 14 to 24, for each patient (see Figure 2). The results reveal that the majority of the patients had 19 to 21 available biomarkers (ie, 19 in 15 patients, 20 in 41 patients, and 21 in 22 patients) with a similarly high prediction accuracy (ie, 93%, 95%, and 86%, respectively). For the patients with 17 and 18 available biomarkers, the accuracy was 75% and 50%, respectively. By contrast, the patients with 14 to 16 biomarkers showed a high accuracy ranging from 83% to 100%.

Figure 2. Accuracy with the number of available blood biomarkers from the 106-patient testing data set.



To further investigate the effect of the number of available biomarkers, we estimated the accuracy values according to the number of available biomarkers (see Figure 3). For the estimation, we randomly selected 1 to 20 biomarkers from all of the testing data points and tested the model with a 100-time repetition. When randomly selecting biomarkers, only samples where the actual available number of biomarkers was equal to or greater than the number of randomly selected biomarkers were simulated. The results show that accuracy increases with the number of available biomarkers until reaching 19 biomarkers.

Figure 3. Estimated accuracy values according to the number of available biomarkers. Red circles represent the median. The bars at the top and bottom represent the 75th and 25th percentiles, respectively. The blue rectangles at the top and bottom represent the 90th and 10th percentiles, respectively. The blue diamonds at the top and bottom represent the 95th and 5th percentiles, respectively.



Furthermore, our developed AI model, EDRnet, was successfully deployed on a public website [25] so that anyone can predict mortality using individual blood test results. The web application provides predicted mortality probability, as shown in Figure 4. A user inputs his or her blood sample results (see Figure 4a), and then the predicted mortality results are presented (see Figure 4b). Currently, the web application does not store any information entered by users. However, we consider and plan to store information entered by users on agreement to improve the AI model via a real-time learning process.

Figure 4. Deployed web application, BeatCOVID19 [25]: (a) input windows where a user inputs his or her blood sample results and (b) the predicted mortality results after entering the blood sample results.

Regarding clinical characteristics (see Table 7), there were no significant differences in comorbidity. In terms of initial symptoms, the deceased group had more frequent dyspnea symptoms than the survivor group (66.7% vs 16.8%; *P*=.04). All patients from the deceased group required oxygen supply. The deceased group had more frequent altered mentality than the survivor group (50.0% vs 1.0%; *P*=.02). There was no significant difference in terms of antiviral drugs (ie, lopinavir or ritonavir, chloroquine or hydroxychloroquine, ribavirin, remdesivir, and oseltamivir) or anti-inflammatory drugs (ie, interferon, dexamethasone, and methylprednisolone) between the deceased and survivor groups. However, the deceased group received more antibiotics or combination therapy.

Table 7. Clinical characteristics of the patient groups from the testing data set.

Discussion

Principal Findings

Our new AI model, EDRnet, was able to predict the mortality of COVID-19 patients using 28 blood biomarkers obtained within 24 hours after hospital admission. In the independent testing data sets, EDRnet showed excellent prediction performance with high sensitivity (100%), specificity (91%), and accuracy (92%). We were able to improve the prediction performance by adopting the ensemble approach combining DNN and RF models. Of note, EDRnet was developed by training with Chinese patients' data and testing with Korean patients' data.

EDRnet has several advantages. First, EDRnet can predict which patients are at a high risk of mortality in the early stage of hospital admission (ie, within 24 hours after admission). This is a substantial improvement compared to the prior AI prediction model reported by Yan et al, which predicted mortality 10 days before the occurrence of survival or death [6]. The mortality prediction at the time of admission can be substantially informative for clinicians because the critical time regarding disease progression is 10 to 14 days from the onset of symptoms, according to previous studies [13,16,26]. EDRnet can provide treatment priority guidance regarding who should be treated intensively. Second, EDRnet only uses blood biomarkers to predict mortality. In general, COVID-19 patients get blood laboratory tests at the time of hospital admission [9,27]. Blood biomarkers are objective indices that are used to estimate patients' conditions in a quantitative manner, which may be beneficial to assure the reliability of the AI model. We did not include subjective biomarkers, such as symptoms, nor predisposing factors, such as underlying comorbidities, because these indices are difficult for quantification and may show high variability between patients. Third, the clinical meaning and significance of blood biomarkers used in our EDRnet model have been well investigated through many prior clinical studies. Thus, the AI's predicted mortality results are explainable and easily understood by doctors. Furthermore, several major blood biomarkers are used in our EDRnet model.

The hematological changes in lymphocytes, neutrophils, monocytes, eosinophils, and platelets are common, as these changes are related to viral replication and hyperinflammation in COVID-19 infection [12,13]. In severe cases, the infiltration and sequestration of CD4+/CD8+ T cells occurred, leading to a decrease in the peripheral lymphocytes. Neutrophil counts [19-21] were significantly higher in the severe group than in the mild group. Platelet count, platelet volume, and platelet large-cell ratio are related to COVID-19 infection because immunologic destruction can lead to inappropriate platelet activation and consumption as well as impaired megakaryopoiesis [28-30].

Regarding blood chemistry, hs-CRP is a major biomarker that represents acute phase inflammation [2,10,14-17]. LDH is related to cell damage, so elevated LDH is an independent risk factor for the severity and mortality of COVID-19 [2,8-11]. Hypoalbuminemia [18,20,21], hypocalcemia [31-33], and elevated aspartate aminotransferase [18] are highly associated with severe COVID-19 infection requiring hospitalization in the intensive care unit. Urea and estimated glomerular filtration rate are important lab findings associated with an underlying chronic renal disease, which is a well-known predisposing factor of mortality [34]. In terms of the coagulation profile, COVID-19 generally presents a hypercoagulation state, thus resulting in an elevated prothrombin time and international normalized ratio in severe COVID-19 cases [3,18].

In this study, no significant differences were observed in the use of pharmacologic agents between the deceased and survivor groups except antibiotics and in the use of antiviral drugs, such as remdesivir. Antibiotics or combination therapy is usually used for suspected bacterial superinfection that represents severe diseases. To date, there has been no successfully effective pharmacologic agent to treat COVID-19. The pharmacologic treatment is not significantly related to survival in this study.

EDRnet does not require all 28 blood biomarkers for the prediction of mortality. EDRnet worked well as long as there were at least 19 blood biomarkers at the time of admission. Compared to prior AI prediction models for COVID-19 mortality, which used three biomarkers, there might be concern that EDRnet requires too many biomarkers. However, these blood tests are commonly performed in our daily clinical practice for hospitalized patients with COVID-19. If more data are accumulated, then we can reduce the number of blood biomarkers for mortality prediction.

Limitations and Future Work

Our study has several limitations. First, the number of patients available for testing might be small. According to Johns Hopkins Coronavirus Resource Center, the mortality rate in South Korea is 1.7%. In the testing data set of 106 Korean patients, the mortality rate was 1.9%, which is almost equivalent to the actual mortality rate. It might be necessary to update EDRnet by training with a large population data set from all over the world. To update EDRnet, we made a web application [25] so that anyone can access the model. We believe that opening the AI model to the public is helpful to improve its performance and generalizability. Second, our data did not include other races, such as Caucasian or Middle East Asian. Our future research plan is to establish a real-time AI training system that can continue to train our model using prospectively collected data from all over the world. In addition, we will upgrade the web application so that the database framework allows a user to input his or her blood sample results along with the outcome. Based on the extended data, we will improve EDRnet for better generalization.

Conclusions

In conclusion, our new AI model, EDRnet, was developed to predict the mortality of COVID-19 patients at the time of hospital admission using blood biomarkers only. It is now open to the public with the hope that it can help health care providers fight COVID-19 and improve patients' outcomes.

Acknowledgments

This work was supported by Korea Medical Device Development Fund grants, funded by the Korean government (the Ministry of Science and ICT; the Ministry of Trade, Industry and Energy; the Ministry of Health and Welfare, Republic of Korea; and the Ministry of Food and Drug Safety) (grant Nos. 202012B04 and NRF-2020R1A2C1014829), and by the Korea Health Industry Development Institute (grant No. HI18C1216). Author RJ is currently an MIT Lincoln Laboratory employee. No Laboratory funding or resources were used to produce the result/findings reported in this publication.

Authors' Contributions

HK and HC carried out the machine learning and deep learning simulation for hyperparameter search and modeling. CP verified blood biomarkers to be applied in COVID-19 patients and wrote an initial draft of the paper. DWK, SEK, CRC, and REK collected and validated the data and performed statistical analyses. HL developed and maintained the web application. KWK, JHS, and TYC validated and confirmed the simulations and helped to draft the manuscript. RJ validated the methodology of machine learning and deep learning techniques. JL and WSK conceived of the study and participated in its design and coordination and wrote the initial manuscript. All authors read and approved the final manuscript.

Abstract

Background: Due to time limitations, the preanesthetic consultation (PAC) is not the best time for patients to integrate information specific to their perioperative care pathway.

Objective: The main objectives of this study were to evaluate the effectiveness of a digital companion on patients' knowledge of anesthesia and their satisfaction after real-life implementation.

Methods: We conducted a prospective, monocentric, comparative study using a before-and-after design. In phase 1, a 9-item self-reported anesthesia knowledge test (Delphi method) was administered to patients before and after their PAC (control group: PAC group). In phase 2, the study was repeated immediately after the implementation of a digital conversational agent, MyAnesth (@+PAC group). Patients’ satisfaction and their representations for anesthesia were also assessed using a Likert scale and the Abric method of hierarchized evocation.

Results: A total of 600 tests were distributed; 205 patients and 98 patients were included in the PAC group and @+PAC group, respectively. Demographic characteristics and mean scores on the 9-point preinformation test (PAC group: 4.2 points, 95% CI 3.9-4.4; @+PAC: 4.3 points, 95% CI 4-4.7; *P*=.37) were similar in the two groups. The mean score after receiving information was better in the @+PAC group than in the PAC group (6.1 points, 95% CI 5.8-6.4 points versus 5.2 points, 95% CI 5.0-5.4 points, respectively; *P*<.001), with an added value of 0.7 points (95% CI 0.3-1.1; *P*<.001). Among the respondents in the @+PAC group, 82% found the information to be clear and appropriate, and 74% found it easily accessible. Before receiving information, the central core of patients’ representations for anesthesia was focused on the fear of being put to sleep and thereafter on caregiver skills and comfort.

Conclusions: The implementation of our digital conversational agent in addition to the PAC improved patients' knowledge about their perioperative care pathway. This innovative audiovisual support seemed clear, adapted, easily accessible, and reassuring. Future studies should focus on adapting both the content and delivery of a digital conversational agent for the PAC in order to maximize its benefit to patients.

Introduction

Currently, in France, a patient requiring scheduled surgery must go through several mandatory steps: a consultation with the surgeon, a consultation with the nurse, a preanesthetic consultation (PAC), and a preanesthetic history and physical examination.

The PAC became compulsory in France on December 5, 1994, by Decree No. 94-1050, which stated that the consultation must be “led by an anesthetist physician” who sets out an anesthesia protocol [1]. In 2018, anesthetists at University Hospital Center of Toulouse (Purpan Hospital, Toulouse, France) performed nearly 12,000 PACs, including 4500 for elective orthopedic surgery (representing over 1500 hours per year devoted to PACs in this unit).

Because only 15 to 20 minutes can be devoted to the PAC per patient, only a few minutes are dedicated to the explanation of the anesthetic (its advantages and disadvantages, and risks and alternatives, if they exist), as well as of the risks inherent in their conditions and the possible ways to reduce them [2]. The amount of new information the patient must process appears disproportionately large when compared with the short duration of the consultation. Moreover, the context of a consultation is a source of anxiety (eg, “white coat effect”) and can thus prove deleterious to the retention of such information.

At the same time, the multiplicity of tasks incumbent on anesthetists reduces the time available, which may explain why the time devoted to presenting patients with information during PACs is often reduced [3]. Providing information tailored to each patient and each situation and ensuring that it is well understood is a daily challenge. In addition, the patient’s knowledge about the anesthesia often appears limited. For instance, a 1994 study by Swinhoe and Groves [4] showed that 35% of the patients did not know that the anesthetist was a physician.

Recently, digital conversational agents (also known as chatbots) have been emerging in the health care field, including in the management of complex older populations [5]. These digital companions are very useful for communicating with the patient before or after care without overloading the clinicians. They have the benefit of being available at any time and can be used repeatedly, at home or elsewhere. In this setting, Bibault et al [6] were able to demonstrate that the quality of breast cancer information delivered by a digital conversational agent was equivalent to a specialized consultation. The interest in this type of approach as compared with the unsupervised open access to information on the internet is the ability to control the content and the accuracy of the information offered.

The main objective of this study was to develop a digital companion that could help patients to prepare for their scheduled orthopedic surgery by providing them with adapted information before their PAC.

We hypothesized that the implementation of this tool, before and in addition to the PAC, would improve the quality of the information delivered in comparison with the standard practice.

Methods

Experimental Design

In this before-and-after study, we planned two successive phases that allowed us to define two groups.

The first phase took place before the implementation of the digital conversational agent. Patients were evaluated by the test before and immediately after the PAC. This control group was referred to as the PAC group.

During the second phase of the study, access to the digital conversational agent, or chatbot, was granted at the moment of the surgical decision and until the PAC. The evaluation by the test was conducted before access to the chatbot and immediately after the PAC. This intervention group was referred to as the @+PAC group.

Timeline of the Study

Phase 1 (PAC group) was carried out for 3 months, from February 1, 2019, to April 30, 2019. Phase 2 (@+PAC group) was carried out for 3 months, from June 1, 2019, to August 31, 2019. The anesthetists in the PACs were not informed of this timeline.

Population

We included patients aged 18 to 85 years who were scheduled for a PAC before elective orthopedic surgery at the University Hospital Center of Toulouse (Purpan Hospital, Toulouse, France). The patient exclusion criteria were (1) having the PAC in a different hospital, (2) the presence of a major sensory handicap (blindness or deafness) compromising the comprehension of the information, or (3) the inability to give informed consent.

During the PAC, the physician consulted the medical documents brought by the patient, questioned and examined the patient, and informed the patient of the benefits and associated risks of the anesthetic procedures. The anesthetist could ask for complementary investigations if necessary. In addition, an information booklet about anesthetic techniques was given to the patient.

Demographic Data Collection

Age, sex, height and weight, profession, education (number of postgraduate years completed), number of previous anesthetics received, smartphone use, type of surgery, and type of hospitalization (outpatient or inpatient) were anonymously collected.

Interventions

The digital conversational agent MyAnesth was developed in collaboration with a company creating secure health companions (BOTdesign, Toulouse, France).

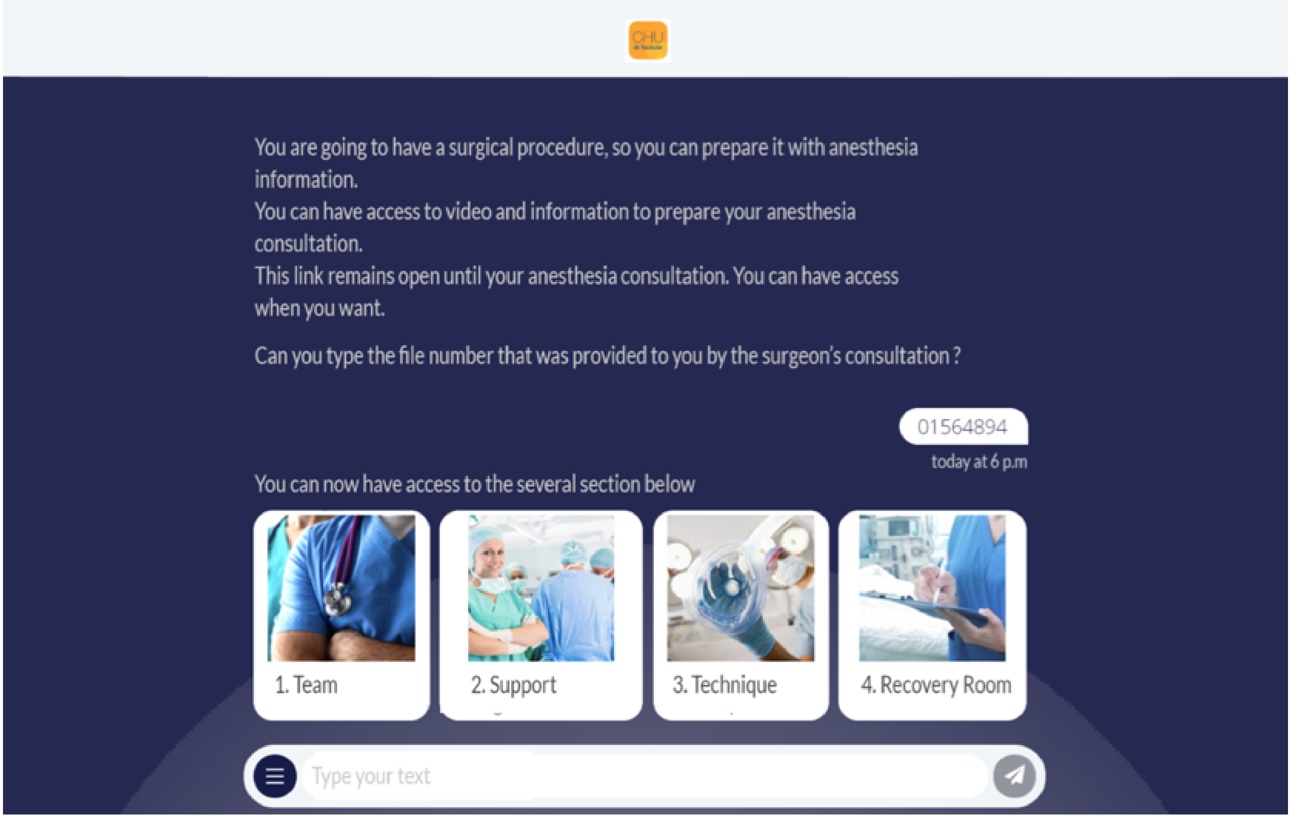
Its content was developed by 6 anesthetists from the University Hospital Center of Toulouse (orthopedic surgery unit, Purpan Hospital, Toulouse, France), taking into account data from the literature on fears generated by anesthesia [7-9]. Information considered important to be delivered to patients was then the subject of a team consensus.

The wording of the informative messages, such as frequently asked questions (FAQs) and their answers, were revised by a specialist in social and human sciences at Paul Sabatier University in Toulouse, France.

Access to the conversational agent was made possible by a URL link sent to the patient and accessible from any electronic device (ie, smartphone, tablet, or computer). This digital tool complies with all French and European regulations in terms of health data security.

Each patient could browse through 4 themed sections in the order of their choice: (1) team, (2) support, (3) technique, and (4) recovery room (Figure 1). Each section included a video, and the most FAQs and their answers, which could be accompanied by a picture (Multimedia Appendix 1). Within the support section, the content was adapted to the type of hospitalization (outpatient or inpatient), which provided the patient with more personalized information. A synthesized voice read the written information (eg, terms and conditions of use, and FAQs). The videos were subtitled in French to optimize patients' comprehension.

Figure 1. Access page to the digital conversational agent MyAnesth (BOTdesign, Toulouse, France).



You are going to have a surgical procedure, so you can prepare it with anesthesia information.
You can have access to video and information to prepare your anesthesia consultation.
This link remains open until your anesthesia consultation. You can have access when you want.

Can you type the file number that was provided to you by the surgeon's consultation ?

01564894
today at 6 p.m

You can now have access to the several section below

A version of the digital conversational agent, for demonstration purposes only, and identical to the one used in the study, is accessible online [10].

Primary Outcome: Self-Reported Anesthesia Knowledge Test

The information was considered successfully delivered if there was a significant increase in the score on the self-reported anesthesia knowledge test (Figure 2). This test consisted of 9 multiple-choice questions developed using the Delphi method [11]. The questions were simple and considered by the panel of experts as constituting the minimum amount of knowledge required before anesthesia. Each multiple-choice question had 4 answers, including the option "I don't know." Only one correct answer (1 point) was possible for each multiple-choice question. A wrong answer or "I don't know" response was worth 0 points, and the total score was between 0 and 9 points.

Figure 2. Self-reported anesthesia knowledge test. The correct answers are 1A, 2B, 3A, 4B, 5B, 6C, 7B, 8A, and 9C.

1. **I can drink:**
A. Up to 2 hours before the intervention
B. Unrestricted until operation
C. Until the evening before
D. I don't know

2. **If the anesthesiologist performs a regional anesthesia:**
A. I will not have pain medication
B. I will need less pain medication
C. Pain medication will be prohibited
D. I don't know

3. **In the event of a complication:**
A. I will be informed
B. My length of hospital stay cannot be changed
C. There is never a complication
D. I don't know

4. **Regional anesthesia:**
A. Just lasts the time of the operation
B. Lasts longer than the operation
C. Lasts less than the operation
D. I don't know

5. **During general anesthesia:**
A. I breathe as usual
B. I breathe through a hose connected to a mechanical respirator
C. I am not breathing
D. I don't know

6. **After the intervention:**
A. My attention may be diminished during the first hours
B. My attention will not be affected by anesthesia
C. My attention can be reduced for several days
D. I don't know

7. **Tobacco:**
A. Has no consequences with anesthesia
B. Should be stopped at least four weeks before anesthesia
C. Should be stopped the day before anesthesia
D. I don't know

8. **Regional anesthesia:**
A. Is performed using an ultrasound scan
B. Has no risk
C. Is performed by the nurse anesthetist
D. I don't know

9. **The day of surgery:**
A. I will see the same anesthesiologist as the one in consultation
B. I will not see an anesthesiologist
C. I will see one of the members of the anesthesiology medical team
D. I don't know

Secondary Outcomes

Patients' Satisfaction

To evaluate patients' satisfaction regarding the acceptability and quality of the delivered information, patients were required to answer questions rated from 1 to 5 according to the Likert method (1=strongly disagree, 2=rather disagree, 3=no opinion, 4=rather agree, and 5=strongly agree) (Multimedia Appendix 2).

Patients' Representation

In order to assess the patient's representational field for anesthesia, we used the Abric method of hierarchized evocation [12]. This method consists of asking patients a question that stimulates them to respond with 3 words or expressions associated with an inductor (word, sentence, or idea). In our case, the inductor was the word anesthesia, which was introduced by the following question: "What are the 3 words that come to your mind when you hear about anesthesia?" Patients were asked to answer this question before and after receiving information. The written order of the patient's answers expressed the level of importance of each response (first row being the most important, third row the least important).

This method allowed us to come closer to the subject's representations by dividing them into the core of the representation and the peripheral elements. The core constitutes "a mental filter through which reality is perceived and judged" [12]. It is rather independent from the context, contrary to the peripheral elements, which adapt the core to the diversity of the context [12].

The treatment of these data consisted of an analysis that took into account the frequencies of response of a word and of the written order of the responses [13,14]. This analysis allowed us to identify the core zone and the first periphery corresponding to the strongest frequencies in rows 1 and 2, followed by the contrasted elements zone and the second periphery corresponding to the weakest frequencies and row 3 [14].

Sample Size Projection

No data were available from the literature to allow us to calculate a priori the sample size required to identify an increase in the anesthesia knowledge test score. In a pilot study conducted on 30 patients, we identified an increase of 1.0 point (SD 1.3 points) in test scores taken before and after the PAC (4 of 9 points and 5 of 9 points, respectively) on the anesthesia knowledge test.

Considering that the implementation of the digital companion could allow the gain of 1 more point (increase judged to be clinically relevant) compared with the PAC alone, we calculated that 48 patients per phase would be required to demonstrate this difference with a type I error of 5% and a power of 90%. Taking into account the number of patients potentially lost, the technical difficulties inherent to the use of a digital conversational agent not yet tested, and the total number of patients seen in our PACs, we planned for 2 successive periods of 3 months each to include all eligible patients.

Statistical Analysis

The normality of the data was assessed using the Shapiro-Wilk test. The qualitative data were expressed as numbers (percentages). The quantitative data were expressed as median (range) or mean (SD) as appropriate. The categorical variables were compared using the Fisher exact test or the chi-square test. Continuous variables were compared using the Wilcoxon signed-rank test or the Student t test as appropriate. The statistical analysis was done using MedCalc Statistical Software, version 12.6.1 (MedCalc Software bvba, Ostend, Belgium). $P<.05$ was considered statistically significant.

Ethics

The connection to the digital conversational agent was made anonymous by a 4-digit number delivered by one of the investigating physicians during the interview with the programming nurse. Even though no information about the participants' health condition was asked at the time of the connection, the company BOTdesign (Toulouse, France) had access neither to the patients' identity nor to their internet protocol address. This strategy of data protection was decided in agreement with the eHealth committee of the University Center Hospital of Toulouse.

This research was considered to be an experimentation in educational sciences looking to (1) evaluate the quality of the information delivered through an innovative pedagogical tool, and (2) investigate the participants' satisfaction. Hence, this research was deemed to fall outside the Jardé law. For each patient, one of the investigating physicians delivered information about the methods of this research and ensured their nonopposition to participate. The lack of return of the questionnaire was considered a refusal to participate.

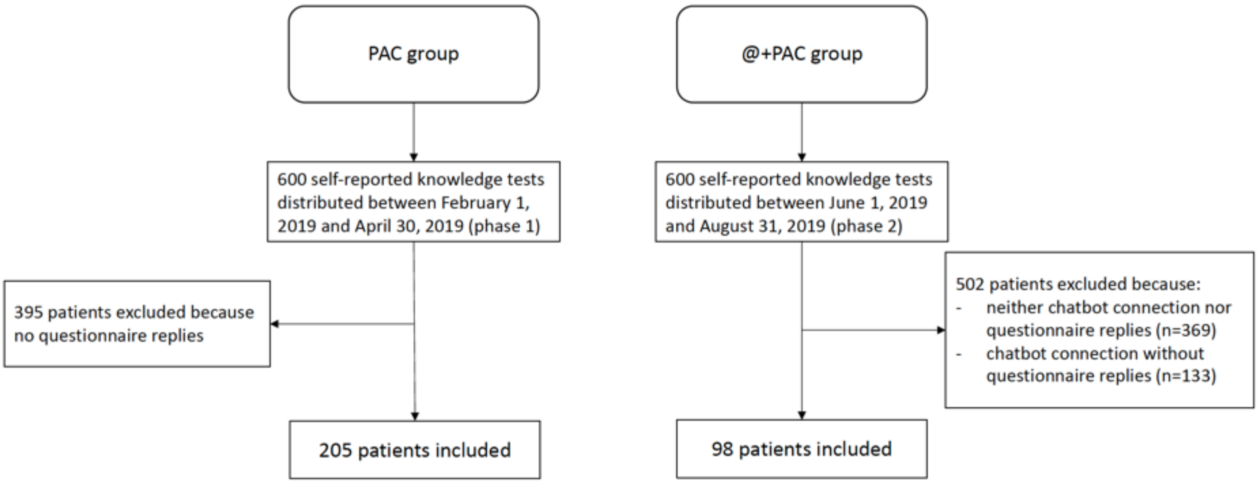
This study did not present any risk to the participants, nor did it modify the regular care process or the time require to care for the patients.

Results

Patients' Characteristics

A total of 303 patients completed the questionnaire and were analyzed during the study period. Of these, 205 patients were included in the PAC group (phase 1) and 98 were included in the @+PAC group (phase 2). The flow chart of patient selection is presented in Figure 3.

Figure 3. Flow chart of patient selection. PAC: preanesthetic consultation; @+PAC: digital conversational agent and preanesthetic consultation.



Demographic characteristics are presented in Table 1. The number of previous anesthetics received and the number of years of postgraduate education were comparable between the groups. Most patients included in the study were outpatients. Both groups had a high rate of internet access on their smartphones or at home (Table 1).

Table 1. Patients' characteristics.

	PAC[a] group (n=205)	@+PAC[b] group (n=98)	*P* value
Age (years), mean (range)	48 (18-85)	50 (18-74)	.73
Female sex, n (%)	95 (46.3)	41 (41.8)	.54
Number of previous anesthetics received, mean (SD)	4 (3.7)	3.9 (2.8)	.79
Number of postgraduate years of education, mean (SD)	1.4 (1.9)	1.5 (1.9)	.70
Internet access at home, n (%)	187 (91.2)	91 (92.9)	.64
Internet access with smartphone, n (%)	174 (84.9)	86 (87.8)	.60
Outpatient, n (%)	137 (66.8)	71 (72.4)	.22

[b] @+PAC: digital conversational agent and preanesthetic consultation.

Anesthesia Knowledge Test

The results of the anesthesia knowledge test are shown in Table 2 and illustrated in Figure 4. The implementation of the digital conversational agent led to an increase in the test score by 0.7 points (95% CI 0.3-1.1; *P*<.001).

Table 2. Anesthesia knowledge test results.

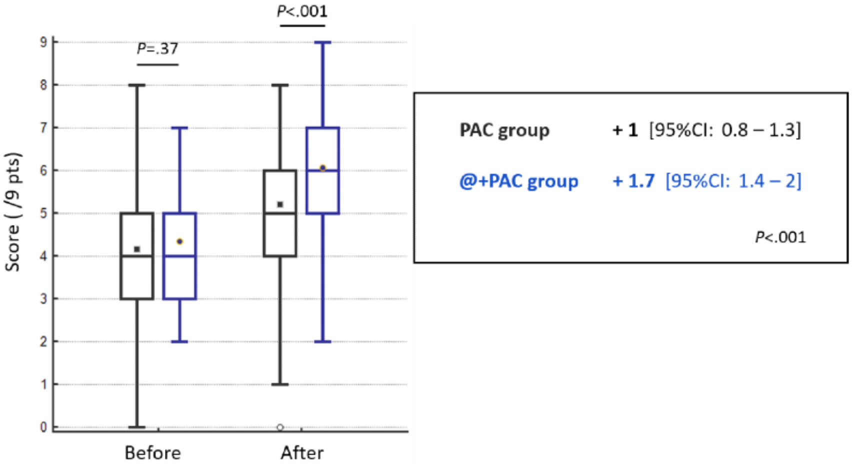
	PAC[a] group (n=205), mean (95% CI)	@+PAC[b] group (n=98), mean (95% CI)	*P* value
Knowledge test score[c] before receiving information	4.2 (3.9-4.4)	4.3 (4.0-4.7)	.37
Knowledge test score[a] after receiving information	5.2 (5.0-5.4)	6.1 (5.8-6.4)	<.001
Score improvement	+1.0 (0.8-1.3)	+1.7 (1.4-2.0)	<.001

[a] PAC: preanesthetic consultation

[b] @+PAC: digital conversational agent and preanesthetic consultation

[c] Score range is 0-9 points.

Figure 4. Comparison of anesthesia knowledge test scores between patient groups. Means are shown as markers within the box of 25th and 75th percentile values; whiskers represent ranges. PAC: preanesthetic consultation; @+PAC: digital conversational agent and preanesthetic consultation; pts: points.



Patients' Satisfaction

Among patients in the @+PAC group, 74% (73/98) agreed that the digital conversational agent was easy to access, and 82% (80/98) found the information to be clear and appropriate (Table 3).

In the PAC group, 34.1% (70/205) of patients agreed and 54.1% (111/205) disagreed with the following statement: "I wish I had received information before the anesthetic consultation."

Table 3. Digital conversational agent users' satisfaction analysis (n=98).

	Digital conversational agent accessibility, n (%)	Digital conversational agent content quality, n (%)
Number of respondents	98 (100)	98 (100)
Number of respondents who rated 1-2[a]	10 (10)	4 (4)
Number of respondents who rated 3[a]	15 (15)	14 (14)
Number of respondents who rated 4-5[a]	73 (74)	80 (82)

[a] Likert scale: 1=strongly disagree, 2=rather disagree, 3=no opinion, 4=rather agree, 5=strongly agree.

Among patients in the @+PAC group, the videos in the support and technique sections of the digital conversational agent were the most watched among viewers (88/98, 90%). The video in the section about the recovery room was the least popular, but was still watched by 68% (67/98) of the patients who logged in.

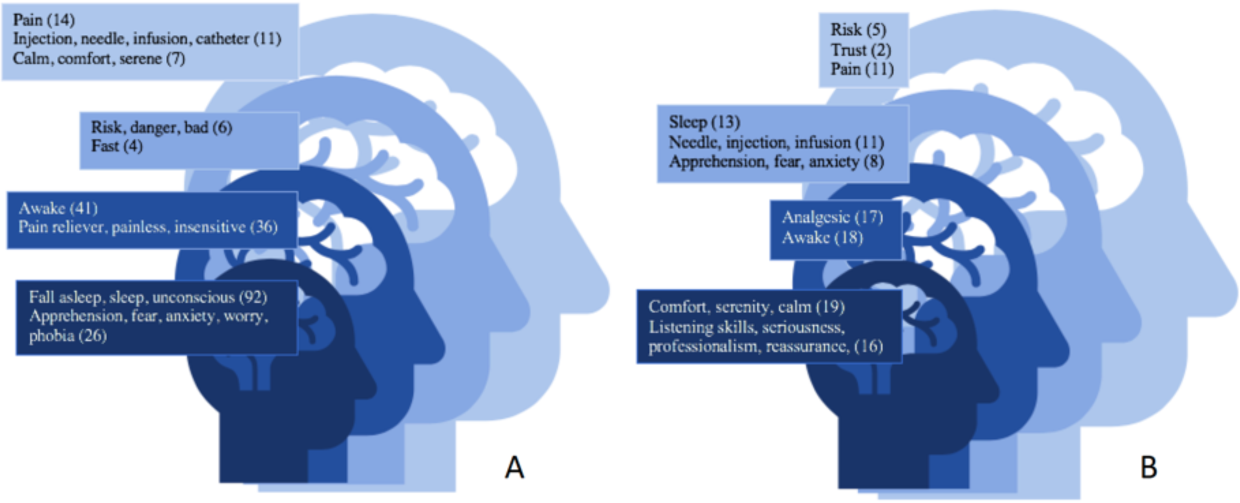
The apparent success of the videos contrasts with the low consultation rate regarding information delivered in the FAQs. Indeed, among the patients in the @+PAC group, only 4% (4/98) consulted all 11 FAQs, and 66% (65/98) did not consult any.

Patients' Representations

Responses from both groups were pooled.

Before receiving the preanesthetic information, the 233 patient responses indicated a core representation of anesthesia made up of concerns related to sedation (92 occurrences in the first row) and to apprehension (26 occurrences in the first row) (Figure 5A). This apprehension was confirmed by the elements from the first periphery, with the notion of awakening in particular (41 occurrences in the second row) associated with the problem of pain expectations (36 occurrences in the second row).

Figure 5. Graphic representation of patients' feelings before (A) and after (B) receiving information using the Abric method of hierarchized evocation. From the center to the periphery are spread out: the central core area, the first periphery, the contrasting elements, and the second periphery. The number of occurrences of the terms is indicated in parentheses.



The contrasted elements were risk and fasting, brought up in row 1, although rarely. Infrequently brought up in lower rows, pain (14 occurrences), injection (11 occurrences), and calm (7 occurrences) defined the second periphery.

After information was received, the 149 responses showed a change in the core representation, with a new interest in comfort (19 occurrences in the first row) and skills of the health care professionals (16 occurrences in the first row) (Figure 5B). Elements related to the absence of pain and the awakening no longer presented the initial strength, with 17 and 18 occurrences, respectively, in the third rows. However, elements related to injections (11 occurrences) came to the first row even if the frequency was still low; elements regarding apprehension remained in the first row but became rarer (8 occurrences). Risk, which was previously in the first row, moved to the third row and at a low frequency (5 occurrences). The notion of trust also appeared (2 occurrences in the second row).

Discussion

Using a digital conversational agent before the PAC lead to a significant improvement in the patients' knowledge of anesthesia. The high rate of internet access in addition to the high acceptability of the digital conversational agent encourage us to widely develop this tool. Our results highlight the lack of patients' knowledge about anesthesia. Indeed, no patient in either group received a passing score on the test before information delivery. In addition, the low increase in test scores (by 1 point) after PAC alone speaks in favor of identifying the best platforms and methods for delivering quality information.

Patient education through the use of information and communication technologies is a rapidly developing field that promises to improve patient outcomes while simultaneously using fewer human resources. In terms of content format, our study found that videos were consulted much more than text (ie, FAQs). Our results are in accordance with the meta-analysis conducted by Lee et al [15] in which patients being offered explanatory videos had better odds of correctly answering questions regarding anesthesia (relative risk 6.6, 95% CI 2.1-21.5). Hering et al [16] also showed an improvement in patients' satisfaction and knowledge by visiting a website before the PAC.

In our study, the most-viewed videos were related to anesthesia techniques and hospitalization modalities. Of course, these results could guide us toward themes that patients may wish to address before surgery.

Managing the content and accuracy of information offered enables better guidance with patients' online research, which may be beneficial because unsupervised online research can occasionally create anxiety [17].

Another advantage of digital tools is monitoring and re-evaluation. The data from the connections to the digital companion enable us to reliably monitor its use, allowing us to regularly readjust and update the content, unlike paper-based materials, where use cannot be evaluated.

Our results confirm that increasing patients' information is necessary to improve their satisfaction [18-21] and knowledge [16,19], as well as to reduce their anxiety [22-25].

We made the choice to place the interaction with the digital companion before the PAC to stimulate patients' curiosity and prompt them to ask themselves questions about the modes of anesthesia and their care pathways. However, surprisingly, we noticed during phase 1 that almost one-half of the patients did not wish to receive any information before the PAC. Thus, the question of information timing remains open. Interestingly, the use of a digital companion is a real advantage because it is easily accessible at any time, before and after consultation. In addition, this kind of interactive online tool could make communication with patients more efficient, especially when hospitals are not accessible, such as during a pandemic.

Giving information before a consultation could also shorten the length of the PAC without impacting patients' satisfaction [26,27]. Taylor et al [27] evaluated patients' completion of a numerical questionnaire before consulting with the anesthetist nurse. The mean consultation time of the group being offered the questionnaire was 12 minutes compared with 27 minutes for the group who was not offered the questionnaire ($P<.001$).

Other studies have shown the possibility of reliably automating the score calculation of patients' anesthetic risks [28]. Using a digital questionnaire before PAC would reduce the consultation duration while insuring a high level of quality and patient satisfaction [29].

For the first time, the method of hierarchized evocation was used to observe patients' feelings toward anesthesia. Overall, our results display patients' anxiety before receiving information and the benefits of getting information on how anesthesia is perceived. The terms skill, listening, seriousness, professionalism, comfort, and reassurance frequently appear after information is received. The semantic field category of these words is the correlate of a low preoperative anxiety level.

Our study presents several limits. First, the results were obtained by enrolling patients scheduled for elective surgery, and the results may not be able to be extrapolated to emergency cases where the consultation with a digital tool may not be feasible. Second, only 16.3% (98/600) of questionnaires distributed during phase 2 were completed. Characteristics of the nonresponders (eg, advanced age) could be very informative in identifying possible barriers. Finally, we have not evaluated physician satisfaction, which could help to identify the best perioperative health education support for the future.

To conclude, we have shown improvement in patients' knowledge about their care pathway when a digital conversational agent was used before the PAC. Despite the encouraging results, the overall uptake of the tool was relatively low and, even when used, did not achieve maximum impact. Future studies should focus on adapting both the content and the delivery of a digital conversational agent for the PAC in order to maximize its benefit to patients.

Acknowledgments

We would like to thank Olivier Thuillart and Jean-Louis Fraysse from BOTdesign (Toulouse, France), the company that created the digital companion. Support was provided solely from department sources. This work should be attributed to the Département d'Anesthésie-Réanimation, Centre Hospitalier Universitaire de Toulouse Purpan, Toulouse, France.

Authors' Contributions

FF, NB, BB, and AP performed all of the statistical analyses and wrote the manuscript. AC, FM, MK, OF, and VM participated in the design of the study and helped to draft the manuscript. FM shared his expertise in patient education. FF, AF, and LB performed all of the preanesthetic consultations. All authors read and approved the final manuscript.

Abstract

Background: The clinical application of voice technology provides novel opportunities in the field of telehealth. However, patients' readiness for this solution has not been investigated among patients with cardiovascular diseases (CVD).

Objective: This paper aims to evaluate patients' anticipated experiences regarding telemedicine, including voice conversational agents combined with provider-driven support delivered by phone.

Methods: A cross-sectional study enrolled patients with chronic CVD who were surveyed using a validated investigator-designed questionnaire combining 19 questions (eg, demographic data, medical history, preferences for using telehealth services). Prior to the survey, respondents were educated on the telemedicine services presented in the questionnaire while being assisted by a medical doctor. Responses were then collected and analyzed, and multivariate logistic regression was used to identify predictors of willingness to use voice technology.

Results: In total, 249 patients (mean age 65.3, SD 13.8 years; 158 [63.5%] men) completed the questionnaire, which showed good repeatability in the validation procedure. Of the 249 total participants, 209 (83.9%) reported high readiness to receive services allowing for remote contact with a cardiologist (176/249, 70.7%) and telemonitoring of vital signs (168/249, 67.5%). The voice conversational agents combined with provider-driven support delivered by phone were shown to be highly anticipated by patients with CVD. The readiness to use telehealth was statistically higher in people with previous difficulties accessing health care (OR 2.920, 95% CI 1.377-6.192) and was most frequent in city residents and individuals reporting a higher education level. The age and sex of the respondents did not impact the intention to use voice technology (P=.20 and P=.50, respectively).

Conclusions: Patients with cardiovascular diseases, including both younger and older individuals, declared high readiness for voice technology.

Introduction

The dynamic growth of telehealth and telemedicine solutions enables patients to access clinical care remotely, which equalizes health care coverage, supports care coordination, and increases the safety of patients and providers through physical distancing. Well-established phone and video consultations [1], along with emerging technologies [2,3], offer a powerful framework for connected health. Among patients with cardiovascular disease (CVD), telemedicine is supported by the European Society of Cardiology and the American Heart Association, which recommend multidisciplinary programs and tele-education for cardiovascular care [4-6]. Moreover, recent meta-analyses concluded that virtual care is more effective for adults with heart failure (HF) compared with standard care, particularly in reducing all-cause mortality, cardiac mortality, and hospitalization rates [7,8]. However, the effectiveness of telehealth programs depends on patient engagement and willingness to use the services [9,10]. Thus, it is crucial to understand patients' expectations and consider them while planning and developing novel telemedical strategies.

The latest advances in the field of artificial intelligence (AI) and natural language understanding have paved a way for the wide application of voice technology (VT) in health care through smart speakers and mobile apps. First real-world implementations have confirmed that AI conversational agents have the potential to support clinical care and optimize workflows [3,11-13]. Nationwide Children’s Hospital (in Columbus, Ohio) implemented voice technology for pediatric medicine [11], while Mayo Clinic developed Amazon’s Alexa software to automatically answer COVID-19–related questions [12]. Furthermore, CardioCube software (CardioCube Corp.) deployed on Amazon Alexa was shown to be functional for paperless medical history collection from patients with CVD [3] as well as for long-term remote follow-up of individuals with HF at home [13]. To evaluate prevailing perceptions and expectations, our study analyzed the opinions of and readiness for VT-based telehealth solutions among patients with CVD.

Methods

Study Design

The cross-sectional study was based on the investigator-designed and validated 19-item questionnaire used to recognize factors influencing readiness for telemedicine among individuals with CVD. The methodology included the (1) preparation of the questionnaire (Multimedia Appendix 1), (2) assessment of the questionnaire’s repeatability (questionnaire validation process), and (3) evaluation of anticipated patient experiences regarding telemedical solutions using the previously validated questionnaire, which was provided to the total studied population.

This study was performed at the Department of Cardiology and Structural Heart Diseases, Medical University of Silesia in Katowice, Poland, which hospitalizes approximately 2700 to 2800 individuals per year. The ethics approval for the study was received from the Bioethical Committee of the Medical University of Silesia in Katowice (approval number KNW/0022/KB1/160/1617) on February 3, 2017.

Questionnaire Validation

The original questionnaire included 19 questions concerning demographic data (sex, age, place of residence, educational level, occupational activity); health status data, such as previously diagnosed diseases, history of cardiovascular treatments, and previous hospitalization; and information about the current form of follow-up contact with a cardiologist. Key questions were related to the patient’s opinions and personal preferences regarding the application of telemedicine for remote contact with a medical doctor. To ensure validity of the questionnaire, the same 30 patients answered the questionnaire twice within the 2- to 3-day interval. The median age of the participants was 65 years. Most of the respondents were men (21/30, 70%), lived in the city (26/30, 87%), had a higher level of education (12/30, 40%), and reported living with another family member (23/30, 77%). To assess the reliability of the questionnaire, the Cohen statistic and interclass correlation coefficient were calculated with simultaneous assessment of the percentage of the repeatability of responses for the key questions of the questionnaire. By the applicable principles, the mean, good, and very good compliance of the Cohen values are represented by the values of 0.41 to 0.60, 0.61 to 0.80, and 0.81 to 1.00, respectively [14]. The key questions had very high repeatability, ranging from 80% to 100%. Detailed results of the validation procedure are presented in Multimedia Appendix 2. As confirmed by the research tool reliability, study participants were surveyed using a validated author-created questionnaire.

Cross-Sectional Study

Between March 2019 and January 2020, each of the patients admitted to the Department of Cardiology was invited to participate in the questionnaire survey. Written consent to participate in the study was obtained from 249 patients (participation rate of 9%). The participants completed the questionnaires while assisted by the medical doctor, who explained the meaning and potential clinical application of the telemedical solutions presented in the survey, assuring that responders understood the questions (Multimedia Appendix 3).

Statistical Analysis

Statistical analysis was undertaken using the Statistica 13.0 package (Dell Software). The missing values were removed pairwise from further statistical analysis. The measures of central tendency (median, quartile) and dispersion (interquartile range) were applied in the statistical description of quantitative variables; their distribution was verified using the Shapiro-Wilk test. Qualitative variables were presented using frequency and percentage. Differences between groups were tested using the chi-square or Fisher test. In all analyses, *P* values below .05 were considered statistically significant. Finally, the relevant relationships between particular variables were verified using multivariable analysis (logistic regression models with Hooke-Jeeves and quasi-Newton estimation). The null hypothesis in the adopted model was that patients’ readiness to use telemedicine solutions in general and to use a voice conversational agent specifically are not related to independent parameters, such as female sex, age, place of residence being in the city, primary level of education, living with family, and previous difficulties with medical care. Only the statistically significant variables obtained in bivariate analyses were included in the model. Additionally, a chi-square test was used to evaluate the goodness of fit of the logistic regression models. A *P* value above .05 indicates a good fit of the model.

Results

Participant Demographics

The total studied group included 249 patients (158/249, 63.5% men) aged 65.3 (SD 13.8) years. Table 1 presents basic characteristics of the studied population.

Hypertension, atherosclerosis, and heart failure were the most common diseases diagnosed in the surveyed population. More than half of the respondents (144/249, 57.8%) were hospitalized approximately twice in the previous year. Coronary angiography (146/249, 58.6%) and percutaneous coronary interventions (105/249, 42.2%) were reported as the most frequent medical procedures (Multimedia Appendix 4). In terms of health care access, approximately half of patients (125/249, 50.2%) obtained medical services at public outpatient clinics. Almost every tenth person (23/249, 9.2%) used only private clinics, while every third patient (90/249, 36.1%) scheduled follow-up visits both at private and public medical centers.

Readiness for Telemedicine Solutions

The vast majority of respondents (228/249, 91.6%) remained under ambulatory follow-up care, with periodic visits to an outpatient cardiology clinic. Consistently, of the 249 total participants, 209 (83.9%) said they would accept telemedicine solutions, while 34 (13.6%) were definitely against telemedicine solutions and 6 did not respond. The results confirmed that nearly three-fourths of the respondents expressed acceptance of telemedicine to maintain contact with a physician as well as for remote monitoring of vital signs. Further details are presented in Table 2.

Furthermore, the results showed that mobile phones (167/249, 67.1%) and VT combined with provider-driven phone support (166/249, 66.7%) were the preferred communication channels between patients and doctors. Furthermore, patients' preferences regarding the envisioned form of care showed that landline phones, email contact, and webpages were chosen by 43.8% (109/249), 17.3% (43/249), and 9.2% (23/249) of participants, respectively. Of note, almost every fifth respondent chose traditional face-to-face contact with a physician (47/249, 18.9%). A total of 34 out of 249 (13.6%) patients reported that the form of contact with the doctor does not matter.

Table 2. Patients' readiness for telemedicine solutions.

Anticipated telemedicine services	Participants, n (%)
Remote contact with a cardiologist	176 (70.7)
Telemonitoring of vital signs (blood pressure, temperature, body weight)	168 (67.5)
Issuing e-prescriptions	161 (64.7)
Alarming health status deterioration	154 (61.8)
Scheduling and managing of medical visits	143 (57.4)
Medication reminder	106 (42.6)

Factors Influencing Readiness for Telemedicine Solutions

Declared readiness for receiving the presented telemedical solutions significantly depended on age, gender, previous difficulties in contacting a medical doctor, and living with family (Table 3).

Table 3. Factors influencing patients' acceptance of telemedicine.

Independent variable	Technology accepted by patients			
	Telemedicine tools, n (%)	*P* value	Voice technology combined with provider-driven phone support, n (%)	*P* value

Internet access		.10		.30
Yes	138 (88.5)		112 (82.9)	
No	68 (81.9)		52 (77.6)	

Over half of patients (133/249, 53.4%) reported having encountered previous difficulties while contacting a doctor during routine clinical care management. The main reasons reported by study participants were long waiting times for a visit to an outpatient clinic (111/249, 44.6%), long waiting time in a clinic due to queue lengths (68/249, 27.3%), and substantial distance and travel time from their place of residence to a clinic (61/249, 24.5%). Results of the multivariate analysis confirmed that male sex, living with other family members, and previous difficulty of contact with physicians resulted in a willingness to use telemedicine solutions (Tables 4 and 5).

Table 4. Multivariate analysis between declared lack of telemedicine solution acceptance and particular independent values[a].

Independent value (n=236)	β coefficient	OR[b] (95% CI)
Intercept	–4.359	0.013 (0.000-0.570)

Previous difficulties accessing cardiologist (yes)	1.072	2.920 (1.377-6.192)

[a] Model: logistic regression (logit); χ^2=13.9; *P*=.03.

[b] OR: odds ratio.

Factors Influencing Readiness for Voice Technology

The readiness for VT was statistically significantly higher among patients with previous negative experience accessing health care (odds ratio [OR] 2.920, 95% CI 1.377-6.192) and was most frequent in patients reporting higher education and in city residents (Tables 4 and 5). The age and sex of respondents did not impact the intention to use voice agents (*P*=.20 and *P*=.50, respectively) (Table 3).

The Null Hypothesis

The study results showed evidence against the null hypothesis, as the readiness to use telehealth services and, specifically, voice technology was associated with independent variables (Tables 3-5). Patients' willingness to apply telemedicine was related to gender (*P*=.006), with women being less likely to declare readiness for telehealth (OR 0.415, 95% CI 0.183-0.943) than men; age (*P*=.05), with patients younger than 68 years being more likely to receive telemedicine (OR 1.009, 95% CI 0.974-1.046); living with family (*P*=.004), with individuals living with other family member declaring higher readiness for telemedicine (OR 2.445, 95% CI 1.021-5.856); and previous difficulties accessing medical care (*P*<.001), with respondents who experienced obstacles to accessing a cardiologist in the past declaring a higher intention to use telemedicine (OR 3.913, 95% CI 1.625-9.426). Place of residence and primary level of education were not associated with readiness for telehealth (*P*=.60 and *P*=.10, respectively).

Positive responses toward voice conversational agents were associated with previous difficulties accessing cardiovascular care (*P*=.003), with individuals who encountered problems obtaining medical care in the past showing higher intention to use voice technology (OR 2.920, 95% CI 1.377-6.192), and education level (*P*=.05), with respondents with a primary education being less interested in the application of conversational agents (OR 0.716, 95% CI 0.436-1.175). Place of residence appeared to be related to the respondent's declared readiness for VT, but it did not reach statistical significance (*P*=.07). Sex, age, and living with family members were not associated with readiness for conversational agents (*P*=.50, *P*=.20, and *P*=.40, respectively).

Discussion

Principal Findings

This cross-sectional study evaluated factors influencing intention to use telemedical solutions. Survey results confirmed that patients with CVD declared readiness for remote health care services, including VT-based virtual care. Previous difficulties accessing cardiologists in routine clinical settings were associated with a 3 times higher likelihood of acceptance of voice assistants for medical purposes.

An increasing number of patients with CVD presents challenges to health care systems to provide ubiquitous and high-quality care [15-17]. Thus, the implementation of telehealth services may enable alternative treatment strategies [18]. Accordingly, telemedicine provides a broad spectrum of possible interventions, including self-management programs [19,20], medication adherence [21,22], monitoring of vital signs [23], medical visit reminders [24], and remote long-term follow-up [7]. However, the applicability and usefulness of new technologies must be viewed from a broader perspective that includes patients’ expectations. Of note, users’ judgments and opinions of services or products reflect dynamic changes in emotions and feelings over time. Anticipated experience refers to the expectations a person has prior to the use of a solution, while momentary experience is associated with a perception after the first interaction. As a continuum, episodic and remembered experience mirror users’ approaches toward the specific usage of a service and their general impressions after a longer period of use, respectively [25]. It is important to apply a systematic methodology while exploring patients' needs. The structured approach is a cornerstone for the creation of patient-oriented telehealth programs promoting high adoption rates [26].

This study evaluating anticipated experience indicated that a vast majority (123/249, 93.9%) of CVD patients with previous difficulties accessing traditional care declared a readiness to use telemedical solutions, including voice assistants. The survey revealed that almost half of respondents experienced delayed medical appointments (eg, long waiting times, queues) and difficulties with physical access associated with the distance between patients' homes and medical centers. In contrast, Edwards et al [27] showed that a relatively low number of patients indicated difficulty in accessing traditional health care as a reason to accept telehealth solutions.

Our study highlighted some sociodemographic variables impacting patients’ approaches toward anticipated telehealth opportunities. Men and individuals living with family reported higher interest in the use of telemedicine. Similarly, men were more likely to accept digital technologies in a study evaluating the adoption of health care apps and online tools [28]. The age of the patients has been reported to play an important role in patients' willingness to use telemedicine [29]. Despite our study showing a correlation between age and readiness for telehealth, it did not reach statistical significance, as 90.2% (111/123) of younger (<68 years) and 81.7% (98/120) of older (68+ years) respondents were interested in using telemedicine tools (*P*=.05). Similarly, a systematic review of 39 studies evaluating age-related acceptance of telemedicine showed no consistent association [30]. Moreover, a recent meta-analysis confirmed that different age groups expressed a specific level of mobile health service interest that depended on ease of use, perceived severity, and perceived vulnerability, especially for middle-aged and older individuals [31]. Interestingly, conversational agents were reported to be anticipated by younger and older adults (*P*=.20), which may help to avoid technological exclusion of older individuals. These findings are promising, as rapid progress and market penetration of voice assistants (ie, Amazon Echo, Google Home) mirror general users’ acceptance of verbal communication interfaces. In the United States, more than 87 million people were reported to use smart speakers in January 2020, which gives potential to the horizontal implementation of this novel telehealth modality [32]. Simultaneously, professional medical applications deployed using conversational agents allow patients to report health status by answering a set of clinical questions in the form of a verbal conversation between human and voice device. This trend is exemplified by the CardioCube application, which has already been tested [3] and implemented in clinical practice for remote monitoring of patients with HF and diabetes [13]. Institutionally, Nationwide Children’s Hospital in Columbus, Ohio, developed a voice service for the care coordination of children with medical complexities [11], which confirms the usability of VT in the routine management of patients.

Furthermore, in line with the findings reported by Lin et al [33], our results showed that patients living with their families showed higher intention to use the presented telehealth solutions. This observation might be associated with additional support from family members while using telehealth services.

It is important to note that patients declared different forms of preferred virtual care, and subsequent analysis showed a willingness to use mobile phones (167/249, 67.1% of respondents) as well as voice conversational agents (166/249, 66.7% of patients). Our results show that the coapplication of VT and provider-driven support through telephone contact meets patients’ expectations. These findings may help to create a basis for telehealth programs providing comprehensive real-time feedback on a patient's health status.

It must be noted that the psychological aspects related to the perception of new technologies are very complex. Our questionnaire focused on the critical elements of determining anticipated experience and readiness to use telehealth. We evaluated (1) reasons patients want to use remote care, (2) the biggest value propositions, (3) the types of patients most interested in using telehealth, and (4) the manner in which patients want to access care. However, there are more components associated with willingness and readiness that were not evaluated by our survey. Other studies have reported that the following factors should be taken into consideration when designing telemedicine programs: previous experience with technology, ability to use the technology, perceived usefulness, quality of design, and user confidence [20,28,34-36]. The last element is of special importance, as previous findings showed that patients trust telehealth services if they are provided directly by a physician [28] with the support of a case manager [33]. Furthermore, studies showed that factors associated with technology itself (performance expectancy and perceived privacy) determine older people's intentions to receive telehealth [37], while readiness might be also facilitated by coexisiting diseases and additional costs [38].

Study Limitations

We would like to note that we did not collect data about previous experience with telemedical solutions, which does not allow us to evaluate acceptance of virtual care. Accordingly, the study results reflected patients' anticipated experiences and intentions toward services described by a medical doctor prior to the survey. To reduce risk of bias, we used a semistructured interview to educate study participants about each of the telehealth services included in the questionnaire. Moreover, a dedicated doctor (BK) assisted all study participants during the survey, answering additional questions regarding the clinical application of telemedicine.

The study is limited by a relatively small number of participants (N=249). However, differences in answers provided by participants had strong statistical significance supporting our findings. Moreover, the validation procedure included 30 respondents, and the e-prescription question showed the lowest Cohen score (patients' responses should be taken with caution).

Taking into consideration that the study design was based on readiness for telemedicine, further investigations are needed to analyze acceptance of VT in clinical practice, including patients' episodic and remembered experiences.

Conclusion

Understanding challenges and barriers associated with the clinical use of telehealth is necessary for its successful and widespread implementation. Among many aspects, patients' expectations and factors influencing readiness play an important role. Our study showed that intention to use VT is associated with previous difficulties accessing health care, especially in city residents and individuals who reported a higher level of education. A telehealth service combining conversational agents with provider-based phone support was anticipated by younger and older adults, which may help provide effective remote management of older individuals. Further evaluation of patients' perceptions of and incentives to use remote health care technologies is critical to designing a patient-centered solution.

Abstract

Background: Recent advancements in active assisted living (AAL) technologies allow older adults to age well in place. However, sensing technologies increase the complexity of data collection points, making it difficult for users to consent to data collection. One possible solution for improving transparency in the consent management process is the use of blockchain, an immutable and timestamped ledger.

Objective: This study aims to provide a conceptual framework based on technology aimed at mitigating trust issues in the consent management process.

Methods: The consent management process was modeled using established methodologies to obtain a mapping of trust issues. This mapping was then used to develop a conceptual framework based on previous monitoring and surveillance architectures for connected devices.

Results: In this paper, we present a model that maps trust issues in the informed consent process; a conceptual framework capable of providing all the necessary underlining technologies, components, and functionalities required to develop applications capable of managing the process of informed consent for AAL, powered by blockchain technology to ensure transparency; and a diagram showing an instantiation of the framework with entities comprising the participants in the blockchain network, suggesting possible technologies that can be used.

Conclusions: Our conceptual framework provides all the components and technologies that are required to enhance the informed consent process. Blockchain technology can help overcome several privacy challenges and mitigate trust issues that are currently present in the consent management process of data collection involving AAL technologies.

Introduction

Background

Society is currently moving into an age of ubiquitous and smart technologies, including mobile and wearable products, portable sensors, and diverse internet of things (IoT) solutions [1]. Examples of such smart technologies are smartphones, smartwatches, wireless blood pressure cuffs, wireless scales, smart thermostats, and smart homes, among others [2-4]. These devices have had a substantial adoption rate; for example, in 2016, 76% of Canadians owned a smartphone [5]. These devices have become a standard and are pervasive even in developing countries; for example, in Brazil, 57% of the population used a smartphone [6], and in Argentina, a similar proportion of the population, that is, 52%, used a smartphone [7]. According to a recent survey of 11 developing countries across 4 global regions, a median of 53% of the population of these nations have access to a smartphone with internet [8]. The wearable market has also experienced rapid growth: the number of global smartwatch users increased from 5 million in 2014 to 75 million in 2017 [9]. The fitness wearable market alone, comprising devices such as fitness bands, smart clothes, and eyewear (eg, smart glasses), has approximately 4 million users in Canada with a revenue of Can $ 290 (US $220) million [10].

These technologies have embedded sensors that can continuously and effortlessly monitor the health of users [11] by collecting data on vital signs [12], environmental variables [13,14], and behavioral metrics such as movement in the house [1]. The collected data can be analyzed for new insights into the health of individuals and populations [15].

Active Assisted Living

One of the fields that IoT technologies and connected devices can greatly improve and support is active assisted living (AAL) [16], defined as "all technology, devices, and wearables connected to the Internet, that enable the collection and exchange of data, and are used for health monitoring or to enhance the daily life of individuals" [17]. The major goal of AAL technology is to help people with activities of daily living, leading them to a better, safer, and more productive life while minimizing the risk of injury and avoidable death [1,17]. Therefore, AAL technologies are usually designed to support vulnerable populations and older adults [1,17].

AAL has become increasingly important because of a shift toward older populations in the global age distribution. It is expected that by 2050, all developing countries, in addition to Latin America, the Caribbean, and most of Asia, will have a median age of at least 40 years [18]. In Canada, 10 years from now, for example, 1 out of 4 people will be aged over 65 years [19].

Aging well and in place requires the older adult population to be as independent, secure, and healthy as possible [1,17]. However, older adults experience declining health as they age and are more likely to develop some sort of impairment, making remaining at home a difficult task [20]. Although assistive technologies have long been used to help older adults with daily activities [20], the benefits of innovative connected devices for monitoring wellness and supporting aging-in-place are being realized only recently. Their sensing capabilities allow for health support, real-time data collection, and detection or warning for emergencies. For example, 1 out of 4 seniors fall each year, resulting in the deaths of 27,000 seniors every year in the United States alone [21]. Another example of how these technologies can support older adults is a smart thermometer that cools the house if the temperature increases to dangerous levels, preventing seniors from experiencing a heatstroke [1].

Controlling access and consent to all these data is still a great challenge in the current technological landscape [18,22-26].

Informed Consent

Informed consent is defined as an "individual's autonomous authorization of medical intervention or participation in research" [18]. Valid informed consent in research and treatment is composed of the following minimum requirements [18,27]:

1. Competence: defined as the ability to perform a task
2. Understanding: defined as the full disclosure of information pertaining to the situation
3. Voluntariness: defined as participation in the event without any coercion and awareness of the possible outcomes.

Additional complexities in the consent management process may arise depending on the case; for example, older adults use AAL systems tend to interact with caregivers, cohabitants, and legal guardians. AAL technologies, such as smart thermostats, will collect data from every person in the environment where they are located. Therefore, the caregivers, cohabitants, and legal guardians must also give consent for data collection and use [18,23].

In addition, AAL technologies have significant benefits for people with cognitive impairments, including older adults and people with dementia [18]. A delicate ethical consideration arises on whether these populations can provide valid informed consent based on the principles outlined above [18]. One solution would be *rolling informed consent*, where the data collector repeatedly provides information on consent while assessing the mental capability of an individual [18,28]. Although rolling informed consent may work well in research environments, in practice, it may not be possible to achieve it in a real-world deployment of AAL systems because of the high complexity, rate, and volume of data collection from devices.

In cases where the individuals whose data are being collected cannot give valid informed consent, substitute decision makers (SDMs) may be necessary to make health decisions on their behalf [29]. SDMs may be family members, caregivers, legal guardians, or any person authorized to make health decisions for or with the individual.

Privacy of AAL Data

Despite the benefits to technology users, health care providers, and the health care system, one major challenge that needs to be addressed is the privacy of patient-generated health data. Although IoT devices allow continuous and zero-effort monitoring of health data, they also increase the complexity of data collection points and make it harder to determine exactly what, why, and how data are being collected. This is especially troublesome when we consider the context of AAL technologies: older adults are a vulnerable population that traditionally do not have advanced technological knowledge [16,23,30,31].

Older populations using AAL technology are at a high risk of being subjected to security and privacy violations because of the mishandling of their data, in which mishandling is characterized by any use of data that are different from what was consented to by the user. Older adults (and technology users in general) must know what they are consenting to and how to manage their consent at any time. In addition, many technologies only allow a *binary* consent in which users consent to all data or no data being collected. Users do not have any choice of which health variables they can give or revoke consent to.

Blockchain

Data ownership, security, anonymity, and privacy are complex topics, and, as exemplified above, the challenges of obtaining consent for increasingly advanced methods of data collection, use, and disclosure call for new solutions to imperfect consent procedures to protect the safety of individuals. One possible solution is using blockchain.

This technology can be seen as a distributed ledger formed of data structures known as blocks, equipped with cryptography techniques to enable trust among parties while being operated by a peer-to-peer network of computers [1,32]. Each computer forms an independent node on the network and maintains a copy of the ledger, which is regularly updated to ensure that it remains consistent with the other copies.

A blockchain can be private or public, depending on its intended application. A public blockchain is open to anyone who wishes to browse its contents or participate in the network [33]. Public blockchains are the most well-known blockchain applications because most cryptocurrencies take advantage of their features to enable trusted monetary transactions without the need of a trusted third party. In contrast, a permissioned or private blockchain allows only authorized users to browse its contents or participate in the network [34]. This type of blockchain solution is appropriate for sensitive or highly regulated information management environments, such as health care data.

A blockchain network receives transactions when two or more users want to transact information between them. Transactions from users are broadcasted to the network, validated, and grouped into a block by network nodes known as *miners* [35,36]. The transactions of a blockchain are data structures modeled to represent real-world processes and objects. For example, a transaction can be modeled to represent monetary transactions [37]; transfer of the ownership of a car [38]; the current state of a business object [39]; or, in our framework, the current state of informed consent of a patient.

Transactions sent to the ledger are secure and private without the necessity of a trusted third party because users of a blockchain do not use personally identifiable information as credentials when sending transactions to the ledger [1,32]. They use techniques such as cryptographic proof of ownership, in which every user has a private and public key pair for each transaction they submit to the ledger [40].

The sender signs the transaction with the private key, and a unique signature is generated and sent, along with the information of the transaction, to the public key of the receiver in the network. Every new blockchain transaction is broadcasted to all miners of the network who concurrently verify the transaction for proof of the private key ownership of the sender and verify whether the contents of the transaction are valid. For example, in the blockchain of Bitcoin [35], all transactions are checked for the private key ownership of the sender to ensure that the sender has enough funds (bitcoins) to send the transaction.

Miners utilize the public key of the sender to verify whether the signature of a transaction is valid. If the signature is not valid, it indicates that the original signature of the sender is wrong or tampered with, resulting in the network rejecting the transaction. The proof-of-ownership method prevents transactions from being corrupted or tampered before being added to the blockchain [34].

After transactions are validated, miners group them in a block; however, before adding it to the blockchain, they must complete a task known as mining [37]. Mining is a process in which miners compete to create a unique hash string for a new block.

A newly generated block hash contains in its composition the unique hash of the most recently added blockchain. The linkage of blocks' hash creates a cryptographical heritage that enables blockchain to tamper-proof its information history. For example, if an attacker wants to change the transaction information contained in block number 50, and miners from the network are currently working on block number 100, the attacker must generate the unique hash of all blocks that come after block number 50 until they reach the end of the chain and generate the unique hash of block number 100 before all the other miners of the network finish working on it. For this type of attack to be successful, a significant amount of processing power from a single miner is required. More precisely, a single miner would have to produce more processing power than the entire network to achieve success. Hence, these types of attacks are improbable [41,42].

In typical cryptocurrency blockchain solutions, such as Bitcoin, miners compete to finish mining a block because the winner gets rewarded for completing the task. This process is known as proof-of-work [35], and one of its major disadvantages is the vast amount of electrical power needed to keep networks running. Newer blockchain solutions, such as Ethereum, take advantage of modern validation processes such as proof-of-authority. In this process, instead of wasting computational power to validate and hash a block, credentials or any other relevant fact about the miner is used to accept a new block as valid or not.

Proof-of-work and proof-of-authority are used by blockchain technologies to help the network achieve consensus. In all consensus methods, a consensus is achieved by the ledger when the majority of nodes in the network agree that the block is valid and add it to their local copies. The consensus process starts when the first miner in the network finishes mining a block. It first adds the new block to its copy of the ledger, then follows to broadcast the new block to its neighboring nodes. Each node that received this new block verifies the unique block hash for validity, and if it is valid, it adds the block to its copy of the ledger. The node then follows to broadcast the new block in the same manner as the miner. This process is repeated until part or all of the network agrees with the current block. Some blockchain solutions define that when more than 50% of the network agrees with a block, consensus is achieved. There is a plethora of blockchain solutions that offer different types of consensus mechanisms. As for our framework detailed in the next sections, we used hyperledger fabric (HF) [38] to take advantage of the pluggable consensus feature, which allows for future changes in the consensus model. This feature is essential to our framework because we cannot instantiate an application that is not capable of adapting to comply with future regulations. More details on the consensus mechanism of HF are presented in the *Results* section.

This paper explores the creation of a blockchain platform for consent management in health care, specifically in the context of AAL. We discuss a general methodology for identifying blockchain use cases developed by Gorenflo et al [43], and we apply this methodology to consent management for AAL technologies. With the identification of consent management as a prime use case for blockchain, we expand upon previous work done by Bublitz et al [1], deriving from their general software architecture for surveillance activities, a conceptual framework for blockchain in AAL consent management. To develop this proposed conceptual framework, we researched which blockchain technology was the best fit. In the following sections, we discuss the methodology for identifying trust issues and software architecture, which served as a basis for our work. Next, we present our framework and explain how it differs from related work.

Methods

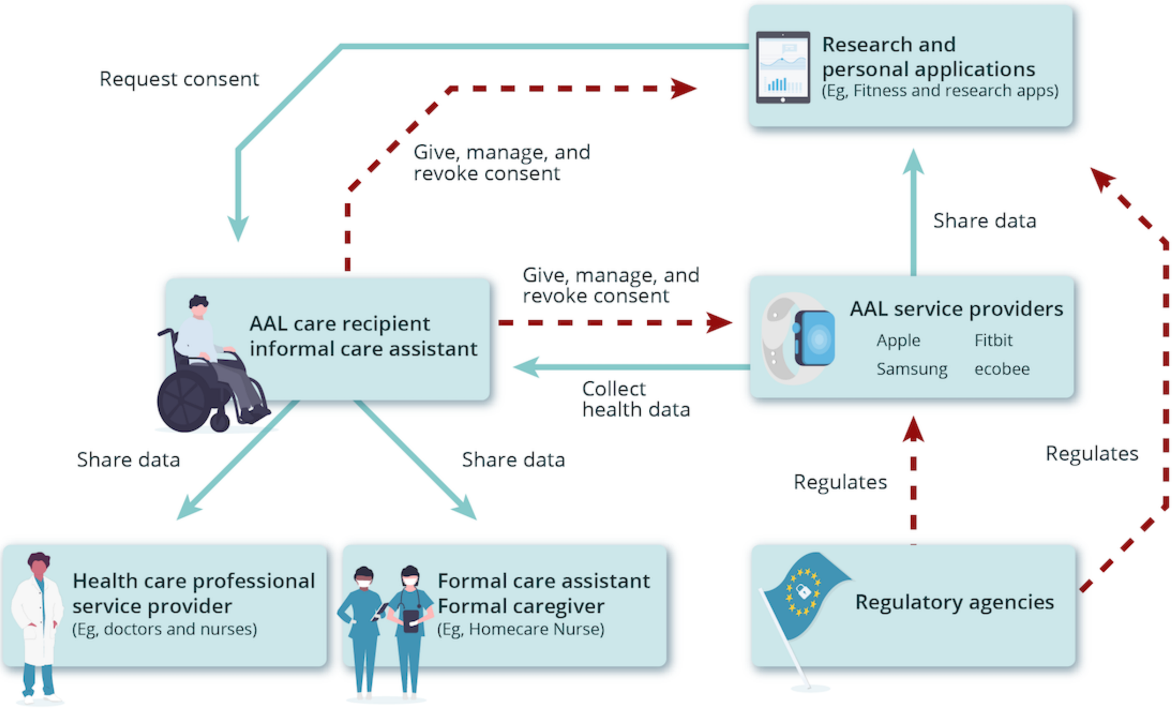
Mapping of Trust Issues

Gorenflo et al [43] defined a general methodology for identifying use cases of blockchain based on the identification of trust relations. This robust approach involves the following sequential steps relevant to this paper:

1. Identify the parties and trust relations between them. If a relationship does not have the required level of trust necessary to achieve the goal of the relationship, it should be marked as a trust issue.
2. Design a minimal blockchain system that resolves the trust issues.
3. Migrate the rest of the existing system to the new blockchain system if such a system exists.

In this study, we followed this methodology to model the consent management process for data collection in the AAL technology space, in consultation with AAL experts, resulting in the diagram presented in Figure 1.

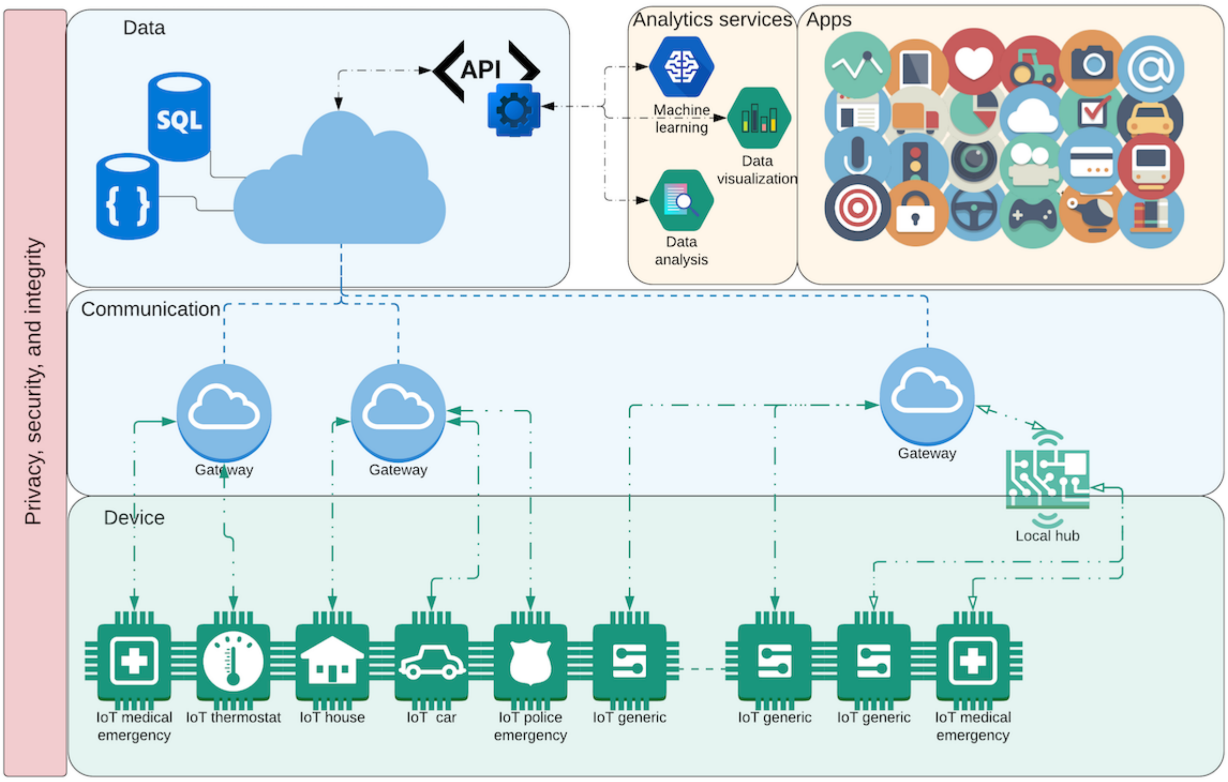
Figure 1. Consent management process and trust issues in active assisted living. AAL: active assisted living.



Framework Development

Once the trust issues were identified, we began work on a conceptual framework that focused on blockchain to mitigate these issues. This framework is based on a general framework architecture for monitoring and surveillance activities created by Bublitz et al [1] to address most of the requirements for the creation and use of IoT systems. The main layers of the architecture, as exemplified in Figure 2 [1], are device, network, data, applications and privacy, security, and integrity.

Figure 2. General architecture for the pan-Canadian surveillance system. API: application programming interface; IoT: internet of things; SQL: structured query language.



Results

Trust Diagram for Consent Management

The trust diagram in Figure 1 follows the nomenclature from the International Electrotechnical Commission or Systems Committees Active Assisted Living [1,17,44]. The identified trust issues are highlighted in red on the arrows included in the trust diagram.

An AAL Care Recipient (or an Informal Care Assistant, a nonprofessional caregiver) uses AAL technology. These users need to manage their consent to data collection and use by the manufacturers or owners of the technology, the AAL Service Providers, and any third-party application that collects the data gathered from the technology, represented as Research or Personal Applications. Trust issues arise between the AAL Care Recipient and entities consisted of Research or Personal Applications and AAL Service Providers because these entities may use the collected data in different ways than what was consented to. Another trust issue between these entities and regulatory acts, such as the Personal Information Protection and Electronic Documents Act (PIPEDA; in Canada), Health Insurance Portability and Accountability Act (HIPAA; in the United States), and General Data Protection Regulation (GDPR; in the European Union), which regulate the collection of personal data, is that the entities may be illegally using the data regarding the current legislation, thus violating the rights of the users.

The diagram clearly demonstrates relations without the necessary level of trust in the consent management process. Blockchain technology can provide an immutable and timestamped log of consent, making the process more transparent for everyone involved. This is extremely important as consent management, traditionally, is subject to many shortcomings and misconducts [45], and not following correct consent procedures can have tragic consequences. For example, in 2016, the trial testing of the drug BIA 10-2474 in France caused the death of a participant and hospitalization of 5 others, an event classified as that of “exceptional gravity, unprecedented in our country” by the Minister of Solidarity and Health [46]. Preliminary investigations showed that after major neurological effects were discovered in 1 patient, the researchers did not obtain reconsent from other participants, allowing them to continue in the trial despite clear dangers to their safety [46]. If the researchers used a platform such as the one proposed here, all their interaction with the participants regarding consent management would be recorded with a timestamp, making it extremely difficult for the researchers to not obtain reconsent as this misconduct would be easily auditable.

With a blockchain platform for consent management, users are able to monitor and manage their consent in real time and with granular variable control, for example, by giving informed consent for certain types of data to be collected but not others or revoking their consent at any time. This is in alignment with privacy regulations, such as the data protection by design of GDPR and right to data deletion by users at any time [47]. This information will be immutably stored in the blockchain and may be accessed by all entities with permission to do so. Users will also be able to ensure that the forms were approved and cryptographically signed by the review ethics boards, ensuring that the researchers are not withholding any information.

Data collectors will also benefit as measures taken to ensure ethical and legal requirements throughout the data collection process will be clearly documented and auditable.

A feature of blockchain called smart contracts [1] can also be leveraged to improve the consent management process. Smart contracts can be seen as codified contract agreements, and because blockchain is an immutable ledger, terms of a contract written into software and embedded in the blockchain will always guarantee the fulfillment of these terms [1]. Smart contracts can be used, for example, to bind SDMs to an individual or to check whether the consent process is compliant with different privacy regulations across territories. Ultimately, with blockchain technology, it will be easier to obtain, track, and update informed consent.

The Blockchain: HF

The HF [48] platform was selected for use as the underlying blockchain technology as it provides the tools to achieve the goals of our proposed conceptual framework (Textbox 1). HF is an open source, permissioned, distributed ledger technology (DLT) platform [38,49] developed to be used in the contexts of enterprise. All enterprise interactions are performed in a private network environment called hyperledger fabric network (HFN). An HFN provides blockchain services so that client applications and network administrators can interact with the HFN, proposing new transactions and querying the blockchain. In an HFN context, a consortium [50] comprises 2 or more organizations on the HFN that need to transact business with each other.

In HF, an organization [51] is a logical driven group of members that can represent big or small corporations. Each HFN organization is composed of members called peers [52]. Peers are responsible for hosting ledgers, smart contracts, handling changes to the ledger, communications between different organizations (channels), and managing external requests from applications. An endorsing peer is responsible for executing smart contracts over a transaction proposal from a client to verify its validity before it can be added to the ledger. A committing peer is a member who keeps a copy of the ledger without any smart contracts, meaning that this is done to keep multiple copies of the ledger to avoid single-point failures. Ordering peers and organizations [53] are responsible for keeping the communication sound between the participants of a channel; however, those components are beyond the scope of this paper.

Organizations can communicate with each other on an HFN by creating and using communication channels. Communication channels are private communication environments for all or a subset of the organization’s members of a consortium. New organizations are enrolled in the HFN through a trusted membership service provider (MSP) [54], which is responsible for issuing and validating certificates and user authentication.

The conduct of business transactions between organizations of an HFN consortium is stored in a ledger. A ledger stores both the current state and the history of states from a business object. To keep a business object, the current state HF uses a database called the world state [55], which is explained later in this paper. To store the history of the transactions of a business object, HF utilizes a blockchain data structure [38]. Together, the blockchain structure and world state are what allow the ledger to hold an immutable history of states of business objects (blockchain) and provide fast access to the most recent state of a single business object.

Participants of the HFN achieve consensus by following a transaction flow that takes into account the endorsement policy assigned to smart contracts [56]. This means that transactions can only be accepted into the ledger if all, or a subset of, the endorsing peers of a consortium approve the transaction. Smart contracts in HFN are a software representation of a contract that governs the processes that alter the state of a business object. In HF, smart contracts are packaged into a structure called chaincode, which consists of multiple smart contracts. Each chaincode is deployed into an HFN channel with an endorsement policy assigned to it. The endorsement represents which organizations must sign a transaction so that it is accepted and added to the ledger.

This transaction flow from HF relies on identity validation for members of the network. All transactions are first sent to the network as a proposal that needs to be endorsed by all HFN organizations included in the policy of the smart contract. The proposal is signed using the cryptographic credentials of the user that generate a unique signature.

Endorsement organizations from HFN verify transactions for several factors: (1) a well-formed transaction proposal, (2) whether the proposal is not repeated, (3) checks with the MSP [54] to verify whether the proposal signature is correct, and (4) then the MSP verifies whether the identity of the proposal submitter has the authorization to perform operations in that channel.

Input parameters are fed to the chaincode that is going to be executed in the current world state. The result is returned after chaincode execution alongside the peer signature to the client as a proposal response. Finally, the client inspects the response from peers, and if all the necessary signatures are valid, the transaction is created.

The client application broadcasts transactions to the ordering service. The service, in turn, creates orderly blocks of transactions and sends them to the channel’s peers. Each peer verifies the block transactions and signatures before adding the block to the ledger. HF is not the only appropriate platform that can provide the necessary infrastructure to instantiate our conceptual framework. For example, Ethereum [57] is a blockchain solution that provides full support for distributed applications over a blockchain network. Even if the main network of Ethereum is public, which is not ideal for the health care domain, it can be instantiated into a private network environment, thus becoming compliant with the privacy and access control requirements of the present conceptual framework. We refer to Modum [58] as an example of an implementation of a supply chain management system applied to Ethereum. Modum enables pharmaceutical companies to monitor the temperature and humidity of medical products by using smart contracts to verify sensor data during their life cycle.

Other honorable mentions of blockchain platforms that are appropriate to this framework instantiation are the IBM blockchain platform [59], the Multichain Private blockchain [60], the Hydra chain [61], and the BigchainDB [62]. It is also worth mentioning that using these technologies will require some changes in the HFN [63] component of the framework.

Textbox 1 contains the minimum requirements of the solution mapped over the attributes of HF, providing a checklist for other blockchain platforms to instantiate the framework.

Textbox 1. Active assisted living conceptual framework requirements and features of hyperledger fabric that support them.

Privacy of patients' information

- Hyperledger fabric (HF) uses cryptographic material to control access to the ledger. Applications from authorized organizations keep information from patients in their infrastructure. HF only stores anonymized consent information from unique keys created for each patient.

Private communications between stakeholders of the informed consent process

- HF maps stakeholders from a network into organizations. Each organization can be a part of a channel composed of some other organizations that constitute the consortium. Communications inside a channel are private to their members.

Scalable and fast querying of the ledger

- HF stores the most recent state of a business object in a state database called world state. Every time an informed consent state changes or a new informed consent is created, a new transaction is inserted into the ledger. However, the world state only updates the business object if it already exists, otherwise it is created. These characteristics also make HF more scalable as querying the complete history of the ledger is not required for determining the most recent informed consent status.

No cryptocurrency

- HF has no cryptocurrency, which complies with our solution's intention to provide the simplest solution possible to our end users, people using active assisted living.

Security of information

- As HF is a private and permissioned blockchain platform, the security of information is much less susceptible to a privacy breach.

Immutability of ledger history

- HF provides an immutable ledger natively.

Accountability of informed consent transactions

- With HF, smart contracts can be created enforcing standards. These smart contracts can be configured to explicitly require the endorsement of an organization that represents an auditing authority.

Software development kit (SDK) for development of end user applications capable of interacting with the ledger

- For our conceptual framework to be instantiated, the creation of web applications capable of interacting with the blockchain network to create and retrieve consent transactions is necessary. HF provides such SDKs in NodeJS, Java, and Go languages.

Smart contracts capabilities

- Smart contracts are needed to ensure the enforcement of standards and endorsements that must be respected so that a new informed consent transaction is accepted and stored in the ledger.

Custom network policies

- Such policies are needed to control network interactions between organizations. The informed consent process has its own unique policing needs, such as endorsement policies, hence the need for customization.

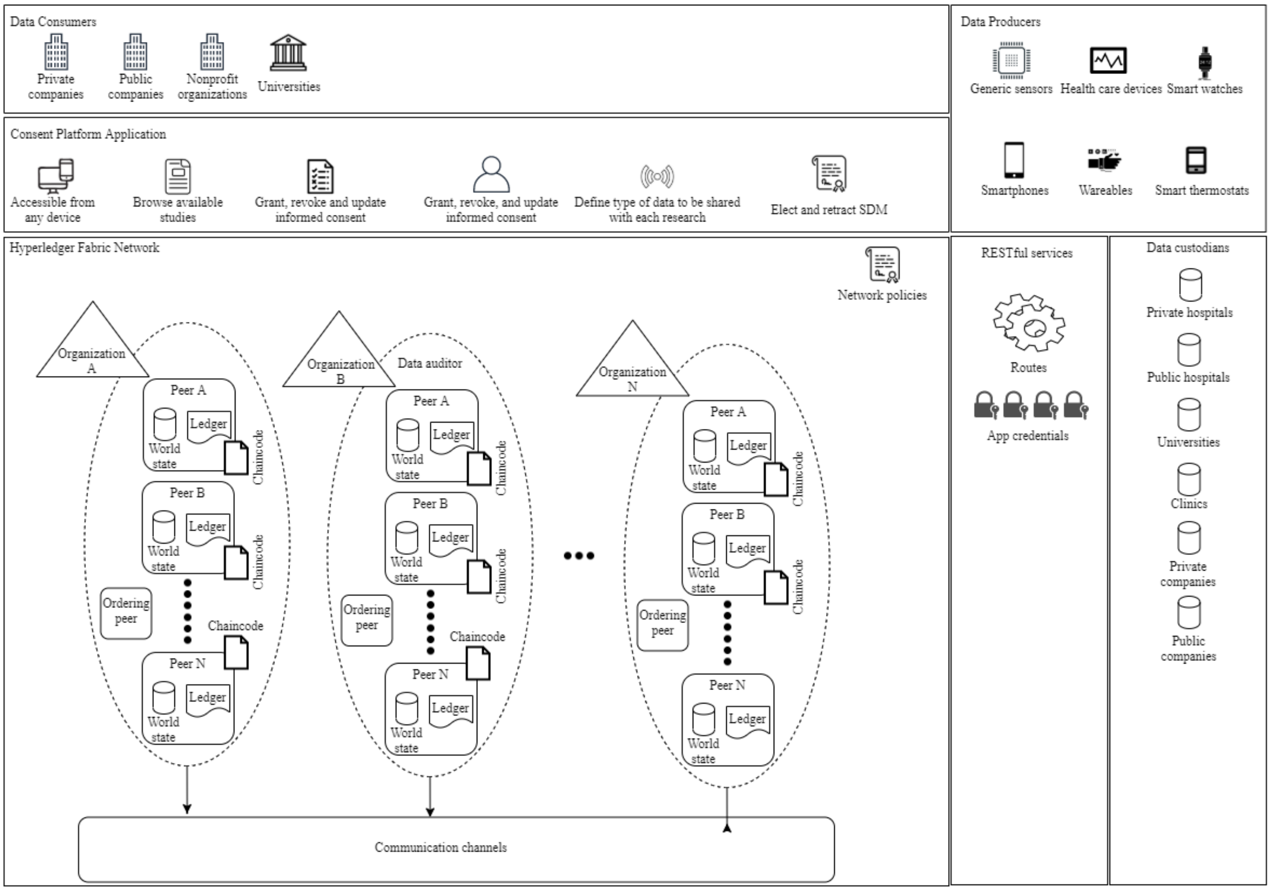
Extensibility of the network

- For our solution's relevancy, the capability of adding new organizations, policies, channels, and smart contracts without having to start a new network is imperative. HF provides the plug-and-play capability for adding new entities into an existing network.

Conceptual Framework for a Blockchain Consent Platform in AAL

As previously mentioned, the main objective of the conceptual framework is to allow a plethora of smart *devices* data to be used by different health care stakeholders while providing trust, security, and privacy. Figure 3 illustrates the conceptual framework components, one for each domain of services and health care data. All stakeholders are either mapped into an HF organization or are end users that interact with the framework through the web application of the consent management platform. Each square in Figure 3 represents a different framework component, and each component maps services, applications, participants, and infrastructures that need to interact with the platform to complete the instantiation of the framework.

Figure 3. Consent management platform conceptual framework. SDM: substitute decision maker.



For example, the data consumer component interacts with the consent management platform component to create requests for informed consent from AAL patients. The data producer component must interact with the consent management platform component to grant informed consent to data consumers and to register the consent into the ledger. The consent management platform component interacts with the RESTful (representational state transfer) services component to send transactions to the ledger. The RESTful services component acts as the middleware between the platform front-end applications and the HFN component.

Finally, the data custodian component interacts with the consent management platform to ensure that a data consumer has the proper informed consent registered in the blockchain before sharing patient data.

The *SecurityModel* section discusses and explains the platform security aspects in details (Figure 3), along with what features from HF were utilized to support the goals of the framework.

Security Model

As seen in Figure 3, the conceptual framework is built on top of an HFN; hence, all communications between organizations and their clients are secure by state-of-the-art authentication methods such as x509 certificates and asymmetric key pairs [38]. We derived our security model from the architecture of HF because it offers cryptographic certificates and keys necessary to access the ledger.

The consent management platform application utilizes HF ordering service [53] to access the HFN. HF applications are bound to an organization, and each time a new transaction is sent from an application, the network verifies the credentials of the organization and users before accepting transactions. If the credentials of the HF application are valid, then the transaction can be submitted to the ledger.

All transactions sent to the ledger are previously checked by cryptographic access control guards, which ensures that only authorized users can access the HFN. Chaincode is used to ensure that all transactions are signed and verified by the necessary endorsing organizations. For each organization endorsement, digital signatures are used to provide data authenticity before adding the transaction into the ledger. If an endorser organization rejects the authenticity of an application's user, then the transaction will not be inserted into the ledger.

Cryptographic authentication mechanisms are simplified by a feature from HF called MSP [54]. An MSP abstracts complexity involved in issuing, validating, and certificating users' and organizations' identities. An MSP is configured to have unique identities and rules that govern these identities. The HFN utilizes the identities of users to control access to the ledger. For example, a user with a *client* type of identity can only transact on the network, but an identity of type *peer* is allowed to endorse or commit transactions to the ledger.

Data Consumer Component

The data consumer component represents stakeholders that are interested in consuming data for a variety of different reasons, such as remote patient monitoring (RPM) [64-67]. To access health care data, obtaining informed consent from participants is essential to protect all participants, and ensuring safe and ethical procedures are in place is also essential [18,22,24,45]. The framework provides such interactions through data consumers interacting with the HFN component. It is also essential to explain that data collected for a data consumer can be real time or historical. This means that levels of security and awareness requirements from participants can differ, thus forcing the utilization of stricter network policies and smart contracts based on the characteristics of the data.

Data Producer Component

The data producer component is constituted by stakeholders that provide health care data in the realm of the conceptual framework [37,68]. Collected data can be from passive or active monitoring [69]. The former relates to data that are continuously or periodically sent to the cloud (eg, smart thermostats), and the latter is the type of data that requires actions to be taken on the part of data producers (eg, clinical exam) [69]. Any request for active data use from a data consumer must be consented to by a data producer for a data consumer to gain access to it. Consent is given when a data producer interacts with the consent management platform and explicitly gives consent to the data consumer. The consent management platform is responsible for creating the transaction and sending it to the HFN. If the transaction is valid and endorsed by all the appropriate peers, then the transaction is stored into the ledger and the world state is updated.

Data Custodians Component

The data custodian component contains stakeholders that are responsible for stored health care data [70,71]. Aside from the PIPEDA and HIPAA considerations with regard to security and privacy standards that all data custodians must adhere to, they must only provide access to data by another stakeholder from the informed consent process if the informed consent exists and if it has not expired. It is worth mentioning that a data consumer may also be a data custodian in some cases, but informed consent must be obtained in the same manner as previously noted. If a stakeholder is a data custodian, in the holistic view of the framework, this does not mean they are entitled to use health care data freely [69]. Data custodians are represented as HFN organizations in our framework, so that they can be part of the channels responsible for storing consent information. Therefore, by querying the world state, they can verify whether the consent given to a data consumer is valid.

HFN Component

The HFN component represents the mapping of all the stakeholders of the conceptual framework into HFN organizations. By creating this mapping, it is possible to create consortiums capable of having private communication channels with their ledgers and smart contracts. These channels are used by the organizations to query, create, and update informed consent state transactions that are stored within the ledger. New organizations can be added to the HFN at any point; thus, the organizations in the framework architecture are generalized. The ledger contains historical data from all the transactions between the organizations, which allows for data auditing from any of the network participants, consequently ensuring that trust evolves as a result of design.

Another feature that comes by design, thanks to the use of HF, is the world state. The world state possesses the current values of a business object (in our case, informed consent data). This is necessary for our conceptual framework, as it would be expensive and time-consuming to go through all transactions stored in the ledger to find the most recent state of a consent document. In HF, the world state is a NoSQL (No Structured Query Language) database that stores key-value pairs as identifiers of each state. The key-value pairs can be, for example, the pair patientID-researchID. Every time a new transaction from this key is stored into the ledger, the key-value or pair state stored in the CouchDB will also be updated.

Finally, as per the current version of HF, we utilize the consensus mechanism from the Raft protocol. The Raft protocol is based on a leader and follower model in which a node is elected as leader and the rest as followers. The Raft protocol is also a crash fault tolerance service that complies with our requirements of ensuring access to patients' consent information at all times [72].

Data Auditor Component

A data auditor can be any organization that represents regulatory authorities such as the PIPEDA and HIPAA. Having data auditors present on the network is important because they ensure that law and regulations are enforced in the HFN by using smart contracts and endorsement policies. By being a participant of the HFN and possessing the endorsement of peers included in the proper channels of interest, for example, channels that store information of the data auditor's jurisdiction, a data auditor can audit the information of multiple ledgers if needed. This HF capability allows the process of informed consent management to be auditable by different authorities, granting the conceptual framework the capability to adapt to new rules and policies that new data auditor added to the HFN might bring to the consortium.

Another possibility is that a data auditor, through the creation of policies, can force transactions to satisfy a set of requirements through smart contracts and network policies. Smart contracts enable the enforcement of standards for data privacy and security that prevent breaches of privacy and misuse of information. Through the proactiveness of a data auditor, it is possible to enhance the informed consent process as it can continuously verify the validity of consent. A data auditor can act upon expired or invalid consent information by being a member or founder of the channels in which the organizations under its jurisdiction are present.

Consent Management Platform Component

The consent management platform is a web-based platform that groups all the functionalities necessary for the processing of granting, revoking, and managing consent. First, to prevent a lack of access from stakeholders because of technology limitations, the framework proposes the use of responsive web applications that can be accessed by any device. The platform uses HF's NodeJS software development kit (SDK) [73] to interact with the HFN from the front end. Different endpoints can be used to control actions allowed only by certain types of users and organizations, for example, a patient (data producer) can elect an SDM to make decisions for him but cannot create requests for consent like a data consumer.

Patients can log into the platform to browse available data consumer requests and choose which to enroll in. For example, if an AAL patient wants to be monitored by an RPM center, the RPM center, as a data consumer, logs into the platform and creates the request for consent to be accepted by its patients. The AAL patient can grant consent to the RPM center through the platform's web application. In doing so, a transaction is created and proposed to the HFN and, if accepted, is stored in the ledger. This ensures that all the stakeholders from the transaction now possess a copy from the current state of consent, and the data consumer can start collecting the patient data from data custodians.

The consent management platform also provides web interfaces that allow patients to revoke consent and update consent. Another feature offered is that data producers can choose to share specific types of data for each request for consent. For example, an RPM center may request 5 types of data to be shared by a patient. However, the patient may choose only to share 2 types if they desire; although this makes the expected data received by the data consumer less predictive, it empowers data producers at the same time. This process ensures accountability, security, and transparency for the informed consent process, helping to improve traditional methods of obtaining consent.

The consent management platform can also be used to enhance the process of electing SDMs for patients. A patient can request that a user becomes their SDM. If the appointed SDM accepts the request, the information about the SDM elected is stored into the ledger and becomes available to stakeholders. Just like an informed consent state stored into the ledger, the SDM state can also be revoked or updated based on the circumstances. Such features can help to empower people under AAL conditions to quickly elect trustworthy SDMs without having to go through current bureaucracies that govern the substitute decision-making process [74].

Finally, the representational state transfer services layer is responsible for managing appropriate access to the consent management platform and for keeping meta-information about the users' identities in the ledger. If any other functionalities are needed, the conceptual framework can be extended to encompass new functionalities and components.

Chaincode

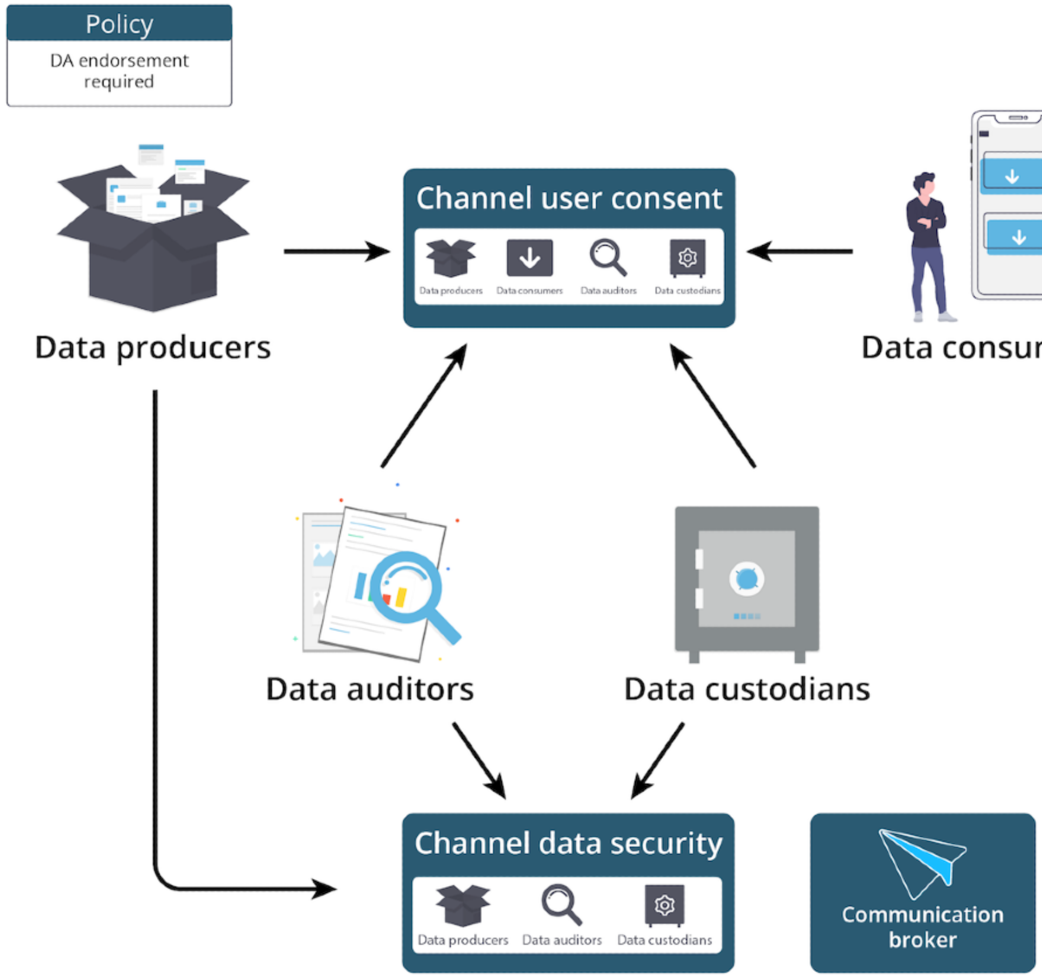
The utilization of chaincode (smart contracts) by the framework ensures that only registered applications can send a transaction to the ledger and that the network's required organizations endorse only valid transactions. A set of endorsement policies is defined for each new chaincode deployed into the network. As we are proposing a conceptual framework, at this stage of our research, we still do not have abstract contracts that can be extended by other developers. However, in the *Framework Instantiation* section, we explain the development of our prototype's chaincode.

Our first implementation of the chaincode will serve as a subject to further enhancements for the framework. In future work, we will study all contracts and their commonalities to create abstract contracts that can be instantiated by developers who want to adapt the framework for other domains.

Framework Instantiation

To exemplify the instantiation of the framework using HF, Figure 4 shows an abstraction of the developed HFN. The consortium is composed of 4 organizations that represent minimum requirements to allow all stakeholders in the system to perform the required tasks.

Figure 4. Organizations instantiated in the framework. DA: data auditors.



In our network, the 4 organizations that compose the consortium are data producer, data auditor, data consumer, and one data custodian. The members of the channel, channel user consent, have access to the ledger containing informed consent information. Before any new consent is given and stored into the blockchain, the data auditor member of the channel must agree and endorse the transaction containing the informed consent (as stated by the network policy in Figure 4). The data custodian, as a member of this channel, knows that the data auditor agreed to that consent if the transaction is valid and stored into the ledger. With the transaction validated, the data custodian is authorized to give access to its health care data to the data consumer as long as the data custodian respects the restrictions defined by a patient or SDM.

The data auditor organization is also a member of a different channel of communication called channel data security. This channel will hold the members of the network responsible for ensuring that the data custodian has the proper consent from users to store their information on their servers. Finally, the communication broker represents an organization responsible for routing the communication between the end user and the communication channels.

We used NodeJS SDK of HF to implement the chaincode responsible for verifying, adding, and querying informed consent of the patients and SDM states for members of the channel *User Consent*. The chaincode of the channel is defined by 2 contracts: contract one (C1) and contract two (C2). C1 is used to manage the informed consent state and to manage substitute decision maker states. C1 ensures that all fields of the informed consent transaction are present and valid. C1 checks for patient and research identification fields; the number of sensors; and, if for each type of sensor shared, the periods of consent are valid. C2 is responsible for managing SDM states from members of the *User Consent* channel. C2 checks for SDM and patient identification, start and end dates of the SDM validity, and the current status of the SDM-patient relationship. A code snippet implementation using NodeJS SDK of HF for C2 is presented below (Textbox 2).

If all requirements are successful, then the organizations, after executing the chaincode, endorse the transaction and return the proposal result to the sender. After finishing the proposal process, the new informed consent status is added to the ledger.

Textbox 2. Code snippet from the chaincode to add a new substitute decision maker.

```
/**
@function addSDMState
@param {*} ctx
@param {*} patientID
@param {*} SDMID
@param {*} rlStatus
@param {*} startDate
@param {*} endDate
*/
async addSDMState(ctx, patientID, SDMID, rlStatus, startDate, endDate) {
try {
// Instantiate a new SDM state to be added to the ledger
let substituteDecisionMakerState = SubstituteDecisionMakerState.createInstance(patientID, SDMID, rlStatus, startDate, endDate);
if (substituteDecisionMakerState) {
// add to the ledger
const response = await ctx.substituteDecisionMakerStateList.addSDM(substituteDecisionMakerState);
// return ledger response
return response;
} else {
console.log(“Error at addSDMState”);
return null;
}
}catch (error) {
console.log(“Error at addSDMState”);
}
}
```

Discussion

Enhancing Consent Management

Ensuring proper informed consent is a major concern for data collection and use [22,45]. Our proposed solution facilitates health data sharing by different stakeholders while increasing transparency and trust. The biggest advantage of our solution is that it was developed based on a systematic process of identifying and mitigating the trust issues in the consent management process [43]. The framework minimizes all trust issues indicated in Figure 1 by providing a virtual space to manage consent, powered by blockchain to provide an immutable and timestamped log of user consent for data owners and collectors. Consequently, AAL care recipients and informal care assistants will have a much better understanding and control over what data they are sharing, with whom, for what purpose, in what manner, and for what time period. Furthermore, it will be easier for regulatory agencies to audit if AAL service providers or research or personal applications are using data for purposes other than what was originally consented to, as they will be able to access the log of consent of the blockchain.

The US Food and Drug Administration (FDA) reported in an overview of clinical trial inspections from 1977 to 2009 that 28% of trials had deficiencies related to inadequate consent forms [45]. In 2012, the FDA cited the main deficiencies related to consent, among others: the failure to obtain informed consent; use of expired, incomplete, or nonvalidated forms; failure to provide copies of the forms to study subjects; missing documents; and changes made to documents by hand and without the approval of ethics review boards [22]. Our platform will provide a secure and immutable virtual space where all stakeholders—data owners, consumers, and regulators—will have complete transparency and surety of the entire process, making the process safer for all involved and ensuring that cases such as the trial of BIA 10-2474 will not happen again.

In short, the proposed conceptual framework tries to generalize the process of consent management for all stakeholders in the health care domain, allowing a clearer understanding of possible interactions and functionalities of the consent management process and, ultimately, providing more transparency. As presented by Novitsky et al [18], this was an important characteristic to help address inefficiencies in the process of consent management, especially for vulnerable populations.

The framework also aims to take full advantage of the features of HF to allow for robust and complex control over the process of obtaining informed consent. Data auditors are an example of such goals, in which they can remove bad actor organizations from the network if they do not comply with the rules.

Related Work

Several companies explore consent management and blockchain. However, they differ significantly from our solution.

Hu-manity.co, for example, developed a mobile app with IBM blockchain to help individuals manage consent for the use of their personal and health information. This app gives users a title for their digital data, declaring them as the user's property [75]. Unlike our proposed platform, this solution does not store the user consent information on the blockchain.

Another company, Bitfury, is producing a blockchain-based consent management system for research and medical data. This solution is closer to what we are envisioning as a blockchain platform [76,77]. The same is true for solutions in academia, such as the work of Benchoufi and Ravaud [26] that use blockchain to provide a timestamped log of consent for clinical trials. We differentiate from these works not only by focusing on IoT and AAL, and outside clinical and research contexts, but also by providing a granular variable control for users, allowing them to manage consent for different data types and periods (eg, user 1 gives consent for the temperature to be collected but not their movement, between June and July).

An interesting related solution is MedRec, developed by researchers at the Massachusetts Institute of Technology. Unlike previous works, this solution was not created to improve the consent management process but to minimize interoperability issues between electronic health records (EHRs) while providing a transparent view of a patient's full medical history. MedRec uses smart contracts to encode metadata with references to medical data from multiple medical data sources, which includes information regarding ownership of the data. Patients permit data to be accessed and shared [25]. In MedRec, consent management is not an explicit concern, but it appears as a form of access control for medical data. Although our solution considers access to data, as described in the sections below, we focus on consent management and improvement of trust relations in this process. In addition, MedRec deals with medical data stored in clinical systems and already collected, whereas our platform deals with real-time, patient-generated health data from sensors and AAL technologies deployed in the real world. Although our solution is distinct from solutions that deal with EHR interoperability, having proper informed consent is always a concern when dealing with personal data. Our proposed solution is a possible facilitator such that future health data sharing solutions do not need to develop tools to manage informed consent.

Limitations

The limitations of this work include the lack of implementation and real-world deployment of our proposed conceptual framework. Therefore, future work will focus on the development of a blockchain-enabled platform for consent management. Additional limitations include the fact that, for our architecture to be implemented at scale, the participation of federal and regional agencies is required to make up the participating nodes in the blockchain. In addition, data collectors will need to enroll in our platform and allow integration with the framework for the users to be able to give proper consent. Given that the platform will increase transparency and compliance with regulations for data collectors and owners alike, the stakeholders will benefit from engaging with such a platform, ensuring their participation. This means that the success of this platform depends upon the collaboration of several governments and industry partners interested in improving the current security and privacy issues.

Another limitation of our work is that the current version of the framework is not prepared to share health care data between data custodians and consumers. The platform serves as a tool for obtaining, managing, and consulting informed consent and SDM information. Custodians can use the platform to ensure that a data consumer has collected proper informed consent from the owners of the health care data they are requesting. For future work, we intend to extend our conceptual framework to be capable of offering data brokerage between custodians and consumers.

Conclusions

AAL technologies have the potential to completely revolutionize how older adults age, minimize risks, and increase independence [17]. However, this must be considered alongside the privacy implications of monitoring technologies [17,18]. Unfortunately, it is currently challenging for individuals to successfully manage their consent for data collection [1]. Blockchain is a novel technology that provides immutability and decentralization, allowing increased transparency across processes [1,32]. In this work, we modeled the trust issues existing in the consent management process of AAL technologies and proposed a conceptual framework based on blockchain to mitigate the identified trust issues. The proposed framework can be applied in different domains that deal with sensor data, such as drug supply chain [78-80] and environmental surveillance [1]. The instantiation of the platform is still in the early stages of development, but the first implementation of a fully functional application prototype has already been developed. The prototype allows researchers to request informed consent from AAL patients, and each new informed consent is wrapped into a transaction and sent into the HFN. Organizations validate and endorse the new transaction by using chaincode before it is added to the ledger. After the new block is added, participants of the network can query the ledger to check for informed consent validity before sharing patients' AAL data. Finally, although our prototype is currently not open source, we hope that researchers will use our framework to create their own blockchain applications.

Correction of: http://www.jmir.org/2020/11/e21329/

(J Med Internet Res 2020;22(12):e26446) doi:10.2196/26446

In “Identifying and Ranking Common COVID-19 Symptoms From Tweets in Arabic: Content Analysis” (J Med Internet Res 2020;22(11):e21329) one error was noted.

This article was originally published with a layout error causing two inline figures representing Arabic keywords to appear as regular figures in the first paragraph of the Methods section. The sentence where these inline figures should have appeared read as follows:

> *First, we searched Twitter for personal reports of COVID-19 from March 1, 2020, to May 27, 2020, using 2 Arabic keywords Inline Figure 6 and Inline Figure 6, which translate roughly to “I have been diagnosed.”*

This has been corrected to place the two inline figures within this sentence instead of the words “Inline Figure 6” in each instance.

The correction will appear in the online version of the paper on the JMIR Publications website on December 14, 2020, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 11.12.20; this is a non–peer-reviewed article;accepted 11.12.20; published 14.12.20.

(J Med Internet Res 2020;22(12):e25738) doi:10.2196/25738

In “Undergraduate Medical Competencies in Digital Health and Curricular Module Development: Mixed Methods Study” (J Med Internet Res 2020;22(10):e22161) the authors noted three errors.

One author's name was displayed as:

> *David Back*

It has now been corrected to:

> *David Alexander Back*

One affiliation for David Alexander Back was listed as:

> *Bundeswehr Hospital Berlin, Clinic for Traumatology and Orthopedics, Septic-Reconstructive Surgery, Berlin, Germany*

It has now been corrected to:

> *Department of Traumatology and Orthopaedics, Septic and Reconstructive Surgery, Bundeswehr Hospital Berlin, Berlin, Germany*

The phone number for corresponding author was incorrectly listed. It has been changed to:

> *49 30 2841 1240*

The correction will appear in the online version of the paper on the JMIR Publications website on December 7, 2020, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Submitted 25.11.20; this is a non–peer-reviewed article;accepted 26.11.20; published 07.12.20.

Correction of: https://www.jmir.org/2020/12/e25070

(J Med Internet Res 2020;22(12):e26225) doi:10.2196/26225

In “Documenting Social Media Engagement as Scholarship: A New Model for Assessing Academic Accomplishment for the Health Professions” (J Med Internet Res 2020;22(12):e25070), one of the authors was not mentioned in the original paper.

The following author has been added:

> *Alice Eaton, Bsc*
>
> *Swansea University Medical School, Swansea, United Kingdom*

One of the contributors was missed in the Acknowledgement section. Previously, the Acknowledgement section read as follows:

> *All authors met the ICMJE authorship criteria, including reviewing and approving this manuscript for publication. Each of the 40 coauthors completed an Authorship Attestation Form confirming that they met all 4 of the ICMJE authorship criteria. In addition, each coauthor described on a shared Google Sheet how they made “substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data.” The authors wish to thank Jocelyn C Anderson, PhD, RN, S Alexander Kemery, PhD, RN, and Chrystal L Lewis, PhD, RN for their comments on the draft of this manuscript.*

The corrected Acknowledgement section now reads as follows:

> *All authors met the ICMJE authorship criteria, including reviewing and approving this manuscript for publication. Each of the 40 coauthors completed an Authorship Attestation Form confirming that they met all 4 of the ICMJE authorship criteria. In addition, each coauthor described on a shared Google Sheet how they made “substantial contributions to conception and design, or acquisition of data, or analysis and interpretation of data.” The authors wish to thank Jocelyn C Anderson, PhD, RN, S Alexander Kemery, PhD, RN, Rebecca Koszalinski PhD, RN, CRRN, CMSRN, and Chrystal L Lewis, PhD, RN for their comments on the draft of this manuscript.*

The affiliation for authors Brendan Huang and Ajay Major was incorrect. They were displayed as:

> *Brendan Huang*
>
> *Department of Clinical Neurosciences, Tulane University, New Orleans, LA, United States*
>
> *Ajay Major*
>
> *University of Chicago, Section of Hematology and Oncology, Chicago, IL, United States*

They have been updated to:

> *Brendan Huang*
>
> *Department of Neurology and Neurosurgery, Tulane University, New Orleans, LA, United States*
>
> *Ajay Major*
>
> *Section of Hematology and Oncology, University of Chicago, Chicago, IL, United States*

The correction will appear in the online version of the paper on the JMIR Publications website on December 9, 2020, together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

Abstract

The COVID-19 pandemic and related public health efforts limiting in-person social interactions present unique challenges to adolescents. Social media, which is widely used by adolescents, presents an opportunity to counteract these challenges and promote adolescent health and public health activism. However, public health organizations and officials underuse social media to communicate with adolescents. Using well-established risk communication strategies and insights from adolescent development and human-computer interaction literature, we identify current efforts and gaps, and propose recommendations to advance the use of social media risk communication for adolescents during the COVID-19 pandemic and future disasters.

(J Med Internet Res 2020;22(12):e21886) doi:10.2196/21886

KEYWORDS

social media; digital health; COVID-19; adolescent; public health; disaster; communication; affordances

Introduction

The COVID-19 pandemic has affected nearly everyone’s way of life, irrespective of their age. The pandemic has particularly challenged adolescents, who at ages 10-19 years are undergoing some of the most dynamic changes of human development [1]. Individuation from family and connection with peers bring fundamental psychological and social benefits to this age group. The loss of in-person social interactions created by stay-at-home mandates, school closures, and social distancing during COVID-19 has strained these developmental processes. Further, because of the protracted nature of the pandemic and its restrictions, pervasive misinformation on the internet, and incorrect perceptions that healthy adolescents are at low risk for infection [2], some young people have dismissed the dangers of infection and their role in transmission in the greater community to spend time with their peers. We are currently witnessing the unsettling crisis of college campuses reopening this fall in the United States, only to face precipitous shutdowns and quarantines in response to outbreaks of COVID-19, brought about by fraternizing young people [3].

Opportunities exist, however, to help counteract some of these challenges during this uncertain time using adolescent-friendly methods. Given the near ubiquitous use of social media (SM) in this age demographic [4], online platforms traditionally used for entertainment purposes can be mobilized to promote health as well. This viewpoint highlights SM’s potential to serve the critical function of protecting and enabling adolescents during this unprecedented time by providing them with accurate and timely health information that will promote individual engagement in healthy behaviors while mitigating risk. Paralleling community adaptation efforts, SM may promote a paradigm shift from passivity and isolationism toward empowerment and activism.

We focus on well-established risk communication strategies and integrate insights from adolescent development and human-computer interaction literatures to identify current efforts, gaps, and recommendations highlighting two main points. First, to adequately support the promotion of healthy behaviors during COVID-19, public health actors should harness the power of SM to address adolescents through their preferred avenues. Second, content must address adolescent-specific needs to activate adolescents as drivers of health protective behaviors and promoters of community adherence.

Adolescent Use of Social Media

A total of 92% of adolescents use the internet daily and 85% have at least one SM account [4]. Since the start of the COVID-19 pandemic, the use of SM has increased across platforms. For many platforms, particularly those with many adolescent users, the number of new downloads, accounts created, and daily use is at an all-time high [5,6]. In the United States, popular platforms among this age group include YouTube (85%); Instagram (70%); Snapchat (65%) [4]; and, increasingly, TikTok [7]. Because of the ubiquity and stability of adolescent SM use, SM is a promising medium to reach adolescents.

The appeal and frequency of SM use by adolescents can be understood through a developmental perspective. Cognitively, adolescence is marked by a greater ability for self-directed learning and shifts from egocentric thinking to understanding the perspectives of others [8]. In addition to major cognitive changes, adolescence is a time for identity formation and exploration. Socially, adolescents spend more time with peers [9], seeking autonomy from adults. Developmental neuroscience and behavioral science have shown a heightened sensitivity to peer feedback [10,11] and social influences [12] in adolescence. Thus, peer norms and social prestige become more important [1].

The affordances framework provides insight on how SM aligns with these unique aspects of adolescent development [13]. Affordances are key design aspects of SM platforms that underlie how users use them. For adolescents, functional, social, cognitive, emotional, and identity affordances encourage exploration, learning, and practicing of skills that are key for development. Functional affordances refer to features that determine how messages are transmitted and saved for scalability and dissemination, for example, the ability to repost another user’s content. Social affordances are platform features that promote interpersonal interaction. One social affordance is belonging to a group based on a characteristic or shared interest. Identity affordances relate to features allowing users to create and develop their identity and portray it to others. For example, SM profiles can range from platforms that encourage sharing one’s true representation to total anonymity. Cognitive affordances are features that help users learn and share information, for instance, through the use of multimedia such as video as a creative way to promote learning. Emotional affordances are platform features that affect users’ emotional reactions. Examples include the use of personal stories, names, and pictures to create empathy.

Through these affordances, adolescents can explore topics of interest and their identity, connect with others, receive feedback to establish peer norms, and build prestige in a social ecosystem separate from adults. This understanding of adolescent development and the advantages of SM affordance features can inform interventions including risk communication during disasters.

Risk Communication During Disasters and During COVID-19

Studies have identified risk communication, defined as “the exchange of real time information, advice and opinions between experts and people facing threats to their health, economic or social well-being” [14], as an effective public health intervention to inform the public about resources and promote healthy behaviors during disasters. Increasingly, risk communication occurs through SM platforms due to extensive community reach [15]. SM allows the public, and adolescents in particular, to have timely access to a wide variety of topics with dynamic interaction beyond traditional interface media. At the same time, the inaccuracy of disseminated information may undermine an effective response, which has been unfortunately demonstrated in the context of COVID-19 [16].

Established authorities such as local governments and the Centers for Disease Control and Prevention (CDC) provide messages during public health events by using communication patterns that allow SM users to differentiate true facts from misinformation. The CDC has developed a six-principle framework for the dissemination of information during a crisis called Crisis and Emergency Risk Communications (CERC; Textbox 1) [17]. The CDC developed CERC to enable public health response officials to promptly and effectively communicate with the community in emergency situations. CERC is built around psychological and communication sciences, studies in the field of issues management, and learned experiences [17] from previous emergency responses to allow for communicators to work alongside the media and responders to impact community response and recovery from these potentially devastating emergencies. A full response in a crisis can take time, requiring multiple levels of information to be acquired that is incongruent with the need for the community to respond right away. This delay can impair an adequate community response. This is addressed through the basic principles of CERC, which emphasize the importance of being first, being right, and being credible in disaster response.

Textbox 1. Crisis and Emergency Risk Communications principles [17].

Be first

- Communicating information quickly is crucial. Historically, the first source of information often becomes the preferred source.

Be right

- Accuracy establishes credibility. Information can include what is known, what is not known, and actions being implemented to fill in the gaps.

Be credible

- Honesty and truthfulness should not be compromised during crises.

Express empathy

- Suffering should be acknowledged. Addressing emotional reactions and the challenges faced by individuals leads to trust and rapport.

Promote action

- Providing examples of meaningful activities for individuals to engage in may promote calm, reduce anxiety, help restore order, and foster a sense of control [18].

Show respect

- Respectful communication promotes cooperation and rapport.

To further promote information sharing, officials from government, health care organizations, and emergency management systems must reach a variety of listeners through their preferred media channels. The implementation of SM for CERC allows for an additional element of interaction to be incorporated into this framework. Whereas traditional news sources release static, precrafted messages in standard formats, such as press releases, the dynamic nature of SM has allowed for shifts in information dissemination. Historically, management agencies or organizers act as senders transmitting information to the receiving community. Through the use of SM, recipients such as adolescents also take on the role of senders by sharing, commenting, or reposting messages to their networks as a functional affordance.

To facilitate the reading and then the sharing of credible health information, content must quickly create resonance with consumers. Given the intentional brevity of SM posts, resonance must be successfully created with concise messages using few characters and through the provision of meaningful messages containing actionable guidance. Because of the rapid turnover of content, online resonance must create “stickiness,” an aspect of functional affordance, so that individuals access and remain on specific content for a greater duration of time. Stickiness can be extended by further engaging audiences with a familiarity of the rules of SM propagation—for example, the use of hashtags to attract readers. Market research and analytics play crucial roles to ensure that content creation and style meet the expectations of the SM user and lead to selective dispersal of accurate information.

In the CERC framework, directives to the community must evolve through the life cycle of a disaster, defined by four phases: preparedness, response, recovery, and mitigation. During these distinct phases the primary needs are concrete and focused on community safety. Nevertheless, some variables remain consistently vital, such as monitoring for hazards and threats, and flexible communication. Messaging about COVID-19 initially focused on reducing the spread of infection by informing, influencing, and empowering readers to wash their hands, stay at home, social distance, and travel only for essential activities such as picking up groceries or prescriptions. As new information has emerged, the current messaging encourages the use of facial masks in public and ongoing promotion of social distancing as communities begin to reduce restrictions and enable reopening.

Exploring CERC as Applied to Adolescents

Given the pre-existing widespread use of online media and online news sources by the adolescent demographic, CERC messaging through SM may be a particularly effective technique to reach this age group. To effectively engage with adolescents online, messaging must, first, be accurate to be considered an effective public health response. Second, content must be appropriate and relevant to adolescents to be identified as valuable. Here, consideration of the various affordances of SM is important. For adolescents to receive intended communication, it must be posted on platforms that adolescents are routinely accessing. Although the popularity of individual SM platforms will change over time, these affordances will not change and, therefore, can more consistently inform SM interventions. Subsequently, communication on SM that is inclusive, empowering, and promoting appropriate health behaviors can be leveraged as a mechanism to support action by youth and youth activists.

Although national or international health organizations frequently excel in the second and third CERC principles of providing “right” and “credible” information [19], these are time-consuming steps that may prevent adherence to step one of “being first.” By prioritizing speed of information dissemination on SM platforms, organizations and providers may more effectively help adolescents find accurate and up-to-date information from reliable health organizations. Crisis- and disaster-related content directed toward adolescents needs to reflect distilled knowledge from health care providers or public health organizations generated through a funnel process. More simply, this encompasses gathering data, filtering for reliable and consistent information, and then developing content written specifically to promote a selected action. Public health authorities have done little to tailor content on SM platforms for adolescents in prior infectious disease outbreaks [19]. Creating verbiage for adolescent-targeted messaging on SM platforms from health organizations also represents a solution to countering misinformation that has become especially prevalent in the pandemic. In addition, leveraging the functional affordance through ease of replicability of messages and the identity affordance (how adolescents portray themselves online), public health authorities can create precrafted messages for adolescents to repost as their own. This aligns with adolescents' desire for independence from adults and for prestige through social approval. Further, considering the functional affordance of scalability and the importance of peer norms, collaboration with influencers, especially those of similar age, to spread messages will likely be beneficial.

Available research shows that online misinformation on SM platforms, including during natural disasters, spreads faster and reaches more people than true information [20]. This is particularly troubling with the potential for disinformation to lead to significant harm when accurate information from leading health professionals is delayed or absent [21]. Adolescents may be particularly vulnerable to misinformation, using SM as a primary news source [22]. A recent study demonstrated that 25% of the most popular YouTube videos on COVID-19 contain misinformation [21], and 40%-60% of Twitter posts about COVID-19 are driven by bots (autonomous or semiautonomous software applications that mimic humans) [23]. Health care organizations and other public health agencies are tasked with combating this misinformation through CERC principles. In line with the cognitive affordances of knowledge acquisition and self-efficacy, use of interactive and visual media such as videos or quizzes testing knowledge about COVID-19 with corrective information may be more appealing to adolescents than messages with text or static images.

The next three principles of CERC communication ("express empathy," "promote action," "show respect") are equally as important; these require more specific adaptation for the target demographic and directly address the content of messaging. Language must be selected so as not to downplay information or incite anxiety. Word choice must be within the developmental and cognitive ability of the target demographic. Content must reflect the priorities of adolescents, show empathy for their concerns, and be engaging and entertaining [24].

Highlighting the loss of interactions with friends and community, and missing milestone achievements during the pandemic communicates that adolescent voices are heard in the uncertainty of the pandemic. Adolescents should be encouraged to maintain their connectedness with friends and peers by virtual means in absence of in-person contact when possible (encouragement of physical distancing over social distancing). With support of educational agencies, SM platforms have been used creatively toward managing the somber and disappointing cancellations of important rites of passage and celebrations of achievements such as graduations, proms, and summer job opportunities. For many, these letdowns have been softened and brightened through virtual graduations using livestreaming, video, and photo commemorations of the events in festive attire; distribution of digital diplomas; and inspirational speeches by celebrities and dignitaries [25].

These virtual efforts represent attempts to instill normalcy, highlight shared values, and create a sense of security, comfort, and community. In addition, they exemplify the social affordances of belonging and support, and the emotional affordances of using personal stories and ceremonies to generate emotion and garner empathy [13]. Adolescent struggles should not be minimized but, rather, respectfully validated. These efforts promote an alliance between health providers and organizations and adolescents, and make adolescents feel understood. If they feel camaraderie with the organizations and authorities, adolescents will be more likely to identify the importance of the messages and listen to them.

In regard to promoting action, adolescents have traditionally been seen as passive participants during disasters rather than primary agents and collaborators. Adolescents can play an important role in disaster response and preparedness [26]. Peek and colleagues [27] identified many youth contributions in response to Hurricane Katrina. They found that children and adolescents helped raise and donate money, collect material goods and supplies, assist with rebuilding, support behavioral health, develop programs and raise awareness, and found new organizations. Many youth initiatives were embedded within larger organizational responses rather than independently started by children and adolescents, though the authors acknowledge that adolescent-initiated and encouraged activities are important. A few papers highlight youth's use of SM to organize volunteering efforts in response to disasters [28,29].

To our knowledge, there have not been any other similar narrative, systematic, gray, or nonscientific literature reviews for adolescent use of SM in response to disasters including infectious disease outbreaks such as COVID-19. Though research in this area is still nascent, SM use aligning with the affordances framework has been identified as a promising medium to promote prevention in adolescents [30], including of sexually transmitted infections [31,32]. A recent systematic review on the use of technology to scale up youth-led participatory action research found few, albeit positive, examples of the powerful nature of adolescent SM engagement [33]. This suggests that adolescents may possess expertise in SM that has been underrecognized and underused, and there is limited documentation of adolescent contributions on SM platforms [27].

This highlights the importance for health care providers to invest in credible communication directed to adolescents and to support their development as emerging and powerful advocates for improving public health behaviors around the world—particularly at this crucial time in public health history. In line with the United Nations' Sendai Framework for Disaster Risk Reduction 2015-2030 [34] call to include adolescents as agents of change, public health directives should be relayed directly to adolescents.

The best messengers for adolescents are often other adolescents. Some organizations already engage adolescents to participate in response, advocacy, and teaching around important topics in public health. Examples include activation of teen community response teams during disasters (Teen Community Emergency Response Teams [35]) and opportunities for teen leaders to pursue projects that help their communities with preparedness and response during emergencies (the Federal Emergency Management Agency Youth Preparedness Council [36]). Other programs focus on education, empowerment, and building awareness of certain issues (health, youth employment, inequities), accomplished through programs where young people serve as youth ambassadors and youth advocates to the community, such as with Teens Take Charge [37] and the Youth Power Coalition [38]. Enlisting young leaders to promote public health interests allows for this demographic to play an active role in shaping their own future.

Young leaders have already demonstrated great motivation and drive to help others. Content that contains a motivational component can help spread adaptive behaviors to support the community, as reflected through SM posts showing adolescents helping vulnerable neighbors [29]. Social distancing directives in the context of COVID-19 may feel isolating; shifting the schema to highlight the altruism of physical distancing may help to influence desired behaviors at both an individual and population level. This aligns with the adolescents' desire to portray themselves in a positive light. Further, crafting immediate and accurate messages for both youth engagement as well as activation on SM can promote self-discovery, personal development, and local and global connectedness to perpetuate lasting behavior change [39,40].

Using the right communication model can positively impact behavior and change in adolescents during this pandemic. Leveraging SM is an essential part of the disaster communication toolkit to reach adolescents, who are often missed in targeted communications. Enormous potential exists to harness the existing skills of adolescents and the affordances of SM.

Current Risk Mitigation Efforts on Social Media

Although there is evidence supporting the use of the CERC framework's principles during prior disease outbreaks [41,42], the adoption has been slower for adolescents. This may be explained by the fact that many public health and medical organizations previously did not disseminate information through the SM platforms most widely used by youth, such as Instagram, TikTok, Snapchat, and YouTube, or consider affordances [13,22,30,43]. The COVID-19 pandemic has spurred some of these authorities to adapt. For example, the World Health Organization (WHO) started a TikTok account in the wake of COVID-19 and, as of October 2020, has over 2.4 million followers. The CDC has used multiple platforms including YouTube and added a dedicated Snapchat account. The United Nations Children's Fund (UNICEF) has sought to empower adolescents by asking them to share messages and graphics created by UNICEF and the WHO on SM platforms. More organizations and authorities would benefit from following the example of these pioneer agencies to develop SM accounts that reach a more diversely aged target population, especially where adolescents search and receive health information.

The developers of SM platforms should also be commended for identifying creative methods to promote accurate information. Instagram, Twitter, and TikTok verify authoritative accounts, making it easier for users to identify reputable sources to be featured. Similarly, many platforms have dedicated advertisement space to credible organizations. Many platforms including Facebook, Reddit, Twitter, TikTok, and YouTube now recommend or display credible sources of information associated with certain topics or hashtags and may fact-check content [16,44]. In an effort to correct misinformation, some platforms have displayed videos from credible organizations adjacent to COVID-19 videos with misinformed or unsubstantiated claims; however, this juxtaposition may be confusing to young viewers and lead to the conclusion that videos spreading misinformation are legitimate based on their proximity to videos by subject matter authorities. This is especially concerning because SM content recommendation algorithms can lead to a preferential though unintentional selection of misinformation. SM platforms can also demote, suspend, or even remove accounts spreading misinformation; however, this has been a less popular option due to first amendment rights.

Although organizations have developed accounts on SM to directly address youth, content on SM accounts is often geared toward adults and has not been developed specifically for adolescents or fails to acknowledge the unique challenges they face [22]. Few organizations have addressed the understandable reactions to remote schooling and the loss of sports activities and graduation ceremonies. This is a missed opportunity to promote behavior change through emotional and social affordances. Because empathy and respectful communication build trust, this type of messaging is necessary to engage adolescents. Some examples of successful and empathic ways to engage young people have been demonstrated by the United Nations Educational, Scientific and Cultural Organization (UNESCO), UNICEF, and TikTok. UNESCO's #MyCOVID-19Story [45] and UNICEF's #VoicesofYouths [46] campaigns ask youth to describe the challenges their communities face and to share creative and humorous content. TikTok's livestream event for the graduating class of 2020 featured multiple influencers and allowed students to receive digital diplomas. TikTok's prom week (#TikTokProm) [47] allowed adolescents to showcase their social distancing prom experience, which generated over 2 billion views. Since the reopening of universities in the United States, some colleges have expanded the role of paid student influencers (hired for marketing their schools to prospective students) to instead model safe behaviors on SM and connect students to resources as part of efforts to contain recent outbreaks on campuses [48].

In addition to empathy, showing respect is likely to activate adolescents. In some cases, adolescents have been admonished or demonized for engaging in risky behavior. Rather than shaming or being condescending, health organizations should provide positive and corrective experiences. Through functional affordance, more efforts should be made to partner with influencers, especially those with large audiences in the target demographic [22]. Indeed, a number of celebrities have streamed conversations with health authorities. Some of these conversations allow users to actively engage by asking questions in real time. For example, users could ask questions on Netflix's weekly livestream on Instagram called "Wanna Talk About It?" [49], which features conversations between Netflix actors and actresses from popular adolescent shows and mental health professionals to address the mental health and wellness of young people during COVID-19. This interactive way to promote learning and skills exemplifies cognitive affordance.

Many challenges or campaigns have been started to promote action. In general, campaigns try to influence people to engage in a discussion or carry out a set of activities reflecting social affordance. The Vietnamese "Jealous Coronavirus" (Ghen Co Vy) song and the related youth-created #GhenCoVyChallenge dance have been used to promote protective behaviors. The challenge video amassed over 31 million views, and UNICEF and the British Red Cross have shared it [50]. A number of handwashing challenges were created organically and in collaboration with the WHO. The South African Ndlovu Youth Choir created a musical rendition of the WHO's COVID-19 safety advice shared through SM platforms [51]. Proctor and Gamble hired the top influencer on TikTok, an adolescent 15 years of age with nearly 90 million followers, to perform a dance promoting social distancing labeled the #Distancedance [52]. Further, users were encouraged to create and share their own dance. Snapchat has also leveraged its location-sharing app, Zenly [53], to gamify sheltering-in-place. These interactive and visual risk communication strategies are likely more appealing for adolescents, as they leverage cognitive and social affordances and have generated millions of views and shares.

Conclusion

Adolescents represent a vulnerable group who are frequently overlooked in disaster and emergency communication. Given the ongoing COVID-19 pandemic and related future challenges of subsequent waves of infection and vaccination, it is a crucial time for risk communication. As explored in this paper, adolescents can be effectively reached and provide positive benefit given their high level of engagement and resourcefulness through online SM platforms. Many global agencies such as UNICEF have highlighted the individual and collective power of adolescent voices emerging as powerful advocates for change, emphasizing the difference between working for adolescents and working with adolescents.

SM can and should be leveraged by health care leaders and public health organizations to access tools to facilitate dynamic, accurate, and actionable risk communication to ensure awareness of public health issues and best practice guidance for adolescents. Nevertheless, this requires adaptation by health authorities to consider the developmental affordances of SM to reach adolescents and to tailor content to adolescent-specific concerns. Though emerging data showcases online connectedness of adolescents and health authorities leads to adherence to safe behavior and civil activism and advocacy, more research is needed to determine the most effective and safest practices as well as the outcomes of such endeavors. We believe that meeting adolescents *where they are at* on SM ensures that voices of young people are heard and represents an investment in their health and well-being during the COVID-19 pandemic and in future disasters.

Abstract

Background: With over 37.8 million cases and over 1 million deaths worldwide, the COVID-19 pandemic has created a societal and economic upheaval of unparalleled magnitude. A positive transformation has been brought about by innovative solutions in the health care sector that aim to mitigate the impact of COVID-19 on human health. For instance, the use of telehealth has been on the rise amidst this public health emergency.

Objective: Given the unprecedented scale of the pandemic with no definitive endpoint, we aimed to scope the existing telehealth-related literature during a defined period of the ongoing pandemic (ie, January to June 2020).

Methods: Our scoping review was guided by the Joanna Briggs Institute Reviewer Manual. We systematically searched PubMed and Embase databases with specific eligibility criteria. Data extracted from the shortlisted articles included first author and affiliation, journal title, publication type, terminologies used to describe telehealth and their accompanying definitions, health discipline or medical specialties and subspecialties wherein telehealth had been applied, the purpose of telehealth use, and the authors' overall sentiment on telehealth use. We collated the available information and used descriptive statistics to analyze the synthesized data.

Results: In all, 543 articles published across 331 different journals were included in this scoping review. The Journal of Medical Internet Research and its sister journals featured the highest number of articles (25/543, 4.6%). Nearly all (533/543, 98.2%) articles were in English. The majority of the articles were opinions, commentaries, and perspectives (333/543, 61.3%). Most authors of the articles reviewed were from high-income countries (470/543, 86.6%), especially from the United States of America (237/543, 43.6%). In all, 39 different definitions were used to describe terms equivalent to telehealth. A small percentage (42/543, 7.7%) of the articles focused on the provision of COVID-19–related care. Moreover, 49.7% (270/543) of the articles primarily focused on the provision of multiple components of clinical care, and 23% (125/543) of the articles focused on various specialties and subspecialties of internal medicine. For a vast majority (461/543, 84.9%) of the articles, the authors expressed a celebratory sentiment about the use of telehealth.

Conclusions: This review identified considerable emerging literature on telehealth during the first six months of the COVID-19 pandemic, albeit mostly from high-income countries. There is compelling evidence to suggest that telehealth may have a significant effect on advancing health care in the future. However, the feasibility and application of telehealth in resource-limited settings and low- and middle-income countries must be established to avail its potential and transform health care for the world's population. Given the rapidity with which telehealth is advancing, a global consensus on definitions, boundaries, protocols, monitoring, evaluation, and data privacy is urgently needed.

(J Med Internet Res 2020;22(12):e24087) doi:10.2196/24087

KEYWORDS

COVID-19; telehealth; telemedicine; scoping review

Introduction

The ongoing COVID-19 pandemic is a defining moment in the 21st century for many reasons. It has affected over 18.3 million people worldwide and led to over 695,000 deaths, resulting in a societal and economic upheaval of unparalleled magnitude [1]. These unprecedented times have also highlighted the power of science in identifying creative solutions to address this mammoth global challenge. Numerous Information and Communication technology (ICT) tools and innovative approaches, such as tools for online education and telecommuting, were being developed even before the pandemic; these tools gained popularity as people sought to find creative solutions to mitigate the impact of the pandemic [2]. In the health care sector, telehealth or telemedicine practices expanded tremendously during the pandemic and continue to flourish [3].

Telemedicine, a term coined in the 1970s, meant “healing at a distance” [4]. Over the following 4 decades, several peer-reviewed definitions for the term have emerged. In 2007, the World Health Organization (WHO) introduced a standardized definition for telemedicine: “The delivery of healthcare services, where distance is a critical factor, by all healthcare professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of healthcare providers, all in the interests of advancing the health of individuals and their communities” [5]. ICT is defined as a “diverse set of technological tools and resources used to transmit, store, create, share or exchange information. These technological tools and resources include computers, the Internet (websites, blogs, and emails), live broadcasting technologies (radio, television, and webcasting), recorded broadcasting technologies (podcasting, audio and video players and storage devices), and telephony (fixed or mobile, satellite, visio/video-conferencing, etc)” [6].

Although used interchangeably, telehealth by definition refers to health care services involving all health care professions (including education of health care professionals themselves), whereas telemedicine refers to services delivered by physicians only [7]. The last 2 decades have seen the emergence of newer terms such as ehealth, mobile health (mhealth), and digital health, to accommodate more recent advances in ICT-enabled health care [8]. For consistency, and as population health researchers with an interest in the broader health care domain beyond the only physician-delivered medical care model, in this paper, we prefer to use the terminology “telehealth” to refer to all forms of ICT-enabled health care.

Global interest within the scientific community for using telehealth was on the rise even before the COVID-19 pandemic, as evidenced by the increasing number of studies published on this topic in recent years [9]. However, the use of telehealth to improve patient care and population health has been predominantly concentrated among high-income countries rather than low- and low-middle–income countries [10]. Some medical specialties, such as radiology, dermatology, pathology, and psychiatry, used telehealth more frequently than others [7]. Health care professionals express varying sentiments regarding the use of telehealth for patient care. Some consider telehealth as the new holy grail in health care, whereas others are guarded in their opinion about its applicability in the field. Some worry about the lack of face-to-face connection between patients and health care providers, which they believe is needed to develop a therapeutic bond, and others express concern that clinicians are unable to perform all aspects of physical examination while using telehealth [11]. The risk of widening inequity across various population subgroups with the advent of telehealth is also a prevailing concern [12].

With the advancement of ICT in the health care sector to ensure accountability, ethical medical practice, and patient data privacy, several countries imposed legal restrictions and strict regulations regarding the use of this rapidly expanding technology. These factors, in addition to the lack of insurance coverage, were reported as primary barriers to advancing telehealth in many countries prior to the COVID-19 pandemic [13]. With the onset of the pandemic, clinics and hospitals rapidly restricted access for emergency care in order to reduce the risk of disease transmission. To manage patient load, safeguard the health of patients and health care professionals, and ensure continuity of patient care, capable health care systems expanded their health care delivery by providing telehealth services. Moreover, several countries relaxed their laws and regulations pertaining to the use of telehealth. Additionally, with the evolving landscape of health care delivery during the COVID-19 pandemic, insurance companies have now started reimbursing expenses for patient care delivered via telehealth [13].

We hypothesized that there has likely been an increase in the delivery of telehealth-enabled care since the onset of the COVID-19 pandemic, with concurrent experiential reporting by health care professionals who are using telehealth as a health care delivery modality. The application of telehealth to promote health, evaluate and manage diseases, and rehabilitate individuals has been documented in other public health emergencies [14]. Given the unprecedented scale of what we are witnessing in the current COVID-19 pandemic, and its surrounding uncertainties and ramifications on future health care delivery, we aimed to scope the existing literature on telehealth during a defined period in the ongoing pandemic (ie, January to June 2020).

Methods

Study Design

We performed a scoping review consistent with the guidance provided by the Joanna Briggs Institute Reviewer Manual [15,16]. The scoping review follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist (see Multimedia Appendix 1) [17]. The protocol was registered on the Open Science Framework (registration DOI: 10.17605/OSF.IO/AXN32) [18] on July 19, 2020.

Eligibility Criteria

The eligibility criteria were established a priori. We considered only publications that had been accepted for publication or had been published in peer-reviewed journals. Preprints were not considered. All publication types were considered, including opinions, viewpoints, original research articles, and reviews, with no geographic, time, or language restrictions. Furthermore, we included all publications examining any aspect of telehealth from direct, synchronous videoconferencing between patients and health care providers, to mhealth monitoring via apps, as well as wearable smart devices. We excluded any article whose primary focus was not telehealth, including articles related to molecular studies, modeling studies, and studies that used technology only for a better understanding of disease dynamics with no immediate and direct benefit for health care workers (including medical students and health care managers) or patients.

Search Strategy

We systematically searched 2 electronic databases (PubMed and Embase) from January 1 to June 10, 2020, using both keywords and controlled vocabulary (such as MeSH terms). The search terms were a combination of 2 concepts: (1) COVID-19 and (2) telehealth or telemedicine. The detailed search strategy is provided in Multimedia Appendix 2. A senior information specialist validated the search strategy. For a comprehensive assessment, we also searched the reference lists of all the included articles to identify other studies that may be relevant to our review.

Article Selection and Data Extraction

Articles identified by our search strategy were imported into Rayyan, the online systematic review software, and duplicates were removed [19]. SD screened the title and abstracts of the identified articles. AA checked the excluded studies and was able to confirm that the exclusion criteria were correctly applied. Subsequently, SD and AA individually extracted data from 50% of the included studies each. We developed a standardized Microsoft Excel (Microsoft Corp.) template for data extraction to tabulate specific information from the included studies, such as journal title, written language of the article, reference to telehealth or its variants in the article title, reference to COVID-19 or its variants in the article title, publication type, country of the first author's affiliation, country of focus of the article, terminologies used to describe telehealth and their accompanying definitions, the purpose of telehealth use, and the health discipline or medical specialty and subspecialties wherein telehealth had been applied during the study period.

Additionally, for each article, we categorized the overall sentiment expressed by the authors about the usefulness of telehealth. This categorization was based on the framework developed by Nettleton et al [20] and subsequently used by Dol et al [21] in their scoping reviews of the use of internet technology and social media in medical, sociological, and popular literature. Accordingly, the sentiments were categorized as "celebratory" (ie, authors provide a positive appraisal of telehealth use during the pandemic), "contingent" (ie, authors recognize the potential positive contribution but also acknowledge its potential limitations), or "concerned" (ie, authors identify challenges and caution on the imbalance that telehealth may create in health care delivery).

Finally, SD and AA randomly cross-checked approximately 10% of each other's extractions to ensure correctness and completeness of the extracted data. No discrepancies were noted.

Data Analysis and Synthesis

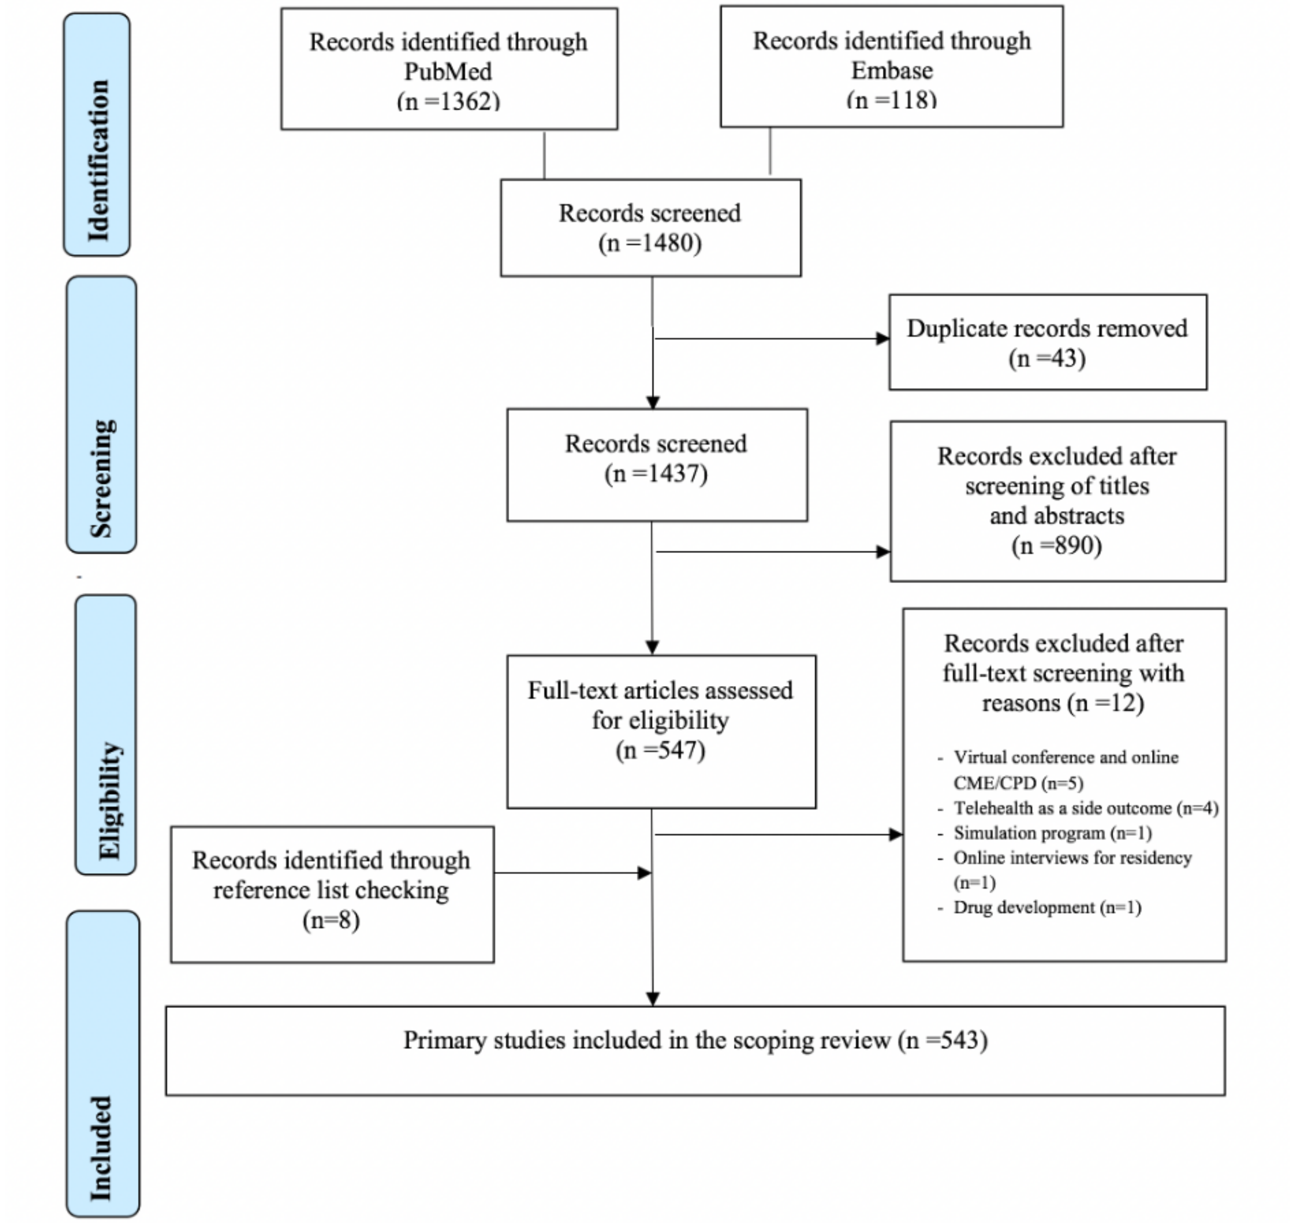
We synthesized the collated data by using descriptive statistics (frequencies and proportions). We used Microsoft Excel and SPSS software (version 26.0; IBM Corp) to analyze the data.

Results

Selection of Articles

After removal of duplicates, we identified 1437 articles in our initial search. Next, based on our eligibility criteria, articles were excluded at various screening stages: 890 at the title and abstract screening stage and 12 at the full-text screening stage. We also searched the reference lists of the included articles and found another 8 relevant articles for inclusion. Thus, a total of 543 articles were included in our review. Figure 1 shows the PRISMA flow chart illustrating the publication selection process. The full list of included studies is provided as Multimedia Appendix 3.

Figure 1. PRISMA 2009 flowchart. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses. CME: continuing medical education. CPD: continuing professional development.



Characteristics of Included Articles

The 543 articles included in our review were published across 331 journals. The *Journal of Medical Internet Research* and its sister journals featured the highest number of articles (25/543, 4.6%), followed by *Telemedicine and e-Health* (19/543, 3.5%). Other journals featuring a high number of included articles were the *Journal of Diabetes Science and Technology* (18/543, 3.3%), *Journal of the American Academy of Dermatology* (9/543, 1.7%), *Otolaryngology-Head and Neck Surgery* (9/543, 1.7%), and the *Journal of Rural Health* (8/543, 1.5%). The remaining journals featured fewer than 8 articles on telehealth in the context of COVID-19. Nearly all (533/543, 98.2%) of the included articles were in English. A small number of articles (8/543, 1.5%) were in French and Spanish, and 1 article each was in German and Hungarian. While the authors of this study read English and French, information from the Spanish, German, and Hungarian articles was extracted from their English abstracts by using Google Translate.

Our manual search of only the titles of the articles included in our study identified that 72.4% (393/543) of the articles made a direct reference to telehealth or its variants and 95.6% (519/543) of them made a direct reference to COVID-19 or its variants. A majority (333/543, 61.3%) of the articles were published as an opinion, commentary, and perspective, followed by empirical research (63/543, 11.6%) and review (narratives or systematic review and meta-analyses: 33/543, 6.1%). In all, 5% (27/543) of the articles were categorized as “others” (ie, Bridging the gap, Business horizons, Care delivery, Clinical forum, Clinical practice guidelines, Consensus statement, Curb side consult, First view, How to do it, Leaders focus, Orthopedic forum, Practice, Practice guidelines, Practice & policy, Special feature, and Training room). Article-type categorization was unclear for 16% (87/543) of the articles.

The first authors of the articles included in our review were affiliated (place of work) in 42 different countries. Most first authors were from the United States of America (237/543, 43.6%), followed by much a smaller number from the United Kingdom, Italy, India, Canada, Australia, France, China, Spain, and Singapore, in decreasing order (Table 1). The geographic focus of the articles also varied, with 32.8% (178/543) of all articles focusing on the United States; this was closely followed by 28.5% (155/543) of all articles had a global or regional focus (Table 2). The geographical focus of the articles largely matched the countries of affiliations of the first authors. We further grouped the countries according to the World Bank's income status [22] and WHO's regional classification [23]. The complete lists of countries based on the above classifications are provided in Multimedia Appendix 4. The vast majority of articles were published from high-income countries (470/543, 86.6%; World Bank classification) and the Americas region (277/543, 51%; WHO classification), closely followed by Europe (168/543, 30.9%). A summary of this comparison is provided in Figures 2 and 3.

Table 1. Country of affiliation of the first authors (N=543).

Country of affiliation[a]	Number of articles, n (%)
USA	237 (43.6)
UK	52 (9.6)
Italy	44 (8.1)
India	25 (4.6)
Canada	25 (4.6)
Australia	16 (2.9)
France	15 (2.8)
China	15 (2.8)
Spain	13 (2.4)
Singapore	11 (2.0)

[a] The first author's place of work

Table 2. Geographic focus of published articles included in the review (N=543).

Country of focus[a]	Number of articles, n (%)
USA	178 (32.8)
Global[b]	155 (28.5)
UK	33 (6.1)
Italy	31 (5.7)
India	19 (3.5)
Canada	18 (3.3)
France	12 (2.2)
Australia	11 (2.0)
China	11 (2.0)
Spain	9 (1.7)
Brazil	9 (1.7)
Iran	6 (1.1)
Germany	6 (1.1)

[a] Some articles focused on more than one country.

[b] Articles that had a global focus, covering more than 3 countries.

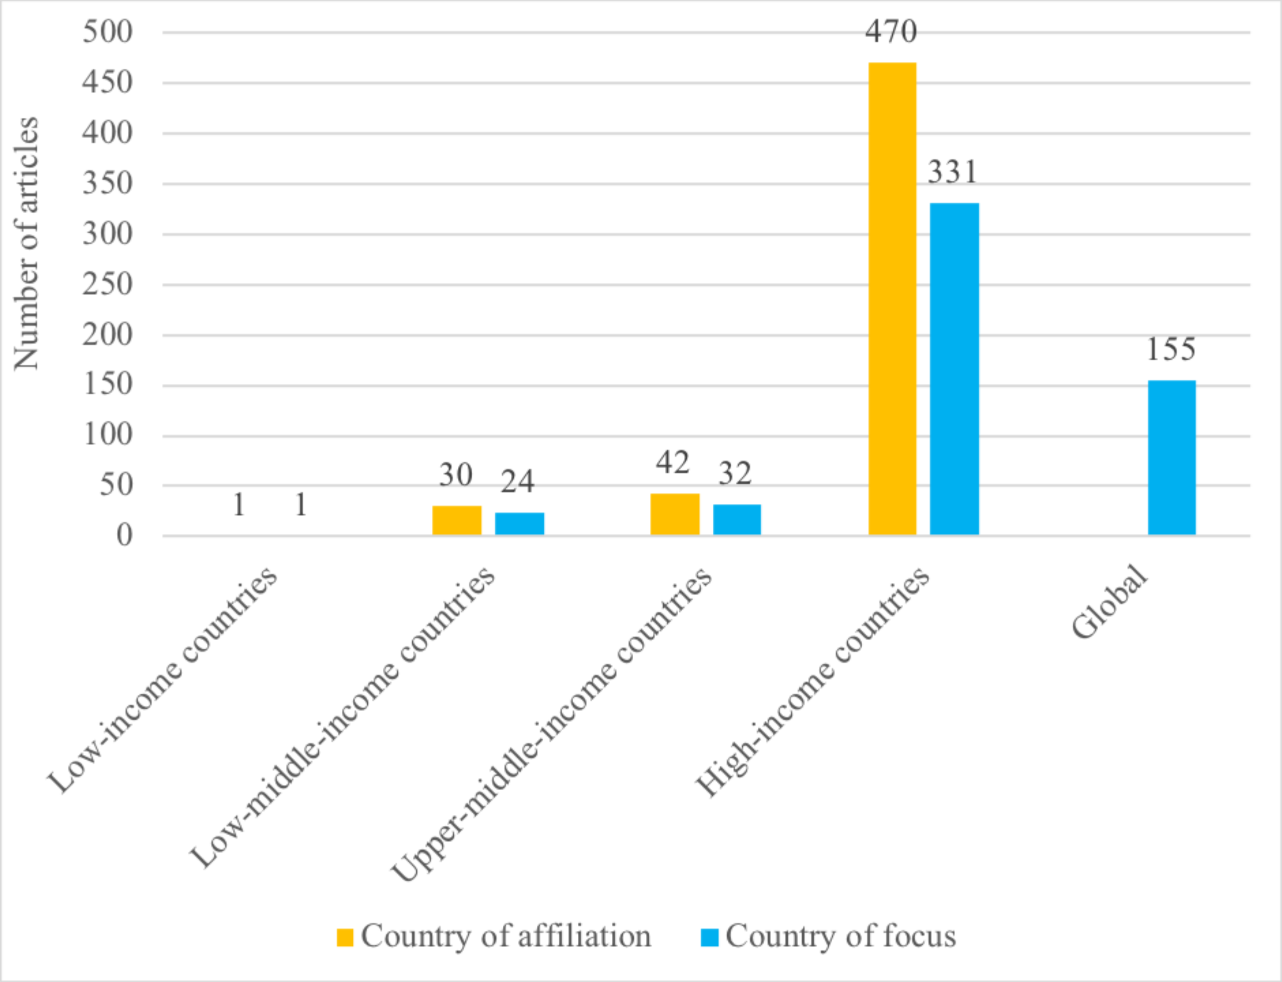

Figure 3. Number of articles based on the World Health Organization's regional classification (N=543).

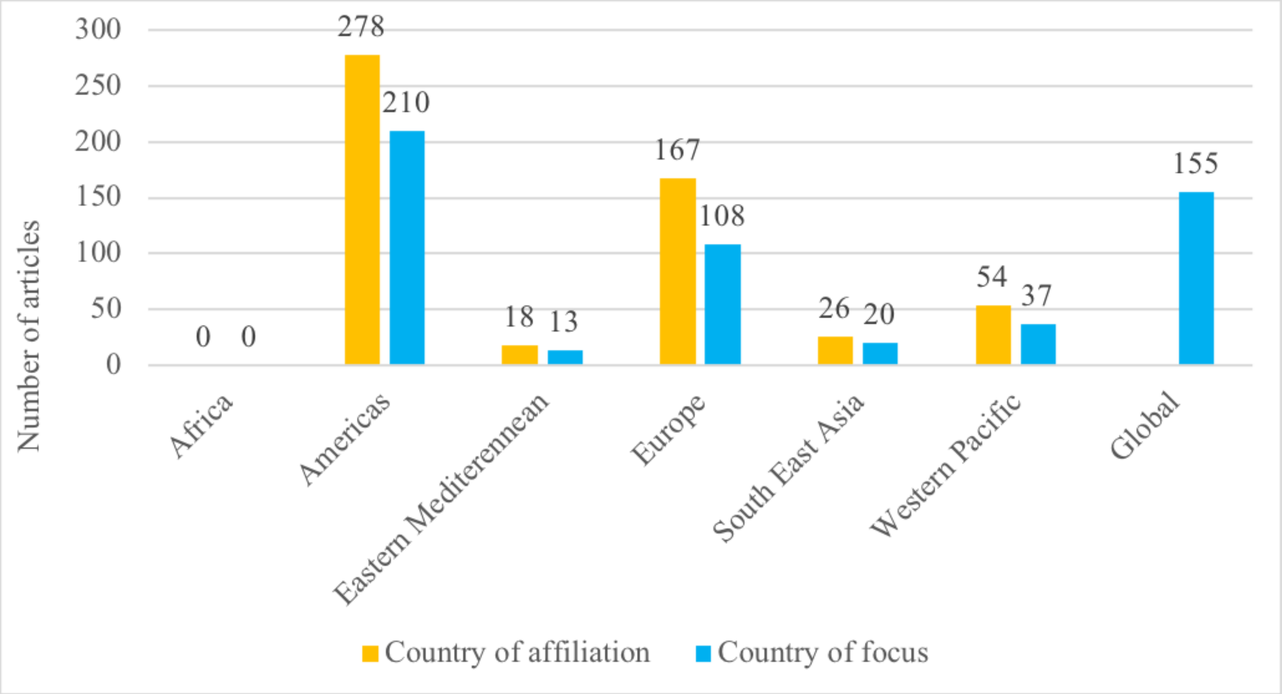

Terminologies Used and Their Definitions

We found 39 different terminologies related to telehealth in the articles included in our review. The most frequent terminologies used were "telehealth" and "telemedicine." Additionally, frequent use of tele-prefix specialty or subspecialty (eg, teleneurology, telestroke), digital health, ehealth, remote health, video visits, and others was observed. Articles also included references to emerging ICT concepts such as artificial intelligence (AI), robotics, and wearable technology in the context of telehealth. Of the 543 articles, 105 (19.3%) articles included a definition of telehealth-related terminologies. Of these, 13 articles attempted to define telehealth, whereas 52 articles used varying definitions for telemedicine, only 2 of which matched the definition put forth by the WHO. The various definitions of "telehealth" and its variants provided in the included articles have been compiled and presented in Multimedia Appendix 5.

Purpose of Telehealth Use

Of the articles included in our review, 7.7% (42/543) articles focused on the provision of telehealth related to COVID-19, whereas 92.3% (501/543) reported provision of health care support for conditions not related to COVID-19 (eg, tuberculosis, HIV, diabetes, and stroke). We found that the actual purpose of telehealth use during the COVID-19 pandemic varied across studies (Table 3), with the most common purpose being providing multiple components of clinical care (270/543, 49.7%), including any combination of triage, diagnosis, treatment, follow-up, and rehabilitation services. Other purposes for telehealth use were follow-up care (83/543, 15.3%), medical education (54/543, 9.9%), diagnosis only (39/543, 7.2%), and rehabilitation (24/543, 4.4%).

Table 3. Various purposes of telehealth use during the COVID-19 pandemic (N=543).

Purpose	Number of articles, n (%)
Clinical care	270 (49.7)
Follow-up	83 (15.3)
Medical education	54 (9.9)
Diagnosis	39 (7.2)
Rehabilitation	24 (4.4)
Health communication	20 (3.7)
Triage	19 (3.5)
Surveillance or contact tracing	16 (2.9)
Research	12 (2.2)
Health care worker wellbeing	6 (1.1)

Telehealth Use in Various Medical Specialties and Subspecialties

With regard to the specialties covered in the articles included in our review, 89.9% (488/543) of the articles discussed the application of telehealth in medicine and dentistry, and 9.9% (54/543) of the articles focused on medical education. Among the 54 articles on medical education, 10 articles discussed residency training, 8 discussed undergraduate medical student training, and the remaining 36 discussed telehealth in the context of medical education in general (covering undergraduate, postgraduate, residency training, and continuing professional development programs). Only 1 article discussed the application of telehealth in dentistry. We further classified the specialties and subspecialties of medicine covered by the articles using the framework proposed by the American Association of Medical Colleges on various specialties and subspecialties of medicine [24]. We found that 12.9% (70/543) of the articles focused on the use of telehealth for medicine in general with no reference to any specialty. The majority of the remaining articles focused on telehealth use in the following medical specialties: internal medicine (125/543, 23%), preventive medicine (56/543, 10.3%), psychiatry (42/543, 7.7%), surgery (36/543, 6.6%), neurology (33/543, 6.1%), otolaryngology (23/543, 4.2%), and dermatology (23/543, 4.2%). Additional analysis of the subspecialties revealed that the top 5 subspecialties deploying telehealth were endocrinology (30/543, 5.5%), oncology (25/543, 4.6%), geriatrics (23/543, 4.2%), cardiovascular (20/543, 3.7%), and orthopedics (10/543,1.8%). The numbers of articles grouped across various specialties and subspecialties of medicine are reported in Table 4.

Table 4. Number of articles included in the review categorized according to various medical specialties, subspecialties, and specific disease conditions (N=543).

Medical specialty[a], subspecialty[b], and specific disease or condition[c]	Number of articles, n (%)

[a] Number of articles in each medical specialty; where not mentioned, the article is included under the general practice.

[b] Number of articles in each subspecialty; where not mentioned, the article is included in the specialty category only.

[c] Number of articles discussing each specific disease or condition; where not mentioned, the article is included in subspecialty category only.

[d] ECMO: extracorporeal membranous oxygenation.

[e] Articles discussed various aspects of medicine without reference to any specific medical specialty.

In the articles included in our review, the top 5 diseases or conditions for which telehealth was used were diabetes mellitus (9/543, 1.7%), head and neck cancers (8/543, 1.5%), HIV (6/543, 1.1%), epilepsy (5/543, 0.9%), and inflammatory bowel disease (5/543, 0.9%). Within the preventive medicine specialty, 7.7% (42/543) of the articles discussed the various forms of COVID-19 prevention, treatment, and control.

Classification of Sentiments on Telehealth Use

As described in the Methods, we categorized the sentiments expressed by the authors based on the framework proposed by Nettleton et al [20] and subsequently used by Dol et al [21]. The majority (461/543, 84.9%) of articles were celebratory in nature, followed by those that were contingent (74/543, 13.6%), and concerned (8/543, 1.5%). Articles that were categorized as contingent and concerned predominantly stated the need for more evidence on (1) patient satisfaction, (2) cost-effectiveness, (3) efficacy and accuracy of care, and (4) health equity.

Discussion

Principal Findings

The findings from our scoping review indicate that substantial published literature on telehealth has emerged and continues to do during the ongoing COVID-19 pandemic. The eagerness of health care providers and expert researchers to share their opinions and research findings on the application and future potential of telehealth is evident. We observed that telehealth remains a topic of interest for a wide variety of journals (generic and specialized). This is not surprising because telehealth not only shows promise but also has the potential to improve health care access globally [25].

The vast majority of published articles in the literature are in the English language. This is also true for articles featuring technology-related information, as often there are no suitable words in native languages to define technological advancements. This gap in communication can consequently be a deterrent to publishing, with the views of experts and researchers from non–English-speaking countries being discounted or overlooked [26]. It is interesting to note that most of the articles included in our review had a direct reference to COVID-19 and telehealth in their titles, emphasizing the value and use of telehealth during the pandemic. Although journals usually prefer to publish empirical research and reviews, the fact that the vast majority of the articles in our review were viewpoints and opinions demonstrates the willingness of journals to publish such articles while empirical research on the topic continues to emerge during the pandemic. These experiences, arguments, and debates can help identify future research questions. Although the majority of shorter communications such as opinions, commentaries, and viewpoints may be useful for future research, studies have found that these article types are often not backed by adequate data and/or are poorly reviewed in a rush to disseminate relevant scientific knowledge [27]. The evolving nature of the COVID-19 pandemic necessitates swift publishing; however, the measures to protect scientific integrity cannot be overemphasized [28]. Any follow-up systematic reviews on telehealth during the pandemic should place high emphasis on the quality of studies included. Moreover, the small proportion of empirical research and reviews on telehealth during this period should also be seen as a call for additional scientifically robust primary studies with hard data and statistics to offer current and reliable evidence on telehealth.

Our analysis of the first authors’ affiliations and the study’s geographic focus showed that a vast majority of the publications originated from high-income and upper-middle–income countries in the Americas, Europe, and the Western Pacific regions. The higher number of publications from the United States of America is commensurate with the recent rapid surge in telehealth use seen in that country. This can be attributed to the flexibility provided by the Health Insurance Portability and Accountability Act of 1996 and the willingness of insurance companies to reimburse for the services provided via telehealth [29]. Among the low- and upper-middle–income countries, the geographic focus was on India, China, Brazil, and Iran. These countries are large, have been profoundly affected by the COVID-19 pandemic, and had some telehealth-related infrastructure in place even before the onset of the pandemic. We found that the list of countries with the maximum number of publications, based on our review, was mostly consistent with the country-wise publication output as published by the National Science Board of the United States of America [30]. Interestingly, we found no publication originating from Africa; this may be because COVID-19 has had a relatively low overall impact on health within the continent to date [31] and the fact that telehealth infrastructure availability is limited in many African countries [32].

The wide range and variation in the definitions of telehealth used by the authors, despite WHO’s efforts to standardize the definition, is concerning. This is reflective of the lack of consensus in the scientific world on what constitutes telehealth [8,33]. Given more recent developments in the field, including the growing scope of wearable technology and AI, that can augment telehealth and compensate for some of its limitations (eg, physical examination and continuous monitoring) [34], there is a need to revisit the definition of telehealth and arrive at a global consensus. We believe that the use of very broad terminologies (such as ehealth) or very narrow terminologies (such as telestroke) might hamper the standardization and introduction of legal and regulatory provisions to facilitate the use of telehealth. Uniformity in terminology is also important for future evidence-generating systematic reviews, such as those evaluating the efficiency and effectiveness of telehealth.

Telehealth and COVID-19

Our study demonstrates that telehealth has been used broadly in the context of the COVID-19 pandemic as an aid to the active management of patients with COVID-19; for surveillance, triage, and diagnosis; treatment including e-prescriptions; follow-up care; and rehabilitation. It is interesting to note that telehealth has been complemented by the use of wearable devices and selfcare equipment, such as glucometers, handheld blood pressure monitors, pulse oximeters, and digital stethoscopes [35,36]. The use of such equipment, as necessitated by the pandemic, has favorably augmented telehealth use. This can be expected to continue to serve as an adjunct to the provision of telehealth and in-person health care delivery in the long-term [37]. Futuristic advancements in the development and deployment of wearable devices and unobtrusive sensing systems in telehealth offer considerable scope for potential applications and research [35].

Our findings suggest that telehealth has been extensively utilized for medical education during the COVID-19 pandemic. Its use must have considerably helped medical schools in the delivery and continuity of medical education and training. It must also have allowed students to keep on track so that they are able to complete graduation requirements in a timely manner despite challenges associated with the pandemic. Telehealth has been previously used for case rounds and case discussions in residency training [38]. Case discussions, in particular, involve an intersection between tele-education and telehealth, as they bring expert (clinical) educators closer to trainees and students based in remote locations [39]. Certain medical specialties such as dermatology, neurology, obstetrics and gynecology, orthopedics, pathology, psychiatry, and surgery were more likely to use telehealth in residency training than other specialties [40]. Moreover, almost all medical specialties have tapped into telehealth for medical care. Specialties such as dermatology, pathology, and psychiatry have long employed telehealth to provide services to patients [7], whereas other specialties such as surgery, anesthesiology, and oncology are beginning to find telehealth useful at least to deliver certain components of their regular service.

Our findings suggest telehealth has been used to manage a wide spectrum of noncommunicable and communicable diseases, including COVID-19. An earlier scoping review had identified the predominant use of telehealth for noncommunicable diseases, but it did not focus on communicable diseases [41].

In addition to supporting disease-specific management, telehealth has also been extended to provide holistic medical care to specific target groups such as adolescents and older people [42,43].

Given the large scope of telehealth services analyzed by our study, it was no surprise to find that authors of an overwhelming majority of published articles expressed a celebratory sentiment regarding the use of telehealth. This finding is in line with that of many past reviews on the subject [9,44-46]. Authors of the few articles that expressed contingent and concerned sentiments cited the need to review additional evidence on the use of telehealth for health care delivery and to further explore ethics and equity in the context of telehealth use [47-51]. Given that the majority of articles were opinions and perspectives, this is a concern that cannot be overlooked.

Study Limitations

Although this scoping review was conducted according to the suggested methodology, we acknowledge our study has some limitations. We searched only 2 databases and did not actively search the grey literature and preprints. Consequently, our search may not have been exhaustive. Furthermore, following best practices in scoping reviews would have required us to have 2 independent reviewers involved in the screening and data extraction or charting stages. Given the time sensitivity and high volume of publications, an optimized approach had to be considered. However, we have ensured transparency by clearly outlining the process followed in the Methods section. Although the initial title and abstract screening was performed by 1 reviewer, given the large number of studies for data charting, the full-text screening for data extraction was completed by 2 reviewers. Any variation between the 2 reviewers would have been mitigated by the standardized, well-defined, self-explanatory data extraction form used. As most of the data (except for the sentiment analysis) extracted from the articles contained factual information (such as the name of the journal, type of publication, country of affiliation of first author) drawn directly from the articles and were objectively verifiable, the likelihood of variation remained low. The fact that both the reviewers cross-verified at least 10% of each other’s work provides an added level of cushion to the process. Another limitation to this scoping review is the rapidity with which articles seem to be published. From the time of our search to the writing of the manuscript, the number of publications in PubMed alone had almost doubled. As a result, this review is expected to serve the purpose of being an interim scoping review only and can be further updated as the need arises.

Conclusions

Our scoping review highlights the exponential use of telehealth during a defined period of the ongoing COVID-19 pandemic. Experiential reports pertaining to telehealth use are being published extensively, albeit mostly from high-income countries such as the United States, in particular. A wide variety of journals, including specialty journals, are increasingly publishing more material on telehealth. This is in tandem with an increasing number of medical specialties beginning to use telehealth for patient care. Our study also found many subspecialties of medicine that utilize telehealth. Emerging technologies, including wearable devices and AI, are futuristic adjuncts to telehealth, which may help mitigate some of its limitations. The positive sentiment expressed by most authors regarding the use of telehealth is reflective of the developing enthusiasm and receptiveness for this technology. However, we cannot overlook the need for additional robust evidence on the safety and effectiveness of telehealth as compared to the traditional health care delivery model, as pointed out by some authors. Our scoping review demonstrates the breadth and depth of data currently being generated in this area and will enable future systematic reviews and meta-analyses to help address research gaps and answer emerging questions.

Telehealth may have a significant effect in advancing health care in the future. If it has the potential to transform health care, we must ensure that low- and middle-income countries can benefit from it. More North-South and South-South collaborations between academics and practitioners are needed to establish the feasibility and utility of telehealth in resource-limited settings. The advances in medical education facilitated through telehealth are noteworthy. The school curricula for health professionals must be reformed to include specific education pertaining to health care delivery utilizing telehealth, as this can have a profound effect on patient outcomes and the overall health of the population. Continuing medical education and continuing professional development in telehealth use must also concurrently be offered to practicing health care practitioners, so they can become cognizant of and comfortable with using this modality to aid the provision of health care delivery. Given the rapidity with which telehealth is advancing, a global consensus on definitions, boundaries, protocols, monitoring, evaluation, and data privacy are urgently needed.

Acknowledgments

We would like to thank Ms. Sinead M O’Rourke, Content Development Specialist, Distributed eLibrary, Weill Cornell Medicine, Qatar, for her assistance in manuscript editing.

Authors' Contributions

All authors collectively contributed to the conception of the study. SD and AA were involved in the literature search, screening, and data extraction. SD conducted the analyses and wrote the manuscript with support from AA, SC, and RM. All authors read, edited, and approved the final manuscript.

Conflicts of Interest

Abstract

Background: Conventional diagnosis of COVID-19 with reverse transcription polymerase chain reaction (RT-PCR) testing (hereafter, PCR) is associated with prolonged time to diagnosis and significant costs to run the test. The SARS-CoV-2 virus might lead to characteristic patterns in the results of widely available, routine blood tests that could be identified with machine learning methodologies. Machine learning modalities integrating findings from these common laboratory test results might accelerate ruling out COVID-19 in emergency department patients.

Objective: We sought to develop (ie, train and internally validate with cross-validation techniques) and externally validate a machine learning model to rule out COVID 19 using only routine blood tests among adults in emergency departments.

Methods: Using clinical data from emergency departments (EDs) from 66 US hospitals before the pandemic (before the end of December 2019) or during the pandemic (March-July 2020), we included patients aged ≥20 years in the study time frame. We excluded those with missing laboratory results. Model training used 2183 PCR-confirmed cases from 43 hospitals during the pandemic; negative controls were 10,000 prepandemic patients from the same hospitals. External validation used 23 hospitals with 1020 PCR-confirmed cases and 171,734 prepandemic negative controls. The main outcome was COVID 19 status predicted using same-day routine laboratory results. Model performance was assessed with area under the receiver operating characteristic (AUROC) curve as well as sensitivity, specificity, and negative predictive value (NPV).

Results: Of 192,779 patients included in the training, external validation, and sensitivity data sets (median age decile 50 [IQR 30-60] years, 40.5% male [78,249/192,779]), AUROC for training and external validation was 0.91 (95% CI 0.90-0.92). Using a risk score cutoff of 1.0 (out of 100) in the external validation data set, the model achieved sensitivity of 95.9% and specificity of 41.7%; with a cutoff of 2.0, sensitivity was 92.6% and specificity was 59.9%. At the cutoff of 2.0, the NPVs at a prevalence of 1%, 10%, and 20% were 99.9%, 98.6%, and 97%, respectively.

Conclusions: A machine learning model developed with multicenter clinical data integrating commonly collected ED laboratory data demonstrated high rule-out accuracy for COVID-19 status, and might inform selective use of PCR-based testing.

Introduction

SARS-CoV-2 is the cause of COVID-19, which continues to spread in an uncontrolled manner across the United States [1]. COVID-19 management includes patient isolation and supportive care [2]. This strategy requires expeditious COVID-19 diagnosis, but components required for the reverse transcription polymerase chain reaction (RT-PCR; hereafter, PCR) assay have been reported to be in short supply in some locations during the pandemic, leading to delays in results [3]. In the absence of a widely available PCR test with rapid turnaround, there is an urgent need to identify alternative means for stratifying risk of patients seeking care during the COVID-19 pandemic.

Risk assessment models might identify those at low risk of active COVID-19 using available data from the clinical encounter [4,5]. In contrast to traditional model-building techniques, machine learning technologies consider complex linear and nonlinear associations between independent variables and identify characteristic patterns of commonly collected data among patients with COVID-19 [6]. A test with high sensitivity and diagnostic yield (ie, fraction of patients ruled out) could be used in a manner analogous to other rule-out tests, such as D-dimer for pulmonary embolism [7].

Using emergency department (ED) patient encounters from a well-established multicenter clinical database, we sought to describe the development of a machine learning model for ruling out COVID-19 using only routinely collected laboratory tests. Furthermore, we aimed to assess the area under the receiver operating characteristic (AUROC) curve of a machine learning model's concordance with both COVID-19 PCR test results (for positives) and prepandemic patients (for negatives). We hypothesized that such a machine learning model would enable the ruling out of the disease with sensitivity >90% and diagnostic yield >50%.

Methods

Study Design and Setting

This analysis and its reporting is compliant with the Standards for Reporting Diagnostic Accuracy Studies (STARD) statement [8]. This cross-sectional study was performed using 3 data sets of deidentified, patient-level electronic medical records of adult patients in an ED. The Premier Healthcare Database (PHD) is a large database of 1041 US hospitals from all 9 US geographic regions defined by the US Census [9]. At time of writing, 155 hospitals contribute SARS-CoV-2 RNA testing results to the PHD. We separately obtained data from Cedars-Sinai Medical Center (CSMC), an 886-bed academic medical center in Los Angeles, CA, and the Beth Israel Deaconess Medical Center (BIDMC), a 673-bed academic medical center in Boston, MA. An inclusion flow diagram and descriptions of these data sets are provided in Section A of Multimedia Appendix 1.

Prepandemic and Pandemic Time Frames

Two time frames were used, defined by the date of ED visit: prepandemic (before January 2020) and pandemic (March 2020 through July 2020). January 2020 and February 2020 were not included due to the lack of widespread monitoring or diagnostic tests for COVID-19 in the United States during this time frame, even though SARS-CoV-2 community transmission was present in the United States during this time [10]. Clinical encounter data from the PHD were available for the prepandemic (January 2019-December 2019) and pandemic (March 2020 through July 2020) time frames. CSMC data were available for patients with COVID-19 during the pandemic time frame only (March-April 2020). BIDMC data were available across an extended prepandemic time frame (2008-2019) only for patients who were admitted through the ED.

Selection of Participants

Eligible patient encounters (hereafter, patients) were adults aged ≥20 years in an ED at an included center during one of the prepandemic or pandemic time frames. Patients were excluded if they were missing a laboratory result included in the model on the day of presentation to the ED or if any of their laboratory results were reported with inappropriate units or incorrect specimen type. Patients were defined as PCR-positive for COVID-19 (hereafter, PCR-positive) if they had a positive SARS-CoV-2 RNA test on the day of presentation to the ED. We chose PCR rather than antigen positivity to define the cases as PCR is commonly used as the reference standard in COVID-19 diagnosis [11,12].

Training Population and Definition of COVID-19 Cases and Controls

Training occurred in the PHD database only. The PHD training and external validation sets were split by hospital, and only hospitals that reported COVID positives as well as the blood tests required for the model were included in the analysis (64 total). Of these, 43 hospitals were randomly assigned to the training set, and 21 to the external validation set (hereafter, PHD holdout). Cases came from the pandemic time frame, and any patients in this time frame without a positive PCR test were excluded. Contemporary COVID-19 PCR assays have elevated false negative rates, which could lead to mislabeled data and hence to degraded model performance [13]. Due to this, prepandemic controls randomly selected from the 43 PHD hospitals in the training set were used in place of PCR-negative patients during the pandemic.

External Validation Populations

The external validation data set used 3 data sources: 952 PCR-positives and 154,341 prepandemic visits from the 21 hospitals in the PHD holdout set; 68 PCR-positive patients from CSMC; and 17,393 prepandemic (2008-2019) patient encounters from BIDMC. Patients in the pandemic time frame without a positive PCR test were excluded. All prepandemic patients were treated as negatives when evaluating the performance of the model in predicting COVID-19 status. The prepandemic patients from the PHD holdout were chosen so as to match the top 20 most frequent primary diagnoses given to patients without COVID-19 during the pandemic, as coded by Clinical Classifications Software Refined (CCSR) codes (listed in Section B of Multimedia Appendix 1).

Sensitivity Analysis Population

To evaluate how the model generalizes to pandemic time frame patients only, we performed a sensitivity analysis using patients presenting to the ED in the 21 centers from the PHD holdout with any SARS-CoV-2 PCR result available on day of presentation. This differed from the other analyses as negatives were from the same time frame as the positives. This resulted in a total of 952 PCR-positive patients and 6890 PCR-negative patients in the pandemic period (March-July 2020).

Subgroup Analyses

The AUROC was tabulated by decile of age, sex, race, admission or discharge status, and intensive care unit (ICU) admission status in the external validation data set. The distribution of risk scores was also visualized for all studied cohorts through box plots. For PCR-positives, this included positives from CSMC, and PHD visits that had a single positive PCR result as well as visits that had a negative result before a positive result (both on the day of presentation). For PCR negatives during the pandemic, this included patients with both single- and double-PCR results on the day of presentation. For prepandemic encounters, the scores for all eligible BIDMC patients were considered, as well as those from the PHD holdout that matched the top 20 CCSR (non–COVID-19) codes observed during the pandemic.

Model Development (Training and Internal Validation With Cross-Tabulation Techniques)

The model was intended to estimate COVID-19 status on the day of presentation to an ED using common laboratory tests collected that day. Model training began with 29 routinely measured features (ie, potential or included model covariates) comprising the comprehensive metabolic panel and the complete blood count with differential. Recursive feature elimination with cross-validation (RFECV) was performed to arrive at the final 15 features [14]. We used the gradient boosting model as implemented in XGBoost [15] for all results. No hyperparameter optimization was performed and default parameters were used. Performance on the training set was evaluated through stratified 5-fold cross-validation. Performance in the external validation and sensitivity analysis data sets was obtained after training the model on the entire training set.

Statistical Analysis

Baseline demographics, ED disposition, and included laboratory features from the training, external validation, and sensitivity analysis data sets were tabulated by COVID-19 status. Visualization of the distribution of features used box plots, ordered by feature importance (compare with list values in Section C of Multimedia Appendix 1). Model discrimination was visualized with receiver operating characteristic (ROC) curves and estimation of the AUROC. AUROC 95% CIs were estimated with bootstrapping. Hosmer-Lemeshow criteria were used to describe performance of discrimination [16]. These criteria considered an AUROC value of 0.5 as no discrimination, 0.5 to <0.7 as poor discrimination, 0.7 to <0.8 as acceptable discrimination, 0.8 to <0.9 as excellent discrimination, and ≥0.9 as outstanding discrimination. Sensitivity, specificity, and negative predictive value (NPV) were defined using conventional definitions. Diagnostic yield was defined as the percentage of patients with a risk score below a given cutoff. All analyses were prespecified. The sample size of this analysis was driven by data availability in this multicenter database.

Analyses were performed in Python (Version 3.7.5; Python Software Foundation) using the XGBoost package (Version 0.82) [17] and the Scikit-Learn library (Version 0.21.3) [18]. The use of deidentified databases as described here met the non–human subjects research by the University of Vermont's Institutional Review Board criteria.

Results

Demographics and Proportion of PCR-Positive Patients in Training Data Set, External Validation Data Set, and Sensitivity Analysis Data Set

The training data set included 12,183 ED visits at 43 centers from the PHD, of which 2183 results were PCR-positive. The validation data set included 172,754 ED visits from 23 centers (21 from the PHD, as well as the independently collected data from CSMC and BIDMC), of which 1020 results were PCR-positive. The sensitivity analysis data set included 7842 records from 21 centers in the PHD holdout group. Patient demographics and visit characteristics are summarized in Table 1.

A total of 192,779 eligible patients were included in the study; the median age decile was 50 (IQR 30-60) years and 40.5% (78,249/192,779) were male. In the training, external validation, and sensitivity analysis data sets, the median age deciles were 50 (IQR 30-70) years, 50 (IQR 30-60) years, and 50 (IQR 40-70) years, respectively. Males represented 42.9%, 40.1%, and 47.4% of patients in the data sets, respectively.

Table 1. Demographics of patients and encounter details, by COVID-19 status[a].

Demographics	Training (N=12,183)		External validation (N=172,754)		Sensitivity analysis (N=7842)

[a] For the training data set: COVID-19 positivity was defined as a positive COVID-19 reverse-transcription polymerase chain reaction (hereafter, PCR) test on the day of presentation to the emergency department among patients in the pandemic time frame (March 2020 through July 2020) in the Premier Healthcare Database (PHD) database among a random selection of 43 of the 64 PHD hospitals reporting PCR positives. COVID-19 negativity was defined as a selection of 10,000 patients in the prepandemic time frame (January through December 2019) in the PHD database from the same 43 hospitals as the patients with COVID-19. For the external validation data set: COVID-19 positivity was defined the same as for the training data set for the PHD data set but also included 952 PCR-positives from the 21 hospitals in the PHD holdout set. Additionally, it included 68 patients with

PCR-confirmed COVID-19 from Cedar Sinai Medical Center from March and April 2020. COVID-19 negativity in the external validation set was defined using 154,341 prepandemic visits from the 21 hospitals in the PHD holdout set (January through December 2019) in which primary diagnoses were among the 20 most frequent primary diagnoses given to patients negative for COVID-19 during the pandemic, using Clinical Classification Software Refined codes. It also included 17,393 prepandemic (2008-2019) patient encounters from Beth Israel Deaconess Medical Center. For the sensitivity data set: COVID-19 positivity included the same 952 PCR-positives from the 21 hospitals in the external validation data set. COVID-19 negativity was defined as visits with at least 1 PCR-negative but no PCR-positive result on the day of presentation, and included all 6890 patients with such results from the same 21 hospitals as the positives.

[b] Census division was defined using US Census classification [19]. Rural areas are considered territory outside of the US Census Bureau's definition of urban [20]. These geographic descriptions pertain to the hospital, not the patient's permanent residence.

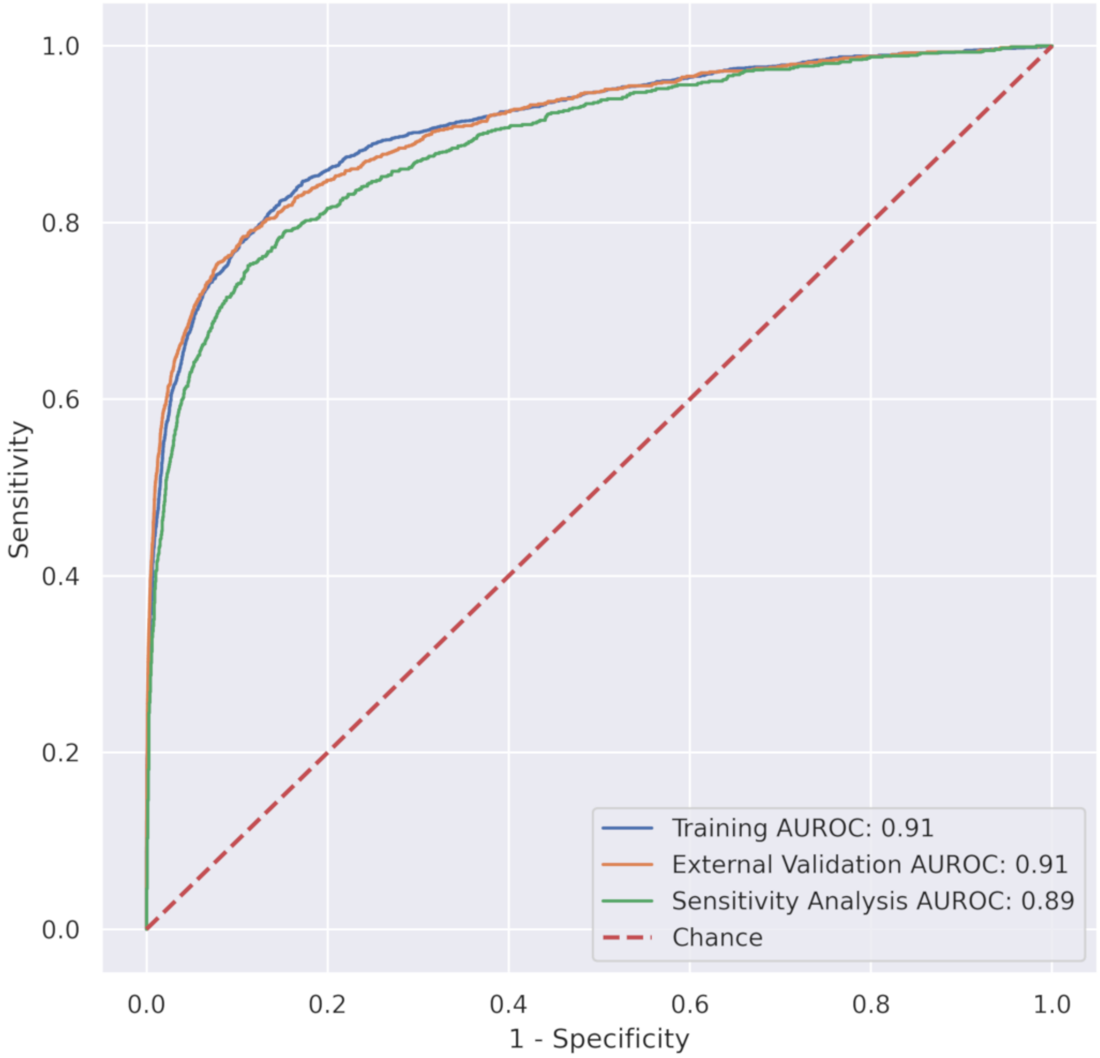
Selected Features Included in the Model and Individual Feature Performance

The RFECV method led to the final set of 15 features listed in Table S1 in Multimedia Appendix 1. The distributions of these features in the training data set, stratified by COVID-19–positive and COVID-19–negative status and ordered by importance to the model, are shown in Figure S1 in Multimedia Appendix 1. The features with the largest calculated importance were eosinophils, calcium, and aspartate aminotransferase. Summary statistics of these features in the training, external validation, and sensitivity analysis data sets, stratified by COVID-19 status, appear in Table S1 in Multimedia Appendix 1.

Performance of Individual Features and Model Performance in the Training Data Set

The AUROC for each individual feature in the training data set is shown in Figure S2 in Multimedia Appendix 1. The highest AUROCs were observed for eosinophils, calcium, and aspartate aminotransferase (0.70-0.80). The final model's AUROC in the training data set was 0.91 (95% CI 0.90-0.92; Figure 1).

Figure 1. Discrimination as assessed by ROC curves for training, external validation, and sensitivity analysis data sets. ROC curves for the 3 different data sets: training (blue), external validation (orange), and sensitivity analysis (green). The training curve was obtained through 5-fold cross-validation, where positive controls are PCR-confirmed cases during the pandemic (N=2183) and negative controls are prepandemic patients (N=10,000) from 43 hospitals in the PHD. The training AUROC was 0.91 (95% CI 0.90-0.92). The external validation curve was performed in the external validation data set after training the model on the training data set. External validation positives are PCR-confirmed cases from Cedars-Sinai Medical Center (N=68) and from the PHD holdout set (N=952) comprising 21 hospitals. External validation negatives are prepandemic (2019) patients, from the same 21 PHD hospitals, that match the top 20 primary non–COVID-19 diagnoses in 2020 (N=154,341), as well as all eligible prepandemic (2008-2019) Beth Israel Deaconess Medical Center patients (N=17,393). The AUROC in the external validation data set was 0.91 (95% CI 0.90-0.92). The sensitivity analysis curve demonstrates the effect of using prepandemic patients as negative controls compared to using PCR-negatives from 2020. In this data set, both positives (N=952) and negatives (N=6890) were PCR-confirmed patients from the PHD holdout set (21 hospitals), and no prepandemic data was included. The AUROC in the sensitivity analysis set was 0.89 (95% CI 0.88-0.90). AUROC: area under the receiver operating characteristic curve; PCR: polymerase chain reaction; PHD: Premier Healthcare Database; ROC: receiver operating characteristic.



Model Performance in the External Validation Data Set

The model’s AUROC in the external validation data set was 0.91 (95% CI 0.90-0.92), as shown in Figure 1. This corresponds to an outstanding discrimination per the Hosmer-Lemeshow criteria [16]. Sensitivity and specificity were 95.9 and 41.7 at a score cutoff of 1, 92.6 and 60.0 at a score of 2, 85.5 and 78.5 at a cutoff of 5, and 79.4 and 87.6 at a cutoff of 10, respectively (Table 2).

With a COVID-19 population prevalence of 1%, each of these cutoffs had an NPV >99%; at 10% prevalence, each was >97%, and at a prevalence of 20%, each was >94%. The diagnostic yield ranged from 34% (20% prevalence, score cutoff of 1) to 87% (1% prevalence, score cutoff of 10).

Table 2. Clinical performance metrics for the model in the external validation data set for various score cutoffs and COVID-19 pretest prevalence[a].

Score cutoff	Sensitivity	Specificity	Likelihood ratio[b]	Prevalence of 1%		Prevalence of 10%		Prevalence of 20%	
				NPV[c], %	Yield[d], %	NPV, %	Yield, %	NPV, %	Yield, %
1	95.9	41.7	0.099	99.9	41.3	98.9	38.0	97.6	34.2
2	92.6	60.0	0.124	99.9	59.4	98.6	54.7	97.0	49.5
5	85.5	78.5	0.185	99.8	77.8	98.0	72.1	95.6	65.7
10	79.4	87.6	0.235	99.8	86.9	97.4	80.9	94.4	74.2

[a] The maximum score was 100; a higher score indicates higher model prediction of COVID-19 positivity.

[b] The likelihood ratio uses the equation for negative tests.

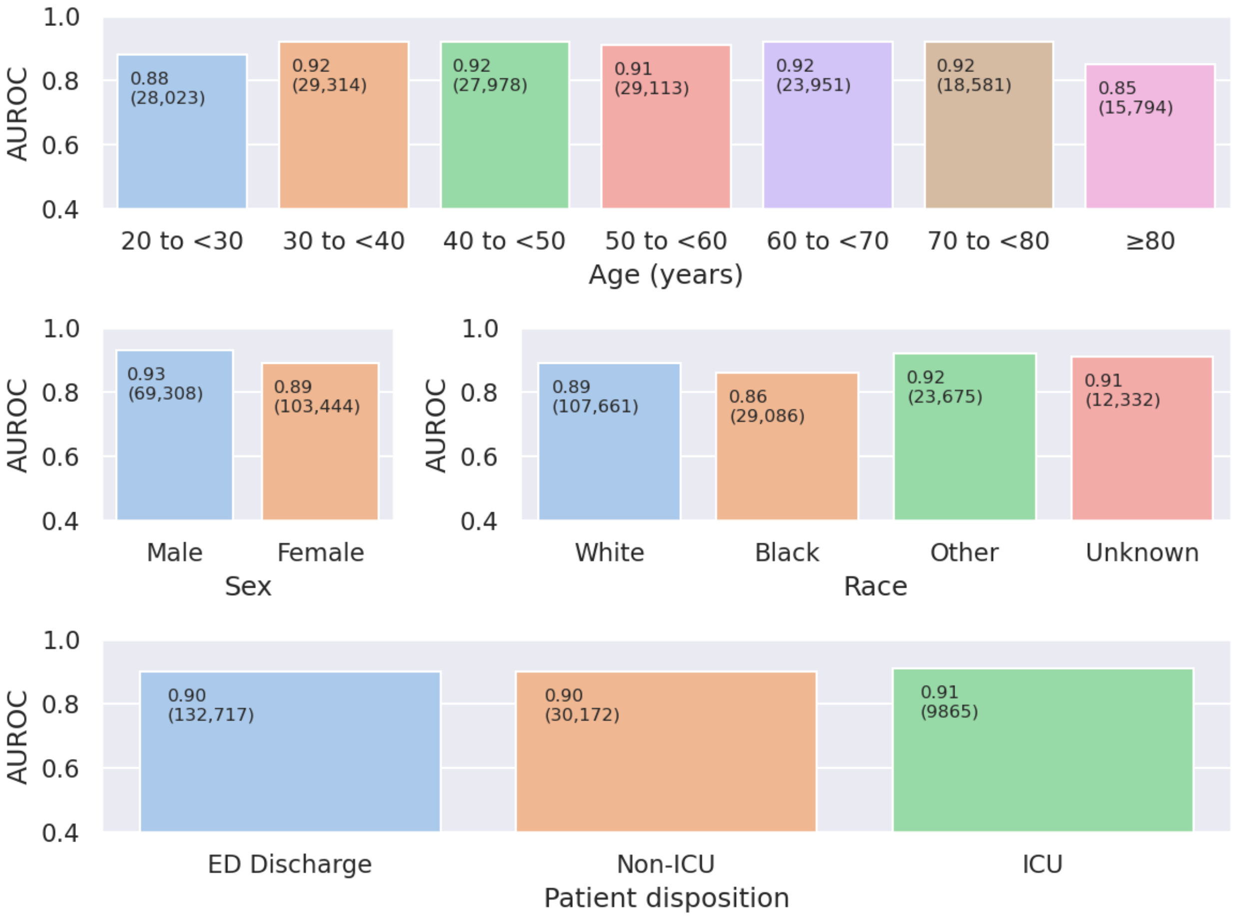
[c] NPV: negative predictive value.

[d] Yield refers to diagnostic yield, which is the percentage of patients that can be ruled out (ie, those with a score below the cutoff).

Sensitivity Analysis and Subgroup Analyses

Figure 1 depicts the ROC curve in the sensitivity analysis data set, which contains only year 2020 patients with PCR-confirmed positive and negative results (ie, no historical negatives). The AUROC was 0.89 (95% CI 0.88-0.90). In Figure 2, the AUROC is presented for various demographic cohorts as well as patient disposition (ED discharge, non-ICU, and ICU) in the external validation data set. AUROCs ranged from 0.86 to 0.93. AUROC by these subgroups was similar in the sensitivity analysis data set, which appears as Figure S3 in the Multimedia Appendix 1.

Figure 2. Discrimination as assessed by AUROC curve in age, sex, race, and ED disposition subgroups in the external validation data set. Non-ICU patients were admitted to the hospital but not to an ICU. Distribution of AUROC curves per demographic, as well as per patient disposition type (ED discharge, non-ICU, and ICU) in the external validation data set. Top numbers are AUROC curves, bottom numbers in parentheses are the number of patients. AUROC: area under the receiver operating characteristic; ED: emergency department; ICU: intensive care unit.



Distribution of Risk Scores in Selected Subgroups

Lastly, an extensive distribution of risk scores for various subgroups is shown in Figure S4 in Multimedia Appendix 1, including prepandemic patients whose primary diagnoses were among the top 20 primary diagnoses among patients without COVID-19 in 2020. From visual inspection, it can be seen that high scores track PCR-positive patients consistently across all cohorts.

Discussion

Principal Results

A development and external validation study of a machine learning model for COVID-19 status using laboratory tests routinely collected in adult ED patients found high discrimination across age, race, sex, and disease severity subgroups. This model had high diagnostic yield at low score cutoffs in a screening population with a disease prevalence of <10%. Such a model could rapidly identify those at low risk for COVID-19 in a “rule-out” method, and might reduce the need for PCR testing in such patients.

Comparison With Prior Work

Prior literature has described the application of machine learning techniques to commonly collected laboratory data for estimation of missing laboratory analytes. For example, an analysis by Waljee and colleagues [21] leveraged machine learning techniques for imputation of missing laboratory data in cohorts of patients with cirrhosis and inflammatory bowel disease at a single institution. In comparison to other common imputation techniques described in this manuscript, the machine learning technique introduced the least imputation error for these laboratory data. Luo and colleagues [22] used similar methods to estimate ferritin from a single medical center, and found that the machine learning technique outperformed traditional imputation methods. These serve as strong evidence of the potential use of machine learning for use in estimation of laboratory data. However, outside of imputation of missing values from research databases, the clinical utility for such techniques was unclear prior to the COVID-19 pandemic.

During this pandemic, there is an urgent need to rapidly identify patients with the disease to inform supportive clinical care. Prior work has attempted to integrate combinations of clinical data points in diagnostic models, though only a few are currently published in peer-reviewed literature [23]. The selection of the specific data points to integrate into machine learning models for COVID-19 diagnosis has implications on integration into existing clinical delivery. In contrast with the results here, which only included components of the routinely collected complete blood count with differential and complete metabolic panel laboratory tests, others have integrated nonlaboratory features. Sun and colleagues [24] reported 3 models including demographics, radiological data, and symptomatology, and obtained AUCs ranging from 0.65 to 0.88 for these models. Symptomatology was not obtained with structured, validated questionnaires and the ability to capture these symptoms in a reproducible manner might be difficult outside of a research setting. Further, modern medical records cannot integrate such symptoms into automated risk scores as they are not documented in a structured way.

Structured data obtained routinely in clinical examinations are the simplest to integrate, and might have the least variability between institutions. These include vital signs, demographics, laboratory findings, and radiological images. There are few studies describing the use of such data for the diagnosis of COVID-19. One study found a machine learning method had an accuracy of 87% for distinguishing between COVID-19 from pneumonia or no relevant findings using chest radiographs [25]. A different model developed from chest computed tomography images reported an AUROC of 0.994 when distinguishing between COVID-19 and atypical or viral pneumonia [26]. However, national organizations recommend against the use of radiological imaging for diagnosis of COVID-19, in part because of the added risk of spreading infection through additional visitation to radiology suites [27]. These models are unlikely to be readily deployed because of the challenges of performing elective radiological tests during this pandemic.

An additional consideration in the development of machine learning models is the inclusion of an adequate sample size for model training [28-30]. Other studies have investigated the role of laboratory data with or without other nonradiological structured clinical data or demographics for the diagnosis of COVID-19 using machine learning techniques. For example, Wu and colleagues [31] reported a C-index of 0.99 but included only 108 patients (12 COVID-19–positive) in their training. Similarly, individual efforts led by Batista, Brinati, and Soares [32-34] describe machine learning models trained on 234, 279, and 599 patients, respectively. These studies are also limited in the small number of centers from which patients were enrolled, and lack of diversity in their patient populations.

Advancement of Scientific Knowledge

The present analysis advances science in several key ways. First, we describe a machine learning model developed in a diverse patient population with routine laboratory data from multiple clinical centers across the United States [35]. Second, the model incorporates common laboratory tests that are widely available with rapid turnaround time. As the machine learning model can be performed essentially instantaneously, the primary time limitation is related to phlebotomy and specimen processing. There is a well-known bottleneck in completing conventional COVID-19 PCR assays; a commercial laboratory recently reported a 7-day reporting lag [36]. Third, the present model could identify those at lowest risk for COVID-19 to inform a “rule-out” method for screening. Those with intermediate or greater risk for COVID-19 could be further assessed with COVID-19 PCR testing, if indicated. Depending on the selected score cutoff and population prevalence, such an approach could rule out 34% to 87% of ED patients requiring conventional COVID-19 PCR testing (see Yield, Table 2). The specific score cutoff for rule out of COVID-19 with this model can be customized based upon what an institution considers to be an “acceptable” target NPV. However, the diagnostic yield will change based upon the screening population prevalence of COVID-19, and the diagnostic yield will be inversely related to the screening population prevalence of COVID-19. For example, assume that an institution determines that an acceptable NPV for this model is 97.5%. If this institution's screening population has a 20% prevalence of COVID-19, the threshold score cutoff would be set at 1, and the diagnostic yield (ie, the percentage of patients ruled out for COVID-19 at a score cutoff of 1) would be 34.2% (Table 2). However, at a prevalence of 10%, the score cutoff threshold would be 10, and the diagnostic yield would be 80.9%. The efficiency of diagnostic yield with this model is higher at lower prevalence. Finally, the sensitivity of the present model at a score cutoff of 1, 2, and 5 (95.9, 92.6, and 85.5, respectively) was similar to COVID-19 antigen assays (66.1-86.3) and sputum and saliva PCR assays (62.3-97.2) [11]. The comparatively similar sensitivities between the model and these existing assays supports the clinical utility of machine learning models as future diagnostic tools.

Weaknesses and Strengths

This study has weaknesses. Although the choice of prepandemic controls partially circumvents the issue of false negatives in PCR testing by ensuring the negatives that the model is trained on are true negatives, it does not ensure that the positives encompass the full spectrum of true positives, since those are sometimes missed by PCR due to changes in viral load as a function of disease progression [37,38]. Additionally, the use of controls from a different time period could introduce a bias of its own, such as different demographics or non–COVID-19 morbidities. However, the sensitivity analysis used COVID-19 positives and negatives from the pandemic time frame, and the performance of the model was reassuringly similar to the performance in the external validation. The performance in demographic, clinical diagnosis, and ED disposition subgroups was also similar to the external validation. Laboratory data were performed locally at each hospital, rather than centrally. The model requires all components of the laboratory data to be included. This study only included patients who visited an ED. Although it is likely that some of the patients in this study were asymptomatic or presymptomatic and were found to have COVID-19 as part of routine admission, we were unable to determine the indications for screening and therefore are unable to determine the performance of this model in asymptomatic and presymptomatic adults. The present analysis only accounted for results from COVID-19 PCR tests and not for alternative diagnostic methods, such as antigen testing for acute infection or antibody testing to demonstrate prior infection. Finally, the research database did not include details about the specific PCR assay used in diagnosis, so we are unable to comment on performance of the model in comparison to the performance of the specific assays.

This study has strengths. This study included data from a large number of patients and hospitals, and to our knowledge is the largest application of machine learning to COVID-19. Data were derived from an electronic medical records database that is commonly used in clinical research. The patient population was geographically and racially diverse. The only features included in the model are those included in blood tests that are already routinely collected in ED encounters. Further, these tests were from multiple hospitals, suggesting that the model is robust against different specimen collection, handling practices, and instrumentation. Sensitivity analyses were performed to evaluate potential biases due to the choice of prepandemic negative controls, and no significant bias was observed across multiple dimensions. Our methods extend on established machine learning–based imputation methods for missing laboratory data [21,22], and suggest there may be clinical utility of these techniques in ruling out the disease. Finally, the external validation was a true external validation since it used data from hospitals that were not included in the training data set. This supports the resilience of the model across institutions with differing specimen handling and laboratory processing methods.

Conclusions

A machine learning model for ruling out COVID-19 in ED patients that integrates commonly collected laboratory data had a discrimination accuracy that can be classified as excellent to outstanding [16]. Using score cutoffs of 5 and 10 points, and assuming a 10% screening population prevalence of COVID-19, 72% and 81% of patients were ruled out with this model while maintaining an NPV >97%, respectively.

Acknowledgments

We thank Alistair EW Johnson, PhD, and John House, MS, for providing technical expertise related to the BIDMC and PHD data sets, respectively. We would also like to thank Ryan McGinnis, PhD, who provided helpful feedback on the manuscript, and Dr Robert A Levine, MD; R George Hauser, MD; and Mark K Fung, MD, for various answers to laboratory medicine questions. We thank Susan Gifford for her helpful review of this manuscript.

Conflicts of Interest

TBP, AB, ASW, and ICJ have no disclosures. VFT received research funding from the National Institutes of Health (paid to the institution) for COVID-19–related clinical trials. ANB is a paid intern at Biocogniv. TSK and ABA have ownership of Biocogniv.

Abstract

Background: COVID-19 resulted in considerable mental health burden in the Chinese general population and among health care workers at the beginning and peak of the pandemic. However, little is known about potentially vulnerable groups during the final stage of the lockdown.

Objective: The aim of this survey study was to assess the mental health burden of different professions in China in order to find vulnerable groups, possible influencing factors, and successful ways of coping during the last 4 weeks of the lockdown in Hubei Province.

Methods: A cross-sectional online survey asked participants about current residence, daily working hours, exposure to COVID-19 at work, and media preferences. We used a shortened version of the Depression, Anxiety and Stress Scale (DASS-21) to assess mental health. Further assessments included perceived stress (Simplified Chinese version of the 14-item Perceived Stress Scale), coping strategies for all participants, and specific stressors for health care workers. We followed the reporting guidelines of the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement for observational studies.

Results: The sample (N=687) consisted of 158 doctors, 221 nurses, 24 other medical staff, 43 students, 60 teachers/government staff, 135 economy staff, 26 workers/farmers, and 20 professions designated under the “other” category. We found increased depression (n=123, 17.9%), anxiety (n=208, 30.3%), and stress (n=94, 13.7%) in our sample. Professions that were vulnerable to depression were other medical staff and students. Doctors, nurses, and students were vulnerable to anxiety; and other medical staff, students, and economy staff were vulnerable to stress. Coping strategies were reduced to three factors: active, mental, and emotional. Being female and emotional coping were independently associated with depression, anxiety, or stress. Applying active coping strategies showed lower odds for anxiety while mental coping strategies showed lower odds for depression, anxiety, and stress. Age, being inside a lockdown area, exposure to COVID-19 at work, and having a high workload (8-12 hours per day) were not associated with depression, anxiety, or stress. WeChat was the preferred way of staying informed across all groups.

Conclusions: By the end of the lockdown, a considerable part of the Chinese population showed increased levels of depression and anxiety. Students and other medical staff were the most affected, while economy staff were highly stressed. Doctors and nurses need support regarding potential anxiety disorders. Future work should focus on longitudinal results of the pandemic and develop targeted preventive measures.

Introduction

Background

In December 2019, pneumonia cases of unknown etiology in Wuhan, Hubei Province, were reported by Chinese authorities. By January 3, 2020, 44 cases requiring hospitalization were officially confirmed [1]. The disease was titled COVID-19 by the World Health Organization in February 2020 [2]. As the infection spread rapidly all over the country [3], the public health response of the government included the largest quarantine in China's history. Starting from January 23, the lockdown in Hubei Province, the epicenter of COVID-19, lasted 76 days and ended on April 8, 2020 [4]. Zhejiang was another province that was put under lockdown [5].

The pandemic put a considerable psychological burden on citizens, which was not simply due to fear of infection but also isolation, helplessness, and grief over the loss of relatives without having the opportunity to take leave or to organize a funeral. Even more aggravating was that trusted persons, like family and friends, could be infected, and thus, became part of an invisible danger [6].

Previous epidemics, like the severe acute respiratory syndrome (SARS) in Hong Kong in 2003 or the Middle East respiratory syndrome (MERS) in Saudi Arabia in 2012, have taught us to care for the mental health of the general population and frontline health care workers [7-10]. In Hong Kong, suicide rates among older adults increased significantly in 2003 and 2004 [11]. It is noteworthy to recall that high-risk health workers suffered from long-lasting depression and posttraumatic stress responses even 1 year after the SARS outbreak [12].

Mental Health and Coping Strategies

Several studies have investigated the mental health consequences of the ongoing pandemic in the Chinese population and its strategies to successfully cope with the demanding situation. Wang et al [13] found increased anxiety in nearly 30% of 1210 participants, especially caused by worrying about family members. The same authors also reported longitudinal results, repeating the measures after 4 weeks in March 2020 [14], and found no changes in the scores despite increased infection rates. A high level of trust in doctors and health information, as well as personal protective measures, was rated as helpful. The harmful effects of hoarding food and medicine were described as being associated with elevated levels of depression at the beginning of the crisis [15]. Another study found that cognitive coping behavior (eg, obtaining knowledge about COVID-19) and prosocial coping styles (eg, adherence to social distancing) proved to be protective for the population [16]. These authors described the high impact of the pandemic on the livelihood of the population and examined the harmful effects of media exposure on mental health.

Besides the obvious impact of the pandemic on mental health like the fear of infection and isolation due to quarantine measures [17], excessive media consumption was linked to mood disorders during the lockdown in China [18,19]. However, little is known about the influence of media preferences on the mental health of the population during the crisis.

The Mental Health of Vulnerable Groups During COVID-19

Since health care workers at the frontline were exposed to particularly demanding conditions during the peak of the pandemic, their mental health and coping strategies have become an early issue of concern. One of the first studies on this topic focused on medical and nursing staff in Wuhan and found elevated levels of subthreshold mental health disturbances in nearly 40% of the 994 participants surveyed [20]. A nationwide study in February reported nearly 5% of medical and nonmedical staff with moderate and high levels of anxiety and about 13% with depression [21]. In this study, nurses and young personnel were found to be particularly at risk for mental distress. A nationwide survey by the end of February showed even higher levels (anxiety: 13%; depression: 12%; insomnia: 38%) for doctors and nurses compared to nonmedical health workers [22]. Risk factors included living in a rural area, being female, and exposure to COVID-19. Additionally, health care workers were burdened by specific clinical and nonclinical stressors (eg, fear of bringing the virus home to family members and the experience of losing colleagues) [23].

There were some specific results on the psychological burden felt by nurses. Nurses in Anhui showed strong emotional responses. Increased exposure to COVID-19 cases evoked more anxiety and anger [24]. Increased levels of insomnia were reported among nurses in Wuhan, which might have been caused by comorbid sleep apnea due to stress [25]. Despite showing symptoms of severe distress, these Wuhan nurses refused to accept psychological help at the beginning of the pandemic [26].

Another vulnerable group included students, the majority of whom lived in quarantine with their families and reported victimization by facing or witnessing various stressful events related to COVID-19 [27]. Other studies found that the COVID-19 crisis impacted sleep quality [28], and increased anxiety among students was reported even after the lockdown ended [29]. Teachers were also affected not only by the outbreak but also by the stress experienced by their pupils [30].

In spite of the many studies regarding the mental health of the general population and health care workers on the frontline of the pandemic, we found no data on further vulnerable groups and professions that may be mentally or emotionally affected by indirect means. Although Huang and Zhao [31] found comparable depressive symptoms among employees in enterprises as in health care workers, and Wang et al [13,14] reported longitudinal results in February and March, these results were from the initial stages of the lockdown and data from the end of the lockdown are missing to date.

Objectives of the Study

The aim of this survey study was to assess the psychological burden of COVID-19 on the mental health of the Chinese population during the last 4 weeks of the lockdown in Hubei Province. We examined different professions in order to find vulnerable groups, possible influencing factors, and successful ways of coping. Moreover, we looked for specific stressors among doctors and nurses.

Methods

Study Design

We used a cross-sectional online survey design in order to investigate the impact of the COVID-19 pandemic on the mental health, stress, specific stressors, and coping strategies of different groups of the Chinese population. The study team of Heidelberg University Hospital developed the concept and the questionnaire, which was translated into Chinese. Its implementation into an online format and sampling was carried out by a publicity enterprise in Wuhan. The Tongji Medical College of the Huazhong University of Science and Technology supported the study by disseminating the link. The study started on March 19 and data were included until April 7. The lockdown in Hubei was officially ended on April 8 by the government [4].

Ethical approval for this study was granted by the Ethics Commission of the Medical Faculty of Heidelberg (S-361/2020). We followed the reporting guidelines of the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement for observational studies [32].

Measures

The questionnaire was derived from validated instruments and structured into four major parts. The first part asked for demographic data (place of residence, gender, age, marital status, educational background, and occupation), exposure to people infected with COVID-19 in general and at work, working hours per day, and media platforms used to obtain information (multiple choice). The second part asked for mental health parameters like depression, anxiety, and stress, measured by a shortened version of the 21-item Depression, Anxiety and Stress Scale (DASS-21) using a 4-point Likert scale [33]. We used the validated Chinese translation [34]. The instrument refers to a time span of the past week and has been shown to distinguish well between symptoms of depression, anxiety, and stress in clinical and nonclinical samples [35]. In order to assess stress levels during the past month, we used the 14-item Perceived Stress Scale (PSS-14) that explicitly refers to a longer time span using a 5-point Likert scale [36]. Again, we used a validated translation (ie, CPSS-14) [37]. The third part of our questionnaire targeted health care workers only and consisted of a questionnaire that was used in a former study on the SARS outbreak in 2003 [38]. The items asked for specific disease-related stressors of doctors and nurses and were rated on a 4-point Likert scale (0=not at all; 1=slightly; 2=moderately; 3=very much). Finally, the fourth part was again available for all participants and asked for successful coping strategies. The items were again taken from the SARS study [38] and recorded the frequency of use of various coping strategies on a 4-point scale (0=almost never; 1=sometimes; 2=often; 3=almost always). Both scales were translated by a Chinese native speaker (JD).

Data Analysis

The responses of the participants were downloaded from the online survey tool and further processed and analyzed using SPSS 24 (IBM Corp) [39]. We collected 1006 data sets and removed all data sets that were filled out after April 7 (n=74) and all questionnaires filled out in less than 513 seconds (n=226), which corresponded to the lowest percentile of the mean processing time for all samples. In these cases, we assumed a lack of credibility if a participant took less than this amount of time. Finally, we removed all participants who were younger than the legal age (n=7) and who were not in China during the survey (n=9). We calculated descriptive statistics and reported frequencies, means, standard deviations, and percentages.

Participants answering from Hubei and Zhejiang provinces were regarded as being affected by the lockdown (n=460). All other participants were not directly affected by the lockdown (n=226).

The scoring of the DASS-21 are calculated as sum scores that have to be multiplied by two. The total depression subscale score was divided into normal (0-9), mild (10-13), moderate (14-20), severe (21-27), and extremely severe depression (28+). The anxiety subscale score was divided into normal (0-7), mild (8-9), moderate (10-14), severe (15-19), and extremely severe anxiety (20+). The total stress subscale score was divided into normal (0-14), mild (15-18), moderate (19-25), severe (26-33), and extremely severe stress (34+). Next, we grouped the levels of severity into normal–mild and moderate–extremely severe for each score. We decided to put mild symptoms into one group together with the normal level, since we considered mild symptoms of depression and anxiety to exist regardless of the pandemic [40].

The CPSS-14 scores were calculated by sum scores as well. We reported the CPSS-14 scores and DASS-21 scores nationwide for each profession. For deeper analysis we calculated Pearson correlations in order to assess the relationship of perceived stress during the past 4 weeks and mental health scores for depression, anxiety, and stress during the past week.

The coping strategies and major stressors were calculated as means and standard deviations. We carried out a factor analysis (principal component analysis [PCA] with varimax rotation) for all coping strategies. The Kaiser-Meyer-Olkin (KMO) and Bartlett Test indicated a sufficient cohesion of the variables (KMO=0.76) [41]. Finally, binary logistic regression models were calculated and thereby investigated the associations of gender, lockdown area, contact with COVID-19 infections at work, and coping strategies (factors) with the odds of belonging to moderate–extremely severe depression, anxiety, or stress group. A nonsignificant value of *P*=.40 in the Hosmer-Lemeshow test indicated the goodness of fit of the models [42], and a Nagelkerkes R^2 of 0.17 showed an acceptable coefficient of determination [41].

In all analyses, *P* values <.05 were considered statistically significant.

Results

Participants

The sample included 687 participants, 72.3% (n=496) of whom were female and 27.7% were (n=190) male. The mean age was 36.92 years (SD 9.83) with a range of 18-71 years. The participants consisted of doctors (n=158, 23.0%), nurses (n=221, 32.2%), other medical staff (n=24, 3.5%), students (n=43, 6.6%), teachers/government staff (n=60, 8.7%), economy staff (n=135, 19.7%), workers/farmers (n=26, 3.8%), and others (n=20, 2.9%). We combined doctors and dentists into one category. Other medical staff referred to health care professionals who were not doctors or nurses. Economy staff consisted of employees and self-employed individuals in the IT (information technology) and finance sectors.

A majority of the participants were from Hubei Province (n=449, 65.4%); 30 (4.4%) came from Jiangsu and 21 (3.1%) each from Shanxi and Guangdong. A small group (n=11, 1.6%) came from Zhejiang, which was affected by a lockdown like Hubei. Demographic characteristics and details of each professional group are summarized in Table 1.

Table 1. Demographic characteristics of the study participants.

Characteristics	Participants, n (%)
Age (years), mean (SD)	36.92 (9.83)
Gender

Hunan	14 (2.0)
Zhejiang	11 (1.6)
Provinces with less than 10 participants	78 (11.2)
Total	687 (100)

Perceived Stress and Mental Health

Perceived stress was measured with a mean score of 23.70 (SD 7.52). The mean values for DASS-21 depression was 6.62 (SD 7.80), for DASS-21 anxiety was 7.01 (SD 7.00), and for DASS-21 stress was 10.18 (SD 8.63). Perceived stress was significantly correlated with DASS-21 depression (r=0.61, P<.001), DASS-21 anxiety (r=0.57, P<.001), and DASS-21 stress (r=0.66, P<.001).

Findings on mental health status for each profession are reported in Table 2; the DASS-21 scores were put into categories normal–mild and moderate–extremely severe.

Table 2. Results of the Simplified Chinese version of the 14-item Perceived Stress Scale (CPSS-14) and the Depression, Anxiety and Stress Scale - 21 Items (DASS-21).

Profession	Participants, n	CPSS-14		DASS-21 depression		DASS-21 anxiety	DASS-21 stress	
		Mean (SD)	NM[a], n (%)	MES[b], n (%)	NM, n (%)	MES, n (%)	NM, n (%)	MES, n (%)
Doctors	158	23.16 (7.26)	134 (84.8)	24 (15.2)	106 (67.1)	52 (32.9)	138 (87.3)	20 (12.5)

Workers/farmers	26	23.15 (6.69)	21 (77.8)	5 (19.2)	19 (73.1)	7 (26.9)	23 (85.5)	3 (11.5)
Others	20	26.25 (7.62)	15 (75.0)	5 (25.0)	14 (70.0)	6 (30.0)	16 (80.0)	4 (20.0)
Total	687	23.70 (7.52)	564 (82.1)	123 (17.9)	479 (69.7)	208 (30.3)	593 (86.3)	94 (13.7)

[a] NM: normal–mild.

[b] MES: moderate–extremely severe.

Working Hours Per Day

The majority of the participants reported working 4-8 hours per day (n=427, 61.4%). This was the case in the following groups—nurses: 145/221, 65.6%; students: 39/43, 90.7%; teachers/government staff: 47/60, 78.4%; economy staff: 97/135, 71.9%; workers/farmers: 18/26, 69.3%; others: 15/20, 75.0%.

A sizeable part of the sample reported working 8-12 hours per day (n=260, 37.4%). This high workload typically affected doctors (103/158, 65.2%) and other medical staff (13/24, 54.2%).

Contact With COVID-19 at Work

In total, 6 (0.9%) participants were infected themselves (2 doctors, 3 nurses, and 1 member of the group teachers/government staff). Of all participants, 180 (26.2%) had contact with people infected by the virus at work. The most affected group were doctors (68/158, 43.0% had contact with COVID-19 at work), followed by other medical staff (10/24, 41.7%), nurses (88/221, 39.8%), teachers/government staff (8/60, 13.3%), economy staff (5/135, 3.8%), workers/farmers (1/26, 3.8%). Participants from the other professions category and students did not report contact with COVID-19 at work.

Media Preferences

When asked about the primary way participants obtained information in the past month, the majority of respondents indicated having done so through WeChat (n=606, 88.2%) (Table 3).

Table 3. Participants' answers to the multiple-choice question: what was your main way of obtaining information during the last month?

Source	Participants, n (%)
Newspaper	53 (7.71)
Television	465 (67.69)
Weibo	304 (44.25)
WeChat	606 (88.21)
Circle of friends[a]	502 (73.07)
Family/colleagues	311 (45.27)
Other	104 (15.14)

[a] Includes WeChat groups and other social media–related groups.

Coping Strategies

The three most successful ways of facing the demands of COVID-19 in daily life and work, out of 12 possible answers, were taking protective measures (mean 2.57, SD 0.67), actively acquiring more knowledge about COVID-19 (mean 2.09, SD 0.78), and engaging in recreational activities (mean 1.94, SD 0.77*)*. All coping strategies are listed in Table 4.

Three dimensions could be extracted after carrying out the PCA and were named as active coping, mental coping, and emotional coping, after analyzing the content of the items. The dimensions accounted for 47.2% of the variance (Table 4).

Table 4. Matrix of coping strategy components and three statistics after varimax rotation (the rotation is converged in five iterations; method of extraction: main component analysis).

Items	Mean (SD)	Factor loadings		
		Active	Mental	Emotional
Coping strategy components				
Taking protective measures (washing hands, wearing a mask, taking one’s own temperature, etc)	2.57 (0.67)	0.77	–0.03	0.01
Actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc)	2.09 (0.78)	0.75	0.17	0.02
Changing one’s thoughts and facing the situation with a positive attitude	1.90 (0.83)	0.53	0.44	–0.12
Engaging in recreational activities (WeChat, Weibo, TikTok, online shopping, online movies, exercises)	1.94 (0.77)	0.42	0.23	–0.06
Video chatting with family and friends by phone to share concerns and support	1.69 (0.80)	0.40	0.43	–0.02
Engaging in health-promoting behaviors (more rest, exercise, balanced diet, etc)	1.76 (0.82)	0.27	0.68	–0.06
Acquiring mental health knowledge and information	1.36 (0.91)	0.27	0.63	0.01

Predictors of Increased Levels of Depression, Anxiety, and Stress

We calculated three binary logistic regression models in order to find associations of gender, lockdown area, contact with COVID-19 infection at work, and coping factors with the odds of belonging to the group for moderate–extremely severe depression, anxiety, or stress. Being female and applying emotional coping strategies increased the probability of belonging to the moderate–extremely severe depression, anxiety, or stress group. Applying active coping strategies reduced the probability of being affected by moderate–extremely severe anxiety, while mental coping strategies reduced the probability in all three moderate–extremely severe mental health groups. Age, being in a lockdown area, having contact with COVID-19 at work, and having a high workload (8-12 hr per day) did not significantly predict the odds of expressing moderate–extremely severe symptoms of depression, anxiety, or stress. The results are displayed in detail in Table 5.

Table 5. Results of a logistic regression predicting the probability of experiencing moderate–extremely severe (MES) depression, anxiety, or stress.

Variable	MES depression		MES anxiety		MES stress	
	B (SE)	OR[a] (95% CI)	B (SE)	OR (95% CI)	B (SE)	OR (95% CI)
Gender (female)	0.81 (0.27)	2.24 (1.33- 3.77)	0.47 (0.22)	1.61 (1.05-2.47)	0.78 (0.30)	2.19 (1.21-3.96)
Age	0.01 (0.01)	1.01 (0.98-1.03)	–0.01 (0.01)	0.99 (0.97-1.00)	–0.01 (0.01)	0.99 (0.96-1.01)

[a] OR: odds ratio.

Major Stressors (Health Care Workers Only)

Out of 18 stressors, the three most demanding aspects for health care workers (n=375) were related to worries about infecting one’s family with COVID-19 (mean 1.46, SD 0.86), followed by the potential deterioration of their patients’ condition (mean 1.42, SD 0.79) and their patients’ emotional reaction (mean 1.3, SD 0.81) (Table 6).

Table 6. Doctors’ and nurses’ responses to the question: when you think about COVID-19 in your life and work, how often did you think or worry about the following things? (0=not at all, 3=very much) (n=375).

Stressor	Response, mean (SD)
Worries about infecting your family with COVID-19	1.46 (0.86)
Deterioration of patients’ condition	1.42 (0.79)
Patients’ emotional reaction	1.30 (0.81)
Emotional reaction of patients’ families	1.29 (0.79)
Uncertainties about when the epidemic will be under control	1.27 (0.78)
Coworkers displaying COVID-19–like symptoms	1.27 (0.79)
Worries about getting infected	1.24 (0.78)
Worries about being negligent and endangering patients	1.23 (0.88)
Worries about lack of proper knowledge and equipment	1.23 (0.79)
Worries about being negligent and endangering coworkers	1.18 (0.83)
Worries about nosocomial spread	1.15 (0.82)
Conflict between duty and safety	1.15 (0.81)
Being infected by colleagues	1.12 (0.81)
Protective gears being a hinderance to providing quality care	1.12 (0.80)
Being blamed by supervisors/managers	1.10 (0.80)
Displaying COVID-19–like symptoms yourself	1.09 (0.77)
Worries about the lack of manpower	1.07 (0.91)
Being without a properly equipped environment	1.05 (0.84)
Physical discomfort caused by protective gears	1.01 (0.79)
Ambiguity in the responsibilities between doctors and nurses	1.00 (0.86)
Frequent modification of infection control procedures	0.96 (0.81)
Coworkers being emotionally unstable	0.96 (0.77)
Unclear documentation and reporting procedures	0.92 (0.78)

Discussion

Predictors of Mental Health Symptoms

This survey aimed to assess the psychological burden and mental health of the Chinese population during the final stages of the lockdown, as well as to determine successful coping strategies and potentially vulnerable professional groups with specific support needs. Our results suggest that being female and, independent of gender, applying certain coping strategies increased the incidence of symptoms of depression, anxiety, and stress. Emotional coping strategies like venting emotions, consuming alcohol, or limiting oneself from information were not helpful for participants dealing with COVID-19–related psychological problems. Active strategies to cope with moderate–extremely severe anxiety, such as taking protective measures and acquiring more knowledge were more beneficial, but the most effective strategy was focusing on mental coping like relaxation techniques and gaining knowledge about mental health. Our results confirm the findings of Guo et al [16], who used another instrument to determine coping strategies but found emotion-focused strategies to worsen mental health, while cognitive and problem-focused coping strategies to be helpful. Interestingly, exposure to COVID-19 at work, living within a lockdown area, and daily workload did not play a significant role in predicting elevated symptoms.

We found no overall increased mean values in perceived stress and depression, anxiety, and stress in comparison to former (pre–COVID-19) samples (eg, compared to the perceived stress levels of patients in Hong Kong [43] or among residents in Beijing [44]) regarding mental health scores. This could be because the Chinese population had already become accustomed to the burden of COVID-19 by the end of the lockdown. The first studies in January investigating the psychological impact of the outbreak on the population reported high levels of burden [16,31,45]. Wang et al [13,14] measured DASS-21 scores twice at the beginning and at the peak of the pandemic in China and found increased anxiety in nearly 30% of participants; yet no longitudinal increases were noted. In our study, we added a third point of measurement at the final stage of the lockdown and found a considerable share of people who expressed moderate to extremely severe symptoms of depression (17.9%), anxiety (30.3%), and stress (13.7%). This result should be taken seriously as our sample revealed a higher percentage of people with increased levels of depression while stress scores were lower compared to the Wang et al [13,14] studies. We also observed a high correlation of perceived stress in the past 4 weeks and actual scores in depression. Previous research on the etiology of depression could show that stress might be one predictor for this mood disorder [46,47]. Following this line of argument, an increase of depressive symptoms by the end of the lockdown could be interpreted as part of a concerning development.

Vulnerable Groups

Some groups in our sample were more affected by symptoms of depression, anxiety, or stress than others. Students were vulnerable to moderate–extremely severe symptoms in all three categories. Outside the pandemic context, Chinese students have been reported to be affected by mental health problems due to stressful academic demands [48,49]. The consequences of the pandemic on students' lives were aggravated by infection control measures, online learning on a tight schedule, and uncertain future prospects [50]. A cross-sectional study among medical students after the lockdown revealed high levels of anxiety (38% of participants) and showed that social media played an important role in adherence to protective measures among them [29]. According to our results, the main method of getting COVID-19–related information was WeChat, directly followed by circle of friends, which in China refers to WeChat groups and other social media–related groups.

Economy staff were highly burdened by stress but did not exhibit more depression or anxiety than other groups. This result does not support that of Huang and Zhao [31], who, using different protocols, questioned enterprise employees in early February, and found depression among 20% of participants and anxiety among 34%. Increased stress levels in our sample could be explained by the fact that we put together all employees and self-employed people in the finance and IT sectors as well as salespersons in one group. Enhanced stress may be a result of the concerns to ensure livelihood for their own family during the lockdown, as shown previously [16]. Further differentiated results are needed to allow for a more specific statement.

Doctors and nurses in our sample were highly affected by anxiety; doctors had the highest workload per day. Nevertheless, perceived stress and DASS-21 stress levels were not higher than other groups, which may be due to a high professional devotion, as reported in previous research [51]. Issues about patient care like the deterioration of the patients' condition and the emotional reaction of patients and their families were perceived as stressful. In another study, nurses in Wuhan were found lacking in training for dealing with uncooperative patients [26]. Several studies have reported on the need for training Chinese medical staff on doctor-patient communication outside the context of the COVID-19 crisis [52]. The anxiety felt by doctors and nurses in our sample may be the result of the fear of bringing COVID-19 to their own families, the most intense stressor in our and other samples [23,51]. A further stressor found in other studies included spending too much time on social media while searching for COVID-19 updates. Doing so promoted symptoms of depression and anxiety in Chinese adults in general as well as in health professionals [19].

Finally, other medical staff, a small group consisting of volunteers, midwives, and pharmacists in our sample, was more affected by depression and stress than other groups and was vulnerable to anxiety as well. During the pandemic, many volunteers supported hospitals in a frontline capacity [53], and our results show that these individuals, who had the second highest workload per day after doctors, have been overlooked so far and should receive more attention since they seem to have special support needs. This group might lack the institutional psychological support that is delivered to the core personnel in a frontline hospital.

Future Implications

By 2017, there were only 33,400 licensed psychiatrists in China [54]. In recent years, the Chinese National Health Commission has established several mental health initiatives to extend mental health care to the general population. During the COVID-19 pandemic, the commission published guidelines and treatment instructions, uploaded videos of mental health education via WeChat, and established expert emergency groups for mental health services at the hospitals [55].

However, health care workers continue to be in dire need of greater access to specific mental health services [56], and further research is needed on the role of media consumption and mental health during such crises. Although the internet provided many supporting measures like telemedicine for patients with COVID-19 [57] and online mental health education and counseling [58], excessive exposure to the media seems to play a significant role in explaining mental health problems during the pandemic [18]. The Chinese population might find itself in a paradox: acquiring knowledge about the virus and mental health measures is helpful but in order to maximize coverage this knowledge is spread by governmental and other institutions via social media [55,58], which has its own harmful mental consequences [16,19]. As a result, it is not possible for individuals to avoid media consumption. More conclusive findings on the role of the media and the mental health of subgroups of the Chinese population are needed.

Limitations

Although we received 687 responses, the professional groups in this study were not of equal size; numbers were especially limited for the students and other medical staff categories, which reduces the power of statistical analysis. Targeted investigations may be needed to assess the status of underrepresented professions in a differentiated way. Further, online studies are unable to allow a valuable diagnostic assessment, and this limitation applies to all former studies. This is further aggravated due to the great variability in instruments used in different surveys, which reduces the comparability of results. Some authors used the DASS-21 previously [13,14] but with different cut off-scores (see below), while some relied on the Self-rating Depression Scale (SDS) [45], the Patient Health Questionnaire (PHQ) [56], the Generalized Anxiety Disorder 7-item (GAD-7), the Center for Epidemiology Scale for Depression (CES-D) [31], or the Post-Traumatic Stress Disorders (PTSD) Checklist [16]. However, only a face-to-face diagnostic interview by a qualified medical doctor or a clinical psychologist could allow a statement regarding a mental disorder. Therefore, our results hint at a certain development but should not be interpreted as a diagnosis of the population. Moreover, we compared our results to the studies of Wang et al [13,14], who used slightly different cut-off scores in interpreting the borders between mild and moderate depression and anxiety as suggested originally by Lovibond and Lovibond [33]. However, even without knowing their exact frequencies for single scores, our findings on increases in depression would have been even higher if Wang et al had used the original cut-off scores. Finally, we only asked for media preferences and not for the time spent on media platforms. A detailed analysis on the reasons for media consumption (entertainment, information, relaxation), the way of usage (alone, together), and mental health is necessary to reveal a more holistic picture.

Conclusion

A considerable part of the general population in China reported elevated symptoms of depression, anxiety, and stress during the final stages of the COVID-19 lockdown. Doctors, nurses, students, and other medical staff were found to be in imminent danger of developing mental health problems. Similarly, economy staff was also highly stressed. Being female was an additional risk factor for potential vulnerability toward developing mental health problems. We recommend providing additional specific information to these subgroups targeting their respective mental health profile and to personalize the successful coping strategies found in our results (ie, active and mental coping). These refer to constructive ways of behavior (eg, actively acquiring knowledge, applying protective measures) and mental health strategies (eg, relaxation techniques, psycho-education, and promoting social contact). Profession-specific mental health prevention programs should be developed and provided in formats preferred by the respective age, gender, or professional groups.

Acknowledgments

We thank all participants for taking part in our study despite the current challenges imposed by the pandemic. We also thank Wuhan CNweb Pioneer Ltd, which was responsible for the implementation of the online survey in collaboration with the QHealth Trusted Doctors Group (Penguin), Wuhan Saidian Consulting Service Company, and Tao Doctor APP. We appreciate the support of Tongji Medical College for disseminating the questionnaire link.

Abstract

Background: Social distancing is an important component of the response to the COVID-19 pandemic. Minimizing social interactions and travel reduces the rate at which the infection spreads and "flattens the curve" so that the medical system is better equipped to treat infected individuals. However, it remains unclear how the public will respond to these policies as the pandemic continues.

Objective: The aim of this study is to present the Twitter Social Mobility Index, a measure of social distancing and travel derived from Twitter data. We used public geolocated Twitter data to measure how much users travel in a given week.

Methods: We collected 469,669,925 tweets geotagged in the United States from January 1, 2019, to April 27, 2020. We analyzed the aggregated mobility variance of a total of 3,768,959 Twitter users at the city and state level from the start of the COVID-19 pandemic.

Results: We found a large reduction (61.83%) in travel in the United States after the implementation of social distancing policies. However, the variance by state was high, ranging from 38.54% to 76.80%. The eight states that had not issued statewide social distancing orders as of the start of April ranked poorly in terms of travel reduction: Arkansas (45), Iowa (37), Nebraska (35), North Dakota (22), South Carolina (38), South Dakota (46), Oklahoma (50), Utah (14), and Wyoming (53). We are presenting our findings on the internet and will continue to update our analysis during the pandemic.

Conclusions: We observed larger travel reductions in states that were early adopters of social distancing policies and smaller changes in states without such policies. The results were also consistent with those based on other mobility data to a certain extent. Therefore, geolocated tweets are an effective way to track social distancing practices using a public resource, and this tracking may be useful as part of ongoing pandemic response planning.

COVID-19; social distancing; mobility; Twitter; social media; surveillance; tracking; travel; index

Introduction

The outbreak of SARS-CoV-2, a coronavirus that causes the disease COVID-19, has caused a pandemic on a scale unseen in a generation. Without an available vaccine to reduce transmission of the virus, public health organizations and elected officials have called on the public to practice social distancing. Social distancing is a set of practices in which individuals maintain a physical distance to reduce the number of physical contacts they encounter [1,2]. These practices include maintaining a distance of at least six feet from other people and avoiding large gatherings [3]. At the time of this writing, in the United States, nearly every state had implemented statewide “stay-at-home” orders to enforce social distancing practices [4].

Social distancing is an important tool in the fight against COVID-19; however, its implementation by the general public can vary widely. Although a state governor may issue an order for the practice, individuals in different states may respond to this order in different ways. Courtemanche et al [5] showed that social distancing policies in the United States reduced the daily growth rate of COVID-19 cases. However, if we only consider the social distancing policy duration and daily confirmed cases, it is difficult to rule out potential confounders, including additional policies for wearing masks and improving hygiene as well as other social norms. Therefore, understanding actual reductions in travel and social contacts is critical to measuring the effectiveness of such policies. Using mobile phone data, Badr et al [6] found that mobility patterns were strongly correlated with decreased rates of COVID-19 case growth for the 25 most affected counties in the United States. These social distancing policies may remain in effect for an extended period of time. Thus, the public may begin to relax their practices, making additional policies necessary. Researchers showed the effectiveness of strict social distancing followed by testing and contact tracing by modeling mobility data from Cuebiq Inc in the Boston metropolitan area [7]. Additionally, epidemiologists have already modeled the impact of social distancing policies on the course of disease outbreaks [8-10]. These models may be more effective when incorporating actual measures of social distancing rather than assuming that official policies are implemented in practice.

It can be challenging to obtain data on the efficacy of social distancing practices, especially during an ongoing pandemic. In a recent Gallup poll that surveyed Americans, it was found that many adults are taking precautions to maintain distance from others [11]. However, while polling can provide insights, it cannot provide a solution. Polling is relatively expensive; thus, it is a poor choice for ongoing population surveillance practices and providing data on specific geographic locales (ie, US states and major cities) [12]. Additionally, polling around public health issues suffers from response bias, as individuals may overstate their compliance with established public health recommendations [13].

Over the past decade, analyses of social media and web data have been widely adopted to support public health objectives [14]. In this vein, several efforts have emerged over the past few months to track social distancing practices using these data sources. Google has released COVID-19 Community Mobility Reports [15] that use Google data to “chart movement trends over time by geography, across different categories of places such as retail and recreation, groceries and pharmacies, parks, transit stations, workplaces, and residential.” The Unacast Social Distancing Scoreboard uses data collected from 127 million monthly active users to measure the implementation of social distancing practices [16]. Researchers at the Institute for Disease Modeling have used data from Facebook’s Data for Good program to model the decline in mobility in the greater Seattle area and its effect on the spread of COVID-19 [17]. Using mobile phone data, the *New York Times* completed an analysis that showed that stay-at-home orders dramatically reduced travel; however, it was found that in states where such orders were not quickly enacted, residents continued to travel widely [18].

Identifying and isolating individuals who have potentially been exposed to a virus can blunt the spread of a pandemic. Contact tracing involves finding people who have had contact with an infected individual during the time the individual was contagious. In the current pandemic, several efforts have been made to develop digital contact tracing tools. Google and Apple announced a joint effort to build a Bluetooth-based contact tracing platform, which enhances the interoperability between Android and IOS devices using apps from public health authorities [19]. Singapore [20] and Australia [21] released similar apps that use Bluetooth to exchange “digital handshakes” to establish contacts. Many countries have developed their own contact tracing responses [22]. Li and Guo [23] presented a review of the development of contact-tracing apps for COVID-19. These efforts provide new and important opportunities to study social distancing and contact tracing in real time.

We present the Twitter Social Mobility Index, a measure of social distancing and travel patterns derived from public Twitter data. We used public geolocated Twitter data to measure how much a user travels in a given week. We computed a metric based on the standard deviation of a user’s geolocated tweets each week, and we aggregated these data over an entire population to produce a metric for the United States as a whole, for individual states, and for some US cities. We found that in the United States as a whole, there was a dramatic drop in travel in the later weeks of the study period, with travel between March 16 and April 27, 2020, showing the lowest amount since January 1, 2019, the start of our data set. Additionally, we found that travel reductions were not uniform across the United States but varied from state to state. However, there was no clear correlation between social mobility and confirmed COVID-19 cases at the state level. A key advantage of our approach is that unlike the other travel and social distancing analyses referenced above, we rely on entirely public data, which enables others to replicate our findings and explore different aspects of these data. Additionally, because Twitter contains user-generated content in addition to location information, future analyses can correlate users’ attitudes, beliefs, and behaviors with changes in social mobility.

One concern regarding the mining of social media data is user privacy. Unlike the data used by the companies described above, all the data we used is publicly available. Users choose to post their location data to Twitter publicly; therefore, these data are accessible to all users. However, while the location data are public, the potential remains for violating user privacy and producing unintended consequences for users, such as highlighting users who are failing to social distance. To ensure privacy in our index, we aggregated all mobility metrics to produce population-level analyses. None of our work considers the identity of individual users, and we removed identifiable user information from the distributed data aggregations. Furthermore, we caution others who pursue work similar to ours to consider privacy ramifications for users when collecting new data and conducting similar analyses.

There is widespread recognition that real-time tweets from millions of users can yield insights into a variety of population-level trends. Our study follows a tradition of using this insight to develop population-level indices and measures from Twitter data. Previous work includes tracking population-level sentiment as an economic indicator that can track stock price [24], political indices that reflect the popular opinion on major socioeconomic issues [25] or opinions about political candidates [26,27], and measures of pop culture such as reception of entertainment programs [28]. The Twitter Social Mobility Index is a measure of this kind, aggregating Twitter data from millions of people to produce real-time measurements of social distancing.

There is a long line of work on geolocation prediction for Twitter, which requires inferring a location for a specific tweet or user [29-32]. This includes work on patterns and trends in geotagged Twitter data [33]. Although most of these works focus on inferences of users' current locations and thus are not suitable for tracking user movements, there may be opportunities to combine these methods with our approach.

Many studies have analyzed Twitter geolocation data to study population movements. Hawelka et al [34] demonstrated a method for computing global travel patterns from Twitter, and Dredze et al [35] adapted this method to support efforts in combating the Zika virus epidemic. Several studies have used human mobility patterns from Twitter data [36-39]. These studies include analyses of urban mobility patterns [40-42]. Finally, some of these analyses considered mobility patterns around mass events [43].

Our findings are presented on a website [44], and we will continue to update our analysis during the COVID-19 pandemic.

Methods

Data Source

Twitter offers several ways in which a user can indicate their location. If a user is tweeting from a GPS-enabled device, they can attach their exact coordinates to that tweet. Twitter can then display the specific place that corresponds to these coordinates to the user and also provide it in their application programming interface (API). Alternatively, a user can explicitly select a location, which can be a point of interest (eg, a coffee shop), neighborhood, city, state, or country. If the tweet is public, this geolocation information is supplied with the tweet.

We used the Twitter streaming API [45] to download tweets based on location. We used a bounding box that covered the entire United States, including US territories. We used data from this collection starting on January 1, 2019, and ending on April 27, 2020. In total, the data set included 3,768,959 Twitter users and 469,669,925 tweets posted in the United States.

Location Data

We processed the two types of geolocation information described in the previous section.

Coordinates

We processed the exact coordinates (latitude and longitude) provided by the user (the "coordinates" field in the Twitter JavaScript Object Notation [JSON] object). Approximately 8% of our data included coordinates.

Place

The "place" field in the Twitter JSON object indicates a known location in which the tweet was authored. A place can be a point of interest (eg, a specific hotel), a neighborhood (eg, downtown Jacksonville), a city (eg, Kokomo, IN), a state (eg, Arizona), or a country (eg, the United States). The place object contains a unique ID, a bounding box, a country, and a name. More information about the location is available from the Twitter Geo API. A place is provided with a tweet in either of two conditions. First, Twitter can identify the coordinates provided by the user as occurring in a known place. Second, the user can manually select a place when authoring the tweet.

Because coordinates give a more precise location, we used them instead of place when available. If only a place was available, we assumed that the user was in the center of the place, as given by the place's bounding box.

For points of interest and neighborhoods, Twitter only provides the country in the associated metadata. Although in some cases, the city can be parsed from the name and the state inferred, we opted to exclude these places from our analysis for states. The full location details can be obtained from querying the Twitter API; however, due to the magnitude of the data in our analysis, this task would have been too time-consuming. This limitation excluded approximately 1.8% of our data.

We performed analyses for the 50 most populous US cities. For these analyses, we included points of interest that c the city name in their names, such as "New York City Center." Specifically for New York City, we included places that corresponded to each of the five New York City boroughs (Brooklyn, Manhattan, Queens, Staten Island, and the Bronx).

In summary, for each geolocated tweet, we obtained an associated latitude and longitude.

Computing Mobility

We defined the Twitter Social Mobility Index as follows. For each user, we collected all locations (coordinates) in a 1-week period, where a week starts on Monday and ends the following Sunday. We denoted the coordinate sequence as , where C_j is the coordinate at time j in week i and n is the number of coordinates in that week. We computed the centroid of all of the coordinates and considered this the "home" location for the user. We then measured the distance between each location and the centroid for that week. To determine distance, we measured the geodesic distance in kilometers between two adjacent records, C_j and C_{j+1}, using geopy [46], resulting in a distance sequence of . After collecting the distances, we measured the standard deviations of these distances. Formally, we defined Twitter Social Mobility Index M for each user as where σ(·) is the standard deviation operator and *N* is the number of weeks considered for the measure. We measured mobility in kilometers.

In summary, this measure reflects the area and regularity of travel for a user rather than the raw distance traveled. Therefore, a user who takes a long trip with a small number of check-ins would have a larger social mobility measure than a user with many check-ins who traveled in a small area. Because the measure is sensitive to the number of check-ins, it reflects when people have fewer check-ins during the pandemic.

We aggregated the results by week by taking the mean measure of all users in a given geographic area. We also present results for a 7-day moving average aggregation as a measure of daily movement. We recorded the variance of these measures to study the travel variance in the population, which indicates if travel is reduced overall but not for some users.

We produced aggregate scores by geographic area for the United States as a whole, for each US state and territory, and for the 50 most populous cities in the United States. We determined the geographic area of a user based on their centroid location for all times in our collection.

We computed the social mobility index for each day and week between January 1, 2019, and April 27, 2020. We selected the date of March 16, 2020, as the start of social distancing on the national level, although individual states implemented practices at different times. Therefore, we divided the data into two time periods: before social distancing (January 1, 2019, to March 15, 2020) and after social distancing (March 16, 2020, to April 27, 2020).

We then computed the group level reduction in social mobility by considering the average values as follows:

We also computed the reduction for each user and then tracked the median value, number of users active in both periods, and proportion of active users who completely reduced their mobility. We conducted a similar analysis for seasonal effects by comparing mobility after social distancing with mobility during the same period in 2019.

To address sparse data issues in our data set, we excluded users with fewer than 3 geolocated tweets overall and excluded the weekly record for a user if they had fewer than 3 geolocated tweets in that week. Additionally, due to data loss in our data collection process, we removed two weeks that contained far less data than the other time periods by taking a 99.75% confidence limit on the number of users and records.

Results

Social Mobility Index

Table 1 shows the Twitter Social Mobility Index measured in kilometers for every state and territory in the United States and the United States as a whole. City results are shown in Table 2. We also included the rank of location by the group level reduction.

Table 1. Reductions of mobility for all US states and territories and for the United States. Ranks are based on group level reduction.

Location	Mobility (kilometers)		Group level reduction (%)	User-level reduction (%)		Rank
	Before distancing	After distancing		Median reduction	Median seasonal reduction

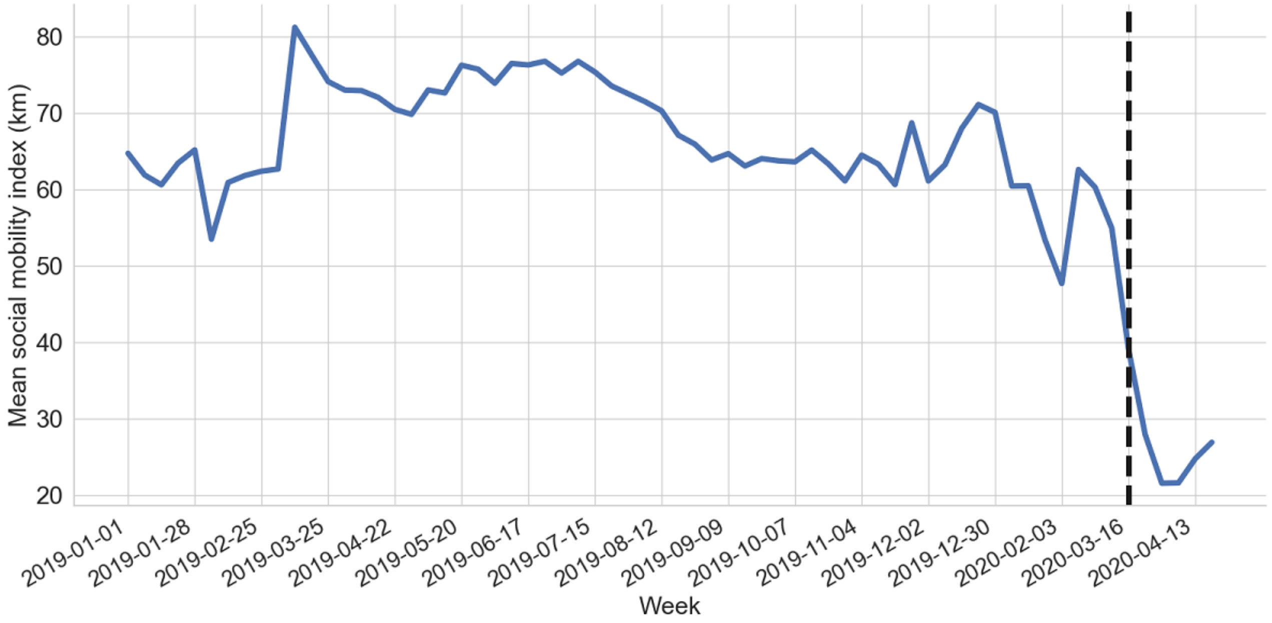
We observed that the overall drop in mobility across the United States was large (61.83%). Figure 1 shows the weekly social mobility index for the United States for the entire time period of our data set. The figure reflects a massive drop in mobility starting in March, and the four most recent weeks showed the lowest mobility on record in our data set. Second, every US state and territory saw a drop in mobility, ranging from 38.54% to 76.80% of travel compared to the numbers before March 16, 2020. However, the variance by state was high. States that were early adopters of social distancing practices ranked highly on the reduction in travel, such as Washington (3) and Maryland (9). In contrast, the eight states that had not implemented statewide orders as of the start of April [4] ranked poorly, namely Arkansas (45), Iowa (37), Nebraska (35), North Dakota (22), South Carolina (38), South Dakota (46), Oklahoma (50), Utah (14), and Wyoming (53). We observed similar trends in the city analysis; however, the median users in cities had a larger mobility reduction than the users in states.

Figure 1. Mean social mobility index (kilometers) in United States from January 1, 2019, to April 27, 2020. Weeks with missing data are excluded from the figure.

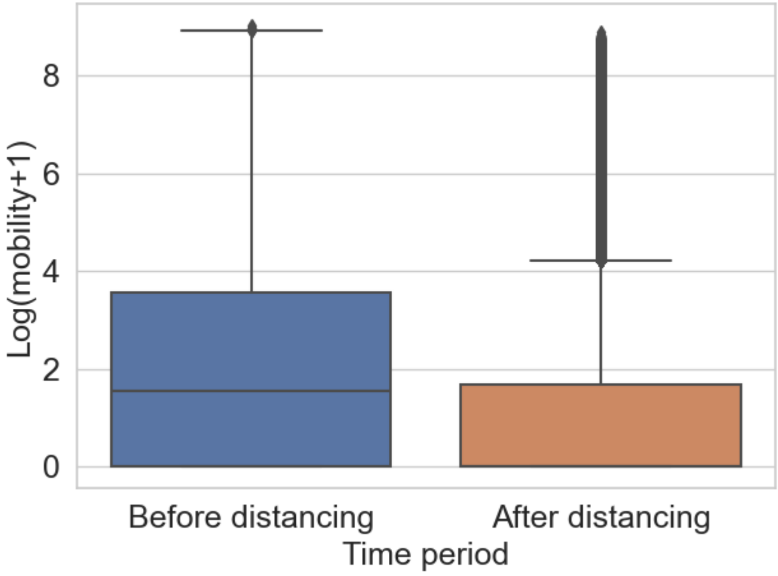


In addition to the group-level mobility travel reduction, we examined the distribution of user-level travel reduction. For this analysis, we only considered the subgroup of users who had at least two check-ins in both periods. The median values for the reduction distribution were close to 100% for most states. The median values for seasonal reduction were all smaller but still suggested that people substantially reduced their mobility during the pandemic. Moreover, in the United States, 40% of the 818,213 active users completely reduced their mobility (ie, the mobility reduction was 100%). In contrast, during the same period in 2019, a 31% reduction was seen among 286,217 active users.

The White House announced "Slow the Spread" guidelines for persons to take action to reduce the spread of COVID-19 on March 16, 2020 [47]. Of the states, 49.06% (26/53) had their largest mobility drop in the week of March 16-22, 2020, and 22.64% (12/53) had their largest drop in the following week. We computed a moving average of daily mobility data and used an offline change point detection method [48] on this trend. In 2020, 62.26% of the change points occurred after the national announcement date but before the dates on which individual state policies were enacted. This suggests that the national announcement had a larger effect compared to state policies, which is a similar finding to that of a mobile phone–based mobility analysis of four large cities [49]. We also observed that among the 40 states that announced stay-at-home policies, 92.5% (37) of the states had a more stationary daily mobility time series before the policy announcement date compared to the mobility time series over the entire time period, suggesting a rapid mobility change during the pandemic.

Finally, Figure 2 shows a box plot of the mobility variance across all users in a given time period. The distribution is long-tailed with numerous zeros; therefore, we took the log of 1 plus each mobility index. Although mobility was reduced in general, some users still showed a lot of movement, which suggests that social distancing is not being uniformly practiced. These results clearly demonstrate that our metric can track drops in travel, suggesting that it can be used as part of ongoing pandemic response planning.

Figure 2. Box plots showing the user distributions of the mean social mobility index (kilometers) before and after social distancing measure were enacted in the United States.



Correlations

To investigate the factors that explain our Twitter Social Mobility Index and how well the index tracks COVID-19 cases compared to other relevant factors, we performed a correlation analysis on our data. We computed the daily infection rate by dividing the number of new confirmed COVID-19 cases in each US state [50] by the population of the state. We compared the daily infection rate with the social mobility index and the trends in the state characteristics category from [51]. We first ran a correlation analysis for the following trends: state size in square miles, population density per square mile, unemployment rate (2018), percentage of the population living under the federal poverty line (2018), number of homeless individuals (2019), percentage of the population at risk for serious illness due to COVID-19, and number of all-cause deaths (2016). We selected these measures to track the size of the state, economic activity, and composition of the population, which were studied in a similar correlation analysis of other countries [52]. These measures may change how far people typically travel in a given state.

In Figure 3 and Figure 4, we show the characteristics that have high correlation with either the number of confirmed cases or the mobility index. These characteristics were the size of the state in square miles, the number of homeless individuals (2019), the unemployment rate (2018), and the percentage of the population at risk for serious illness due to COVID-19.

For each day, we computed the correlations between the daily infection rate and the above data by state.

Figure 3. Pearson correlations between daily COVID-19 infection rates and various factors at the state level.

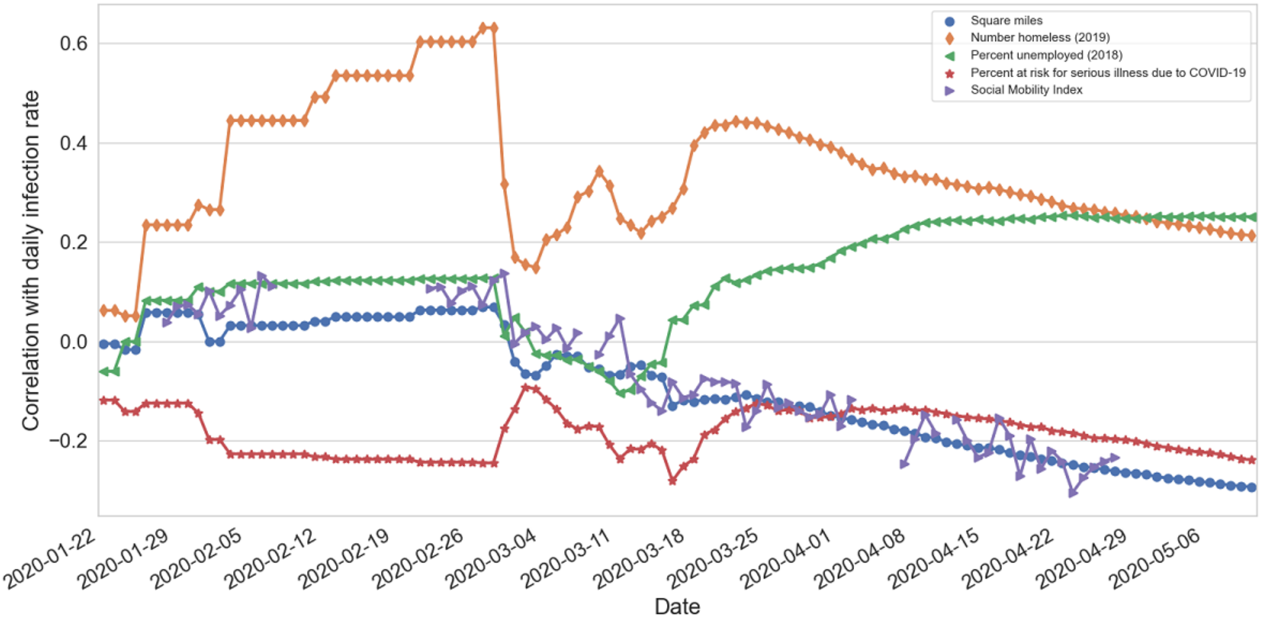


Figure 3 shows the correlations by day. We adopted the infection rate because the raw number of confirmed cases is not as informative, as the population has the highest correlation. However, the most significant factors in the early stage were still population-related factors (eg, the number of homeless people). We did not see significant correlations with other factors, including the social mobility index. Starting from mid-March, we observed trends of increasing correlation with the unemployment rate, size of the state, and social mobility index; however, these correlations were not significant (absolute correlation values <.5). A fluctuation occurred in the middle of the period, when states started to report confirmed cases of COVID-19.

We conducted a similar correlation analysis between each data source and the social mobility index, as shown in Figure 4. As expected, geographical state size showed the highest positive correlation. We also observed that the number of people at risk for serious illness due to COVID-19 had a negative correlation at the early stage of the pandemic.

Figure 4. Pearson correlations between the social mobility index and various factors at the state level.

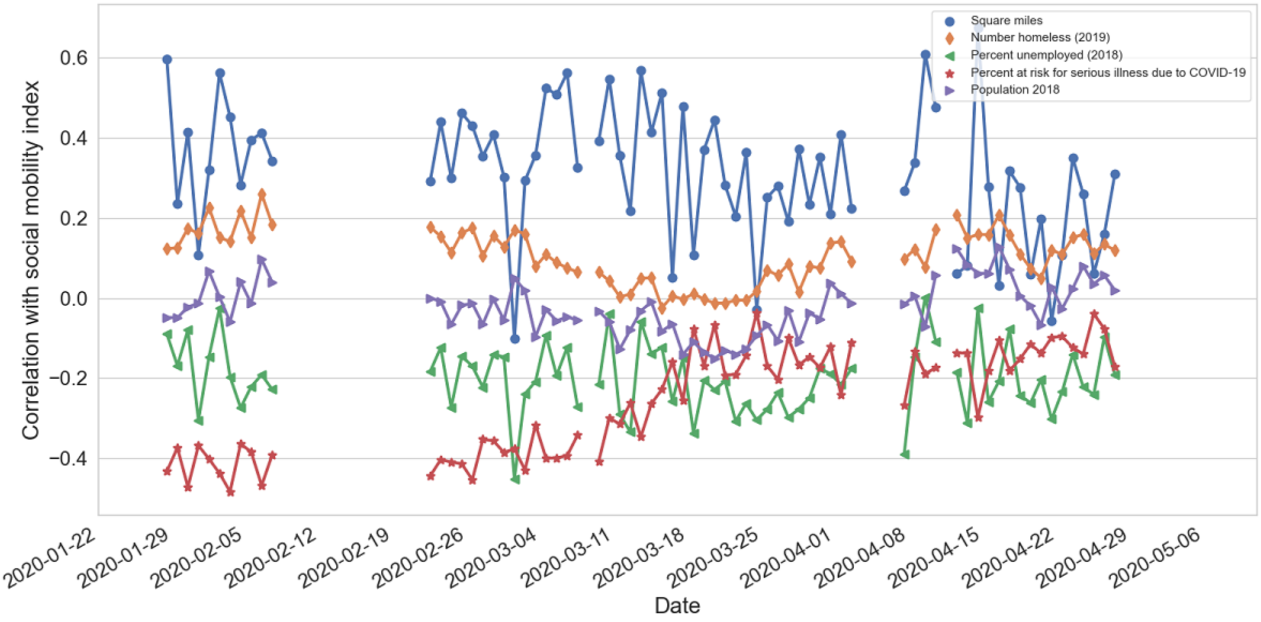

Table 3 demonstrates the effects of various restriction policies on confirmed cases by running a similar correlation analysis on the cumulative confirmed cases for each state on May 10, 2020. The policy types follow the data from [51]. We used the time difference (in days) between May 10, 2020, and the policy release date as the input for the analysis, and we assigned a negative value (–1000) to states that had not announced a policy. The factor with the highest correlation with the social mobility index is the declaration of a state of emergency, which is the broadest type of policy.

Table 3. Pearson correlations between the cumulative number of confirmed COVID-19 cases on May 10, 2020, and the dates on which policies were released in each state.

Policy	Correlation	*P* value
State of emergency	0.2587	.07
Date banned visitors to nursing homes	0.151	.29
Stay-at-home or shelter-in-place order	0.1507	.29
Evictions frozen	0.1411	.32
Nonessential businesses closed	0.1359	.34
Gyms closed	0.0765	.59
Movie theaters closed	0.0737	.61
Day cares closed	0.0563	.70
Restaurants closed except takeout	0.0341	.81
Kindergarten to 12th grade schools closed	–0.0821	.57

Discussion

We present the Twitter Social Mobility Index, a measure of social mobility based on public geolocated tweets. Our analysis shows that there was a large drop in mobility overall in the United States. However, the drop was inconsistent and varied significantly by state. It appears that states that were early adopters of social distancing practices experienced more significant drops than states that had not yet implemented these practices.

Several limitations of using geo-tagged tweets as the subject of our study must be kept in mind. First, users on Twitter and other social media platforms are not representative of the general population. Their demographics, such as age, race, ethnicity, education level, income, and political affiliation, do not perfectly mirror the larger population. In the United States, Twitter users are younger, more educated, have higher incomes, and are more likely to identify as Democrats than the general public [53,54]. Therefore, while our sample of users is large, it is highly biased.

Second, not all users are equally likely to use geotagging features on Twitter, and they may use the features in different ways. For example, in a previous study [32], demographic differences were found in the groups of people who used the two different types of geolocation information (ie, coordinates and place). GPS-tagged tweets are posted more often by young people and by women compared to tweets with self-reported locations.

Third, while we obtained access to millions of geotagged tweets, this is still a relatively small proportion of the total number of nongeotagged tweets on the platform, and it is also small compared to private measures of social mobility computed by companies such as Google and Apple.

Fourth, a small proportion of geotagged tweets report fake geolocation information. However, we believe that this is a negligible problem, as previous work found the rate of fake geolocation to be around 0.22% on social media in general [55] and even lower on Twitter. In our preliminary analysis, we considered mobility data based on GPS from mobile devices alone while excluding place information, as this method has greater precision. However, our results with these limited data were similar to our results with the full data set, except that they were less stable. Therefore, we decided to include all location data.

Despite these limitations, our results produced metrics that align with expected trends given national social distancing guidelines and related statewide policies. This suggests that there is sufficient information in our data to overcome these limitations. Additionally, the public nature of Twitter data has advantages over proprietary and private data sources. More work is needed to compare our mobility trends with those of other data sources.

Our work on this data is ongoing, and there are several directions that warrant further study. First, as states begin to reopen and some states maintain restrictions, tracking changes in population behaviors will be helpful in making policy decisions. Second, we focused on the United States; however, Twitter data provides sufficient coverage to replicate our analysis for many countries. Third, tweet content exists for each user in the data set; this content can reflect the user's attitudes, beliefs, and behaviors. Studying these factors together with users' mobility reduction could yield further insights. Our findings are presented on a website [44], and we will continue to update our analysis during the pandemic.

Conflicts of Interest

Abstract

Background: Emerging evidence suggests that people with arthritis are reporting increased physical pain and psychological distress during the COVID-19 pandemic. At the same time, Twitter's daily usage has surged by 23% throughout the pandemic period, presenting a unique opportunity to assess the content and sentiment of tweets. Individuals with arthritis use Twitter to communicate with peers, and to receive up-to-date information from health professionals and services about novel therapies and management techniques.

Objective: The aim of this research was to identify proxy topics of importance for individuals with arthritis during the COVID-19 pandemic, and to explore the emotional context of tweets by people with arthritis during the early phase of the pandemic.

Methods: From March 20 to April 20, 2020, publicly available tweets posted in English and with hashtag combinations related to arthritis and COVID-19 were extracted retrospectively from Twitter. Content analysis was used to identify common themes within tweets, and sentiment analysis was used to examine positive and negative emotions in themes to understand the COVID-19 experiences of people with arthritis.

Results: In total, 149 tweets were analyzed. The majority of tweeters were female and were from the United States. Tweeters reported a range of arthritis conditions, including rheumatoid arthritis, systemic lupus erythematosus, and psoriatic arthritis. Seven themes were identified: health care experiences, personal stories, links to relevant blogs, discussion of arthritis-related symptoms, advice sharing, messages of positivity, and stay-at-home messaging. Sentiment analysis demonstrated marked anxiety around medication shortages, increased physical symptom burden, and strong desire for trustworthy information and emotional connection.

Conclusions: Tweets by people with arthritis highlight the multitude of concurrent concerns during the COVID-19 pandemic. Understanding these concerns, which include heightened physical and psychological symptoms in the context of treatment misinformation, may assist clinicians to provide person-centered care during this time of great health uncertainty.

KEYWORDS

COVID-19; SARS-CoV-2; novel coronavirus; social media; Twitter; content analysis; sentiment analysis; microblogging; arthritis

Introduction

Social media contains a plethora of health information pertaining to individuals living with chronic illness [1,2]. Social media provides a unique opportunity to observe thoughts, feelings, and interactions between individuals living with chronic illness, and to leverage this information to promote positive health outcomes [3,4]. The COVID-19 pandemic has seen widespread uptake of social media use. Twitter, a well-known social media platform primarily used for microblogging, plays a significant role in crisis communications and can be a powerful tool to communicate to entire populations during a time of rapid change [5]. Twitter is already frequently used by individuals with arthritis to communicate with peers [6] and to receive up-to-date information from health professionals and services about novel therapies and management techniques [7].

Many inflammatory arthritis medications act as immunosuppressants, which are advantageous in controlling arthritis-mediated inflammatory responses, but can increase the risk of infection [8]. Long-term use of immune-modulating therapies or glucocorticoids may place individuals with arthritis in a higher-risk category for contracting the novel coronavirus SARS-CoV-2, although the level of risk is poorly understood [9-12]. Current guidelines suggest that individuals living with arthritis should physically distance from other individuals and their communities [13], and will likely need to do so for a longer duration than the general public. Heightened stress due to potential medication shortages, reduced opportunities to personally consult health care professionals, and enforced limitations on physical activity (which, for many, is a core component of arthritis self-management [14]) contribute to worsening arthritis symptoms, including disease flares. At present, individuals with arthritis have already reported increased physical pain and psychological distress during the COVID-19 pandemic [15,16].

In the current COVID-19 outbreak, Twitter's overall daily usage has surged by 23% in 2020 [17], presenting a unique opportunity to assess the content and sentiment of tweets. Examining publicly available tweets allows exploration of important proxy topics through microblogging data, without directly burdening this population. This research aims to identify proxy topics of importance for people with arthritis (of any diagnostic category) during the COVID-19 pandemic by characterizing the textual content and sentiment of tweets, and to explore the emotional context of tweets by people with arthritis during the early phase of the pandemic.

Methods

Design

An exploratory content and sentiment analysis was undertaken. All data were collected and reported according to the terms and conditions of Twitter, which state that content posted by individuals is publicly available to syndicate, broadcast, distribute, retweet, promote, or publish, excluding private information (eg, home addresses or identity documents) [18]. Use of tweets by individuals outside of Twitter can be carried out with no compensation paid to the individual tweeter, as use of Twitter is agreed upon as sufficient compensation [18]. The Monash University Human Research Ethics Committee (Project ID 24354) approved this project.

Inclusion and Exclusion Criteria

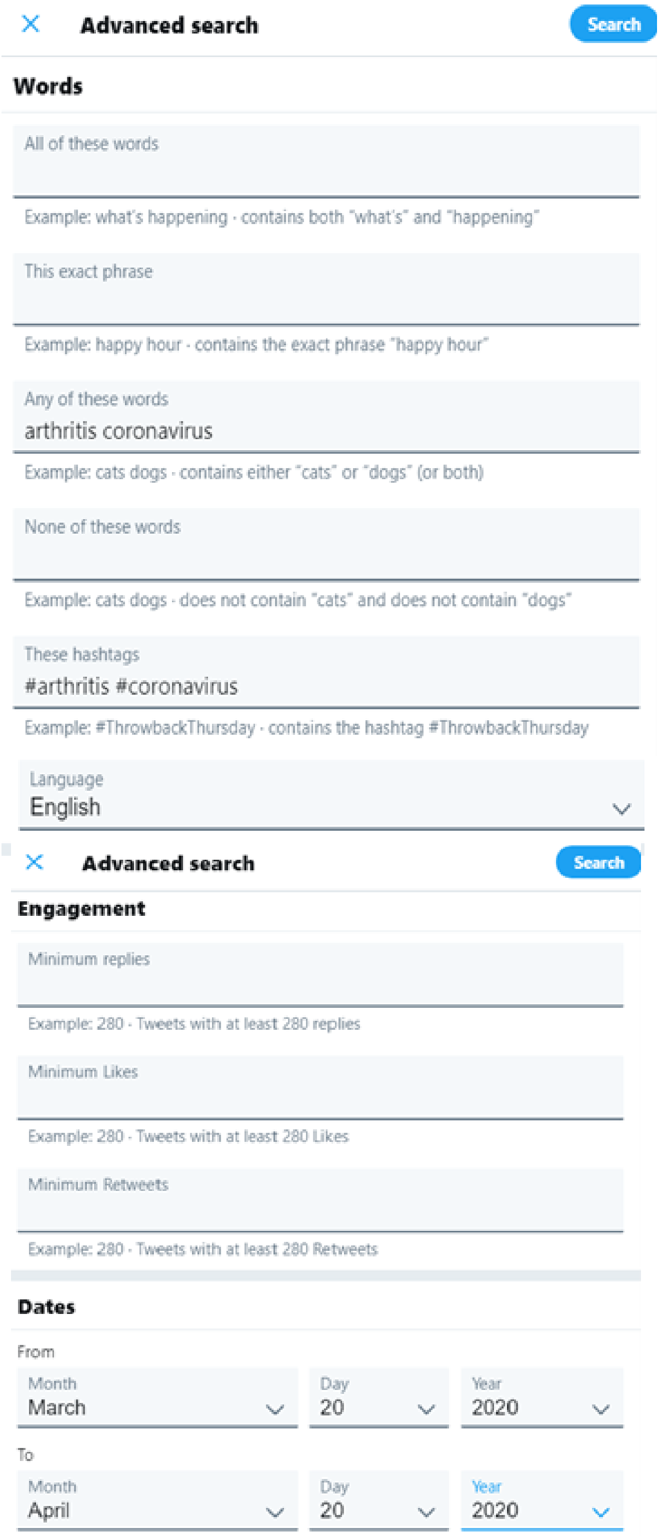
Publicly available tweets posted in English or with English translation (automated through Twitter), with the hashtags shown in Table 1 were included.

Table 1. Hashtags categorized by topic.

Topic	Hashtag
COVID-19	• #coronavirus • #covid19 • #isolation • #socialdistancing
Arthritis	• #arthritis • #spoonie • #rheumatologist • #rheumatology

Hashtags were selected based on trialing various combinations through Twitter's search function. The highest number of tweets retrieved were for the hashtags #coronavirus, #covid19, #arthritis, and #spoonie (the latter term coined by people living with chronic illness to describe various methods of pain management [7]). Hashtags were also searched as words; for example, where #arthritis was searched, arthritis without a hashtag was searched as well. This ensured that specific arthritis types mentioned in tweets without hashtags (eg, rheumatoid arthritis or psoriatic arthritis) were included. Hashtags and words were combined through the advanced search function on Twitter using the domains Hashtags, Words, Language, and Dates (Figure 1 [19]). Tweets were excluded if they originated from organizations, news outlets, or health professionals rather than individuals in order to focus on the personal perspective.

Figure 1. The advanced search function on Twitter [19].



Words

All of these words

Example: what's happening · contains both "what's" and "happening"

This exact phrase

Example: happy hour · contains the exact phrase "happy hour"

Any of these words: arthritis coronavirus

Example: cats dogs · contains either "cats" or "dogs" (or both)

None of these words

Example: cats dogs · does not contain "cats" and does not contain "dogs"

These hashtags: #arthritis #coronavirus

Example: #ThrowbackThursday · contains the hashtag #ThrowbackThursday

Language: English

Engagement

Minimum replies

Example: 280 · Tweets with at least 280 replies

Minimum Likes

Example: 280 · Tweets with at least 280 Likes

Minimum Retweets

Example: 280 · Tweets with at least 280 Retweets

Dates

From

Month: March
Day: 20
Year: 2020

To

Month: April
Day: 20
Year: 2020

Data Collection

Tweets were retrospectively extracted from March 20 to April 20, 2020. The search strategy and search results are included in Multimedia Appendix 1. The search timeframe was chosen to align with the early phase of the COVID-19 pandemic and the period when many developed countries (eg, the United States, the United Kingdom, Italy, Australia) announced enforceable physical distancing or isolation measures [20-23].

The desktop version of the Twitter website (versus the mobile app) was used for data collection for ethical purposes with only publicly available tweets extracted, rather than through a private login. In addition to the tweets themselves, accompanying data fields were extracted from each tweet using a customized template. Extracted data fields included (where possible): Twitter profile blurb, gender of tweeter, country of tweeter, number of likes, number of retweets, number of replies, hashtags used, number of hashtags, and use of accompanying photos.

Data were stored in a Microsoft Excel spreadsheet (v16.0, Microsoft Corp).

Data Analysis

To address the research aims, two data analysis techniques were utilized: summative content analysis and sentiment analysis. Content analysis was used to characterize the textual contents of tweets related to arthritis and COVID-19. Content analysis is exploratory; it aims to quantify and describe unknown phenomena [24]. During the content analysis process, the primary researcher (DB) read each tweet and categorized the tweets into a representative theme and subtheme related to a topic of importance for people with arthritis during the study period.

Summative content analysis occurred through a process of coding, which involved counting and comparisons of Twitter content, followed by interpretation of the underlying context [25]. To begin with, the first 10 tweets were analyzed and allocated a summary code. The code represents the theme of a tweet (eg, “health care experiences”). As additional tweets were examined, they were given one of the original codes or allocated a new code based on new content. This process was repeated until each tweet was coded and themed. Once these original themes were finalized, they were recoded for additional context, and a second researcher (DA) checked the coding. For example, “health care experiences” was coded for similarities in people’s health care experiences, such as difficulties accessing medications. Given Twitter’s character limits, each tweet only contained one theme. The frequency of original themes and subthemes was counted to indicate importance [26].

Sentiment analysis enables an examination of written and spoken words for positive and/or negative emotion. When applied to health care or social media research, sentiment analysis facilitates interpretation of textual information about patient experience from a person-centered perspective [27]. Once tweets were coded and categorized into themes, sentiment analysis was employed to assess the emotion associated with the theme using Glaser and Strauss’s [28] 6 codes for sentiment analysis, a common framework used for Twitter-based research [29,30]:

1. No sentiment: the tweet has no emotion or words or special punctuation; is matter-of-fact sounding;
2. Wretched: the tweet is purely negative;
3. Bad: the tweet contains mainly negative phrases and words that outweigh any positive sentiment;
4. So-so: the tweet has a mediocre and balanced sentiment where positive and negative statements are balanced;
5. Swell: the tweet contains mainly positive phrases and words which outweigh negative sentiment;
6. Great: the tweet is purely positive.

The presence of emojis, which are shorthand facial expression symbols that are frequently used to facilitate communication of mood and emotion, in tweets were also analyzed. To provide information regarding the emotional content of the tweets, Emoji Sentiment Ranking, as outlined by Kralj Novak et al [31], was applied. Tweets containing an emoji were categorized into one of three sentiment scores: (1) negative, (2) neutral, and (3) positive. Together, the content and sentiment analyses provide a proxy indicator of the topics of interest for, and perceived emotions of, people with arthritis during the COVID-19 pandemic.

Even in social media studies, it is imperative to protect participant anonymity [32]. To avoid reverse identification of participants based on their tweets (which can be found through internet searches), tweets analyzed in this study are not quoted verbatim. Instead, all data are expressed in aggregate form through descriptive statistics and qualitative syntheses.

Results

The analysis included 149 tweets posted during the study period. The majority of tweeters were female and based in the United States. The most common arthritis type was rheumatoid arthritis. Table 2 outlines gender, country of residence, and arthritis type.

Table 2. Demographics of Twitter users sampled.

Characteristic	Users (N=149), n (%)
Gender	
Female	105 (70.0)
Male	31 (21.0)
Unknown	13 (9.0)
Country	
United States	68 (45.5)
United Kingdom and Northern Ireland	39 (26)
Canada	18 (12.0)
Australia	1 (0.7)
France	1 (0.7)
Germany	1 (0.7)
India	1 (0.7)
New Zealand	1 (0.7)
Unknown	19 (13.0)
Diagnostic category	
Arthritis (specific arthritis type unclear)	86 (58.0)
Rheumatoid arthritis	32 (21.0)
Systemic lupus erythematosus	12 (8.0)
Psoriatic arthritis	10 (7.0)
Ankylosing spondylitis	3 (2.0)
Osteoarthritis	3 (2.0)
Juvenile idiopathic arthritis	3 (2.0)

Content analysis revealed seven themes from the tweets: (1) health care experiences, (2) personal stories, (3) links to or advertisements of relevant blogs, (4) discussion of arthritis-related symptoms, (5) advice sharing, (6) messages of positivity, and (7) stay-at-home messaging. Table 3 details the original themes and subthemes.

Table 3. Content analysis of themes and subthemes.

Theme and subthemes	Tweets, n (%)	Examples of phrases or #hashtags describing content
Health care experiences	55 (37.0)	• "I'm a long-term user of #hydroxychloroquine"
Difficulties accessing hydroxychloroquine	20 (36.5)	• "#Hydroxychloroquine destroyed my red blood cells"
Past experiences using hydroxychloroquine	20 (36.5)	
Support for President Trump's advice to use hydroxychloroquine to cure COVID-19	9 (16.0)	
Experiences within the National Health Service (UK NHS)	4 (7.0)	
Managing medication changes during COVID-19	2 (4.0)	
Personal stories	29 (20.0)	• "My rheumatologist has asked that I go into isolation. Now all I can do is enjoy the world from my window"
Explanation of history of managing arthritis, and subsequent fears of contracting or dying from COVID-19	9 (31.0)	• "My immune system is compromised but I'm being told to go to a germy hospital???"
Description of ways to self-manage physical symptoms (eg, exercising, staying connected with friends)	7 (24.0)	
Physical and psychological challenges of socially distancing	7 (24.0)	
Perceived barriers to attending rheumatologist appointments (eg, discomfort of wearing masks, fear of entering a high-risk location)	6 (21.0)	
Links to or advertisements of relevant blogs and forums	22 (14.0)	• "To our members, subscribers, followers, and fans: we are here for you. #BeSafe"
Recommendations and links from individuals to official patient- and consumer-led blogs (eg, CreakyJoints)	10 (45.0)	
Personal blogs on individual COVID-19 experiences (eg, how to manage worsening symptoms)	7 (32.0)	
Unofficial patient blogs (eg, online communities and forums) to create support networks for individuals	5 (23.0)	
Discussion of arthritis-related symptoms	15 (10.0)	• "Anyone else's arthritis flaring due to extra phone use?"
Increased physical pain	11 (73.5)	
Difficulty sleeping	2 (13.5)	
Reduced dexterity	2 (13.5)	
Advice seeking and sharing	14 (9.0)	• "Any suggestions for chronic pain sufferers? Coronavirus has been very rough #arthritis #spoonie"
Questions directed at government bodies (eg, the NHS and national working-from-home regulations)	5 (36.0)	• "Do we know if those of us with autoimmune conditions (arthritis) have a higher risk from #coronavirus"
Seeking advice from physiotherapists on at-home exercises to manage physical symptom burden	3 (22.0)	
Advice on whether to temporarily cease taking immunosuppressant medications	2 (14.0)	
Advice on how to protect airways if dexterity limitations prevent mask-wearing	2 (14.0)	
Questions directed to delivery services regarding delays	2 (14.0)	
Messages of positivity	8 (6.0)	• "It's amazing how motivating isolation can be! On my bike but knee sore #arthritis"
Gratitude for friends, family, and to still be able to appreciate life	4 (50.0)	
Spare time as a result of physical distancing facilitating more time to exercise and reduce physical symptom burden	4 (50.0)	
Stay-at-home messaging	6 (4.0)	• #stayathome
Emotional appeals for people to stay at home	4 (67.0)	• #arthritissucks
Angry appeals for people to stay at home	2 (33.0)	• #arthritiswarrior

The most common theme identified was experiences of navigating the health care system during the COVID-19 pandemic. Hydroxychloroquine (brand name Plaquenil) featured prominently in tweets, in terms of difficulties accessing the medication, past experiences using the medication, and recommendations from the President of the United States to use this medication to cure or prevent COVID-19, despite the lack of evidence or medical advice. Some individuals tweeted about their experiences within the National Health Service (NHS) in the United Kingdom, where patients were subject to longer-than-usual delays for rheumatology appointments, medication infusions, and general health check-ups.

Many individuals used Twitter as a platform to connect with and seek support from peers with arthritis. Tweets contained personal stories, links to personal and consumer-led blogs, discussion of arthritis-related symptoms, and advice seeking and sharing. Some individuals shared their challenges managing arthritis symptoms whilst being confined to their homes and questioned their physical and psychological capacity to function if they were to contract COVID-19. Others described the physical and emotional challenges associated with isolation, including increased physical pain, reduced dexterity, and missing family. Strategies to manage these symptoms included exercising and staying socially connected online with friends to ease mental strain. Tweeters were willing to guide others to potentially helpful resources, particularly blogs run by professional organizations (eg, CreakyJoints, the Arthritis Society [Canada]). Several tweets contained questions were directed toward government bodies (eg, regarding national working-from-home policies), whereas others reached out to physiotherapists or peers with arthritis for advice on appropriate exercises or lifestyle modifications to manage symptom burden during the isolation period. Some tweeters noted dexterity limitations that were highly relevant to COVID-19, such as being incapable of placing a mask behind their ears.

Some tweets were positive with tweeters noting they used their newfound spare time to concentrate on exercise, which was beneficial for mental health and pain reduction. Finally, some individuals expressed their desire for people to stay at home to flatten the curve of infections to return to normal life. Disapproval was voiced toward those refusing to practice physical distancing, whereas others expressed anger toward people not adhering to stay-at-home orders.

Sentiment analysis provided complementary information about the emotions associated with the content analysis themes. Table 4 details the original themes and corresponding sentiment, with phrases or hashtags describing tweeters' personal experiences.

Table 4. Sentiment analysis of tweets.

Original theme and sentiment[a]	Tweets, n (%)	Examples of phrases or #hashtags
Health care experiences	55 (37.0)	
Great	5 (9.0)	“doddle,” “virus gone in 3 days,” “NO SIDE EFFECTS,” “credible and good”
Swell	3 (5.0)	“thankful,” “it must be working,” “don’t be afraid”
So-so	8 (15.0)	“hope it helps,” “minimal risk,” “might work,” #BeWarnedBeWell, “it might fight COVID-19,” “take care world!” “interesting to see”
Bad	6 (11.0)	#plaquenilshortage,” “no tests will be done for 2 months,” “facing shortages,” “no proof #Hydroxychloroquine makes us safe”
Wretched	28 (51.0)	“seriously ill,” “madness,” “pissed off,” #coronavirushoax, #painsomnia, “f*ck all chance,” “made me sick,” “I could die,” “harmful results,” “side effects unbearable,” “I call bullsh*t,” “[medication] shortages & living with symptoms,” #EVIL!!, “shorten my life,” “life threatening for us,” “true danger,” “scared,” “fear a shortage,” #drugshortage, “will end up in hospital,” “write us all off,” “it made me so sick,” “NO real testing,” “it’s not safe”
No sentiment	5 (9.0)	“research says,” “UK government wants,” “prove hypothesis,” “IL-6 is raised,” “from the CDC”
Personal stories	29 (20.0)	
Great	5 (17.0)	“all good during this #covid19,” “it makes me feel better on a personal level,” “bring it on world,” “I am a champion!” #livingmybestlife
Swell	5 (17.0)	#AloneTogether, #nevergiveup, #hope, #makethebestofit, “trying to keep active”
So-so	3 (10.0)	“it is what it is,” “I hope they have a lot of masks and sanitizer!”
Bad	2 (7.5)	“I didn’t want to risk heading out,” “limiting my usual walk”
Wretched	12 (41.0)	“give us a break, FFS!” #HighRiskCovid19, “I hate #Coronavirus,” “literally a pain,” “holy sh*t,” “screaming into the void,” “I am not #expendable,” “being told to go to a germy hospital,” “my chances of surviving #covid19 are horrible,” “vulnerable patients like me”
No sentiment	2 (7.5)	“info is changing daily,” “I’m immunocompromised because”
Links to or advertisements of relevant blogs and forums	22 (14.0)	
Great	1 (5.0)	“so grateful”

No sentiment	1 (17.0)	#GoHomeStayHome

[a] Great: the tweet is purely positive; swell: the tweet contains mainly positive phrases and words that outweigh negative sentiment; so-so: the tweet has a mediocre and balanced sentiment where positive and negative statements are balanced; bad: the tweet contains mainly negative phrases and words that outweigh any positive sentiment; wretched: the tweet is purely negative; no sentiment: the tweet has no emotion or words or special punctuation and is matter-of-fact sounding.

[b] Not available.

A few tweets contained messages of positivity. While overall "keeping positive [was] a challenge," some people encouraged others to "enjoy the little things" and that "life is too short to be scared." Still, the extent to which people with arthritis were concerned for their health was evident in people's stay-at-home messaging. Tweeters were notably anxious and angry, writing that "#arthritissucks so stay the f*ck home," that "coronavirus could kill me #StayHomeSaveLives," and "#PLEASESTAYHOME I'm devastated."

Using Glaser and Strauss's [28] classifications, more than half of the tweets contained wretched (purely negative) or bad (mainly negative) sentiment (n=83, 56%), whereas only one-fifth of tweets contained great (purely positive) or swell (mainly positive) sentiment (n=27, 18%). In total, 16 (11%) tweets contained sentiment that was so-so (balanced negativity and positivity), and 22 (15%) tweets contained no sentiment (matter-of-fact sounding).

Individuals in the United States appeared particularly despondent regarding their health care experiences during the COVID-19 pandemic. When referencing interactions with the health care system, tweets contained phrases such as "true danger," "seriously pissed off," and "scared." Tweeters noted "it's not safe" for people with arthritis facing hydroxychloroquine shortages, and that the #drugshortage was "life threatening." Some individuals mused that there is "minimal risk" trying hydroxychloroquine to cure COVID-19, and that it might be "interesting to see" the results of this medication. Outside of the United States, Canadians tweeted that engaging with the health care system during the pandemic was a "doddle" and that they were "thankful" to continue to have access to their health professionals.

Many individuals described their personal stories negatively. People with arthritis discussed barriers to accessing care, such as being surprised at "being told to go to a germy hospital" and that they "didn't want to risk going out." Tweets with links to blogs were accompanied by captions "fear of dying," "unpredictability and fear," and "we worry about everyone." Some were more positive, encouraging followers that they are "hoping to support others." Although their representation was small, people with arthritis in Ireland and New Zealand viewed the isolation measures as an opportunity for #hope, encouraging others to #makethebestofit and to #nevergiveup.

A consistent sentiment was that people with arthritis were negative in their discussion of physical and psychological symptoms, with many individuals seeking advice from peers and health professionals to remedy symptoms. Tweets highlighted the spectrum of symptoms that individuals experienced during the pandemic, with people “struggling to sleep/be active,” experiencing “worsening arthritis pain,” and having “pain in the knees.” Some noted that attempting to manage physical symptoms while in isolation was “literally a pain” and that the psychological toll was like “screaming into the void.” One tweeter mentioned that their arthritis was “flaring due to extra phone use,” which was frustrating since this was a primary method of maintaining social connection and communication with family or colleagues during the pandemic. Similarly, individuals tweeting and asking for advice did so by prefacing that “things have been rough,” that they have “zero immune system,” and that they are “so stressed about #coronavirus.”

Our sentiment analysis included an overview of emoji use in tweets, as summarized in Table 5.

Table 5. Sentiment analysis of emoji use in tweets.

Emoji[a]	Count, n	Emoji name	Phrases or #hashtags accompanying the emoji	Emotion	Link to original themes
	3	Face with no good gesture	“my feet are burning,” things are very painful,” “my chances of surviving are horrible”	Negative	Discussion of arthritis-related symptoms, personal stories
	2	Clapping hands sign	“my team have worked so hard,” “massive thanks”	Positive	Links to or advertisements of relevant blogs and forums, advice seeking
	2	Smiling face with smiley eyes	“hope it helps all”	Positive	Health care experiences
	2	Confused face	“I might be screwed,” “I think my consultant is wrong”	Negative	Health care experiences, discussion of arthritis-related symptoms
	2	Person with folded hands	#lupuswarrior	Positive	Personal stories, health care experiences
	2	Red heart suit	“hoping to support others,” #BeSafe	Positive	Links to or advertisements of relevant blogs and forums
	2	Purple heart	“choose to spread awareness”	Positive	Personal stories
	1	Crying face	“#coronavirus has opened my eyes”	Neutral	Health care experiences
	1	Smirking face	“#makingthebestofit	Positive	Personal stories
	1	Fisted hand sign	“I’ve got a morphine patch on to help”	Positive	Personal stories
	1	Face with tears of joy	“happy sitting in the sun”	Positive	Messages of positivity
	1	Leaves fluttering in the wind	“I’m laying outside”	Positive	Personal stories
	1	Face with mouth open	“could potentially lead to the cure for #Coronavirus”	Positive	Health care experiences
	1	Winking face	“I made healthy Easter treats in self isolation”	Positive	Personal stories
	1	Pill	“I really miss anti-inflammatories”	Negative	Stay-at-home messaging
	1	Front-facing baby chick	#livingmybestlife	Positive	Personal stories
	1 each	See-no-evil monkey, speak-no-evil monkey, hear-no-evil monkey, monkey, monkey face	“my rheumatologist said I wasn’t at high risk”	Positive	Health care experiences

[a] Emoji Sentiment Ranking did not include the upside-down face, the spectacle face, or the high-five emoji. There was one of each included in our data collection.

The emoji within tweets established tone and emphasized emotions. Most tweets used an emoji to express positive sentiment, such as clapping hands to thank colleagues for their support and a person with folded hands in acknowledgment of the personal commitment to the ongoing management of arthritis symptoms in isolation. The main emoji used to express negative sentiment were the face with “no good” gesture, and the confused face. Tweeters used the face with “no good” gesture to highlight their physical pain, and the confused face was used to express confusion around what arthritis patients perceived to be ill-informed health advice during the pandemic.

Discussion

Principal Findings

This study aimed to identify proxy topics of importance for people with arthritis during COVID-19 by characterizing the textual content and sentiment of tweets, and exploring the emotional context of tweets by people with arthritis during the early phase of the pandemic. We anticipated that this novel approach would ascertain contemporary topics of importance for immunocompromised and isolated individuals. Content analysis revealed seven themes relating to health care experiences, and sentiment analysis revealed that the majority of tweets contained negative emotion, particularly around medication shortages, increased arthritis symptoms, and the physical and mental toll of physical distancing or living in isolation. Our findings provide a starting point for understanding the impacts of COVID-19 on vulnerable arthritis populations and provide some insights for physicians and researchers regarding current concerns that may inform tailored care.

More than one-third of tweets discussed health care experiences, primarily focusing on the reduced availability of hydroxychloroquine. Individuals were highly anxious about hydroxychloroquine shortages after preliminary research found that the drug might act as a potential preventive measure, or possible cure, for COVID-19 and these early findings were highly publicized around the world. The original published article has since been retracted after researchers were unable to verify the reliability of their results [33]. Regardless, President Trump tweeted his support for hydroxychloroquine as “one of the biggest game changers in the history of medicine” [34], causing panic about medication shortages, particularly from those with systemic lupus erythematosus for which it is the first-line therapy [35]. Due to off-label prescriptions and hoarding practices, difficulties accessing hydroxychloroquine have been reported globally [36]. Hydroxychloroquine shortages pose a threat to the health and safety of people with inflammatory arthritis, with reports that many will experience flare-ups and may develop irreversible organ damage without their regular dose [35]. Our findings highlight the need for accurate information about treatments and their effectiveness and the critical role that clinicians play in dispelling myths and inaccuracies during times of rapidly changing information. A growing body of literature describes the potential benefits of using Twitter in clinical settings, and reports ways that clinicians are using platforms such as Twitter to communicate health information to the broader population [37-39]. In the context of infectious diseases in particular, evidence suggests that Twitter is beneficial to translate real-time clinical information [40,41]. Use of Twitter, being a component of mobile health (mHealth), also empowers patients to more positively perceive their abilities to manage chronic illness [42]. This presents an opportunity for clinicians and professional societies to use social media platforms such as Twitter to overcome evidence dissemination methods (eg, peer-reviewed articles and care guidelines) that are traditionally slow. Together, clinicians and patients can contribute to care in adults with arthritis, encouraging positive health outcomes throughout, and beyond, the pandemic.

Several tweets contained very personal narratives that highlighted individual fears of contracting COVID-19, and the challenges associated with being vulnerable to infection. Individuals described perceived barriers to accessing care, citing discomfort caused by wearing medical-grade personal protective equipment. Tweets contained accounts of neck pain attributed to wearing a mask; a documented side effect in other vulnerable populations [43]. Fitting a mask is also a dexterous task that some people with arthritis struggled to perform, and as a result, encountered abuse from others when buying groceries or going for a walk. The long-term psychosocial impact of this stigma should receive consideration in future research. Clinicians should consider COVID-19–related functional concerns for physically impaired patients, and incorporate new aspects of information-seeking into clinical consultations. For example, asking patients about their degree of difficulty with COVID-19–related functional tasks would help to elicit relevant functional challenges faced by people with arthritis and inform the provision of tailored patient education. Asking these questions also contributes to factors beyond patient education and care, such as facilitating access to nonacute symptom or pain management services such as allied health. These health services still need to be maintained during and after the pandemic, and for musculoskeletal health in particular, there is emerging commentary around the physical and psychosocial impacts of inhibited access [44,45].

Tweets detailed marked increases in general physical symptom burden; a concerning prospect as COVID-19 has impacted face to face consultations, with indications that disruptions to traditional service models will likely persist for some time. Evidence about the utility of telemedicine to manage pain is emerging, with consideration of barriers to implementation, and potential inequity in access [46], although health systems have been generally slow to implement this approach at scale. While the included tweets provide preliminary information about the growing symptom burden during the pandemic, the collection of systematic patient-reported outcomes data is needed to ensure that health care services are meeting the needs of people with arthritis during and after the COVID-19 pandemic.

A proportion of tweets related to social connection, that is, people reaching out to likeminded peers with arthritis through potentially informative blogs. Most links provided were to official (eg, CreakyJoints) or unofficial (eg, online communities and forums) blogs and provided information on how to manage physical and mental health in isolation, a range of arthritis-appropriate exercises, and existing evidence on the association between arthritis and risk of COVID-19 infection. Access to resources that are relevant, credible, and trustworthy appears to have been challenging for people with arthritis throughout the pandemic [47], and combined with high levels of misinformation online [48,49], this may account for the recent growth of platforms such as Twitter for sourcing information and advice.

Before the COVID-19 pandemic, people with arthritis primarily used social media for self-expression and positive messaging [50,51]. Our sentiment analysis (enhanced by classifying emojis to further characterize common emotions) demonstrates that the role of Twitter has evolved throughout the current pandemic to act as a space for people to share symptoms; to reach out to peers, organizations, and health professionals for information; and to create a sympathetic community of care. This is advantageous as it fosters connection between individuals with shared experiences but conversely may enable proliferation of misinformation [52]. Already, Twitter has been shown to inform clinical practice by capturing the experiences of patients with multiple sclerosis during the pandemic [53]. Understanding the COVID-19–related concerns of people with arthritis is also key to providing person-centered care and reducing distress during these rapidly changing times.

Strengths and Limitations

The observational exploratory nature of this study enabled us to examine topics of importance for individuals with arthritis through a person-centered lens, without ethical issues or compromising the well-being of immunocompromised patients during the pandemic. Social media research is still in its infancy, and this novel method of data collection demonstrates the concerns of people with arthritis during a time of peak anxiety. There is some indication that tweeters were representative of the general inflammatory arthritis population; the majority were female and the most common arthritis type identified was rheumatoid arthritis. Nearly half (44.0%) of tweeters were based in the United States, which currently leads the world in COVID-19 cases and deaths [54].

We also acknowledge the research limitations. It is important to note that only 15% of adults regularly use Twitter, and that younger adults and minority communities tend to be more highly represented on Twitter than the general population [55], although minority communities have been significantly impacted by COVID-19 [56,57]. Our results should therefore be interpreted as representing a small subset of people with arthritis, and not all people with the disease. Data were extracted rather than collected directly from people with arthritis and critics of social media research purport that posts or tweets are often curated and may not be reflective of reality. We have attempted to minimize this potential bias by conducting sentiment analysis, which helped us determine the emotional tone associated with Twitter content. Regardless, sentiment analysis has its limitations: populations and individuals are constantly stimulated by their political and socioeconomic surroundings and individual demographics, which can influence the content and sentiment of people's tweets [58,59]. We also recognize the potential limitations of our search strategy (eg, we did not search for hashtags related to specific symptoms, such as pain or function, that are not unique to arthritis) that may have impacted the number of retrieved tweets. While we had a modest sample size of tweets due to our focused study aims, sentiment analysis has previously been conducted in studies with comparable sample sizes of tweets (n=260 and n=200) [60,61]. We were unable to determine the specific diagnostic category for over half the people tweeting; while a small number of tweets were from people with osteoarthritis, it is possible that more may be represented within the "diagnosis not specified" category. We were only able to analyze tweets in English, and these largely came from high-income, developed countries. Tweets in other languages and those from people in low-and-middle income countries may provide further insights, especially where the prevalence of COVID-19 infection is high [62].

Conclusion

This study highlights the spectrum of concerns facing people with arthritis during the COVID-19 pandemic. By exploring the content and sentiment of recent tweets, we found that individuals with arthritis conditions experience marked anxiety about medication shortages and increased physical symptom burden, and are seeking connection with and information from peers. These findings can be used to raise awareness of key issues relevant to people with arthritis during the pandemic, and to guide clinicians to tailor care that addresses the specific concerns and needs of their patients during the pandemic.

Abstract

Background: The emergence of SARS-CoV-2, the virus that causes COVID-19, has led to a global pandemic. The United States has been severely affected, accounting for the most COVID-19 cases and deaths worldwide. Without a coordinated national public health plan informed by surveillance with actionable metrics, the United States has been ineffective at preventing and mitigating the escalating COVID-19 pandemic. Existing surveillance has incomplete ascertainment and is limited by the use of standard surveillance metrics. Although many COVID-19 data sources track infection rates, informing prevention requires capturing the relevant dynamics of the pandemic.

Objective: The aim of this study is to develop dynamic metrics for public health surveillance that can inform worldwide COVID-19 prevention efforts. Advanced surveillance techniques are essential to inform public health decision making and to identify where and when corrective action is required to prevent outbreaks.

Methods: Using a longitudinal trend analysis study design, we extracted COVID-19 data from global public health registries. We used an empirical difference equation to measure daily case numbers for our use case in 50 US states and the District of Colombia as a function of the prior number of cases, the level of testing, and weekly shift variables based on a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R.

Results: Examination of the United States and state data demonstrated that most US states are experiencing outbreaks as measured by these new metrics of speed, acceleration, jerk, and persistence. Larger US states have high COVID-19 caseloads as a function of population size, density, and deficits in adherence to public health guidelines early in the epidemic, and other states have alarming rates of speed, acceleration, jerk, and 7-day persistence in novel infections. North and South Dakota have had the highest rates of COVID-19 transmission combined with positive acceleration, jerk, and 7-day persistence. Wisconsin and Illinois also have alarming indicators and already lead the nation in daily new COVID-19 infections. As the United States enters its third wave of COVID-19, all 50 states and the District of Colombia have positive rates of speed between 7.58 (Hawaii) and 175.01 (North Dakota), and persistence, ranging from 4.44 (Vermont) to 195.35 (North Dakota) new infections per 100,000 people.

Conclusions: Standard surveillance techniques such as daily and cumulative infections and deaths are helpful but only provide a static view of what has already occurred in the pandemic and are less helpful in prevention. Public health policy that is informed by dynamic surveillance can shift the country from reacting to COVID-19 transmissions to being proactive and taking corrective action when indicators of speed, acceleration, jerk, and persistence remain positive week over week. Implicit within our dynamic surveillance is an early warning system that indicates when there is problematic growth in COVID-19 transmissions as well as signals when growth will become explosive without action. A public health approach that focuses on prevention can prevent major outbreaks in addition to endorsing effective public health policies. Moreover, subnational analyses on the dynamics of the pandemic allow us to zero in on where transmissions are increasing, meaning corrective action can be applied with precision in problematic areas. Dynamic public health surveillance can inform specific geographies where quarantines are necessary while preserving the economy in other US areas.

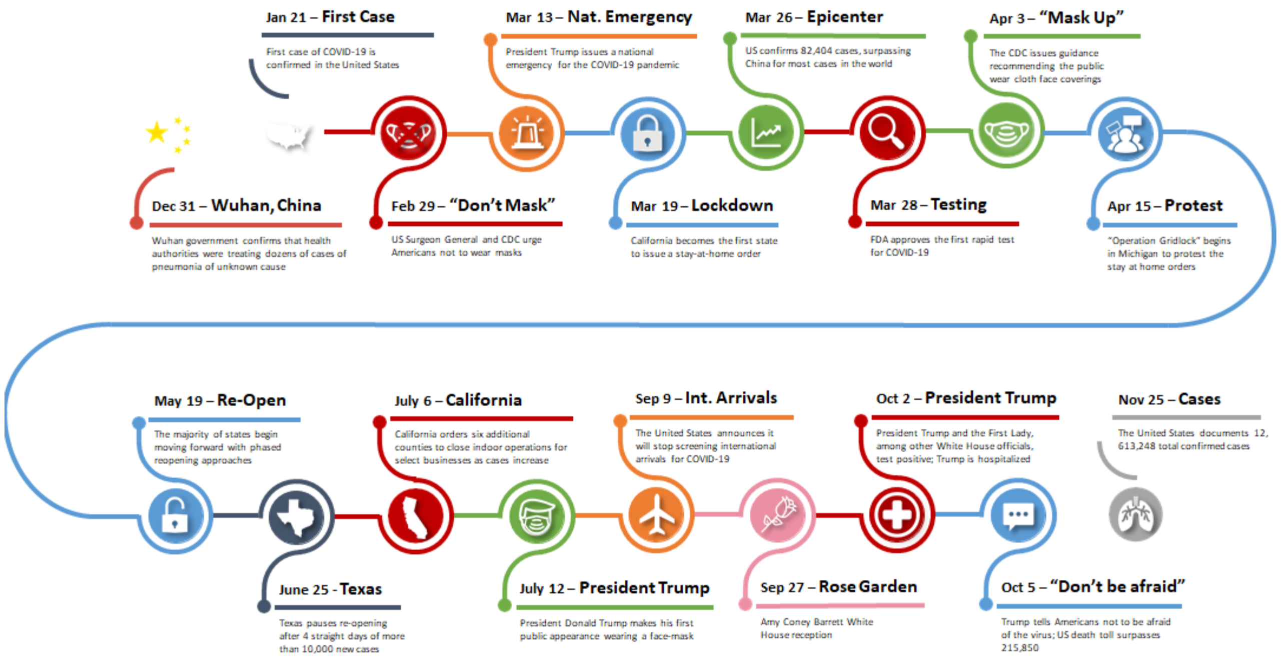
Introduction

Background

The emergence of SARS-CoV-2 in 2019 led to its associated disease, COVID-19, becoming one of the most severe and widespread disease outbreaks in modern history [1]. On January 21, 2020, the first confirmed case of COVID-19 was recorded in the United States (see Figure 1) [2]. Over the next 2 months, cases spread worldwide at an alarming rate, leading the World Health Organization on March 11, 2020, to officially recognize COVID-19 as a pandemic [3]. Around the world, countries quickly implemented public health policies to mitigate the public health and economic impacts caused by the virus. Nations have had varying levels of success at controlling the transmission of COVID-19 due to numerous political, cultural, economic, and structural factors [4]. By November 13, 2020, the daily number of new COVID-19 cases in the United States reached 177,224, the highest number for any single day recorded since the pandemic began, contributing to the 11,485,176 cumulative cases of people infected by COVID-19 and the 250,029 people who have died from it [5].

Figure 1. Timeline of COVID-19 in the United States. CDC: Centers for Disease Control and Prevention; FDA: Food and Drug Administration.



It is logical that the United States experienced technical difficulties at the beginning of the pandemic because we were dealing with a new virus, a pandemic unprecedented in modern times, and uncharted territory [6], which explains why the United States became the third global epicenter of the pandemic due to a delayed response [7]. It is illogical that the United States continues to underperform every country worldwide in controlling COVID-19 because of our wealth of resources and that we now know the epidemiological risk factors, cultural norms, and politicized public health policies that result in case clustering in the United States [4]. Unfortunately, the current US response to COVID-19 parallels President Wilson's response to the 1918 Influenza Pandemic that killed 675 million Americans because of no national response to control the outbreak, misinformation, unclear communication with the public, and widespread mistrust and panic [8-13].

Public Health Policies and Governance

Without a national plan to control COVID-19, some mayors and governors implemented policies such as public masking mandates, prohibitions on gatherings, school closings, restrictions on commercial activities, and broad social distancing measures in an attempt to "flatten the curve" [1,14,15]. Empirical evidence supports social distancing, quarantines, and wearing masks as a means to stop the transmission of COVID-19 [14,16-18]. Leaders who minimize the pandemic, such as White House Press Secretary Kayleigh McEnany, who stated that rising cases are nothing more than "embers that need to be put out" [19], have fostered a false optimism bias that undermines public health guidelines [20]. Framing adherence to those guidelines as a civil liberties issue discourages safe practices, such as advisories by Trump coronavirus advisor Scott Atlas, who urged Michigan to *rise up* against new COVID-19 policies put in place by Governor Whitmer [21]. Conflicting messaging and politicization of COVID-19 have fueled the pandemic. Although the United States only comprises 4% of the global population, it exceeds 20% of the global COVID-19 caseload [22]. Presently, the world is implementing policies to control the second wave of COVID-19, while the United States is responding to its third wave [23-25].

Research has explained why the Unites States consistently leads the world in COVID-19 cases and how we lost control of the outbreak; however, what has not been widely recognized is the need for ongoing systematic public health surveillance to gain control of the pandemic [26-28]. Surveillance informs prevention efforts and signals whether policies put in place to combat COVID-19 are effective or where outbreaks are occurring unabated [26,27]. There are several excellent sources of surveillance data that enumerate the daily and cumulative number of new infections and deaths, the rates of infections and deaths, as well as moving 7-day averages of infections and deaths [29]. Although these indicators are useful, they also have incomplete case ascertainment [26-28]. Without universal testing, surveillance systems are limited to only those cases that are reported from those who are tested, hence erring toward individuals with more severe symptoms [26-28]. Moreover, traditional surveillance metrics are static and provide a proxy of the pandemic for what already has occurred while omitting the pandemics' dynamics that will inform future effective public health guidelines at the epicenter of outbreaks [30]. Dynamic surveillance allows public health leaders to be proactive rather than reactive, which can prevent novel infections. Without universal testing and a national plan to control the pandemic, public health surveillance is even more essential. Moreover, those leaders concerned with choosing between protecting the public from COVID-19 versus protecting the economy require dynamic public health surveillance to understand which parts of each state can remain open and which must go into quarantine [31-34].

Objective

The objective of this paper is to use static and dynamic surveillance metrics to measure the caseload and dynamics of the COVID-19 pandemic at the national and state level [30,35-38]. The basic question we are trying to inform is: how are we doing this week relative to previous weeks? From a public health perspective, we need to understand if there are more cases per day this week than last week, the number of new cases is increasing from day to day, and the number of day-to-day increases in the number of cases is bigger this week than last week. Additionally, we would like some indicative information about significant shifts in how the pandemic is progressing—positive shifts could be the first indicators of the emergence of a new or recurrent hot spot, and negative shifts could be the first indicators of a successful public health policy.

Methods

This study relies on a longitudinal trend analysis study design to investigate the transmission of COVID-19 at the national and the state level over time. The COVID Tracking Project [39] compiles data found on the web [40] from public health departments, universities, and the media to track COVID-19 [3,29,41-43]. Data for the past several months were accessed from the GitHub repository [44]. This resulted in a balanced panel of all 50 states and the District of Columbia (51 x 46 days = 2346). There were in total 3927 observations used to estimate 46 days of data for US states in this analysis. An empirical difference equation was specified in which the number of positive cases in each state at each day is a function of the prior number of cases, the level of testing, and weekly shift variables that measure whether the contagion was growing faster, the same, or slower than the previous weeks. This resulted in a dynamic panel model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R (The R Foundation for Statistical Computing) [45,46].

Arellano-Bond estimation of difference equations has several statistical advantages: it allows for statistical examination of the model's predictive ability and the validity of the model specification, it corrects for autocorrelation and heteroscedasticity, it has good properties for data with a small number of time periods and large number of states, and it corrects for omitted variables issues and provides a statistical test of correction validity. With these advantages, the method is applicable to ascertaining and statistically validating changes in the evolution of the pandemic within a period of a week or less, such as changes in the reproduction rate. Oehmke et al [28,30] provide a detailed discussion of the methods. Finally, we calculated these indicators to inform public health leaders where to take corrective action at a local level.

To ascertain whether pandemic growth was explosive, we examined whether the acceleration and jerk were positive and if the persistence effect was positive as well as if it was larger than the speed. We examined these indicators week over week for 7 weeks along with the daily caseload. The persistence effect is an indicator for mathematically explosive growth (ie, it indicates if the difference equation has a solution that lies outside the unit circle), but large positive acceleration and jerk as well as persistence are indicative of explosive growth in a practical sense (ie, the COVID-19 caseload is expected to increase much more rapidly than in the current or recent week). However, this is a forward-looking statement and must be interpreted with due circumspection. To discuss potential explosive growth, we looked at five data points including speed, acceleration, jerk, persistence, and daily caseload each week for 7 weeks.

Results

State Regression Results

We present regression results for the panel comprising all 50 US states and the District of Columbia in Table 1. The subsequent weekly surveillance products were based on these regressions.

Table 1. Arellano-Bond dynamic panel data model of COVID-19 dynamics at the state level.

Variable	Values	*P* value
7-day lag, coefficient	1.09	<.001
Cumulative tests, coefficient	0.01	.48
7-day lag shift, coefficient	0.108	<.03
Wald statistic for regression, chi-square (*df*)	13,504 (8)	<.001
Sargan statistic for validity, chi-square (*df*)	48.3 (367)	>.99

The regression Wald statistic was statistically significant (χ^2_8=13,504, *P*<.001). The Sargan test was insignificant, failing to reject the validity of overidentifying restrictions (χ^2_{367}=48.3, *P*>.99).

The coefficients on the 7-day lag were both positive and statistically significant (*P*<.001), demonstrating that the number of infections 1 week prior to data collection had a significant effect on number of infections at the point of data collection. Cumulative tests also had a slightly positive but insignificant effect (coefficient 0.01, *P*=.48). The shift parameter 14 days ago was positive and significant (coefficient 0.108, *P*<.03), suggesting that exogenous shift events had a positive effect on cases.

Interpretation: Regression Results

The lagging indicators and shift parameters suggested recent change in disease transmission in the United States between September 28 and November 15, 2020. Specifically, the most recent 7-day lag this week was 10% faster than last week. The shift in the most recent 14 days, or 2 weeks, was positive and significant (*P*<.03).

Surveillance Results

Table 2 demonstrates the dynamics of the pandemic for the leading six states in speed, acceleration, jerk, 7-day persistence, and 7-day moving average over the course of the 7-week study beginning on September 28 and ending November 15, 2020. Table 2 is truncated and only lists the leading six states for our metrics. For a complete view of each state, Multimedia Appendix 1 contains Tables S5-S18 that list the traditional surveillance metrics as well as the dynamic surveillance metrics of speed, acceleration, and 7-day persistence rate.

Although Texas and California ranked in the top six states for daily average of new infections for 7 consecutive weeks, they did not rank high for rates of speed, acceleration, jerk, or 7-day persistence. Florida ranked in the top for daily average of new infections for 6 of the 7 weeks, and in the middle of the study during the week of October 22, 2020, Florida had a positive jerk of 1.9 per 100,000 people, indicating that the pandemic was not just accelerating but accelerating at an increasing rate. North Carolina ranked in the top six states for novel infections for 3 of the 6 weeks but did not rank high for rates of speed, acceleration, jerk, or persistence. Illinois was ranked in the top six states for novel infections all 7 weeks; during the week of November 5, Illinois ranked high in acceleration at 4.0 additional new daily infections per 100,000 people per day, or 28 per week, and had a positive jerk of 2.4 infections per 100,000 people during the same week, indicating that acceleration increased from 1.6 in the prior week to 4.0 the week of November 5.

In Table 2, we examine speed, acceleration, jerk, persistence, and caseload each week for 7 weeks for the top six states for each metric. Dynamic metrics for North Dakota during the 7-week study were alarming with 22 positive data points that indicated explosive growth even though North Dakota never made the top six list of largest case load. North Dakota had the highest rate in the United States in terms of speed of new infections all 7 weeks. The pandemic accelerated 6 of the 7 weeks. The jerk was positive 3 of the 7 weeks. North Dakota had the highest persistence rate all 7 weeks, meaning new cases today were statistically attributable to novel infections a week ago. There was some underlying condition or events that have echoed forward with increasing numbers of new infections each week. During the week of November 12, 2020, North Dakota had the highest speed of infections in the United States at 175 new infections per 100,000 people; measures of acceleration indicated the speed of infections was increasing at 4.9 new daily infections per 100,000 people per day, which over a week cumulates to over 34 more new daily infections per 100,000 people than a week ago. The jerk of 6.5 new infections per 100,000 people indicates that the state moved from a deceleration the prior week to a rapid acceleration the week of November 12. Finally, North Dakota had the highest persistence effect in the United States at an average of 195.3 new infections per day for the week of November 12 that were statistically attributable to infections the prior week. Not only was North Dakota experiencing explosive growth, the surveillance indicators suggested that the outbreak is still strengthening. Corrective action is needed immediately.

South Dakota has 24 positive upward trending data points for speed, acceleration, jerk, and persistence week over week for 7 weeks, indicating explosive growth. South Dakota had the second highest rate of novel infections and persistence in the United States; for 5 of the 7 weeks, North and South Dakota's acceleration and jerk were positive, indicating that the pandemic was strengthening at an increasing rate. Utah has 12 data points in Table 2 of the leading six states in speed, acceleration, jerk, and persistence. During the past week of November 12, 2020, Utah had positive acceleration and jerk. Montana had 17 data points, indicating explosive growth. Montana was a top-six state in speed for 6 of the last 7 weeks, acceleration 3 of the last 7 weeks, and jerk 2 of the last 7 weeks. Utah ranked in the top six states for persistence for 6 of the last 7 weeks.

Arizona is more promising. Although Arizona ranked sixth in the rate of new infections during the week of October 1, 2020, and had a leading persistence rate for the weeks of October 1 and October 8, Arizona does not appear in the leading states in Table 2 afterward. Iowa had six indicators and Idaho and Nebraska each had seven indicators of explosive growth.

Wisconsin had a high caseload, and it was in the top six states for speed, acceleration, and persistence. Wisconsin remained a leader in speed across all 7 weeks and cumulatively had the highest number of new infections per 100,000 people over those weeks. Wisconsin's pandemic accelerated in 3 of the 7 weeks. During the week of October 1, 2020, Wisconsin had a speed of 42.7, and by the week of November 12, 2020, its speed had reached 112.9. Wisconsin ranked as a leading state all 7 weeks for persistence, indicating there was some underlying condition that persisted and echoed forward.

Wyoming showed the largest acceleration over the 7 weeks, with speed accelerating from 19.2 new daily cases per 100,000 people during the week of October 1, 2020, to 125.1 during the week of November 12, 2020.

Table 2 demonstrates the utility of dynamic surveillance metrics because traditional surveillance metrics only report caseloads of each state. Larger states (Table 3) will more likely be captured in those types of metrics, missing the dynamics of the pandemic and missing those states who demonstrate high rates of infection speed, speeds that are accelerating, accelerating speeds that jerk upwards, and those new cases today that are statistically attributable to new cases last week or those new cases with an underlying biological or social condition (eg, attending mass events without face masks or social distancing), that is, echoing forward and leading to additional infections.

Table 3. Most populous US states.

State	Population as of 2020
California	39,937,500
Texas	29,472,300
Florida	21,993,000
New York	19,440,500
Pennsylvania	12,820,900
Illinois	12,700,381

Table 4 provides the average of the US states or the US rates for speed, jerk, and 7-day persistence. During the week of October 1, 2020, the speed was positive at 12.91 infections per 100,000 people. In the speed column, for each subsequent week in the study, the speed increased to a maximum speed of 39.38 during the week of November 11, 2020. This explains why the acceleration rate per 100,000 people increased weekly, as acceleration was the measure of increases in speed week over week. In the final column, we see the 7-day persistence begins at 13.99 per 100,000 people during the week of October 1 that are statistically attributed to the number of novel infections 7 days earlier. By the week of November 12, this persistence had increased to 33.62, meaning that 85% of the 39.38 average daily new cases the week of November 12 were statistically attributable to new cases in the prior week. This could happen if, for example, in-restaurant diners last Saturday became infected and then dined in-restaurant again this Saturday and infected other diners, who then eat in-restaurant next Saturday and infect the next cohort, etc. Sequential sports, election, and postelection watch parties could generate the same effect. The novel measures, thus, suggest that a return to stricter guidelines is appropriate for regaining control of the pandemic and were indicated as early as the week of October 22, 2020, which was the third consecutive week of positive acceleration and jerk, and increasing persistence. Weekly trends by state are displayed in Figure 2. See Multimedia Appendices 2-5 for US maps displaying weekly acceleration, jerk, and persistence.

Table 4. US pandemic dynamics.

Date	Speed	Acceleration	Jerk	7-day persistence effect

Discussion

Principal Results

The United States has had an uncoordinated, decentralized response to COVID-19. Although traditional public health surveillance provides a static view of the pandemic, the data are limited by secondary bias from undercounting, reporting delays, testing issues, and other forms of contamination. The novel measures presented in this study take steps toward resolving these shortcomings and measure the dynamics of the pandemic. They also provide greater insight into the evolution of a pandemic, such as where COVID-19 is transmitted and whether rates of transmission are increasing. Measures like 7-day persistence control for incomplete case ascertainment and look retrospectively to understand current infection rates, and speed, acceleration, and jerk provide a dynamic perspective on future cases.

The data presented in Tables S5-S18 in Multimedia Appendix 1 indicate that some states are responding well to the pandemic, while others are responding poorly in the present or suffering from past mistakes. States can be examined systematically to determine their relative performance. At a high level, the static metrics demonstrate national and state burden of disease over a 7-week period. Acceleration and jerk indicate the potential progress of disease burden. A state with a high number of new cases but a negative acceleration and jerk is more likely to have a good trajectory than a state with a high number of cases and a positive acceleration and jerk. The 7-day persistence metric hints at both past decision making and future progress. A state with a high 7-day persistence may have experienced a super-spreader, causing an echo in transmissions to the present and potentially into the future. These echoes may be particularly susceptible to control by identifying the causal event and performing rigorous contact tracing or eliminating the offending behaviors (eg, gatherings without face masks and social distancing).

Overall, the state of the pandemic in the United States is concerning based on static surveillance and dynamic metrics. All 50 states and the District of Colombia have positive rates of new infections. Moreover, the rates of infection are higher and faster than at any other time since the onset of the pandemic.

Why the COVID-19 Response Differs From Previous Infectious Disease Outbreaks?

COVID-19 has been politicized and polarized, flamed by social media and misinformation [47-56]. Scientists have consistently emphasized that a reduction in COVID-19 transmission is predicated on social distancing, quarantines, hand hygiene, crowd control, and wearing masks [14,16,17]. Others weighed COVID-19 safety measures against shutting down the economy to prevent financial hardships that dynamic surveillance can inform. In the absence of policy actions, COVID-19 experienced exponential growth rates of approximately 38% per day [57]. Countries with anticontagion policies significantly and substantially slowed the growth of COVID-19 [57], yet many US states are unable to implement COVID-19 control policies. Finally, since the start of the COVID-19 pandemic, there was confusion about who is “in charge” of the US epidemic response

[58]. Federal government powers do not allow it to impose specific restrictions on states [59]; however, its resources are *vast*, with the ability to develop national guidelines, promote scientific research and vaccine development, and direct resources toward COVID-19 relief [60-62]. Unfortunately, city mayors and state governors must patch together uncoordinated piecemeal COVID-19 control policies [63-65].

Conflicts in Adopting Policy

The US COVID-19 epidemic has rebounded and is accelerating rapidly with multiple outbreaks in most US states, indicating shortfalls in preparedness and a dearth of nonpharmaceutical control measures. Although standard surveillance techniques such as daily and cumulative infections and deaths are helpful, they have incomplete case ascertainment, err on the side of the most severe cases, and provide a static view of what has already occurred during the pandemic, which is less helpful in prevention. Public health policy that is informed by dynamic surveillance can shift the country from reacting to COVID-19 transmissions to being proactive and taking corrective action when indicators of speed, acceleration, jerk, and persistence remain positive week over week. Implicit within our surveillance is an early warning system that indicates when there is problematic growth in COVID-19 transmissions as well as to signal when growth will become explosive without action.

A public health approach that focuses on prevention can prevent major outbreaks in addition to endorsing effective public health policies and may resolve conflict between various government entities. Moreover, subnational analyses on the dynamics of the pandemic allows us to zero in on where transmissions are increasing, meaning corrective action can be applied with precision in problematic areas. Dynamic public health surveillance can inform specific geographies where quarantines are necessary, preserving the economy in other US areas.

Without a unified national policy to address COVID-19, individual cities and states have launched efforts to control the spread of the pandemic. Similar studies have found that states that imposed strict guidelines saw drastic reductions in COVID-19 spread and avoided significant increased case counts and fatalities [66,67].

Discord between New York City Mayor Bill De Blasio and New York Governor Andrew Cuomo has resulted in delays in shutting down new virus hot spots in neighborhoods across New York City [68]. In other states, governors have faced problems passing public health safety measures with proposed legislation ruled unconstitutional by state courts. In early May, the Wisconsin Supreme Court overturned a statewide stay-at-home order put in place by Governor Evers to control rising cases [69]. Wisconsin has since faced a large increase in COVID-19 cases and reports some of the largest numbers of new infections per day. Recently, Governor Whitmer of Michigan also experienced issues with an executive order she passed when the Michigan Supreme Court ruled her statewide mask mandate as unconstitutional [70]. Even within states, some cities have imposed mask mandates on their own accord, while others have refused, leading to different outcomes. In South Carolina, areas with mask mandates reported a 46% greater reduction in COVID-19 case rates than those areas without mask mandates [71]. The Tri-State area of New Jersey, New York, and Connecticut coordinated travel restrictions, public health guidelines, and economic activities [72]. After initial success, four additional states joined to quell the COVID-19 pandemic [73]. These coordination challenges and frictions between levels of government have been observed in other countries as well, including Brazil, India, and Nigeria [74], and can be especially pronounced in settings of vertically divided authority where subnational governments are led by opposition parties. Germany is a notable exception; states have control over their own health systems and each state was able to pursue its own testing without waiting for approval from a national health laboratory—a factor that has been partially credited for the country's swift testing response [75].

Current State of the Pandemic

An important change in the dynamic of COVID-19 transmission occurred starting mid-August when universities and schools around the country started to open for their new academic year [30]. Approximately 53 million US children between the ages of 5-17 years resumed school in fall of 2020 [76]. The CDC confirmed over 2800 COVID-19 cases at the University of Wisconsin within the first month of reopening [77]. Similarly, the University of Missouri has confirmed over 1600 COVID-19 cases among its students since reopening on August 19, 2020 [78]. Reinstating college sports also resulted in novel infections [79].

States such as Wisconsin and Indiana have reported pandemic highs in daily COVID-19 new infection counts [3,80]. As October 2020 began, Utah reported the nation's highest positivity rate [81]. This trend was high throughout September, suggesting a potential dearth in testing that caused an undercount [81]. Florida, which saw a surge increase over the summer, has seen a steady decline in its daily case counts after stricter measures were put in place by the governor; however, these measures have since been lifted [82]. Wisconsin, Iowa, and Utah have not instituted mask mandates and have seen worsening infection counts that have not improved. The four states of greatest concern are Wisconsin, North Dakota, South Dakota, and Illinois. Wisconsin, North Dakota, and South Dakota have multiple data points indicating explosive growth. Wisconsin and Illinois both top the nation in daily new infections and have positive growth rates. California and Pennsylvania have positive speed, acceleration, jerk, and persistence, suggesting the outbreak in these two populous states will be significant in terms of caseload.

Conclusion

The variation in speed, acceleration or deceleration, and jerk between and within states is consistent with varying degrees of compliance with public health guidelines to combat COVID-19 in terms of social distancing, masks, hand hygiene, and crowd control. Some states have overall higher caseloads because they have higher populations, such as California, New York, Illinois, Texas, and Florida, and others have alarming speed, acceleration, and jerk. Nationally, the US COVID-19 epidemic has rebounded and is accelerating rapidly in multiple states, indicating shortfalls in preparedness and a dearth of nonpharmaceutical control measures. Although standard surveillance techniques such as daily and cumulative infections and deaths are helpful, they also have incomplete case ascertainment, err on the side of the most severe cases, and provide a static view of what has already occurred in the pandemic, which is less helpful for future planning. Public health policy that is informed by dynamic surveillance can shift the country from reacting to COVID-19 infections and deaths to being proactive and taking corrective action when indicators of speed, acceleration, jerk, and persistence remain positive week over week.

Implicit within our surveillance is an early warning system that indicates when there is problematic growth in COVID-19 transmissions as well as signals when growth is likely. For example, at the US level, the novel metrics indicated a need for strengthening public health measures as early as the week of October 22, 2020, when the highest numbers of new daily cases were 82,000-84,000 per day. In the absence of these novel metrics, little action was taken until the number of new cases had more than doubled to over 161,934 new cases on November 17, 2020 [5]. At the state level, the indicators suggested that explosive growth occurring in the Dakotas, Wisconsin, and Wyoming could also have been identified in late October. Public health actions taken at that time in those and other states and areas might have significantly reduced the number of new cases and prevented the severe overtaxing of hospital and medical resources that is now happening.

A public health approach that focuses on prevention can prevent major outbreaks in addition to confirming when public health guidelines are effective and controlling the pandemic. Moreover, subnational analyses on the dynamics of the pandemic allows us to zero in on where transmissions are increasing, meaning corrective action can be applied with precision on problematic areas. However, this approach requires subnational, dynamic public health surveillance that can inform specific geographies where lockdowns or other measures are necessary. This paper provides novel surveillance measures that can help fill that exact need.

Limitations

Our data are limited by state-level granularity and differences in testing and reporting within states. State-level granularity, although superior to national reporting, provides less detail than county- or city-level reporting. This limitation is particularly pronounced in states with large urban centers governed by powerful mayors. Testing and reporting varies across and within states for many reasons, including the decentralization of US health care. Both insurers and providers have inconsistent policies in place and resources deployed for COVID-19 testing. To address this need for small area surveillance, we have generated static and dynamic surveillance for larger metropolitan areas in the United States in an additional publication.

Comparison With Prior Work

This study is part of a broader research program at Northwestern Feinberg School of Medicine, The Global SARS-CoV-2 Surveillance Project: Policy, Persistence, & Transmission. This research program developed novel surveillance metrics to include rates of speed, acceleration, jerk, and 7-day persistence [28,30]. We have also derived surveillance metrics for all global regions.

Abstract

Background: The massive scale of social media platforms requires an automatic solution for detecting hate speech. These automatic solutions will help reduce the need for manual analysis of content. Most previous literature has cast the hate speech detection problem as a supervised text classification task using classical machine learning methods or, more recently, deep learning methods. However, work investigating this problem in Arabic cyberspace is still limited compared to the published work on English text.

Objective: This study aims to identify hate speech related to the COVID-19 pandemic posted by Twitter users in the Arab region and to discover the main issues discussed in tweets containing hate speech.

Methods: We used the ArCOV-19 dataset, an ongoing collection of Arabic tweets related to COVID-19, starting from January 27, 2020. Tweets were analyzed for hate speech using a pretrained convolutional neural network (CNN) model; each tweet was given a score between 0 and 1, with 1 being the most hateful text. We also used nonnegative matrix factorization to discover the main issues and topics discussed in hate tweets.

Results: The analysis of hate speech in Twitter data in the Arab region identified that the number of non–hate tweets greatly exceeded the number of hate tweets, where the percentage of hate tweets among COVID-19 related tweets was 3.2% (11,743/547,554). The analysis also revealed that the majority of hate tweets (8385/11,743, 71.4%) contained a low level of hate based on the score provided by the CNN. This study identified Saudi Arabia as the Arab country from which the most COVID-19 hate tweets originated during the pandemic. Furthermore, we showed that the largest number of hate tweets appeared during the time period of March 1-30, 2020, representing 51.9% of all hate tweets (6095/11,743). Contrary to what was anticipated, in the Arab region, it was found that the spread of COVID-19–related hate speech on Twitter was weakly related with the dissemination of the pandemic based on the Pearson correlation coefficient ($r=0.1982$, $P=.50$). The study also identified the commonly discussed topics in hate tweets during the pandemic. Analysis of the 7 extracted topics showed that 6 of the 7 identified topics were related to hate speech against China and Iran. Arab users also discussed topics related to political conflicts in the Arab region during the COVID-19 pandemic.

Conclusions: The COVID-19 pandemic poses serious public health challenges to nations worldwide. During the COVID-19 pandemic, frequent use of social media can contribute to the spread of hate speech. Hate speech on the web can have a negative impact on society, and hate speech may have a direct correlation with real hate crimes, which increases the threat associated with being targeted by hate speech and abusive language. This study is the first to analyze hate speech in the context of Arabic COVID-19–related tweets in the Arab region.

Introduction

Social media platforms such as Twitter provide valuable venues for information sharing, communication, and knowledge production. However, these platforms have also been increasingly exploited for the propagation of hate speech. Hate speech can be generally defined as language that aims to target a specific group on the basis of characteristics such as ethnic origin, religion, or gender [1].

Hate speech on the internet is a complex concept with a wide spectrum of targets, forms, and other related concepts [2,3]. While there is no formal definition of hate speech, there is general agreement among scholars and service providers to define it as any language that attacks a person or a group based on a characteristic such as race, color, ethnicity, gender, sexual orientation, nationality, or religion [3]. This type of discriminatory and hateful speech can have a destructive impact on society, as it threatens the culture of coexistence and unity. It is also evident that hate speech has a strong connection with actual hate crimes [3,4], which increases the risks associated with being targeted by hate speech and abusive language.

In mid-February 2020, the COVID-19 virus pandemic started to penetrate the Arab region physically and virtually, and Arab social media users started talking about the spread of the disease using different platforms. The pandemic became a trending topic that was visible to all users on Twitter within the Arab region. Since then, multiple voices have been raised across social media using the COVID-19 pandemic as a vehicle for spreading hate speech.

The use of social media during pandemics for a variety of public health purposes has been demonstrated in a growing body of literature. One systematic review on social media and emerging infectious diseases identified three major approaches, namely assessment of public opinion, social media use by organizations, and evaluation of information accuracy [4]. Another systematic review on studies that primarily use web-based social networks for pandemic detection and tracking found that social networks have rich information that can be utilized to develop an almost real-time pandemic surveillance system [5]. Other studies have used Twitter and other sources of data to build a surveillance system [6] and develop automatic methods for quantifying the scientific quality and sensationalism of individual news records during the pandemic [7].

During the unfolding COVID-19 pandemic, many research studies have focused on Twitter to characterize the impact of the pandemic on public responses and behaviors. One of these studies analyzed the main topics discussed by Twitter users during the crisis by leveraging techniques such as latent Dirichlet allocation (LDA) and sentiment analysis [8]. Another study found that frequent use of social media during the pandemic contributed to information overload, which had a significant impact on individuals' coping perceptions [9]. In addition, web-based social question-and-answer forums have been analyzed to identify topic communities and asses the appropriateness of the answers during the early stage of the COVID-19 outbreak [10]. Other studies have analyzed Twitter data to understand the impact of COVID-19 on specific public attitudes and behaviors, such as xenophobia [11] and the spread of the 5G conspiracy theory [12]. As discussed in [11], the pandemic has triggered discrimination and stigma toward specific groups on social media. This phenomenon was further explored in [13], with a specific focus on building an automatic tool for detecting hate speech in Spanish tweets related to newspaper articles about the COVID-19 pandemic. The preliminary results showed that 9% of the tweets contained hate speech.

As can be seen, the massive scale of social media platforms requires an automatic solution for detecting hate speech. Such solutions will help reduce the need for manual analysis of content. Most previous literature has cast the hate speech detection problem as a supervised text classification task using classical machine learning methods or, more recently, deep learning methods. However, studies investigating this problem in Arabic cyberspace are still limited compared to the published work on English text.

The aim of this study is to automatically identify hate speech posted by Arabic-speaking Twitter users related to the COVID-19 pandemic using a deep learning approach. We opted to analyze the spread of hate speech on the Twitter platform given its increasing popularity among Arab users [14]. According to [15], nearly 9 out of 10 Arab adults use the internet, and 22% of them use the Twitter platform actively. In Saudi Arabia alone, there are more than 10 million active Twitter users, akin to almost 38% of the population.

Our research objectives are to answer the following research questions: (1) In which Arab country were the most COVID-19–related hate tweets posted during the pandemic? (2) When were the highest number of hate tweets posted in the Arab region during the pandemic? (3) Does the increase in the number of COVID-19 cases or deaths coincide with an increase in the number of hate tweets? and (4) What are the main topics and issues being discussed in hate tweets during the COVID-19 pandemic?

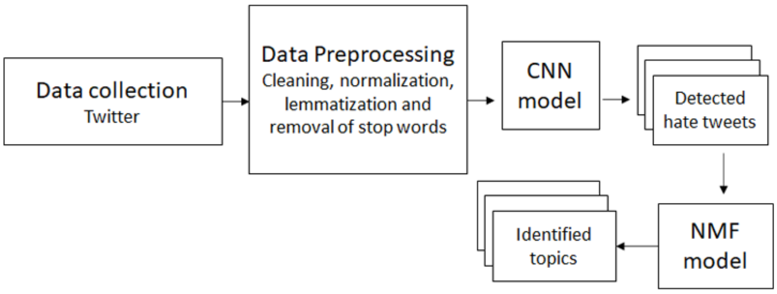
The rest of the paper is structured as follows: the Methods section presents our methods, including a description of the neural network models and the preprocessing steps. In the next sections, we provide the results and discuss them. Finally, we conclude our work and discuss future directions.

Methods

In this study, we aimed to automatically detect hate tweets posted by Twitter users in the Arab region during the COVID-19 pandemic using a deep learning approach and topic modeling.

The workflow of our methodology is depicted in Figure 1. In the following subsections, we describe each step in more detail.

Figure 1. Methodology workflow. CNN: convolutional neural network; NMF: utilized nonnegative matrix factorization.



Data Collection

We used the ArCOV-19 [16] dataset, which is an ongoing collection of Arabic tweets related to COVID-19 starting from January 27, 2020. The tweets were collected using the Twitter search application programming interface (API) to obtain the most popular tweets using different queries, such as simple keywords (eg, *Corona*), hashtags (eg, *#Corona*), or phrases (eg, *novel Coronavirus*). The search was customized to exclude retweets and non-Arabic tweets. At the time of writing this paper, the ArCOV-19 dataset contained almost 1 million popular tweets (ie, tweets that received the maximum social interactions and impressions) collected from January 27 to April 30, 2020. In compliance with the Twitter content redistribution policy, the authors of the ArCOV-19 dataset only released the tweet IDs. Therefore, we recollected the full tweet objects using the *Twarc* library [17], which is a Python library for retrieving Tweets as JavaScript Object Notation (JSON) objects using the Twitter API based on the given IDs. We started the preprocessing pipeline by removing retweets and duplicate tweets that had identical content to reduce the effect of malicious tweets posted by social bots. After that, and due to the inaccessibility of some tweets (deleted tweets or deactivated accounts), the total number of tweets we retrieved was reduced to 975,316.

Data Preprocessing

The retrieved JSON object for each tweet is a mix of many attributes. For this study, we retained the following attributes: tweet ID, tweet text, creation time, user ID, and location. The location field represents the location profile metadata as declared by the Twitter user. However, this field contains free-form text entered manually by the user; hence, this field can be noisy, as users can type anything. Therefore, we needed to resolve the text to an exact location (in our case, a country).

The procedure to extract the country from the location text was as follows. First, for each country in the Arab region, we prepared a list that contains the country names and all possible city names derived from GeoNames [18], a geographical database that contains over 25 million geographical names. After that, each list was translated into Arabic and automatically extended to include different morphological variant forms of the same word. Also, each list was manually modified to include more informal terms and forms that Twitter users frequently use to refer to their countries or cities. For example, Emirati users might type “Dar Zayed” in their location field instead of “United Arab Emirates” or “UAE”, and Kuwaiti users usually write “Q8” instead of “Kuwait”. Also, to minimize the mismatching problem between the prepared list and the location field, we normalized the names in our lists and the location field to reduce orthographical variations; for example, different forms of ”” (“”, “”, and “”) were replaced with “”, while the letter “” was replaced with “” and the letter “” was replaced with “”. After that, we performed several cleaning and denoising steps on the lists and location fields, including the removal of punctuation marks, additional white spaces, and diacritics. Then, to map each text location to a specific country, we checked if at least one of the words in the location text appeared in the list for any country. If it did, the location was resolved to that specific country. For example, if a user typed “Riyadh”, “Najd”, “Jeddah”, or “Saudi”, we resolved this location to “Saudi Arabia.” Finally, we dropped all tweets that belonged to users with no detected location.

To prepare the tweets to be fed as inputs into the convolutional neural network (CNN) classification model and the nonnegative matrix factorization (NMF) model, we firstly applied several preprocessing steps to the text of the tweets. First, we removed punctuation, consecutive words, additional white spaces, and non-Arabic letters. We also replaced emojis with their descriptions for CNN inputs and removed them for the NMF model. We also normalized Twitter-specific tokens by converting the links and mentions to “URL” and “mention,” respectively. After that, various forms of the same word were lemmatized by converting them to the main word using the Farasa tool [19]; finally, we removed stop words from the text.

Hate Speech Detection Using the CNN Model

The processed tweets were analyzed for hate speech using the pretrained CNN model. The CNN model used in this study is based on our previous work [20] in which we addressed the problem of hate speech spread in the Arabic Twittersphere. In this study, a CNN was trained on almost 10,000 tweets that were manually labeled as hate tweets or non–hate tweets. The model contained five layers: an input layer (embedding layer), a convolution layer, which basically consists of 3 parallel convolution layers with different kernel sizes (2, 3, and 4), a pooling layer, a hidden dense layer, and a final output layer that assigned a “hate score” (ranging from 0 to 1) to each text. The results showed that the CNN model achieved the best performance (compared to other models), with an F1 score of 79% and accuracy of 83%. Therefore, we used it in this study.

The analysis was performed on the tweet texts, and each tweet was given a score between 0 and 1, with 1 being the most hateful text. We used the default threshold of 0.5 (or 50%) to classify a prediction with a probability of 0.5 or more as a hate tweet and any value less than 0.5 as a non–hate tweet. We further classified hate prediction into three levels based on score: low (0.50-0.67), average (0.68-0.85), and high (0.86-1.00). The hate tweets were then categorized into three levels (low, colored yellow; average, colored orange; and high, colored red) based on the detected hate scores.

Topic Modeling Using NMF

NMF is an unsupervised approach for reducing the dimensionality of nonnegative matrices [21], and it has been widely used to discover the underlying relationships between texts and identify latent topics [22,23]. In this study, we opted to employ NMF to discover the semantic structure and discussed topics within the set of hate tweets. We particularly chose NMF given its ability to produce more coherent topics than other popular topic modeling techniques such as the LDA model, as shown in this study. We used the sklearn library [24] to implement the NMF model. To apply NMF, we first preprocessed the tweets as described earlier. Then, we created the features by transforming the processed tweets into term frequency–inverse document frequency vectors (unigrams and bigrams).

Results

Model Results

As mentioned, the first step in the hate speech analysis was to analyze the processed tweets using the pretrained CNN model. Table 1 presents the total numbers of detected hate tweets and non–hate tweets in the Arab region, along with the three levels of hate (low, average, and high). It can be observed in Table 1 that 535,811 of the 547,554 collected tweets related to the COVID-19 pandemic (97.8%) could be classified as non–hate tweets, while 11,743 (3.2%) were classified as hate tweets. Generally, most of the hate tweets fell in the low level range (8385/11,743, 71.4%). On the other hand, only 2.89% of hate tweets (340/11,743) were categorized as high level.

Table 1. Total numbers of hate tweets and non–hate tweets in the Arab region during the period of study (N=547,554).

Type of tweet	Number of tweets, n (%)
Non–hate tweets	535,811 (97.8)
Hate tweets	11,743 (3.2)
Hate levels[a] (n=11,743)	
Low	8385 (71.4)
Average	3018 (25.7)
High	340 (2.9)

[a] Based on scores assigned by the convolutional neural network model (low: 0.50-0.67; average: 0.68-0.85; high: 0.86-1.00).

Descriptive Statistical Analysis

To obtain more insight into the obtained results, we analyzed the hate tweets from two different aspects: by country and by time period. In addition, we obtained the WHO COVID-19 statistics (number of cases and deaths) for each country and during the aforementioned time periods.

By Country

The map in Figure 2 displays the number of hate tweets and their distribution across the Arab countries, where the number of hate tweets is shown in red, the number of total tweets is shown in black, and a dark color depicts a high number of hate tweets in that country.

Figure 2. Number of hate tweets (red) and total tweets (black) in each Arab country, where a darker color depicts a higher number of hate tweets in that country (MA: Morocco, MR: Mauritania, DZ: Algeria, TN: Tunisia, LY: Libya, EG: Egypt, JO: Jordan, LB: Lebanon, SY: Syria, IQ: Iraq, SA: Saudi Arabia ,YE: Yemen, KW: Kuwait, QA: Qatar, AE: United Aran Emirates, OM: Oman).

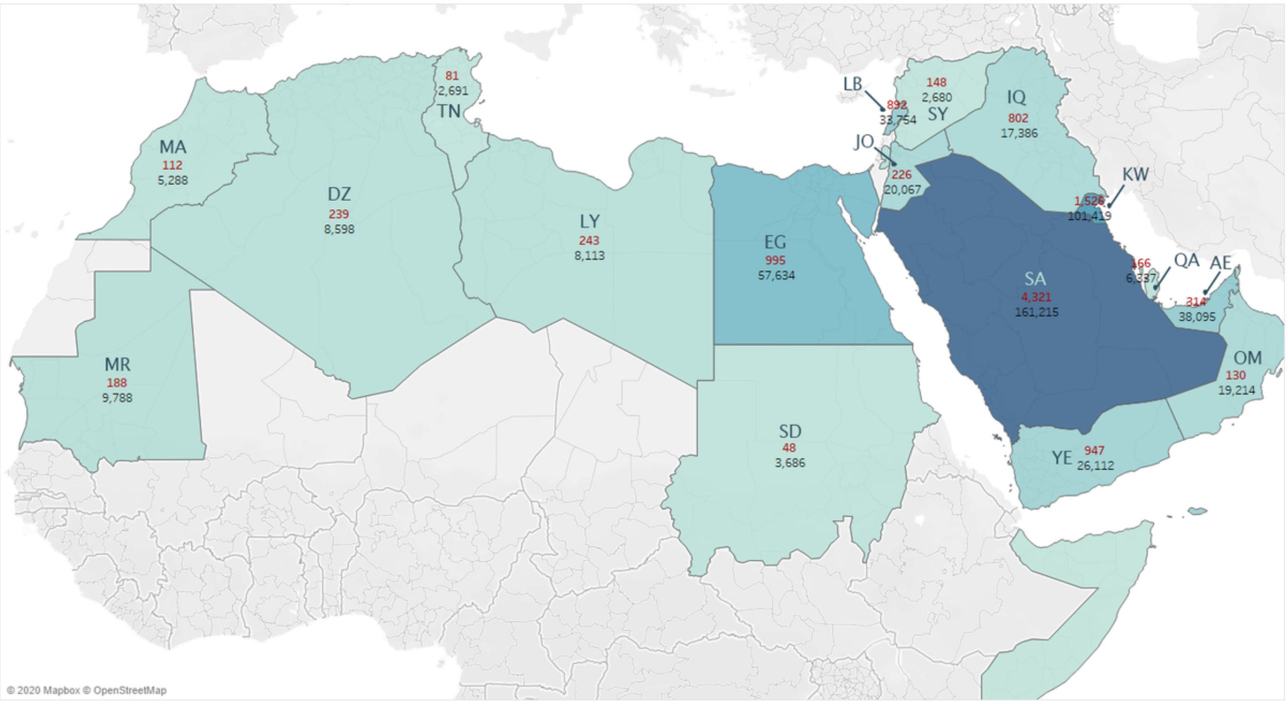


Table 2 compares the number of hate tweets in Arab countries and the distribution of hate tweets with different hate levels (low, average, and high). Out of the 22 Arab countries, the 10 most Twitter-active countries with respect to the number of COVID-19–related tweets are shown in the table. The results of the other 12 countries are combined in one column, titled “Other Arab countries.” In addition, Table 2 presents COVID-19 statistics (number of cases and deaths) for each country. It can be observed from Table 2 that country-wise, most COVID-19 tweets are of the non-hate class, and the percentages of hate tweets are considerably low. For instance, Saudi Arabia, which is the most Twitter-active Arab country as stated in the Digital 2020 Global Report [25], has the highest number of COVID-19–related tweets (165,536 tweets), of which only 4321 (2.61%) were classified as hate tweets.

In line with our previous observation, where most of the hate tweets were at the low level of hate, we found that the largest numbers of hate tweets were at the low hate level. For example, 2813 of the 4321 hate tweets in Saudi Arabia (65.10%) fell in the low level range, while 200 (4.63%) were at a high level. Similar results can be seen when considering Mauritania, which has the smallest number of COVID-19–related tweets among the top 10 Arab countries. 81.4% of hate tweets (153/188) in Mauritania are at the low hate level, and only 1.1% (2/188) are at a high level.

Table 2. Statistics of COVID-19–related hate tweets posted in Arab countries.

Variable	Country										
	Saudi Arabia	Kuwait	Egypt	UAE[a]	Lebanon	Yemen	Jordan	Oman	Iraq	Mauritania	Other Arab countries[b]
Population (million)	34	4	102	10	7	30	10	5	40	5	187
Posted tweets (N=535,811), n (%)	165,536 (24.2)	102,945 (15.0)	58,629 (8.6)	38,409 (5.6)	34,646 (5.1)	27,059 (4.0)	20,293 (3.0)	19,344 (2.8)	18,188 (2.7)	9976 (1.5)	52,529 (7.1)
Hate tweets (n=11,743), n (%)	4321 (2.6)	1526 (1.5)	995 (1.7)	314 (0.8)	892 (2.6)	947 (3.5)	226 (1.1)	130 (0.7)	802 (4.4)	188 (1.9)	1402 (2.7)
Hate levels of tweets[c]											
Low (n=8385), n (%)	2813 (65.1)	1153 (75.6)	747 (75.0)	245 (78.0)	700 (78.5)	640 (67.5)	160 (70.8)	104 (80.0)	624 (77.8)	153 (81.4)	1046 (74.6)
Average (n=3018), n (%)	1308 (30.3)	347 (22.7)	224 (22.5)	65 (20.7)	184 (20.6)	277 (29.2)	62 (27.4)	21 (16.6)	168 (20.9)	33 (17.6)	329 (23.5)
High (n=340), n (%)	200 (4.6)	26 (1.7)	24 (2.4)	4 (1.3)	8 (0.9)	30 (3.2)	4 (1.8)	5 (3.8)	10 (1.2)	2 (1.1)	27 (1.9)
Average hate level score	0.643	0.613	0.617	0.606	0.605	0.634	0.623	0.602	0.610	0.602	0.623

Deaths (n=1593)	162	26	392	105	24	0	8	11	92	1	772

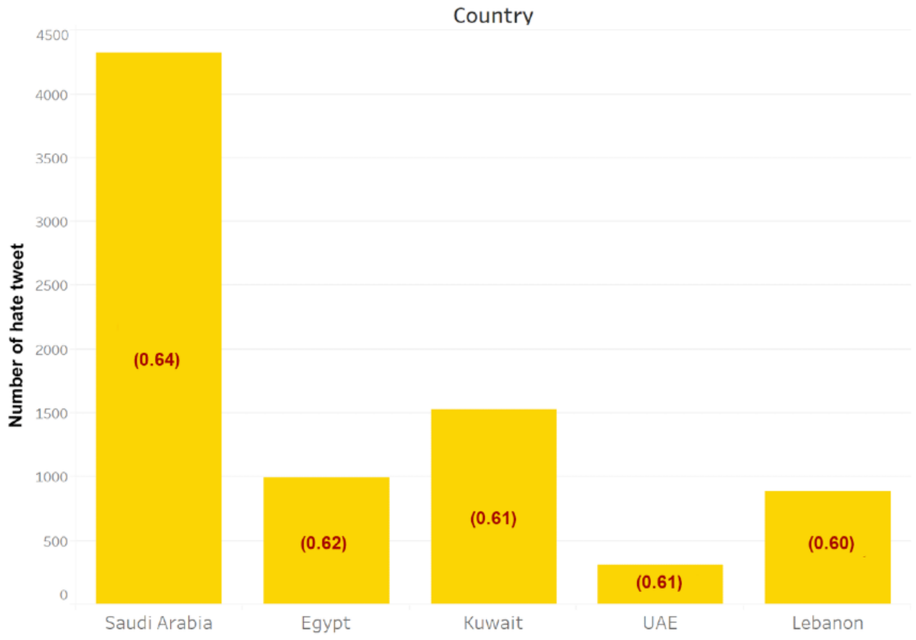
[a] UAE: United Arab Emirates.

[b] Other Arab countries: this column combines the results of the remaining Arab countries (Palestine, Algeria, Libya, Bahrain, Morocco, Qatar, Sudan, Syria, Tunisia, Comoros, and Somalia).

[c] Based on scores assigned by the convolutional neural network model (low: 0.50-0.67; average: 0.68-0.85; high: 0.86-1.00).

Figure 3 illustrates the statistics of hate tweets for the top five Arab countries with respect to number of COVID-19–related tweets, showing the average hate level of all hate tweets in red. It can be seen from Figure 3 that average hate level for the countries shown falls in the low hate range, which is coded in yellow. This strongly supports our first finding that the majority of hate tweets do not contain a high level of hate.

Figure 3. Number of COVID-19–related hate tweets per country with the average hate level scores in brackets (low: 0.50-0.67; average: 0.68-0.85; high: 0.86-1.00). UAE: United Arab Emirates.



By Time Period

The ArCOV-19 [15] data used in our study cover the period of January 27 to April 30, 2020. This period was divided into three specific time durations: January 27 to February 29, March 1-30, and April 1-30. Table 3 includes the number of COVID-19–related tweets in the Arab region during each time period, together with the number of hate tweets and their distribution in the three different hate levels. It also presents the number of COVID-19 cases and deaths in each time period.

Table 3. Statistics of COVID-19–related hate tweets per time period (N=547,554).

Variable	Time period (2020)		
	January 27-February 29	March 1-30	April 1-30
Total tweets (N=547,554), n (%)	118,991 (21.7)	253,806 (46.4)	174,757 (31.9)
Hate tweets (n=11,743), n (%)	3014 (25.7)	6095 (51.9)	2634 (22.4)
Hate levels of tweets[a]			
Low	2198 (72.9)	4300 (70.5)	1887 (71.6)
Average	741 (24.6)	1617 (26.5)	660 (25.1)
High	75 (2.5)	178 (2.9)	87 (3.3)
Average hate level score	0.622	0.628	0.625
COVID-19 statistics (n)			
Cases	133	7447	70,092
Deaths	0	202	1350

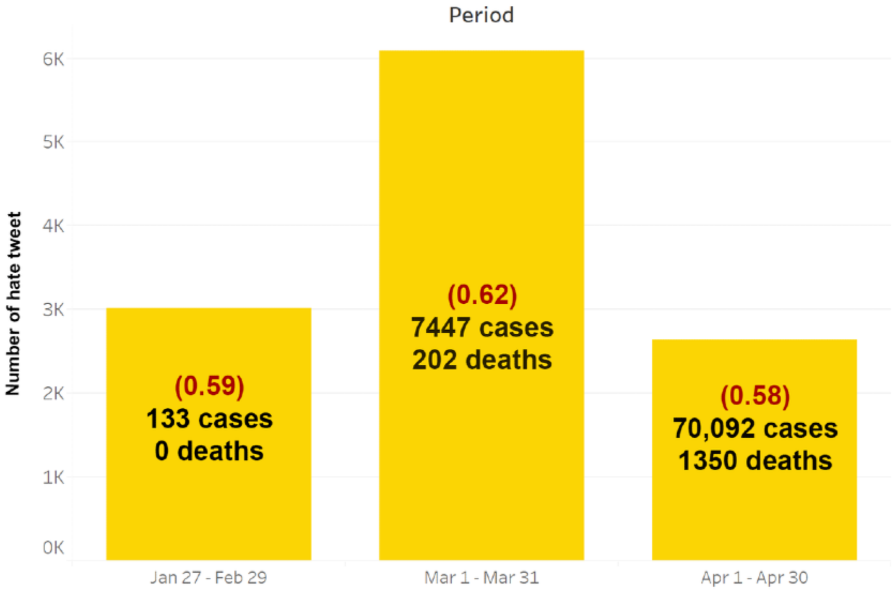
[a] Based on scores assigned by the convolutional neural network model (low: 0.50-0.67; average: 0.68-0.85; high: 0.86-1.00).

From Table 3, it can be clearly noted that after the end of the first period (January 27 to February 29), the number of COVID-19–related tweets spiked, with an increase of 113.3% compared to the first period. However, the number then decreases by 31.1% in the third period (April 1-30). Likewise, the number of hate tweets increased by 102.2% in the second period, then decreased by 56.8% in the third period. In contrast, the number of identified COVID-19 cases continued to grow during all three periods.

Looking at the levels of hate tweets per time period, it can be seen that although the number of hate tweets falling in the high level range is extremely small compared to those in the low level range, the high-level hate tweets have a tendency to increase with increasing number of COVID-19 cases and deaths, showing percentages of 2.49% (75/3014), 2.9% (178/6095), and 3.3% (87/2634) for the first, second, and third periods, respectively. On the other hand, the low and average hate levels do not follow the same behavior.

Figure 4 illustrates the statistics of the number of hate tweets per time period and the numbers of COVID-19 cases and deaths together with the average hate levels of all hate tweets (shown in red). It can be observed from Figure 4 that the average hate levels for the three time periods are in the low-level range, which is in line with our initial finding that the majority of hate tweets do not reach the high level of hate.

Figure 4. Numbers of hate tweets and numbers of COVID-19 cases and deaths per time period with the average hate level scores in brackets (low: 0.50-0.67; average: 0.68-0.85; high: 0.86-1.00).



From the previous results, it can be seen that there is a weak link between the number of hate tweets and the spread of COVID-19 per country or time period. This is because the number of hate tweets does not follow the same pattern of the number of COVID-19 cases, as illustrated in Table 2 and Table 3. To investigate this further, we tested the correlations between the number of COVID-19–related hate tweets and the number of COVID-19 cases in the data of 21 Arab countries during the 3 time periods under study. Using the Pearson correlation test [26], we obtained an *r* value of 0.1982 at *P*=.50. Although *r* is technically positive, the relationship between the number of hate tweets and the number of COVID-19 cases is weak (the nearer the value of *r* to zero, the weaker the relationship [26]).

NFM Results

To understand the main topics discussed by Arab users during the pandemic, we employed NFM as discussed earlier in this paper. We extracted 7 topics from the hate tweets. The distributions and examples of the top terms associated with each topic are shown in Table 4. As shown in Table 4, the most relevant terms for Topic 1 were terms that were usually used to criticize China as a country for being the source of SARS-CoV-2, the virus that cause COVID-19. Within the same theme, tweets in Topic 4 expressed hate speech toward Chinese people and their eating habits as being responsible for spreading COVID-19 worldwide. China was also the target of attack in Topic 5, in which many users expressed their belief that COVID-19 served as a “divine punishment against China” because of the Uyghur-Chinese conflict.

Table 4. Identified topics in hate tweets and examples of the most common words in each topic.

Topic number	Main theme	Examples of the top unigrams and bigrams	Distribution
1	China and COVID-19	Cursed, China, curse China, Curses on, life, new	4.3%
2	Iran as a source of COVID-19	Export, Gulf, country, Terrorism, disease, spread	5.07%
3	Saudi citizens visiting Iran	Saudi Arabia, Saudi, Bahrain, citizen, travel, passport	9.44%
4	Chinese eating habits and COVID-19	Dog, animal, bat, eating, meat, snake	5.72%
5	China and Uighur	China, Muslim, Uyghur, Chinese, pig, punishment	7.38%
6	Iran regime	Regime, Mullahs, Iran, Iranian People, Tehran, outbreak	5.60%
7	General political tweets, conspiracies, COVID-19 as an exaggerated threat	Country, people, disease, party, Iraq, Egypt	62.45%

On the other hand, Topic #2 contained several tweets accusing Iran of deliberately spreading COVID-19 to the Gulf Cooperation Council (GCC) countries. Topic #6 is also about Iran and COVID-19; however, the tweets in this topic were more political, attacking the Iranian regime and its politics. Topic #3 included cases of hate speech against Saudi citizens who visited Iran during the pandemic as being responsible for the spread of COVID-19 in Saudi Arabia.

Finally, in Topic #7, we observed that most of the inspected tweets were written in a political context, where the most frequently mentioned countries were Iraq and Egypt. We also observed many tweets spreading conspiracy theories about the scale of the pandemic and its origin, and some tweets stated that COVID-19 is an exaggerated crisis compared to the current regional crises and conflicts.

Discussion

Principal Results

This study aimed to address four research questions: (1) In which Arab country were the most COVID-19 hate tweets posted during the COVID-19 pandemic? (2) When were the highest number of hate tweets posted in the Arab region during the pandemic? (3) Does the increase in the number of COVID-19 cases or deaths coincide with an increase in the number of hate tweets? and (4) What are the main topics and issues being discussed in hate tweets during the COVID-19 pandemic?

In regard to the Arab country from which the highest number of hate tweets related to the COVID-19 pandemic originated, Saudi Arabia, which has the highest number of COVID-19–related tweets (165,536 tweets), had the highest number of hate tweets (4321), as shown in Table 2. Therefore, Saudi Arabia is the country in which the most COVID-19 hate tweets were posted during the pandemic. This can be attributed to Saudi Arabia numbering in fourth place in the top 20 countries and the only Arab country in the top 20 based on the largest active Twitter audience worldwide as mentioned in the Digital 2020 Global Report [25].

However, the percentage of hate tweets in Saudi Arabia, which is 2.6% (4321/165,536), is not the highest in the Arab region. This indicates that the number of COVID-19–related tweets does not necessarily reflect the number of hate tweets (as highlighted in Table 2). This can be clearly seen in the case of Yemen, where 27,059 tweets were posted, 3.5% of which were classified as hate tweets (n=947). Yemen having the highest percentage of hate tweets can be linked to the political and security instability in Yemen due to the Yemen Civil War, which began in 2014, and its psychological effect on the citizens of this country.

In addressing the second research question, this paper identifies the time period during which the number of hate tweets was the highest in the Arab region. As shown in Table 3, the second period (March 1-30) has the highest number of hate tweets (6095 tweets), which represents 51.9% of the 11,743 hate tweets in the three-month period of January 27 to April 30, 2020. Despite the fact that the highest numbers of cases and deaths occurred in the third period (April 1-30), the number of hate tweets reached its maximum during the second period. There are two possible explanations for this finding. First, it may be related to the beginning of the spread of COVID-19 in the Arab region, which occurred in March 2020. This period witnessed the highest level of public attention, which can be seen through the high number of Twitter interactions during the pandemic. The other explanation is that people began to adjust to coping with the pandemic and health precautions in the third period, and the severity of their panic and anxiety decreased.

The third research question investigated whether the number of hate tweets coincided with the spread of COVID-19 in the Arab region. As clearly shown in Table 2 and Table 3, the spread of COVID-19 hate tweets does not follow the same trend of the increase or decrease in the number of COVID-19 cases or deaths in any Arab country or during the studied time period. This can be interpreted as a weak relationship between the two variables because the *r* value obtained from the Pearson correlation test was 0.1982 (*P*=.50) [26]. Moreover, it can be observed from Table 3 that most of the hate tweets appeared in the second period, while the numbers of COVID-19 cases and deaths are highest in the third period, with percentages of 90.2% and 87%, respectively.

Regarding the fourth research question, this study sought to identify the topics discussed by Arab Twitter users in hate tweets. We analyzed the 7 topics extracted from the NFM model, and as shown in Table 4, most of the identified topics revolved around two themes: China (topics 1, 4, and 5) and Iran (topics 2, 3, and 6). It can be clearly noted that the COVID-19 pandemic fueled nationalism and ethnic conflict among Arab Twitter users. This spike of hate speech against China and Iran (and Arab individuals who traveled to Iran) can be attributed to the fact that China and Iran were increasingly accused in the media of spreading SARS-CoV-2 worldwide and to Arab countries, respectively. The United Nations recently published a guidance note [27] on addressing and countering COVID-19–related hate speech. The note stated that the pandemic has given rise to a new wave of hate speech and discrimination, which our results clearly confirm. After manual inspection of a few sample tweets from the identified topics, we observed that most of the tweets incited hatred and blame against individuals or groups belonging to certain ethnicities or from certain countries. This type of COVID-19–related hate speech could entail serious consequences, making the targeted groups more vulnerable to violence and discrimination and exposing them to political and social exclusion, isolation, and stigmatization.

Limitations and Future Work

One strength of this study is that it automatically identified hate tweets posted during the COVID-19 pandemic in the Arab region using deep learning and topic modeling. The model was trained on data from similar domains with similar characteristics (ie, noisy tweets with a high variety of dialectal Arabic). The model was able to identify a total of 11,743 hate tweets, which allowed us to study the phenomenon of hate speech on Twitter. However, some limitations of our study do exist. One limitation is that the used model was trained on a dataset collected in a span of 6 months, and certain events and topics dominated social media at that time. This may have affected the model performance and prevented it from capturing new forms of hate, violence, and racism that could be exacerbated by the COVID-19 pandemic. Additional limitations are the short duration of the study and the chances of misclassification of countries due to self-reporting of users' locations.

In future research, a follow-up analysis could be conducted to compare the prevalence of hate with other psychological aspects, such as anxiety, fear, and depression, in Twitter data during the COVID-19 pandemic.

Conclusion

The COVID-19 pandemic poses a significant threat to public health in nations worldwide. This study conducted an analysis of hate speech in Twitter data in the Arab region using deep learning and topic modeling. The analysis revealed that the number of non–hate tweets greatly exceeds the number of hate tweets. We also found that the majority of hate tweets were at a low level of hate. This study has shown that in the Arab region, Yemen is the Arab country from which the highest percentage of COVID-19 hate tweets spread during the pandemic. Moreover, it was noted that the time period of March 1-30 showed the highest number of hate tweets, representing 51.9% of all hate tweets.

Contrary to what was expected, the results in this study showed that the number of hate tweets did not follow the same trend as the increase or decrease in the number of COVID-19 cases or deaths. In fact, it was found that the spread of COVID-19 hate speech on Twitter is weakly related to the dissemination of the pandemic based on the Pearson correlation test.

This study also explored the main topics discussed by Arab users in tweets that were identified as hatful. After analyzing the NMF model results, we found that the COVID-19 pandemic clearly triggered hate speech against China and Iran. We also found that most Arabic hate tweets posted during the pandemic propagated hate speech in a political context, which may have been triggered by the ongoing crisis and political tension in the Arab region.

Abstract

Background: Telemedicine has been used for decades. Despite its many advantages, its uptake and rigorous evaluation of feasibility across neurology's ambulatory subspecialties has been sparse. However, the COVID-19 pandemic prompted health care systems worldwide to reconsider traditional health care delivery. To safeguard health care workers and patients, many health care systems quickly transitioned to telemedicine, including across neurology subspecialties, providing a new opportunity to evaluate this modality of care.

Objective: To evaluate the accelerated implementation of video visits in ambulatory neurology during the COVID-19 pandemic, we used mixed methods to assess adoption, acceptability, appropriateness, and perceptions of potential sustainability.

Methods: Video visits were launched rapidly in ambulatory neurology clinics of a large academic medical center. To assess adoption, we analyzed clinician-level scheduling data collected between March 22 and May 16, 2020. We assessed acceptability, appropriateness, and sustainability via a clinician survey (n=48) and semistructured interviews with providers (n=30) completed between March and May 2020.

Results: Video visits were adopted rapidly; overall, 65 (98%) clinicians integrated video visits into their workflow within the first 6 implementation weeks and 92% of all visits were conducted via video. Video visits were largely considered acceptable by clinicians, although various technological issues impacted their satisfaction. Video visits were reported to be more convenient for patients, families, and caregivers than in-person visits; however, access to technology, the patient's technological capacity, and language difficulties were considered barriers. Many clinicians expressed optimism about future utilization of video visits in neurology. They believed that video visits promote continuity of care and can be incorporated into their practice long-term, although several insisted that they can never replace the in-person examination.

Conclusions: Video visits are an important addition to clinical care in ambulatory neurology and are anticipated to remain a permanent supplement to in-person visits, promoting patient care continuity, and flexibility for patients and clinicians alike.

Introduction

Telemedicine has been used for decades, yet its uptake and rigorous evaluation of feasibility across neurology's ambulatory subspecialties has been sparse [1,2]. Studies have shown several advantages of telemedicine including improved access to care [3,4], less travel burden, and fewer associated out-of-pocket and health care costs [1,5-8]. Nonetheless, integration of virtual visits into ambulatory neurology care, where the physical examination and nuanced communication play a strong role, has been received with some hesitation [7,9-13]. Further, issues related to technology, compensation, payor reimbursement, policy, hardware/software costs, credentialing, liability, and requirements for in-person evaluations prior to virtual care, have also limited its adoption [1,8,11,13-17].

The declaration of COVID-19 as a pandemic in March 2020 prompted health care systems worldwide to reconsider traditional health care delivery and quickly transition to telemedicine [18-21]. In regions with rapidly increasing COVID-19 cases and early stay-at-home directives, health care systems rapidly built and implemented infrastructure for telemedicine technologies to protect health care workers and patients, and conserve personal protective equipment. To further support this pivot and maintain health care access, the United States loosened previously stringent federal regulations on reimbursements, licensing, and Health Insurance Portability and Accountability Act (HIPAA) compliance [22,23]. In neurology specifically, the urgent need to provide care safely to patients with chronic illnesses while preventing disease transmission during clinic visits, led to rapid implementation of video visits across all subspecialties [24-29].

In this study, we evaluate the implementation of video visits in Stanford Health Care's (California, United States) ambulatory neurology clinics using mixed methods to assess adoption and explore clinicians' perspectives on the acceptability, appropriateness, and sustainability of this broad expansion.

Methods

Setting

This quality improvement project received a nonresearch determination by Stanford University's Institutional Review Board (IRB-55644). It was conducted at Stanford University's Department of Neurology and Neurological Sciences, which includes 11 ambulatory subspecialties staffed by 60 physicians and 8 advanced practice providers (APPs). As previously described [27], at the beginning of the local COVID-19 stay-at-home directive in March 2020, approximately 50 in-clinic computers were video visit–enabled, and 50 additional computer devices were readied for remote use by providers. Clinic staff converted >90% of scheduled in-person visits to video. In-person visits were reserved for procedures such as autonomic testing, implanted device programming, injections, electromyography, and electroencephalograms, as well as patients determined either during previsit screening or initial video visit to require a full examination.

Primary Outcomes, Data Collection, and Analysis

Overview

The primary implementation outcomes assessed were adoption, acceptability, appropriateness, and perceived sustainability of video visits [30], as described in Table 1. Clinician-level scheduling data were used to assess adoption. A combination of a clinician survey and interviews were used to assess acceptability, appropriateness, and perceived sustainability. Clinicians included physicians and APPs.

Table 1. Implementation outcomes, definitions, and data sources applied in the evaluation of the implementation of video visits in ambulatory neurology.

Proctor et al's [30] implementation outcomes	Definitions	Data sources
Adoption	Uptake of video visits in ambulatory neurology	Scheduling data
Acceptability	Clinicians' overall satisfaction with video visits	Clinician interviews and clinician survey
Appropriateness	"Fit for purpose": clinicians' perceived suitability and practicability of video visits for a successful patient visit to achieve similar patient outcomes to an in-person visit	Clinician interviews and clinician survey
Sustainability	Clinicians' views on the future use of video visits in their practice	Clinician interviews and clinician survey

Scheduling Data

Clinician-level scheduling data were extracted for all clinicians who had the opportunity to conduct video visits. The first week of the stay-at-home order (March 15-21, 2020) was considered a transition week where the physician champion onboarded physicians onto the video visit platform. To assess our primary outcome, adoption, scheduling data from the 8-week implementation period (March 22 through May 16, 2020) was used for analysis; the transition week was excluded. Adoption was assessed in three ways: (1) proportion of clinicians who conducted video visits, (2) proportion of visits completed via video during the COVID-19 pandemic, and (3) proportion of all "expected" visits that were done via video, where "expected" was defined as the estimated number of visits completed had COVID-19 not occurred (ie, visit volume from the same calendar period in the prior year, March 24 through May 18, 2019).

The number of visits completed during the implementation period (ie, numerator) and comparator period (ie, denominator) included visit types that could be feasibly conducted in-person or via video. Visit types inherently requiring in-person patient interaction, such as procedures and research visits, were excluded. The percentage of "expected" visits is shown for video and in-person visits separately, along with the percentage of lost potential visits. The proportion of all "expected" visits completed is a measure of the proportion of "saved" or "protected" visits attributable to video visits during the COVID-19 stay-at-home period.

Clinician Survey

We developed a 20-item survey informed by early interview findings and reflections from the clinical improvement team. The survey was administered via Stanford's REDCap platform [31] and emailed to all clinicians using video visits in May 2020, followed by two reminders. To increase response rates, clinicians were encouraged to complete the survey during division meetings and reminded personally by clinical leaders. Descriptive analyses were conducted on 5 items (Multimedia Appendix 1): (1) need for and timing of in-person visits to supplement video visits, (2) top three concerns regarding video visits, (3) top three reasons for excitement for video visits, (4) video visits support of overall clinician wellbeing, and (5) video visit usage to shift uncompensated to compensated work. The number and percentage of clinicians indicating each response are reported for questions 1-3 and for those indicating "agree" or "strongly agree" for questions 4 and 5.

All quantitative data were processed and analyzed using SAS (Version 9.4; SAS Institute Inc), R (Version 4.0.2; R Foundation for Statistical Computing) [32] and associated packages [33-36].

Clinician Interviews

We designed the interview guide (Multimedia Appendix 2) to encompass three implementation outcomes of interest: acceptability, appropriateness, and perceived sustainability [30]. A purposive sample of 47 clinicians who had conducted at least one video visit were invited to participate in semistructured phone interviews held between March and May 2020. Stakeholders were intentionally recruited from different neurology subspecialties to obtain a representative departmental sample. In total, 30 clinicians were interviewed and interviews lasted 25 minutes, on average.

Interview notes and transcripts were used for analysis. To ensure anonymity, identifiable information was removed from transcripts and subspecialties with <5 clinicians were grouped. Data were analyzed using both deductive and inductive approaches. Deductive codes were derived from the implementation outcomes of interest [30]. During analysis, barriers, facilitators, and other emergent themes were identified and coded. A multiphase analysis approach leveraged rapid analytic procedures (eg, template summaries) to extract early themes, consensus coding of transcript summaries to produce interim results, and a matrix analysis [37] of interview excerpts for final comparison of themes across neurology subspecialties. First, individual interview transcripts were summarized independently by two coauthors into a templated summary document. After review and consensus discussion, transcript summaries were consolidated into a matrix to identify themes and allow for comparison across participants using Microsoft Excel (Microsoft Corp). Four qualitative coauthors met weekly for two months to discuss preliminary results and achieve reporting consensus.

Mixed Methods Analysis

Quantitative and qualitative data were consolidated during analysis and interpreted in parallel to understand the impact of video visits in ambulatory neurology more comprehensively. This approach allowed us to harness strengths and offset weaknesses of the two methodologies [38,39]. We were also able to identify converging and diverging issues regarding adoption, acceptability, appropriateness, and perceived sustainability of video visits.

Results

Participants

Out of the 68 clinicians in the department's 11 ambulatory subspecialties, 66 clinicians conducted regular video visits during the 8-week implementation period and were included in analyses (two clinicians were on leave and thus excluded). Table 2 summarizes the number of surveyed and interviewed clinicians, by subspecialty. In total, 48 (73%) clinicians responded to the survey and 30 (45%) were interviewed. In total, 21 (32%) clinicians participated in both the survey and interviews. Only 9 (14%) did not participate in either modality.

Table 2. Number of ambulatory neurology clinicians who completed the video visit survey and were interviewed, by subspecialty.

Subspecialty	Interview respondents, n	Survey respondents, n	Total clinicians, n
Autonomic, neuro-oncology, and neuro-ophthalmology[a]	3	4	9
Epilepsy	4	9	10
General neurology	2	5	5
Headache	4	3	5
Memory	3	4	6
Movement disorders	3	8	9
Neuroimmunology	3	5	5
Neuromuscular	4	5	8
Stroke	4	5	9
Total	30 (45%)[b]	48 (73%)[c]	66 (100%)

[a] The autonomic, neuro-oncology, and neuro-ophthalmology subspecialties had <5 clinicians and were therefore grouped to ensure anonymity.

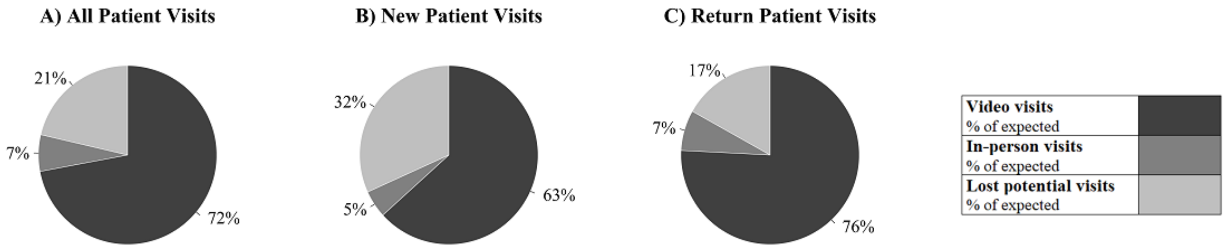
[b] Of the 30 interviewees, 29 were physicians and 1 was an advanced practice provider.

[c] Of the 48 survey respondents, 41 were physicians and 7 were advanced practice providers.

Adoption

During the transition week, the clinician champion onboarded 30 of the 66 physicians included in this study, and 129 video visits were conducted. Prior to this transition week, clinicians in these ambulatory neurology clinics had not used video visits. During the 8-week implementation period, video visit adoption was high based on both percentage of clinicians using them, and percentage of visits completed via video. Within the first two weeks, 52 (79%) clinicians integrated video into their practice, increasing to 65 (98%) clinicians by week 6. Almost all (92%) visits were conducted via video and adoption of video visits was high for both new and return patient visits (93% and 91% of completed visits, respectively). The total number of completed visits, conservatively estimated, was almost 80% of expected visits based on the 2019 comparison period (Figure 1A). Clinics recuperated more expected return patient (83%) than new patient visit volumes (68%; Figures 1B-C).

Figure 1. Percentage of video visits conducted between March 22 and May 16, 2020, as a proportion of (A) all "expected" visits overall, (B) "expected" new patient visits, and (C) "expected" return patient visits. The "expected" number of visits is defined as the number of completed visits in the comparable 2019 time period. Data only reflect operational scheduling data captured through the EPIC Hyperspace Platform. The data do not reflect no shows, visits conducted on other HIPAA-compliant software or visits that reverted to phone calls. (HIPAA: Health Insurance Portability and Accountability Act).



Acceptability

Overall acceptability of video visits was high, but clinicians experienced technological and scheduling issues, and identified additional needs. Two themes emerged related to acceptance: technology and workflow efficiency.

Technology

While some clinicians experienced a smooth transition to video visits and seamless connection with patients, others dealt with numerous technical issues, jeopardizing their overall satisfaction. Indeed, technology was one of the top 3 concerns regarding video visits for 30 (63%) survey respondents (Table 3).

Table 3. Ambulatory neurology clinicians' (n=48) top 3 areas of concern related to video visits as reported through survey data.

With regard to video visits, clinicians (n=48) were concerned about... (indicated top 3)	Survey respondents, n (%)
Technological limitations	30 (63)
Being able to engage in training and education of residents and fellows	21 (44)
Missing/losing the in-person connection/relationship with patients	18 (38)
Including interpreters on video calls	17 (35)
Difficulties arranging and completing necessary follow-ups after the video visit	14 (29)
Insurance reimbursements for video visits are not the same as for in-person visits	8 (17)
Patients' unwillingness to come into clinic for requested in-person visits in the future	7 (15)
Press-Ganey scores	5 (10)
Patient expectations to have video visits as an option	3 (6)
Maintaining access to readily available technology and equipment needed for video visits	2 (4)
Other (providers listed various reasons)	9 (19)

Several video functionalities were suggested for a successful visit, including the following: (1) *screen sharing* to facilitate patient education and explain imaging results, (2) a *waiting room function* to replicate "stepping out of the room" when engaging with trainees, (3) a *chat box* for troubleshooting, (4) *file sharing* capabilities, (5) *screenshot* capabilities to support efficient charting, and (6) *multiperson teleconferencing* to include other members of the multidisciplinary team, interpreters, trainees, and family members in different physical locations. These functionalities were not available during the study period.

> *...when we're discussing end-of-life care issues, to have the physician and respiratory therapist, social worker and palliative care physician, all present in the same 'virtual room', that would be really nice.* [MD19]

Engaging in education of trainees was one of the top 3 concerns for 21 (44%) surveyed clinicians (Table 3). The initial interface available through the electronic medical record (EMR) only allowed for a two-way call; therefore, parallel software was needed to include trainees.

Workflow Efficiency

Perceptions of workflow efficiency were mixed. Major issues included rigid video visit scheduling, note-taking efficiency, and previsit planning. Several clinicians mentioned that, provided there were no technological issues, video visits helped them stay on schedule. However, hard time limits set by the video visit platform caused frustration. Clinicians could not notify the next patient when running late nor initiate the next visit earlier than scheduled as they might do at the clinic.

> *…it's much easier for someone to wait in a physical waiting room if you do happen to run over with a patient who's before them. It's a lot harder or less acceptable if someone is waiting to see you via video and staring at their computer screen for 10 or 15 minutes. … You can't open up another video and say, 'I'm here. I'm just with somebody else, and I'm going to switch back.'* [MD10]

Views on documentation during a video call also differed. Note-taking was considered easier by some during video visits, reducing after-hours charting time. Others were unable to document simultaneously, making them less efficient. Dictation was considered a possible solution.

> *…unless you get the screen set up correct[ly], it actually can be really hard to document and type while doing the video visit. The typing can be noisy on the patient's end…* [MD5]

However, most surveyed clinicians (n=34; 71%) agreed or strongly agreed that video visits allowed them to shift uncompensated to compensated work (ie, scheduling a video visit to address concerns that would previously have been managed through either EMR messaging or unscheduled and uncompensated phone calls).

The lack of integration of medical assistants (MAs) in the video visit workflow, resulting in a lack of previsit charting and medication reconciliation, was another concern. Incorporating MAs, or even involving the patient in their own previsit preparation, was deemed necessary for video visits to be sustained.

> *I'd like to see it be more efficient… In advance of the visit, it would be nice if they [patients] could do their medication reconciliation. …enter in the last set of vitals that they took for themselves. …enter in their own review of symptoms and chief complaints.* [MD16]

Appropriateness: Suitability, Usefulness, and Practicability of Video Visits

Three themes emerged related to appropriateness of video visits: benefits and barriers, physical examination, and continuity of care, each of which are described below.

Benefits and Barriers of Video Visits for Patients and Families/Caregivers

Clinicians highlighted several benefits of video visits for patients and families/caregivers, including convenience, impact on travel and cost, and seeing the patient's home environment. Barriers noted included access to technology, patient’s technological capacity, and language. Video visits were considered advantageous and convenient, saving patients time and money, particularly for older adults and those who travel long distances for appointments. Survey respondents (n=37; 77%) agreed that saving patients unnecessary travel was one of the top 3 benefits (Table 4). Several clinicians supported referring patients to local laboratories to further avoid unnecessary travel. Clinicians also noted that for patients who required assistance (eg, patients with dementia, epilepsy, or mobility issues), the video visit alleviated the travel burden on families/caregivers.

> *…it's very convenient for our patients, especially those who are elderly or have neurologic issues. [It] Spares them unnecessary travel and costs...* [MD16]

Table 4. Ambulatory neurology clinicians’ (n=48) top 3 areas of excitement related to video visits as reported through survey data.

With regard to video visits, clinicians (n=48) were excited about... (indicated top 3)	Survey respondents, n (%)
Saving patients from unnecessary travel	37 (77)
Increased access for vulnerable populations	33 (69)
Ability to see my patients from my home or nonclinic location	23 (48)
Reduced uncompensated work	18 (38)
Flexible scheduling of patient visits	17 (35)
Ability to see patients in their home environment	3 (6)
Ability to connect with patients’ caregivers/family members	3 (6)
Other (providers listed various reasons)	4 (8)

Several clinicians saw value in seeing patients in their home. Not only did it allow more family involvement, but clinicians could also troubleshoot daily functioning issues or modify the patient’s environment by directly assessing fall hazards, medications, and home devices.

> *…maybe you see … a lot of stuff strewn over the floor and that is why they're falling so much … you might observe things … that might impact their neurological disease on a day to day basis … or you don't think to ask about … in a clinic visit because you're not seeing the world that they're actually living in.* [MD25]

Even though increased access to vulnerable populations was rated as one of the top 3 benefits of video visits (n=33; 69%; Table 4), numerous clinicians mentioned that some patients, particularly older adults and lower-income patient populations (eg, unhoused individuals or rural farm workers), lacked the necessary access to technology and technological capability to support a video call. In the absence of a supportive family member/caregiver, video visits with patients with cognitive, hearing, or visual impairment were also considered nonideal.

> *... not suited are patients with some mild to moderate cognitive impairment. ...they have more trouble interacting with the physician and understanding who they’re talking to.* [MD25]

Language barriers were also considered a possible limitation of video visit utilization by both interviewees and survey respondents. Specifically, 17 (35%) surveyed clinicians indicated inclusion of interpreters was one of their top 3 concerns (Table 3).

Virtual Physical Examinations

Clinicians reported that video visits were superior to a phone call, allowing them to gather more information than just a medical history. Although exam needs varied by clinician and subspecialty, several clinicians described that despite challenges, they were pleasantly surprised to be able to perform several modified physical examinations over video. Nevertheless, many stated that the inability to perform a hands-on physical examination was a limitation of video visits that was best paired with a timely in-person follow-up. Several clinicians mentioned that virtual exams were more time-consuming and occasionally required assistance from a caregiver to position the phone to properly observe the patient, perform certain physician-directed exams, confirm what the patient says, or catch the patient if s/he is at risk of falling.

> *You have to have a caregiver, you can’t check gait without it [a caregiver] or the patient needs some sort of stand or desk or something where they can put the computer down at the end of a hallway and then asking the patient to find a hallway that they can walk back and forth is really the best way to do it. But a caregiver probably works best.* [MD21]

Additional limitations were related to the patient’s immediate environment, including adequate space for the patient to move around, and sufficient lighting. Camera positioning was also critical. If positioned too close, the clinician lacked sufficient visual field to observe the patient’s entire body. Clinicians also noted that occasionally patients took their video call at inappropriate times (eg, while working or driving), despite previsit counseling.

Promoting Continuity of Care

Clinicians considered video visits beneficial to ensure continuity of care for chronic conditions. There was general agreement that video visits are best suited for established patients, especially those who are stable/uncomplicated, or for a quick checkup without extensive examination or testing. Although several clinicians felt that most patients were appropriate for video visits, the majority agreed that new patient visits, and patients with acute conditions and declining health, were less suited due to relative ease of the complete physical examination when conducted in person. Many preferred to first see the patient in person before determining whether further follow-up care can be provided, at least partly, over video. Clinicians also recognized that some patient populations encounter significant barriers to attending the clinic in person and that video offers an opportunity to continue care.

> *We deal with progressive conditions, and once you get into that moderate to advanced stage of illness it just becomes not worth their effort to come anymore. It's too difficult on the patient, it's too difficult on the family, and so we lose contact with the vast majority of our patients as they become more advanced. ...telemedicine actually might allow continuity of care into the more advanced stages…* [MD12]

Perceived Sustainability

Most clinicians were positive toward video visits and believed they could incorporate video into their practice long-term, although several insisted that video cannot replace a full in-person examination. Moreover, 40 (83%) surveyed clinicians agreed or strongly agreed that video visits supported their overall well-being. The general view was that for long-term sustainability, patient video visits will need to be selected carefully to optimize care and respect preferences. Patients' suitability for video visits would need to be determined during scheduling based on several criteria (eg, physical examination needs, patient's technological capacity and demographics, new versus return). However, previsit screening and triage to determine which patients are best suited for video was considered burdensome, which could compromise their sustainability. Seldom was the video visit itself considered a good tool for triage.

> *I would like to be able to offer it for my patients who are a little less mobile and who come from far away. I don't think it will completely replace in-person visits, but if we can alternate visits and do in-person versus telehealth, I think that'll be huge.* [MD21]

Most survey respondents (n=39; 81%) agreed that video visits should be supplemented with in-person visits. The recommended frequency of supplemental in-person visits varied among the respondents: 6 (15%) recommended quarterly, 11 (28%) biannually, 17 (44%) annually, and 5 (13%) every 2 years. A concern mentioned by a minority of interviewees and 7 (15%) surveyed clinicians was that patients may find video too convenient and opt out of recommended in-person visits. In contrast, 9 (19%) survey respondents with representation from epilepsy, memory, headache, stroke, and neuro-oncology, indicated that an all-video practice would be feasible for their patient population.

Discussion

Principal Findings

Video visits were rolled out rapidly at Stanford University's Department of Neurology and Neurological Sciences during the COVID-19 pandemic. A high proportion of visits were conducted via video at volumes near prepandemic volumes, indicating robust and rapid adoption by both clinicians and patients. This necessary and widespread adoption allowed for thorough assessment of new opportunities and barriers in video-based care across almost all ambulatory neurology subspecialties.

Clinicians recognized the patient benefits of video visits, including saving patients unnecessary travel and increasing access to vulnerable populations, as is well-documented [1,3-8]. As patients with chronic progressive neurologic conditions lose function, in-person visits become increasingly challenging and care by video is a welcome new supplemental resource. Video visits could improve the experience for these patients and others, but various challenges remain. As clinicians noted, the most vulnerable high-need patients were often the hardest to care for virtually. Vulnerability is not uniform across patients and could be related to diagnosis (eg, patients with sensory or cognitive deficits), support (eg, caregiver status), socioeconomic status, or access (eg, poor access to technology). New creative solutions are being explored to address these challenges at various levels, with the goal of rendering virtual care an effective catchment for all. For instance, a pilot program delivering tablets to patients cared for by the US Department of Veterans Affairs has been successful in addressing concerns related to diagnosis and technology [40]. Further, municipality-level internet and broadband for all could address access issues [41].

Clinicians reported that video visits were beneficial for seeing the patient's home and meeting caregivers and family members. Observing patients at home is a documented benefit of video visits; it can reduce patient and caregiver anxiety, and allow assessment of fall hazards and habitual behaviors that are not always possible to capture during an in-person visit [6,42]. These benefits were rarely identified within the top 3 benefits of video visits in the survey, which is likely related to the many perceived benefits of video visits as well as the diverse needs of neurology subspecialties' patient populations. Interviewed clinicians emphasized that the presence of a caregiver is often essential to a successful video visit. For example, a caregiver is essential for collateral history when the patient has cognitive impairment or for safely examining gait for a complaint of parkinsonism, but not for a younger patient presenting with headache. Communicating the importance of including caregivers in certain video visits is thus important for optimal care provision.

Previously, the perceived limitations of virtual physical examinations have been a source of hesitant incorporation of telemedicine into neurology practice [10-12]; however, virtual physical examinations are possible, especially to supplement heavily history-based presentations [1,6,43]. A previous investigation demonstrated that virtual exams were adequate even for many patients with multiple sclerosis and neuroimmunology issues [44]. Presence of a caregiver can further facilitate a detailed and complete medical history and examination [28]. In this study, several clinicians reported that video cannot replace a full in-person examination, but others reported that the virtual physical examination was more feasible than expected. Best practices that were followed across clinics included consenting patients and explaining video limitations prior to the visit, and scheduling patients for in-person follow-up as soon as they are able to do so safely whenever an in-person examination was deemed important during the video visit. As clinics adjust to new routines and workflows, measures are also being taken to further optimize the virtual exam experience. For instance, the department has organized teleneurology professional development webinars on optimal virtual physical examination techniques [23,45], and guidance documents on this topic have also been developed internally. Together with time and experience, these efforts may further increase clinician comfort with the virtual physical examination.

Clinicians were keen about the ability to work remotely, reduction in uncompensated work, and flexible scheduling facilitated by video visit use. In the current configuration, video visits are not constrained by clinic spaces nor specific staffing needs, thereby allowing clinicians flexibility to vary timing and length of both their overall clinic session and individual patient appointments. This is a clear benefit, as lack of flexibility in work is a key driver of burnout [46], and even more salient given increased family and childcare duties for many due to the pandemic. Furthermore, reducing uncompensated work has potential well-being benefits. Historically, clinicians with full clinic schedules answered patient messages and phone calls uncompensated outside of normal clinical hours; this is another driver of physician burnout [47]. Video visits have relatively fewer constraints than in-person visits that are often booked out for months, and could enable the ability to address a new patient concern in short order “on the clock” and compensated. Further, most respondents also reported that video visits support their well-being, which is key in a specialty where an estimated 60% of clinicians reported at least one symptom of burnout even before the pandemic [48].

Perceived sustainability of video visits was high; clinicians emphasized a desire for video visits to remain a permanent fixture in their practice. However, the proportion of video visits and in-person visits within their practice was anticipated to change in their postpandemic practice and vary by individual providers and subspecialty. Most clinicians preferred to have a practice that uses both video and in-person visits, but more than half (57%) expressed a preference for less frequent in-person visits (ie, every 1 or 2 years). Perhaps most surprisingly, nearly 20% of clinicians from a variety of neurology subspecialties indicated that an all-virtual practice was possible. This variation in preferences may reflect the wide variation in the nature and examination demands of neurologic subspecialties, with subspecialties known to be especially exam-dependent (eg, movement and neuromuscular disorders) notably absent from those indicating feasibility of an entirely virtual practice.

The capabilities of mobile technology and remote monitoring have facilitated great advances in telemedicine [2,6,8,14]; however, several challenges remain and need to be addressed to enable long-term sustainability of video visits. Audio and video connectivity issues may be partially ameliorated by software updates and through increased experience with telemedicine, particularly for clinicians. On the other hand, some technological issues experienced by patients could potentially be addressed with targeted efforts, including more previsit planning and education with a staff member. To enhance the video visit experience for both patients and clinicians, pertinent features included virtual waiting rooms and multiuser interfaces to promote incorporation of trainees, interpretation services, and multidisciplinary care. Some of these features were added in subsequent updates and parallel workflows were developed to use other HIPAA-compliant platforms for visits including trainees or interpreters. In our experience, this parallel platform and approach were important for resolving some issues of functionality and service; however, the lack of integration and interoperability with standard EMR video functionality could impact sustainability.

Further analysis of the workflow around telemedicine in ambulatory neurology is needed as there is growing recognition that workflow is nontrivial and complex [49]. In this study, initial workflows for video visits did not include MAs taking patient vitals and performing medication reconciliation, key aspects of in-person visits for new patients. Clinic processes should reincorporate MAs in video previsits, perhaps through phone or video visits in the days prior to the clinical video visit. As clinical workflows evolve to sustain video visit use and meet the needs of the most vulnerable patient populations, these video previsits could potentially also provide patient education on optimal lighting, how to position devices, space, and presence of caregivers.

Strengths and Limitations

Perceptions of clinicians using video visits were captured in real time during early rapid implementation through interviews and/or a survey across many ambulatory neurology subspecialties. However, given its nascent state, operational scheduling data only captured data of video visits conducted via the EPIC Hyperspace Platform and did not consistently reflect visits conducted on other HIPAA-compliant software, such as Zoom. Therefore, the data presented herein likely underestimate the actual total number of completed visits. Further, when video visits were diverted to phone calls or other software during the 8-week implementation period, the scheduling system incorrectly categorized the encounter as cancelled, no show, or patient left without being seen. This limitation has been recently addressed, presenting an opportunity to investigate the impact of video visits on clinic utilization in future investigations. Finally, views of other essential health care staff, such as patient care coordinators and MAs, who performed essential activities (eg, scheduling and confirming patients’ technology capabilities), as well as residents and patients/caregivers, are not presented here.

Conclusions

Video visit adoption was rapid at Stanford’s ambulatory neurology clinics. Almost all clinicians conducted video visits by the eighth week of implementation and achieved near-normal patient volumes during the COVID-19 pandemic stay-at-home order. Despite the sudden change in workflow, clinicians largely expressed positive views toward video visits; clinicians supported permanent integration of video visits and noted them to be conducive to physician well-being. However, overall clinician satisfaction was impacted by technological issues, limitations with the physical examination, and challenges accessing vulnerable patient populations. Although our mixed methods evaluation confirmed the success of video visits in all subspecialty neurology clinics across many dimensions, innovations must be developed to address their limitations. Additional solutions are also needed for the most vulnerable patient populations. A crucial next step for optimization is to understand patients' experiences and preferences.

Acknowledgments

We would like to extend our gratitude to all participating clinicians who shared their insights with us. Thank you to Dr Frank Longo, Dr Yuen So, Alison Kerr, Sophia Loo, and Dana Gonzales for their support of this clinical innovation. We also thank Dr David Larson and the leadership of the Improvement Capability Development Program for arranging the partnership between the Department of Neurology & Neurological Sciences and the Evaluation Sciences Unit.

This project was supported by Stanford Health Care as part of the Improvement Capability Development Program. The Stanford REDCap platform was used for quantitative survey data collection. The Stanford REDCap platform [31] is developed and operated by the Stanford Medicine Research information technology team. The REDCap platform services at Stanford are subsidized by both the Stanford School of Medicine Research Office and the National Center for Research Resources and the National Center for Advancing Translational Sciences, National Institutes of Health, through grant UL1 TR001085.

Authors' Contributions

RMK, SMRK, CGBJ, LY, JFW, JGS, SMA, CAG, and MW contributed to conception and design. RMK, LY, JFW, and CAG contributed to implementation. EASG, SMRK, and DWG contributed to data acquisition, analysis, and interpretation. CGBJ, ASL, and MRV contributed to data acquisition and analysis. EASG, RMK, SMRK, MW contributed to manuscript drafts and significant revisions. CGBJ, DWG, ASK, MRV, LY, JFW, JGS, SMA, and CAG contributed to manuscript revisions. All authors gave final approval of the published version.

Abstract

Background: A vast amount of mobile apps have been developed during the past few months in an attempt to “flatten the curve” of the increasing number of COVID-19 cases.

Objective: This systematic review aims to shed light into studies found in the scientific literature that have used and evaluated mobile apps for the prevention, management, treatment, or follow-up of COVID-19.

Methods: We searched the bibliographic databases Global Literature on Coronavirus Disease, PubMed, and Scopus to identify papers focusing on mobile apps for COVID-19 that show evidence of their real-life use and have been developed involving clinical professionals in their design or validation.

Results: Mobile apps have been implemented for training, information sharing, risk assessment, self-management of symptoms, contact tracing, home monitoring, and decision making, rapidly offering effective and usable tools for managing the COVID-19 pandemic.

Conclusions: Mobile apps are considered to be a valuable tool for citizens, health professionals, and decision makers in facing critical challenges imposed by the pandemic, such as reducing the burden on hospitals, providing access to credible information, tracking the symptoms and mental health of individuals, and discovering new predictors.

mobile apps; systematic survey; COVID-19; mobile health; eHealth

Introduction

The COVID-19 outbreak, which first emerged in China, has spread worldwide. On March 11, 2020, the World Health Organization (WHO) declared COVID-19 as a pandemic [1]. The disease has disrupted global trade, employment, and travel, and many governments had to take strict measures to control the spread of the virus and minimize the burden of morbidity and mortality so that health care systems remain functional [2]. In many countries around the world, citizens have been recommended to stay at home and practice social distancing for as long as possible as a primary measure of preventing the spread of COVID-19.

Although mobile apps are successfully used for managing chronic diseases [3,4], the ongoing COVID-19 pandemic has pushed the need for mobile app solutions at the forefront to reduce the risk of cross-contamination caused by close contact [5-7]. Mobile technology has been leveraged in a number of ways to control the spread of COVID-19. Mobile apps are accessible, acceptable, and easily adopted, and have the ability to support social distancing efforts. As such, they have been widely developed and implemented during the previous months in an attempt to “flatten the curve” of the increasing number of COVID-19 cases, providing knowledge and information to civilians while attempting to relieve the pressure from health care systems.

Despite increasing reliance on mobile health (mHealth) solutions as part of COVID-19–related response plans, major knowledge gaps exist about their utility and efficacy during the current pandemic for both health professionals as well as for the general population. To this direction, this systematic review aims to shed light into studies found in the scientific literature on the use and evaluation of mobile apps for the prevention, management, treatment, or follow-up of COVID-19.

Other recent reviews have focused merely on the exploration of COVID-19 mobile apps in app stores in general [8] or were restricted to apps deployed in specified countries such as the United States, the United Kingdom, and India [9]. Although there are already related generic COVID-19 information and communication technology surveys [10,11], they focus on specific topics such as contact tracing [12,13]; specialized health sectors like pediatric health care delivery [14], mental health [15], epilepsy [16], and palliative care [17]; or countries like India [14], China [18], and the United Kingdom [19]. To the best of our knowledge, there has been no other work dedicated to the systematic review of pragmatic studies that have demonstrated the real-life use and evaluation of COVID-19 mobile apps.

Methods

Search Strategy

The bibliographic databases of PubMed and Scopus, along with the global research database on COVID-19 developed by the WHO [20], were searched to identify mHealth apps used for the purposes of prevention, treatment, or management of COVID-19 and assessed in pragmatic studies.

Eligibility Criteria

In this context, the inclusion criteria for study selection were the following: features of the COVID-19 mobile app should be described, the study should show evidence of the implementation of the COVID-19 mobile app in real life and provide quantitative outcomes, the study should show that clinical professionals were involved in the design or validation of the mobile app, the paper describing the study must have been written in English. Case reports, letters to editors, preprint papers, qualitative studies, surveys or reviews, simulation studies, and studies describing protocols were excluded from the review.

Study Selection

The string “(mobile health) OR (mhealth) OR (smartphone) OR (mobile phone) OR (mobile application) OR (mobile app) OR (app) AND (COVID-19),” was used for a search within the title, abstract, and keywords of the manuscripts. Authors HK, AT, AK, FL, DGK, and IK independently screened the identified papers to minimize possible errors and bias in the selection process. Any disagreements were resolved by discussion between the authors to reach consensus. The authors first screened the abstracts of the candidate papers for inclusion and assessed their eligibility according to the defined inclusion and exclusion criteria. Moreover, the authors selected the final papers for inclusion after reading the full manuscripts of the eligible papers, as well as their references.

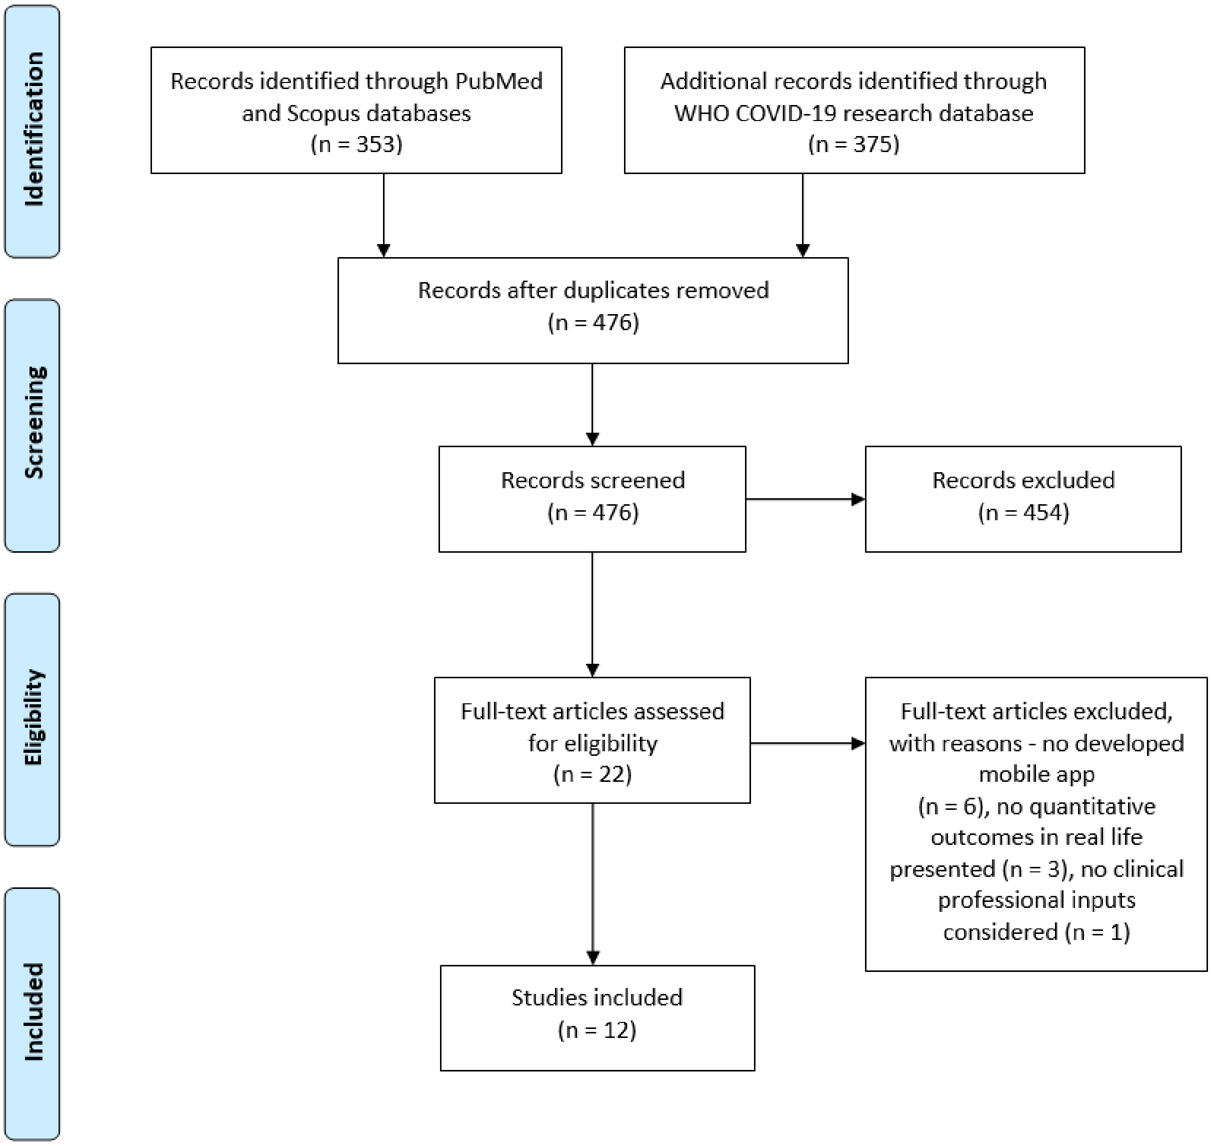
The Effective Public Health Practice Project (EPHPP) tool was adopted to assess the methodological quality of the included studies. The EPHPP tool is suitable for evaluating quantitative studies in a wide range of health-related topics, and it has demonstrated reliability [21]. The included studies were synthesized (by HK, AK, FL, and DGK) according to their target, mobile app main features, study design, number of enrolled participants and their age, follow-up duration, outcomes and whether these were positive or negative, and implications for clinical practice. This systematic review was conducted following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [22]. A completed PRISMA checklist is shown in Multimedia Appendix 1.

Results

Statistical Analysis

Our last search in June 2020 returned 165 manuscripts from the PubMed database, 188 manuscripts from the Scopus database, and another 375 manuscripts from the WHO research database. All the retrieved records were imported in the Zotero bibliography management software (Center for History and New Media at George Mason University), which identified 252 duplicates. We screened the abstracts of the remaining 476 papers according to our inclusion and exclusion criteria, and 22 papers were found to be eligible. After reading the full text of the papers, the authors agreed to include 12 papers. The screening procedure along with reasons for excluding papers are shown in the PRISMA flow diagram in Figure 1.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. WHO: World Health Organization.



Study Outcomes and Quality Assessment

On the basis of the EPHPP criteria for selection bias, design, confounders, blinding, data collection, and dropouts, we found the methodological quality to be moderate for 2 of the 12 (17%) studies [23,24] and weak for the remaining 10 (83%) studies (Table 1). Most studies were poorly rated because of their observational or cross-sectional nature, insufficient care in controlling for confounders, insufficient reporting on the validity and reliability of the tools used for data collection, and the absence of description on withdrawals and dropouts. The design of a randomized or controlled clinical trial was not reported in any of the reviewed studies.

Table 1. Quality assessment of included studies based on the EPHPP criteria.

Comparison

In the following sections, we provide a comparison of the included studies, in terms of intervention target and main features, study design, and outcome and clinical implications.

Intervention Target and Main Features

The reviewed papers varied in intervention target and main features (Table 2). One paper discussed a COVID-19 tracking app informing users about risk assessment and offering relevant advice [28]. The paper did not provide further details about app features. Apps that offered education and information material were discussed in 3 papers. They either targeted patients or health care professionals. Patient education included hospital information (appointments, visiting hours, self-isolation, and general COVID-19 information [32]) and education related to SARS-CoV-2. For health care professionals, they included information about how to handle patients with COVID-19 [31,34]. One paper [25] described how the hospital information system was adapted to handle COVID-19 with the incorporation of relevant templates. An app for recording general health information was discussed in 1 paper [33], and apps for self-assessment focusing on symptoms were found in 1 paper [32]. Self-monitoring based on a symptom diary and health observation data were also reported in 4 papers [26,29,32,33].

Table 2. A comparison of intervention target and main features.

Studies	Intervention	Main features
Kodali et al [28]	Tracking app	Risk assessment and advice
Timmers et al [32]	Education and information	Information for patients
Ros and Neuwirth [31] and Zamberg et al [34]	Education and information	Information for health care professionals
Bourdon et al [23]	Hospital information system	Adaptation to pandemic
Yamamoto et al [33]	Health assessment	General
Bae et al [25], Medina et al [29], Timmers et al [32], and Yamamoto et al [33]	Health assessment	Self-monitoring
Medina et al [29]	Home monitoring	Telephone outreach
Bourdon et al [23]	Home monitoring	Vital signs with smart devices
Drew et al [26]	Home monitoring	Internet of Things
Timmers et al [32]	Interactive map	Demographics and health status
Yamamoto et al [33]	Data sharing	Patient email to specific recipients
Medina et al [29]	Data sharing	Nurse outreach
Ben Hassen et al [27]	Student mental health	Behavior during the pandemic
Menni et al [30]	Prediction model	Progress of disease
Huckins et al [24]	Teleophtalmology	Emergency eye care

Home monitoring was handled based on telephone outreach [29], smart vital sign monitoring devices [25], and Internet of Things [27]. An interactive map of user demographics and health status was discussed in 1 paper [32]. Two apps offered data sharing capabilities via email to specific recipients based on patient options [33], or as symptoms were worsening, the app sent messages to be assessed by nursing staff to provide appropriate advice [29]. One paper assessed student behavior to determine whether the mental health of participants changed due to the COVID-19 pandemic [24]. One paper used data collected by Drew et al [26] to develop a prediction model about disease progress as well as tracking the disease progress in real time [30]. Finally, 1 paper [23] reported on a smartphone app to manage emergency eye care.

Study Design and Structure of Research

Regarding the *study design*, almost all selected studies were proof of concept, observational studies, or both, aiming to evaluate the practical use, usability, or user satisfaction with the corresponding apps that were developed to support individuals, health care providers, and policy makers during the COVID-19 pandemic (Table 3).

Table 3. A comparison of study design and structure of the research.

Study	Study design	Participants, n	Age	Follow-up duration (study period)
Bourdon et al [23]	Online surveys on patient and medical staff satisfaction with the mobile app and the wearables	12 patients and 24 medical staff	Patient mean age: 25 years; no information for medical staff	No follow-up
Huckins et al [24]	Observational cohort study measuring behaviors through the StudentLife smartphone sensing app	500	Mean: 40.7 (SD 20.3; 0.6-92) years. The number of patients older than 60 years was small.	No follow-up
Bae et al [25]	Observational data collection that helped develop predictive models. Participants that were already enrolled in ongoing epidemiologic studies were approached to use this app.	>2 million users; 75% female	Mean: 41 (range: 18-90) years	The launching of the COVID Symptom Study app occurred in the United Kingdom on March 24, 2020, and in the United States on March 29, 2020. 265,851 individuals were enrolled by March 27, 2020.
Drew et al [26]	Observational study on the COVID Symptom Tracker mobile app	5 hospitalized patients and 5 doctors	Patients range: 45-61 years	No follow-up
Ben Hassen et al [27]	The StudentLife app was used for smartphone mobile sensing. Ecological momentary assessments were used to assess depression and anxiety.	217; 67.8% (n=147) were female	Range: 18-22 years at the time of enrollment	178 (82.0%) students provided data during the Winter 2020 term (January 6 to March 13, 2020).
Kodali et al [28]	Observational study using descriptive statistics and thematic analysis on the mHealth[a] app Arogya Setu.	503 most relevant reviews were identified based on the Google algorithm	Not reported	All reviews that were available publicly and posted in English by the users until April 21, 2020, were included. The start date of app reviews collection was not reported.
Medina et al [29]	Observational cohort study carried out at the Cleveland Clinic, OH, US. It included a self-monitoring app for patient engagement and early intervention.	COVID-19 patients enrolled by May 25, 2020: 1924. Most (85%) patients were enrolled 5 days from symptom onset.	25% (n=483) were older than 60 years, and 3.5% (n=67) were younger than 18 years.	Engagement with MyCare Companion app reached 32%; 25% continued under monitoring for longer than 14 days due to persistent symptoms.
Menni et al [30]	Observational data collection and statistical analysis that helped develop predictive models	Symptoms were reported by 2,450,569 from the UK and 168,293 from the US	Average age for tested positive, tested negative, and not tested: (UK: 41.25, 41.87, and 43.38; US: 41.87, 47.25, and 53.00).	Data analyzed had been collected between March 24 and April 21, 2020.
Ros and Neuwirth [31]	A tutorial feedback survey was conducted. User feedback was requested from health care workers and responders about the presented global public health educational outreach technology.	12,516 users, learners, health care workers, and responders downloaded the app in 1 month.	Not provided	366 replies received during the first 72 h of deploying the survey. During this time period, there were 512 subscribers that had downloaded the app (71.48% response rate).

Study	Study design	Participants, n	Age	Follow-up duration (study period)
Timmers et al [32]	Observational cohort study (based on the data collected at the ETZ[b] hospital), assessed the use of the app as well as its usability. Data were gathered for health care providers and policy makers.	6194 individuals downloaded the app.	Average: 50.87 years	The study focused on data collected between April 1-20, 2020. The app was being used by over 15 hospitals in the Netherlands, Belgium, and Germany, accumulating over 30,000 downloads.
Yamamoto et al [33]	Proof of concept and practical use study in a real-world setting. The study aimed to develop a PHR[c]-based COVID-19 symptom-tracking app to determine whether PHRs could be used for efficient health observation outside a traditional hospital setting. The practical aspects of health observations for COVID-19 using the smartphone or tablet app integrated with PHRs was demonstrated. Moreover, a usability evaluation of the app was carried out based on interviews with help desk managers of the app.	In the context of the active epidemiological investigation period (from March 6-19, 2020) at Wakayama City Public Health Center, 72 individuals who had close contact with a COVID-19 confirmed case were discovered. Among them, 57 had adopted the use of the health observation app.	N/A[d]	The active epidemiological investigation period was carried out from March 6-19, 2020, at Wakayama City Public Health Center. In this period 57 of 72 individuals (health observers) adopted the use of the app. By mid-May, the app had been used by more than 20,280 users and 400 facilities and organizations. These included companies, schools, hospitals, and local governments across Japan.
Zamberg et al [34]	Utilization-focused evaluation study to identify the use of an mHealth platform for information sharing	125 members of the hospital staff	25-30 years: 28 members; 31-35 years: 24 members; 36-40 years: 18 members; 41-50 years: 29 members; 51-60 years: 24 members; >60 years: 2 members	The mHealth platform was used for 18 days from February 25, 2020, until March 13, 2020.

[a] mHealth: mobile health.

[b] ETZ: Elisabeth Twee Steden.

[c] PHR: personal health record.

[d] N/A: not applicable.

One study [24] used the corresponding mobile app (StudentLife app) as a tool for an ecological momentary assessment, aiming to assess depression and anxiety of college students to determine whether there was a change in behavior and mental health of participants in response to COVID-19.

The *number of participants* was mentioned in all selected studies. Some studies reported a relatively low numbers of participants using the corresponding app, whereas others a relatively large number of participants and users. The studies that reported the largest number of users were those described by Drew et al [26] (over 2 million users) and Menni et al [30] (2,450,569 users in the United Kingdom and 168,293 from the United States that had reported symptoms through the smartphone app). Studies that reported the lowest number of participants were the ones described by Bae et al [25] (12 patients and 24 medical staff) and Ben Hassen et al [27] (5 hospitalized patients and 5 doctors).

The *age of participants* was also reported in most of the studies except 3 [28,31,33]. The average age or age range for participants varied depending on the corresponding study.

Concerning the *follow-up duration (study duration)*, 3 out of the 12 selected studies [23,25,27], did not report the study duration. Kodali et al [28] reported the end date but did not mention the start date of app use, Drew et al [26] reported only the start date of the app launch, Ros and Neuwirth [31] reported 3 days of app use, Yamamoto et al [33] reported 14 days, Zamberg et al [34] reported 18 days, Timmers et al [32] reported 20 days, and Huckins et al [24] reported 67 days of app use. Finally, Medina et al [29] mentioned that the engagement with the app reached 32%, whereas 25% of users continued under monitoring for longer than 14 days due to persistent symptoms.

Outcomes

Outcome assessments were varied across studies. An overview is shown in Table 4.

Table 4. A comparison of outcomes for the various studies.

Paper	Primary outcomes	Positive/negative outcomes
Timmers et al [32]	• The information provided by the app satisfied the user needs. • Users indicated the added-value of the symptom tracker diary to be high.	• Successful implementation and use of a COVID-19 app for individuals • An interactive map displayed the data collected through the app. • COVID-19 screening results produced at the hospital were linked to app data. • Health care providers and policy makers could use the data in developing their health care strategy based on the distribution of the reported infection load.
Yamamoto et al [33]	• 72 health observers were identified who were in close contact with a confirmed case. Among them, 57 adopted the app, while 14 used telephone as a means for conducting investigations. • Before the introduction of the app, phone interviews required more than 2 hours and four epidemiological officers for contact tracing. After the introduction of the app, only one epidemiological officer was needed to perform health observations. • The visualization of health observation data improved the investigation efficiency and comprehensiveness.	• The ability of individuals to record health status on a daily basis was an important countermeasure against COVID-19. • The use of the app improved the efficiency and completeness of the investigation process for COVID-19 cases carried out by epidemiological officers.
Zamberg et al [34]	• Three documents related to COVID-19 were made available to medical staff via the mobile platform. • Information was viewed 859 times, which accounted for 35.6% of total document views. • The number of sessions per day increased significantly in the study period (more than doubled) compared with the sessions per day in previous weeks. • Usability evaluation: 70 (83.3%) said it was easy to find information about SARS-CoV-2. On a 10-point Likert scale, the mHealth[a] solution scored 8.5 for time-saving and 7.6 for COVID-19 patient care assurance in daily practice.	• Using the mHealth solution as a communication channel turned out to be effective within the organization for dissemination purposes during the pandemic. • Daily practice was conducted by more confident and better-informed health care professionals.
Kodali et al [28]	• Mixed evidence about the use of the app but mainly optimistic	• Error correction, improved data collection quality, and user privacy should be considered in mHealth apps. • Steps must be taken to ensure the reliability of the information provided by users. Therefore, predicting multiple verification of data entered by users could be critical.
Huckins et al [24]	• With the rise of news relevant to COVID-19, college students spent more time seated, had fewer visits, and showed increases in anxiety and depression. • The authors did not observe a return to baseline over the break, although they observed decreases in stress and depression that paralleled the typical drop after the final examination, suggesting some resilience in the face of COVID-19.	• Mobile apps can be effectively used for tracking the mental health of college students.
Drew et al [26]	• The app captures the dynamics of COVID-19 onset days before traditional measures such as positive tests, hospitalizations, or mortality. • The collection emphasizes the potential usefulness of symptom monitoring in real time to help guide the allocation of resources for testing and treatment, as well as advising for tightening or loosening appropriate measures in specific areas.	• With the participation of groups with underrepresented populations, the study aimed to encourage enrollment of individuals from populations that have traditionally been difficult to recruit. • The study could capture correlations based on individual variations over time, a remarkable advantage over repetitive cross-sectional surveys that introduced significant variation between individuals.

Paper	Primary outcomes	Positive/negative outcomes
Medina et al [29]	- Mobile and home-based interventions were feasible for a wide range of conditions with a related risk of poor outcome from COVID-19. - Approximately 10% of the patients in active monitoring presented symptoms such as shortness of breath that required escalation to a virtual provider. The median time to escalation ranged between 7 and 8 days. - Patients with a pulse oximeter at home escalated a few days earlier due to reduced oxygen saturation measurements before subjective complaints of dyspnea. - 2% of patients in active supervision were eventually admitted, and 3% were readmitted for persistent COVID-19 symptoms or due to complications of other underlying diseases. - 9 patients monitored at home died, either due to complications related to COVID-19 or complications of another underlying disease.	- Mobile engagement platforms have the potential to reduce the need for caregiver communication for patients whose symptoms are mild or persistent, freeing up the health care professionals to focus on patients who need it more.
Menni et al [30]	- Besides more established symptoms such as high fever and a persistent cough, loss of smell and taste were possible prognostic factors for COVID-19. - A combination of symptoms such as anosmia, fatigue, persistent cough, and loss of appetite together could identify individuals with COVID-19.	- Physiological assessments of olfactory and taste function or nucleotide-based testing for SARS-CoV-2 could not be replaced by self-reporting. - The authors did not know if anosmia was acquired before or after other COVID-19 symptoms, or during or after the illness.
Ross and Neuwirth [31]	- This app was considered by the users as appropriate to learn and review skills relevant to COVID-19. - More than 95% of respondents gave a score ≥5 for skills acquisition. - 88% of respondents said it matched their health care needs. - 93% of the respondents stated that the app gave them a better understanding. - 87% of the respondents felt quite or very confident about the execution of the procedures, as shown in the lessons. - 94% of respondents said that this particular COVID-19 training program made them feel ready to care for COVID-19 patients. - 95% of respondents would suggest the application to other users.	Advantage over medical videos: - It allowed the user to live the experience of seeing through a first-person view to learn through the eyes of the expert. - The ability for a health care professional to instantly download locally (in a smart phone) material that can be accessed at any time in real time before, during, or after patient care interactions. - When downloaded, the end user could access and view the tutorial at any time, regardless of network signal issues. - Allowed health care professionals to navigate on their own or to jump to sections that were of greater importance to them
Bae et al [25]	- Mobile app: usefulness showed the highest score, followed by satisfaction and perceived ease of use. - Wearable vital sign monitoring perceived usefulness scored the highest, followed by perceived ease of use and satisfaction. - For carers, there was an overall satisfaction score of 4.10/5.	- During periods of pandemics and disasters, automated exchange of information between health care institutions plays an important role in dealing more efficiently with the problem at hand.
Ben Hassen et al [27]	- Patients and doctors alike accepted the home hospitalization system very well.	- Adjustments should be made for COVID-19 patients safely. - Vital signs had to be measured by the patients themselves. - Video communication between patients and doctors was added.
Bourdon et al [23]	- Allowed doctors and patients to maintain social distance, avoiding three or four physical trips per person.	- A physical appointment followed 27% of the teleconsultations. - Average delay of 4.12 days between the onset of symptoms and advice, and <1 day for emergency episodes. - There was 96% sensitivity and 95% specificity for the correct evaluation of the indication of a physical consultation and only 1.0% misdiagnoses.

[a] mHealth: mobile health.

In most of the cases, app users were satisfied with the educational and risk assessment information provided in the mobile apps (both citizens [32] and health personnel [31,34]). They felt reassured and informed. However, there were also concerns [28] about the measures that would need to be taken to ensure the reliability of information provided to users.

In addition, 3 studies [26,30,32] showed the feasibility of the implementation and use of COVID-19 apps to support education, self-management, and symptom tracking through diaries. Symptom tracker apps had even identified potential predictors of COVID-19, such as loss of smell and taste [30]. To this direction, mobile app sensing revealed that, during the COVID-19 pandemic, individuals were more sedentary, visited fewer locations, and showed increases in anxiety and depression [24], which is in line with the "Stay safe, stay home" policies mandated by local and national governments. However, there were concerns that cross-verification of data entered by the users could be crucial [28] and that the self-reported nature of the data collected by these apps could not replace physiological assessments and clinical examinations [30].

Additionally, mobiles apps were used for home monitoring, as reported in 4 studies [23,25,27,29], with satisfactory usability for both patients and health care professionals. These apps were focused on the management of patients who are at high risk, the moderation of exposure risk for health care workers, and the reductions of community spread through appropriate education on home-based care for individuals who are exposed or infected.

Based on the data reported in the reviewed papers, interactive maps and dashboards could be created for the quick visualization of the status summary of patients with COVID-19 and disease spread to be used by policy makers and health care providers for decision making at regional levels [26,32,33]. In addition, the dynamics of incidence days could be effectively captured, guiding allocation of resources for testing, treatment, and lockdown recommendations [26]. Mobile apps could significantly improve the efficiency and completeness of contact tracing workflows [33].

Discussion

Main Findings

A systematic review on COVID-19 mobile apps, as used and evaluated in research studies published in the scientific literature, is presented. Our literature search returned a significant number of records (476 unique published manuscripts), despite the short time period covered (December 2019 to June 2020), thereby showing the high interest of the scientific community in the research of mobile apps for COVID-19.

Our main finding is that, despite that the current research evidence is fragmented and requires greater methodological rigor, mobile apps have been found to benefit citizens, health professionals, and decision makers in facing the COVID-19 pandemic. In particular, mobile apps can help in solving several COVID-19–related challenges by increasing the reach of reliable information to both citizens and health professionals, decreasing misinformation and confusion, tracking symptoms and mental health of citizens, home monitoring and isolation, discovering new predictors, optimizing health care resource allocation, and reducing the burden of hospitals.

The participants in the studies were mainly young and middle-aged adults. Further studies are needed that will involve older participants, who are in greater risk of developing serious complications due to COVID-19. Understanding the needs of older individuals in the COVID-19 pandemic period would be the first necessary step toward designing and developing mobile apps to encourage their physical and mental well-being [17].

Our review, in contrast to other reviews that have not examined the evaluation of COVID-19 mobile apps in pragmatic studies [8], identified that the majority of included studies were not of high methodological quality, mainly because of their observational nature. This could be justified by the fact that the COVID-19 pandemic crisis generated an international appeal for fast response and rapid development of digital health tools by the research community, which might have inevitably led to the publication of early results by observational studies. This result can be seen as complementary to other reviews [8] that report that many of those apps are of high quality, offering many functionalities and advanced user experience. Longitudinal studies with rigorous design such as randomized controlled trials are now required to systematically assess COVID-19 mobile apps and provide strong evidence of their value. However, ethical implications might arise due to possible conflicts between liberty and privacy, equity, fairness, and justice [35-37]. In this direction, health outcomes that have scarcely been used so far, such as infection rate and quality of life, could be used as primary end points.

Implications for Clinical Practice

The implications for clinical practice for each one of the discussed works is shown in detail in Textbox 1.

Textbox 1. Implications for clinical practice.

Timmers et al [32]

- eHealth mobile apps for COVID-19 that support several functionalities such as tracking of symptoms and provision of accurate and timely information as well as self-assessment can be implemented in a short time to be used by individuals.
- Those apps provide valuable information to both governments and health care providers, since they support monitoring of patient health status and provide summary statistics regarding the progress of health.
- Such apps could be used in future outbreaks of other viruses to support all involved stakeholders.

Yamamoto et al [33]

- Such apps could be used in future outbreaks of other viruses to support all involved stakeholders.

Zamberg et al [34]

- Mobile health (mHealth) apps could help solve some of the COVID-19 challenges by providing more accurate and timely information to health care professionals. This benefit is sourced by the centralized management and storage of main, up-to-date, validated, and easily accessed information in one platform.
- mHealth apps used in health care organizations as communication tools of validated information should be assessed in the context of clinical studies, with regards to their impact on clinical outcomes.

Kodali et al [28]

- According to users, the app should be enhanced with additional functionalities including tracking of location, provision of up-to-date information on COVID-19 as well as information on areas with high/medium/low epidemiological burden, and deployment in nonmobile platforms.

Huckins et al [24]

- According to the findings, since the beginning of the COVID-19 pandemic, there has been an extended negative impact both on the physical health of individuals, resulting in an increased number of deaths, and in their mental health, resulting in changes in their behavior.

Drew et al [26]

- The research of a broader range of potential risk factors for COVID-19 results will be largely supported by the use of the app within several large epidemiology cohorts for which there are a large amount of data on lifestyle, diet and health factors, and genetic information.
- It will be useful to deploy the tool in several clinical studies, in centralized actions related to biobanking, and in health care worker monitoring programs.

Medina et al [29]

- The intervention impacts several organizational matters and provides answers regarding the following questions related to COVID-19:
    - Which situations should we focus on to provide effective care to prevent patient admission to intensive care unit and mechanical support?
    - How can those situations be better supported by increased patient self-reporting?
    - Can we predict, based on time data, future inpatient demand?
    - How can we manage not having conflicts between patient choice and availability of treatment?

Menni et al [30]

- Routine screening for COVID-19 could also include loss of sense of taste and smell. These two symptoms should also be included in the related symptom list provided by the World Health Organization.

Ros and Neuwirth [31]

- The implementation and deployment of the described digital tutorials, as an effective and swift global public health educational tool, help alleviate the burden that hospitals, health care professionals/responders, and patients face due to the COVID-19 pandemic.

Bae et al [25]

- Episode triage, timely diagnosis, isolation of patients, and their treatment can be largely supported by telemedicine solutions.

Ben Hassen et al [27]

- Mobile apps can be used by patients, their caregivers, and health care professionals to better monitor and manage patient health status in the context of patient hospitalization. Moreover, such apps are cost-effective, reliable, and safe, providing important economic benefits to hospitals. Overall, they are accepted to a great extent by patients and individuals.

Bourdon et al [23]

- The use of telemedicine tools for consultation purposes improved the access to health care services for patients with ophthalmological problems. At the same time, such tools preserved social distancing and sanitary measures.
- Such tools can be used in emergency situations by ophthalmological patients who have limited access to specialized care.

As reported in the textbox, eHealth solutions can be implemented rapidly and can offer essential tools in supporting the COVID-19 pandemic for all stakeholders including citizens, health care providers, policy makers, and governments. The impact of the COVID-19 pandemic goes beyond the illness and deaths that are directly associated with the SARS-CoV-2 pathogen and toward an expanded scope encompassing mental health and several behavioral changes.

However, there are still several areas to explore, such as better geolocation tracking; timely COVID-19 updates; deployment on nonsmartphone platforms; better incidence visualization and prediction; investigation of a much broader range of putative risk factors for COVID-19 outcomes (based on other longitudinal data on lifestyle, diet, genetics, etc); and the integration with clinical systems, digital health literacy, and engagement with mobile apps.

Apps such as the ones presented in these studies can give the research community the opportunity to monitor long term effects of COVID-19; answer questions such as the number of people truly affected, why some people get sicker than others, and how long people can stay immune to the disease; and perform better resource allocation of medical equipment.

In case of future disease outbreaks, the mobile apps already developed for COVID-19 can be valuable tools ready to support people, health care providers, and policy makers. This study can provide a guide for future developers and researchers regarding the current methodological gaps and challenges that need to be addressed to develop well-designed and evaluated apps for similar future circumstances.

Limitations

We used terms related to mobile apps, mHealth, and mobile phones for our literature search according to the review objectives and did not use related terms such as “telehealth,” which might have resulted in an inadvertent omission of studies. Our literature search was conducted in a limited number of bibliographic databases (Pubmed, Scopus, and the WHO’s COVID-19 database), which nevertheless have been largely used worldwide. The gray literature was not explored. The interrater reliability between the authors was not assessed. A meta-analysis was not possible due to the heterogeneity of the included studies. For many cases, the quality of the study might not reflect the quality or the effectiveness of the developed mobile app. As such, useful and effective apps might have not been included in this review study due to the limited quality of the related studies.

Acknowledgments

This research was supported by the Computational Biomedicine Lab and the Center for eHealth Applications and Services of the Foundation for Research and Technology – Hellas, and the Information Technologies Institute of the Centre for Research and Technology – Hellas.

Work presented in the paper is part of the KRIPIS project “Novel technologies to monitor, support and improve the quality of life of patients and other vulnerable user groups (Quality of Life)” funded in the context of the National Strategic Reference Framework 2014-2020, European Regional Development Fund.

Abstract

Background: Telehealth is a recommended method for monitoring the progression of nonsevere infections in patients with COVID-19. However, telehealth has not been widely implemented to monitor SARS-CoV-2 infection in quarantined individuals. Moreover, studies on the cost-effectiveness of quarantine measures during the COVID-19 pandemic are scarce.

Objective: In this cohort study, we aimed to use telehealth to monitor COVID-19 infections in 217 quarantined Taiwanese travelers and to analyze the cost-effectiveness of the quarantine program.

Methods: Travelers were quarantined for 14 days at the Taiwan Yangmingshan quarantine center and monitored until they were discharged. The travelers' clinical symptoms were evaluated twice daily. A multidisciplinary medical team used the telehealth system to provide timely assistance for ill travelers. The cost of the mandatory quarantine was calculated according to data from the Ministry of Health and Welfare of Taiwan.

Results: All 217 quarantined travelers tested negative for SARS-CoV-2 upon admission to the quarantine center. During the quarantine, 28/217 travelers (12.9%) became ill and were evaluated via telehealth. Three travelers with fever were hospitalized after telehealth assessment, and subsequent tests for COVID-19 were negative for all three patients. The total cost incurred during the quarantine was US $193,938, which equated to US $894 per individual.

Conclusions: Telehealth is an effective instrument for monitoring COVID-19 infection in quarantined travelers and could help provide timely disease management for people who are ill. It is imperative to screen and quarantine international travelers for SARS-CoV-2 infection to reduce the nationwide spread of COVID-19.

KEYWORDS

COVID-19; international travelers; quarantine; telehealth; cost-effectiveness; cohort; monitoring; telemedicine

Introduction

COVID-19 is caused by SARS-CoV-2 and was first detected in Wuhan, China, in December 2019. This disease caused a rapidly accelerating global pandemic in 2020 [1]; as of November 13, 2020, more than 51.8 million individuals were infected with COVID-19 globally, with the official death toll reaching 1.3 million [2].

As the COVID-19 outbreak emerged, the Taiwanese government implemented several strategies to prevent the nationwide spread of COVID-19, including border controls, proactive screening measures, and quarantine procedures [3,4]. According to the Taiwan Communicable Disease Control Act [5], as of January 2020, all international travelers who visited regions with a declared COVID-19 outbreak were required to complete a 14-day mandatory quarantine. By November 13, 2020, 597 laboratory-confirmed COVID-19 cases were reported to the Taiwan Centers for Disease Control, including 505 imported cases (84.6%) [6]. The national mortality rate among laboratory-confirmed COVID-19 cases was 1.2% [6].

Currently, no effective pharmacological interventions or vaccines are available to treat or prevent COVID-19 [7,8]. Therefore, nonpharmacological public health measures such as quarantine, isolation, social distancing, and community containment are the only effective ways to prevent infection and control the COVID-19 outbreak [9]. Quarantine is the most effective tool for controlling the COVID-19 outbreak [9]; it refers to the restriction of asymptomatic healthy people who have had contact with confirmed or suspected COVID-19 cases. Quarantine can be voluntary or mandatory, and it can be applied at an individual or group level. A recent Cochrane review [10] showed that the quarantine strategy could significantly reduce the number of people infected with SARS-CoV-2 and decrease the number of COVID-19–related deaths.

During quarantine, all individuals should be monitored for the onset of symptoms; otherwise, there is risk of delays in the detection and prompt management of the virus. Telehealth through a line of communication is an efficient way to monitor quarantined individuals and can assist in providing timely care for people who require it [11]. Although telehealth has been recommended to screen patients with COVID-19 in emergency departments [12] and provide care for nonsevere COVID-19 cases [13], it has not been widely implemented in the monitoring of COVID-19 infection in quarantined individuals.

Quarantine strategies have been used in many countries in an attempt to curb the ongoing COVID-19 pandemic. However, the cost-effectiveness of these strategies has not been extensively studied [10]. A current report [14] indicates that the quarantine strategy is efficient in curbing the spread of COVID-19, and the cost of a quarantine strategy is lower than that of lockdown of workplaces.

This cohort study reports on a model used for screening and quarantining Taiwanese travelers following an evacuation flight from Hubei, China. In this model, telehealth was used to monitor COVID-19 infection among travelers at a centralized quarantine center, and the cost-effectiveness of the 14-day mandatory quarantine strategy was analyzed.

Methods

Background Information and Study Subjects

In late January 2020, the Taiwanese government established a centralized quarantine center to screen and monitor COVID-19 infections in international travelers who had visited countries with a declared COVID-19 outbreak [5]. On March 30, 2020, the government of Taiwan arranged a special charter flight to evacuate Taiwanese travelers who had become stranded in Hubei, China, and return them to Taiwan. Upon arrival in Taiwan, the travelers proceeded to one of the largest national centralized quarantine centers, Taipei Yangmingshan, for the mandatory 14-day quarantine period. The Yangmingshan quarantine center included six quarantined wards on three floors.

This cohort study included all the passengers of the charter flight, who were subsequently followed up until their discharge from the quarantine center or until April 15. This study was approved by the Institutional Review Board of Taipei City Hospital (no. TCHIRB-10904014-E).

Infection Control Strategies

The body temperature of the Taiwanese travelers was checked at the international airport in China, and individuals with fever were not allowed to board the charter flight. All travelers were required to disinfect their hands with alcohol-based hand sanitizer at the boarding port and to wear personal protective equipment (PPE) provided by the Taiwanese government, which included a face mask and medical gown. Meals were not provided during the flight to avoid cross-infection between passengers.

Upon arrival at the international airport in Taiwan, National Defense chemical troops used a 1:10 diluted sodium hypochlorite solution (5000 ppm) to disinfect the travelers' luggage. The travelers then proceeded to the Yangmingshan quarantine center for the 14-day quarantine period. They were required to record their body temperature twice daily with a thermometer that was provided to them. Additionally, daily meals were delivered to the individuals' rooms, and janitors used a 1:10 diluted sodium hypochlorite solution to clean the quarantine center once daily.

COVID-19 Screening and Monitoring

During admission to the Yangmingshan centralized quarantine center, the travelers were screened for COVID-19 using a real-time reverse transcriptase–polymerase chain reaction (RT-PCR) test. If an individual tested positive for COVID-19, they were transferred to a hospital for medical isolation and treatment.

Travelers' clinical symptoms were recorded twice daily by their primary care nurses via telephonic communication. If an individual developed fever or became ill, a multidisciplinary team (MDT) consisting of 15 medical workers used telehealth to assess the traveler's condition.

Telehealth System

The telehealth system at the Yangmingshan quarantine center was developed based on a popular social media app called LINE, which is a freeware app operated by the NAVER Corporation in South Korea. The LINE-based telehealth system established two-way communication between the MDT and 217 quarantined travelers. Through a unique ID, the quarantined individuals were invited to join an official LINE group in which the quarantined travelers could report their symptoms to the MDT members. When the MDT members received a message regarding a quarantined traveler's symptoms, the MDT members initiated a one-to-one video call through LINE to clinically evaluate the patient. The MDT members collaboratively discussed the traveler's condition during the telehealth session and provided appropriate management and treatment interventions for the traveler. If a quarantined traveler presented with fever or shortness of breath, they were transferred to the hospital for further treatment.

Personnel and Cost at Yangmingshan Quarantine Center

The personnel who were responsible for overseeing the travelers' quarantine at the Yangmingshan quarantine center included the MDT, police officers, janitors, a logistics group, and administration staff. The MDT consisted of 3 physicians, 10 nurses, a pharmacist, and a psychologist. Three physicians, including a general practitioner, a pediatrician, and a cardiologist, gave treatment advice according to the traveler's condition during the telehealth session. The 10 nurses were responsible for taking care of the travelers during 12-hour day and night shifts in the six quarantined wards. The nurses communicated daily with the quarantined travelers to evaluate their clinical condition and record their body temperature. The pharmacist delivered medications to ill quarantined travelers. Physicians and nurses wore PPE when examining the travelers in person.

The police officers were responsible for the security of the travelers at five sentry points and ensured that all travelers obeyed the COVID-19 quarantine rules and completed the 14-day mandatory quarantine order. In total, 18 police officers were divided into three groups, with one leader in each group. The three groups of police officers worked in 12-hour day and night shifts. Three janitors were responsible for environmental disinfection in the six quarantined wards, and one janitor was responsible for two quarantined wards on one floor. The logistics group, composed of 10 people, was responsible for meal preparation and ensuring that sufficient supplies were provided to the 217 travelers during the 14-day quarantine.

The cost of the quarantine for the travelers at the Yangmingshan quarantine center was covered by the disaster reserve of the national Ministry of Health and Welfare, which included payment of the MDT, nonmedical personnel, and telehealth services as well as the provision of PPE.

Statistical Analysis

First, the participants' demographic data were analyzed. Continuous data are presented as mean (SD), and two-sample *t* tests were used for comparisons between groups. Categorical data were analyzed with Pearson chi-square tests where appropriate. A P value <.05 was considered to indicate statistical significance.

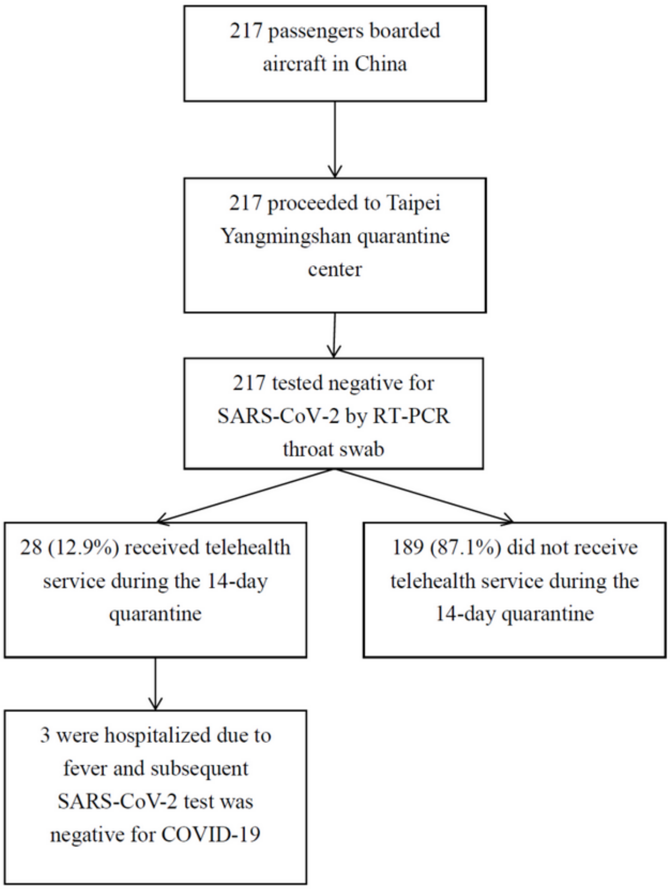
A timeline infographic was used to display the progression of clinical symptoms in hospitalized travelers. The labor and overall costs of the quarantine were calculated according to the disaster reserve data from the Taiwan Ministry of Health and Welfare. All data management and analyses were performed using SPSS 19.0 (IBM Corporation).

Results

Participant Selection and Epidemiologic Features

Our sample comprised 217 Taiwanese travelers who were stranded in Hubei, China, due to the COVID-19 pandemic and who returned to Taiwan on March 30, 2020 (Figure 1). The mean age of the sample was 30.0 years (SD 19.4), and 130 of the 217 subjects (59.9%) were female. All travelers tested negative for COVID-19 by an RT-PCR throat swab upon admission to the Taipei Yangmingshan quarantine center. During the 14-day quarantine, 28 of the 217 travelers (12.9%) underwent telehealth consultations due to illness.

Figure 1. The process of follow-up in Taiwanese travelers quarantined at the Yangmingshan centralized quarantine center. RT-PCR: reverse transcriptase–polymerase chain reaction.



Characteristics of Quarantined Travelers With and Without Telehealth Evaluation

Table 1 shows the characteristics of quarantined travelers who were and were not evaluated with telehealth. There was no significant difference in the age or sex of the quarantined travelers who were and were not evaluated with telehealth. Three travelers had fever and underwent clinical assessment using telehealth during the 14-day quarantine period.

Table 1. Characteristics of Taiwanese travelers who were and were not evaluated with telehealth at a centralized quarantine center.

Characteristic	Total (N=217)	Evaluated with telehealth (n=28)	Not evaluated with telehealth (n=189)	*P* value
Age (years), mean (SD)	30.0 (19.40)	33.0 (18.1)	29.6 (17.3)	0.33
Age (years), n (%)				0.68
<20	78 (35.9)	8 (28.6)	70 (37.0)	
20-39	54 (24.9)	8 (28.6)	46 (24.3)	
≥40	85 (39.2)	12 (42.8)	73 (38.7)	
Sex, n (%)				0.61
Female	130 (59.9)	10 (35.7)	77 (40.7)	
Male	87 (40.1)	18 (64.3)	112 (59.3)	
Number of family members, n (%)				<.001
1	79 (36.4)	19 (67.9)	60 (31.7)

No	214 (98.6)	25 (89.3)	189 (100)	
Yes	3 (1.4)	3 (10.7)	0 (0)	
Hospitalization, n (%)				<.001
No	214 (98.6)	25 (89.3)	189 (100)	
Yes	3 (1.4)	3 (10.7)	0 (0)	

Symptoms and Management in Quarantined Travelers Receiving Telehealth Care

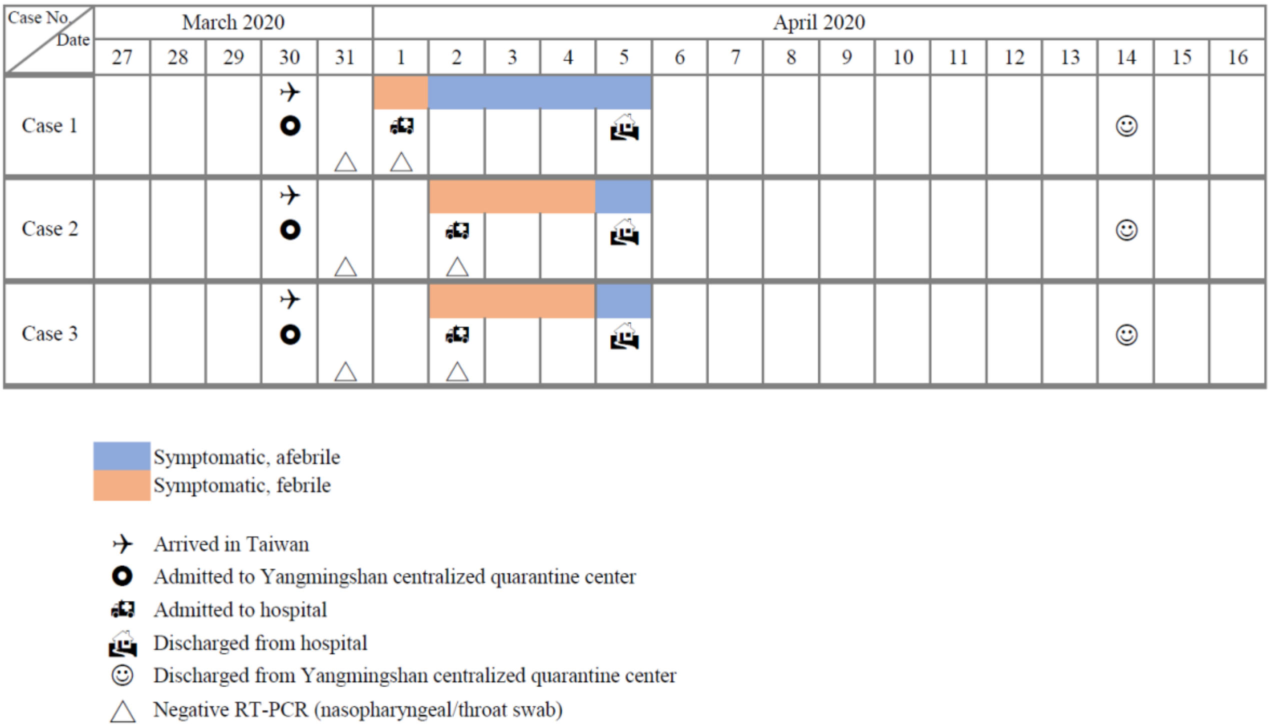
The symptoms and management of quarantined travelers receiving telehealth care were recorded during the 14-day mandatory quarantine (Multimedia Appendix 1). The most common symptoms requiring telehealth consultations in quarantined travelers were fever (n=3), diarrhea (n=3), toothache (n=3), and skin rashes (n=3). Of the 217 travelers, 3 (1.4%) developed fever during the 14-day quarantine period and were hospitalized after a telehealth assessment.

Of the 28 quarantined travelers evaluated with telehealth, one traveler with diabetes presented with dizziness and weakness on the fifth day and was suspected to be hypoglycemic during the telehealth clinical evaluation. The patient's blood glucose test indicated a level of 75 mg/dl when health care workers wearing PPE visited this individual.

Clinical Features of Hospitalized Patients

Figure 2 shows the progression of clinical symptoms in three hospitalized travelers. One traveler developed fever and illness 2 days after quarantine, and two additional travelers developed fever 3 days after being admitted to the centralized quarantine center. Chest x-rays of all three patients were negative for pneumonia. Moreover, a second round of SARS-CoV-2 testing by RT-PCR throat swab was negative for COVID-19 in all three individuals. They were subsequently discharged from the hospital on April 5 and returned to the Yangmingshan quarantine center to complete the mandatory quarantine.

Figure 2. Time course of clinical symptoms in the three hospitalized travelers.



Cost Analysis of the 14-Day Mandatory Quarantine of Taiwanese Travelers

Table 2 shows the labor and overall cost incurred during the 14-day mandatory quarantine. The major personnel consisted of police officers (n=18), followed by the MDT (n=15). Moreover, the major expense was the labor cost of the MDT (US $72,334, 37.30%), followed by police officers (US $66,427, 34.25%) and the cost of PPE (US $16,016, 8.26%). The total cost incurred during the 14-day quarantine was US $193,938, which equated to US $894 per traveler.

Table 2. Cost analysis of the 14-day mandatory quarantine of 217 Taiwanese travelers.

Variable	Personnel, n	Cost (US $), amount (%)
Personnel costs		
Multidisciplinary medical team	15	72,334 (37.30)
Police officers	18	66,427 (34.25)
Janitors	3	10,880 (5.61)
Logistic group	10	8033 (4.14)
Administration staff	1	894 (0.46)
Nonpersonnel costs		
Telehealth equipment	N/A[a]	2838 (1.46)

Discussion

Principal Findings

This cohort study reports a model for the screening and quarantining of international travelers who visited countries with a declared COVID-19 outbreak. All travelers tested negative for COVID-19 during the 14-day mandatory quarantine period. Three travelers with fever were hospitalized after the telehealth assessment, and subsequent tests for COVID-19 were negative for all three patients. The total costs during the quarantine were US $193,938, which equated to US $894 per individual. Our study demonstrates that strict infectious control measures, proactive screening, and an MDT integrated with the use of telehealth contributed to the successful quarantine of international travelers while remaining cost-effective for containing the spread of COVID-19.

Quarantine is an effective strategy to control and prevent COVID-19 outbreaks [9]. However, monitoring individuals in quarantine is essential to provide prompt management and early detection of COVID-19 cases. By establishing a line of communication between health care workers and quarantined individuals, telehealth can provide timely assessment of quarantined individuals and fast-track the hospitalization of people who develop symptoms of COVID-19. Although telehealth has not been widely adopted in monitoring COVID-19 infections in quarantined individuals, one study in China [15] used a telehealth system to monitor 188 home-quarantined individuals; it was found that 74 individuals (39.4%) were infected with SARS-CoV-2. Moreover, 6 of the 74 confirmed COVID-19 cases (8.1%) were hospitalized after the telehealth assessment [15]. Our study used telehealth to monitor COVID-19 infections in 217 international travelers during the 14-day mandatory quarantine. Three travelers with fever were hospitalized after the telehealth assessment, and subsequent tests for COVID-19 were negative for all three patients. Because telehealth can assist in providing timely assessment and does not delay hospitalization of quarantined individuals, our study suggests that it is imperative to adopt telehealth to monitor COVID-19 infections in this population.

Our report is among the first to analyze the cost-effectiveness of an enforced quarantine program. We found that the total cost of a 14-day quarantine for 217 international travelers was US $193,938, equating to US $894 per traveler. Although none of the 217 Taiwanese travelers tested positive for SARS-CoV-2 during the 14-day mandatory quarantine period, this study highlights the importance of screening and immediately quarantining returning international travelers because of the high risk of COVID-19 in this population [16]. The quarantine strategy in our report is also corroborated by a recent study [14], in which it was reported that the quarantine strategy is efficient in curbing the COVID-19 outbreak, and its relative efficacy increases when supplemented with other measures designed to reduce disease transmission.

LINE-based telehealth can provide timely assessment and care for patients who require it. During the COVID-19 surge, LINE-based telehealth could provide care for nonsevere COVID-19 cases in hospitals [13], and health care workers can provide timely assessment and management of patients with COVID-19 through the telehealth system and reduce the transmission of SARS-CoV-2 in health care facilities [11].

Limitations

The present study has two limitations. First, our study did not compare the cost-effectiveness of a 14-day quarantine for high-risk COVID-19 individuals. In this cohort study, none of the 217 Taiwanese travelers tested positive for SARS-CoV-2 during the 14-day mandatory quarantine period. As SARS-CoV-2 is highly contagious [17], it is imperative to screen and quarantine travelers who have visited countries with a declared COVID-19 outbreak. Second, the external validity of our findings may be a concern because all our patients were Taiwanese. The generalizability of our results to other non-Asian ethnic groups requires further verification. However, our findings suggest new avenues for future research.

Conclusion

This prospective cohort study reports an enforced quarantine program integrated with a telehealth system to monitor COVID-19 infection in quarantined individuals. Telehealth not only provided timely management of quarantined individuals with illness but also reduced the risk of COVID-19 infection in health care workers. Our study suggests that it is imperative to screen and quarantine international returning travelers to reduce the nationwide spread of COVID-19.

Acknowledgments

The authors are grateful to the members of the Research Office for Health Data, Department of Education and Research, Taipei City Hospital, Taiwan, for their valuable contributions to the data management and statistical analysis.

Abstract

Background: The COVID-19 pandemic, caused by the novel coronavirus SARS-CoV-2, has instigated immediate and massive worldwide research efforts. Rapid publication of research data may be desirable but also carries the risk of quality loss.

Objective: This analysis aimed to correlate the severity of the COVID-19 outbreak with its related scientific output per country.

Methods: All articles related to the COVID-19 pandemic were retrieved from Web of Science and analyzed using the web application SciPE (science performance evaluation), allowing for large data scientometric analyses of the global geographical distribution of scientific output.

Results: A total of 7185 publications, including 2592 articles, 2091 editorial materials, 2528 early access papers, 1479 letters, 633 reviews, and other contributions were extracted. The top 3 countries involved in COVID-19 research were the United States, China, and Italy. The confirmed COVID-19 cases or deaths per region correlated with scientific research output. The United States was most active in terms of collaborative efforts, sharing a significant amount of manuscript authorships with the United Kingdom, China, and Italy. The United States was China's most frequent collaborative partner, followed by the United Kingdom.

Conclusions: The COVID-19 research landscape is rapidly developing and is driven by countries with a generally strong prepandemic research output but is also significantly affected by countries with a high prevalence of COVID-19 cases. Our findings indicate that the United States is leading international collaborative efforts.

KEYWORDS

scientometric analysis; COVID-19; SARS-CoV-2; citation analysis; research; literature; citation

Introduction

The global pandemic caused by the novel coronavirus SARS-CoV-2, leading to the disease COVID-19, has instigated immediate and massive worldwide research activities. Literature on preprint servers is increasing enormously. Prominent servers such as bioRxiv and medRxiv receive numerous new manuscripts each day and currently list 6063 articles (as of July 4, 2020). Additionally, peer-reviewed literature is growing at an unprecedented rate with articles published in various leading medical and related journals [1-3]. Rapid publication of research data can be desirable but also carries the risk of quality loss. In fact, some manuscripts have been accepted on the day of submission, which calls into question the completion of a sufficient peer-review process [4], leading to a relatively high number of retractions even in high-ranking journals [5,6].

This scientometric study aimed at providing profound insights into the current scientific SARS-CoV-2 research landscape. According to the World Health Organization, on July 4, 2020, the United States reported the highest absolute number of confirmed COVID-19 cases with 2,724,433 positive test results and 128,481 associated deaths [7]. In Europe, the United Kingdom and Italy reported the highest number of infected persons, with 284,280 and 241,184 cumulative cases, respectively, while China reported 85,287 cases [7]. The present study also aimed to correlate the severity of the COVID-19 outbreak with COVID-19–related scientific output per region during the pandemic, as well as to assess international collaboration.

Methods

Data Search Strategy

The online database Web of Science Core Collection (WoS) was searched to retrieve all analyzed data, containing the words “covid19,” “covid-19,” “sarscov2,” or “sars-cov-2” in the title or abstract. We refrained from adding the word “corona” to our search term, as this may identify publications unrelated to the COVID-19 pandemic. The exact search term in WoS was as follows: [TI=(covid19 OR covid-19 OR sarscov2 OR sars-cov-2) OR AB=(covid19 OR covid-19 OR sarscov2 OR sars-cov-2)]. All articles found through this search were eligible and analyzed up until and including the date of retrieval on June 14, 2020. A second search was performed on October 25 to assess changes in the scientific landscape following the initial search. There were no exclusion criteria if the article was identified by the above-mentioned search terms, including no restrictions on language, article type, or region of publication. A cross-check was performed with other medical databases such as PubMed to avoid missing articles.

Data Acquisition and Processing

By applying the web application SciPE (science performance evaluation), a dedicated web-based scientometric tool, the full set of research items was analyzed, as described elsewhere [8].

In brief, metadata of the retrieved publication data extracted from WoS were processed and visualized accordingly. WoS is the standard database for citation analyses, as it provides more details compared with other medical databases [9]. Hence, SciPE was programmed to process WOS metadata for further analysis. All institution-specific data were compared to a normalized and comprehensive list of an online university ranking list [10]. All data were coupled to a fee-based Google API (application programming interface) key enabling the assessment of exact geo-positions for all analyzed institutions by internal processing utilizing SciPE. Consecutively, institution heatmaps were created according to these results. Information on each country’s population size was extracted from the World Factbook [11].

Assessment of Collaborations Between Institutions and Countries

To assess the level of collaboration between institutions and different countries, the affiliations of the first author were analyzed and compared with the affiliations of all other coauthors. Each institution of a country that was distinct from the first author’s country was counted as one cooperation and visualized in a chord diagram. The width of each chord is proportional to the amount of existing cooperation between institutions or countries.

Ethical Approval

Since this was a metadata analysis of published work, ethics committee approval was not required.

Results

Overview

In the initial search on July 4, 2020, a total of 7185 publications were extracted from WoS, including 2592 articles, 2091 editorial materials, 2528 early access papers (likely comprising mostly of articles and letters), 1479 letters, 633 reviews, and other contributions (Figure 1). Of note, some publications could be classified into various categories (Figure 2). For example, 1014 publications fell in the categories article and early access at the same time. An additional 670 items were both letters and early access papers; interestingly, 15 items were categorized as early access and correction. Of all articles, 0.8% (58/7185) were corrections or retractions of published material. As of October 25, a total of 44,944 articles were identified on WoS with the same search terms used in the initial search. Of these, 21,218 (47.2%) were original articles, 8727 (19.4%) were editorial material, 8389 (18.7%) were letters, 4634 (10.3%) were reviews, and 342 (0.8%) were corrections or retractions.

Figure 1. Publications included in the study. Bubble size reflects the number of instances of each item class.

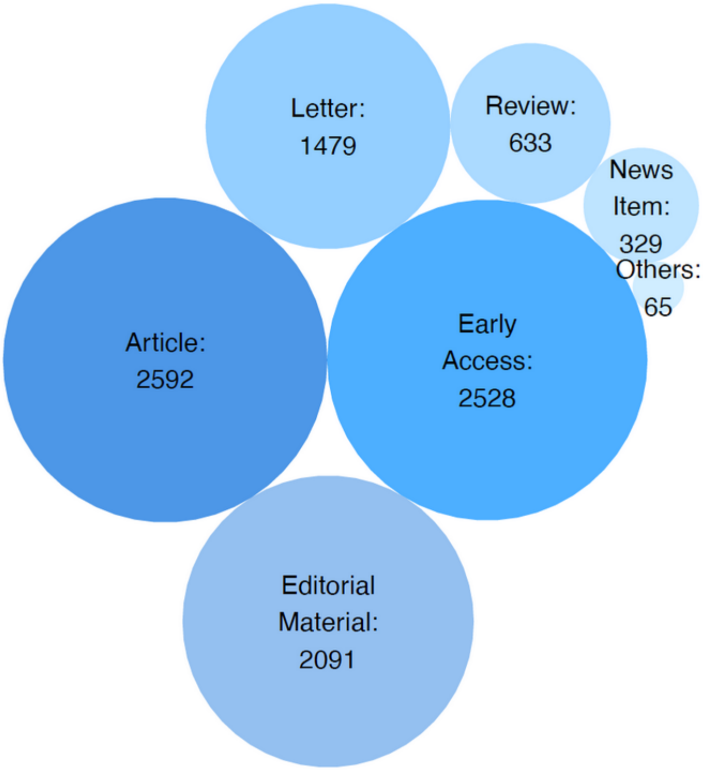

Figure 2. UpSet plot that provides details on publications that are attributed to more than one category.

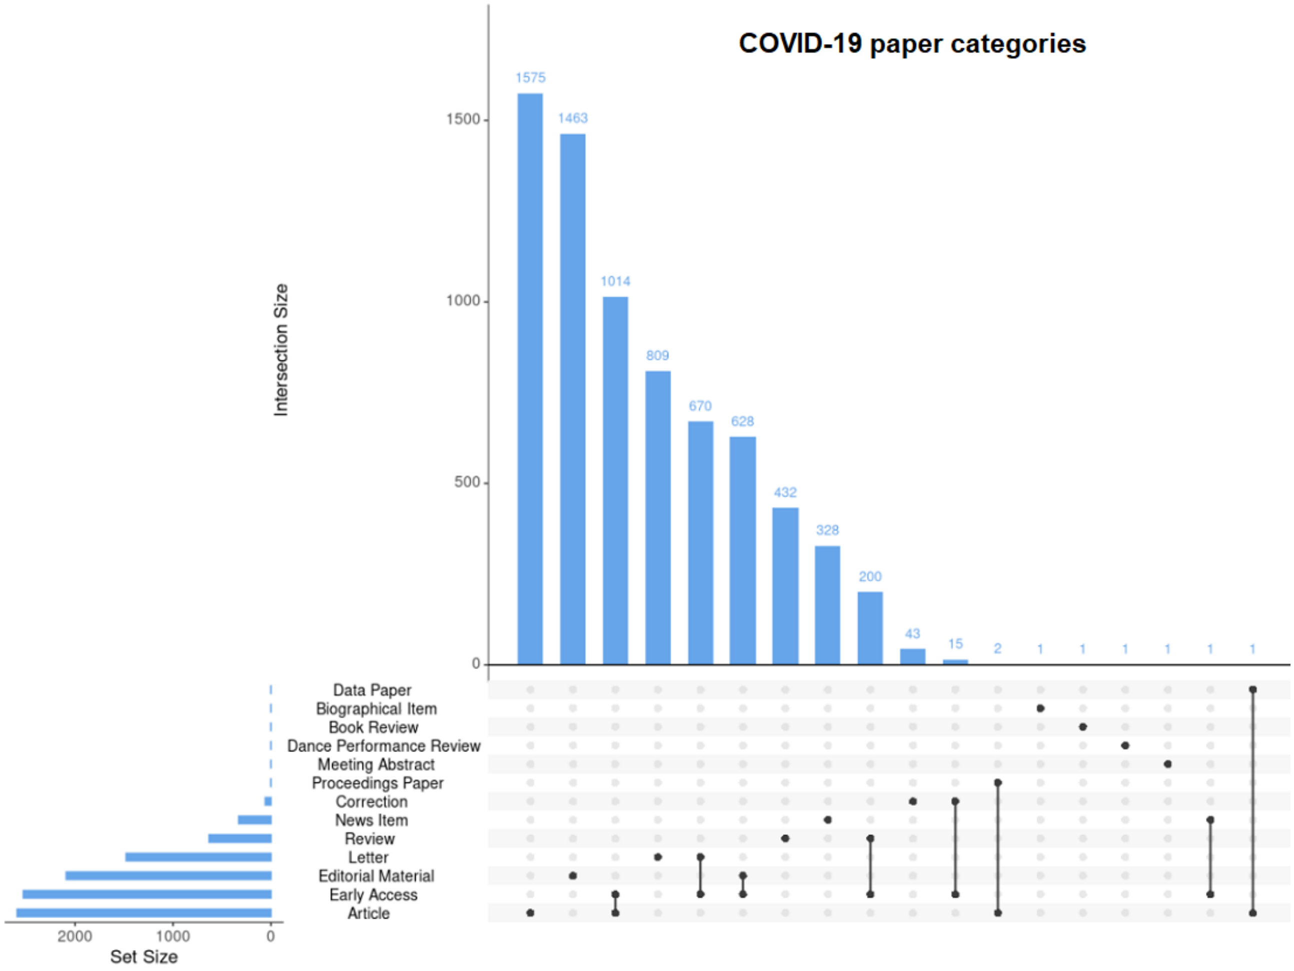

The top 3 authors were medical journalists not affiliated with research or academic institutions, who published news updates. The fourth most active author (with 25 senior authorship positions) primarily published "letters to the editor," commenting on various medical research fields.

International Collaboration in COVID-19 Research

The analyses of collaborative literature on SARS-CoV-2 and COVID-19 revealed a significant amount of joint publications (Figure 3A). The cooperation landscape for the leading countries (United States, United Kingdom, China, and Italy) are highlighted in thumbnail graphics (Figure 3B). For China, the United States was the most common cooperation partner, followed by the United Kingdom. Italy also shared several manuscripts with the United States and the United Kingdom. Here, China played a far less significant role while neighboring European countries such as France, Germany, and Switzerland were frequently found to collaborate. Similarly, researchers from other European countries such as Spain often coauthored publications with researchers from Italy. The international publication behavior did not significantly change between July and October 2020: the United States, the United Kingdom, China, and Italy remained the leading nations in terms of the number of publications. The extent of international collaboration has been stable (Multimedia Appendices 1-4). With respect to universities and institutions, the Chinese University of Hong Kong played a leading role (Figure 4), collaborating on research with many different institutions, both in China and other countries. Likewise, the Wuhan University and the Massachusetts College of Pharmacy and Health Sciences shared several national and international publications. Of note, frequently only one or two manuscripts between the respective universities were found.

Figure 3. (A) Research collaborations identified by joint publications. Each edge corresponds to a joint publication between the connected countries. (B) Leading countries—United States, United Kingdom, China, and Italy—in the cooperation landscape.

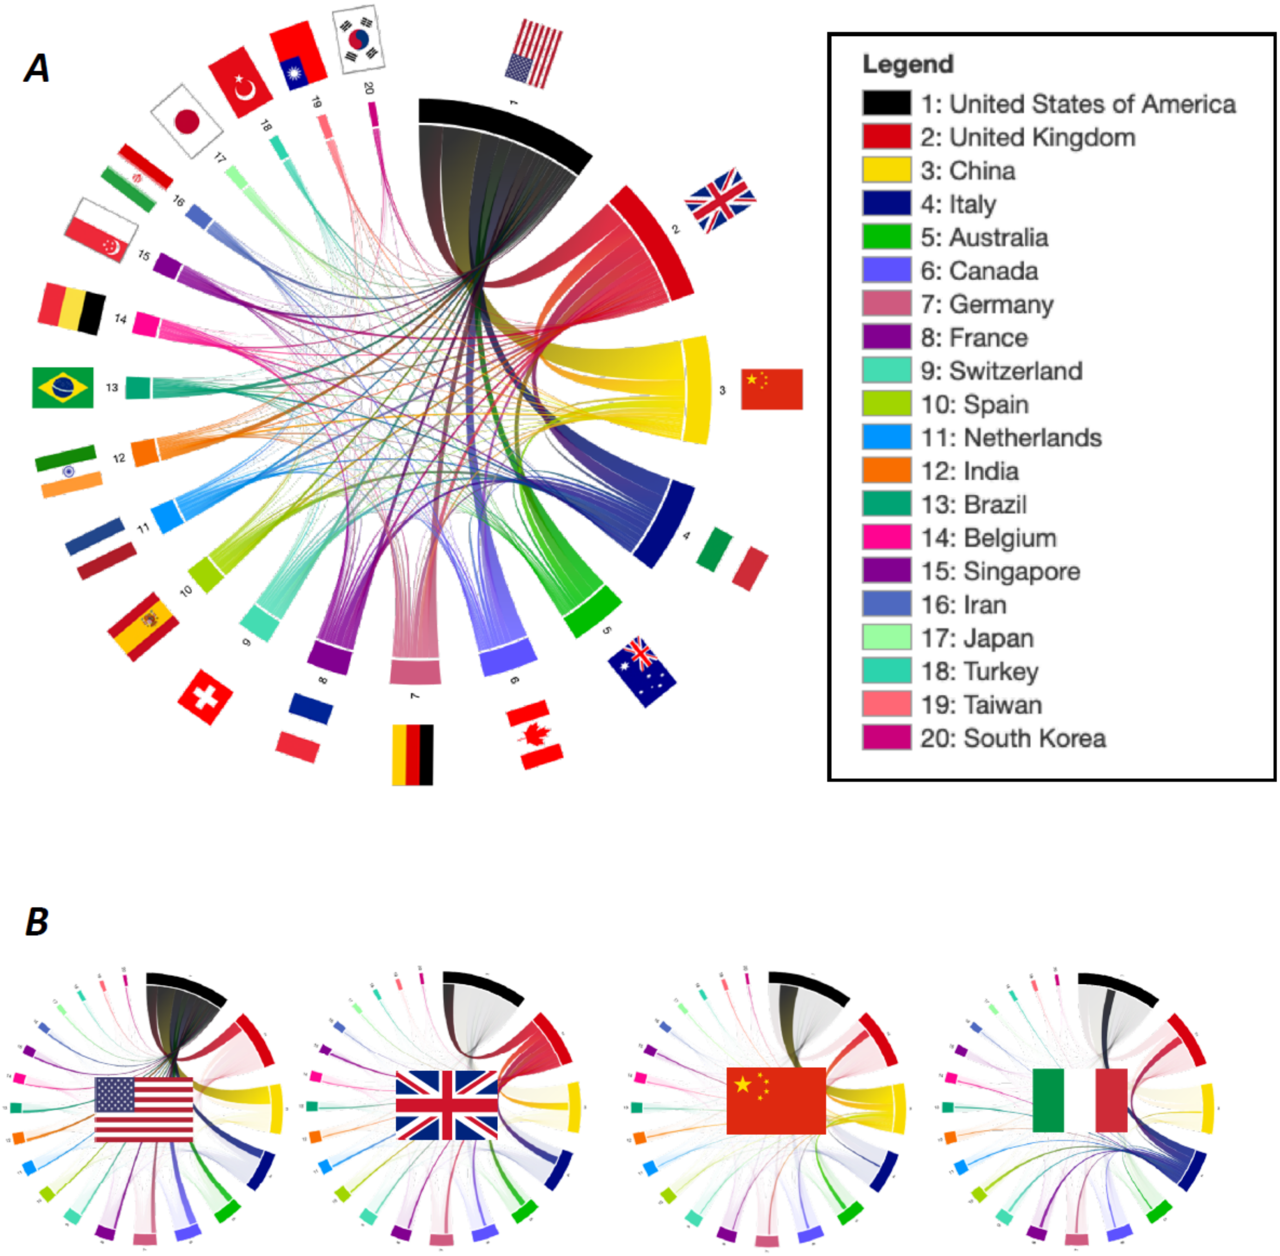

Figure 4. COVID-19 research collaboration according to institutions. Each edge connects 2 institutions that share a publication. The flags in the middle represent the countries where the institutions are located. MCPHS: Massachusetts College of Pharmacy and Health Sciences.

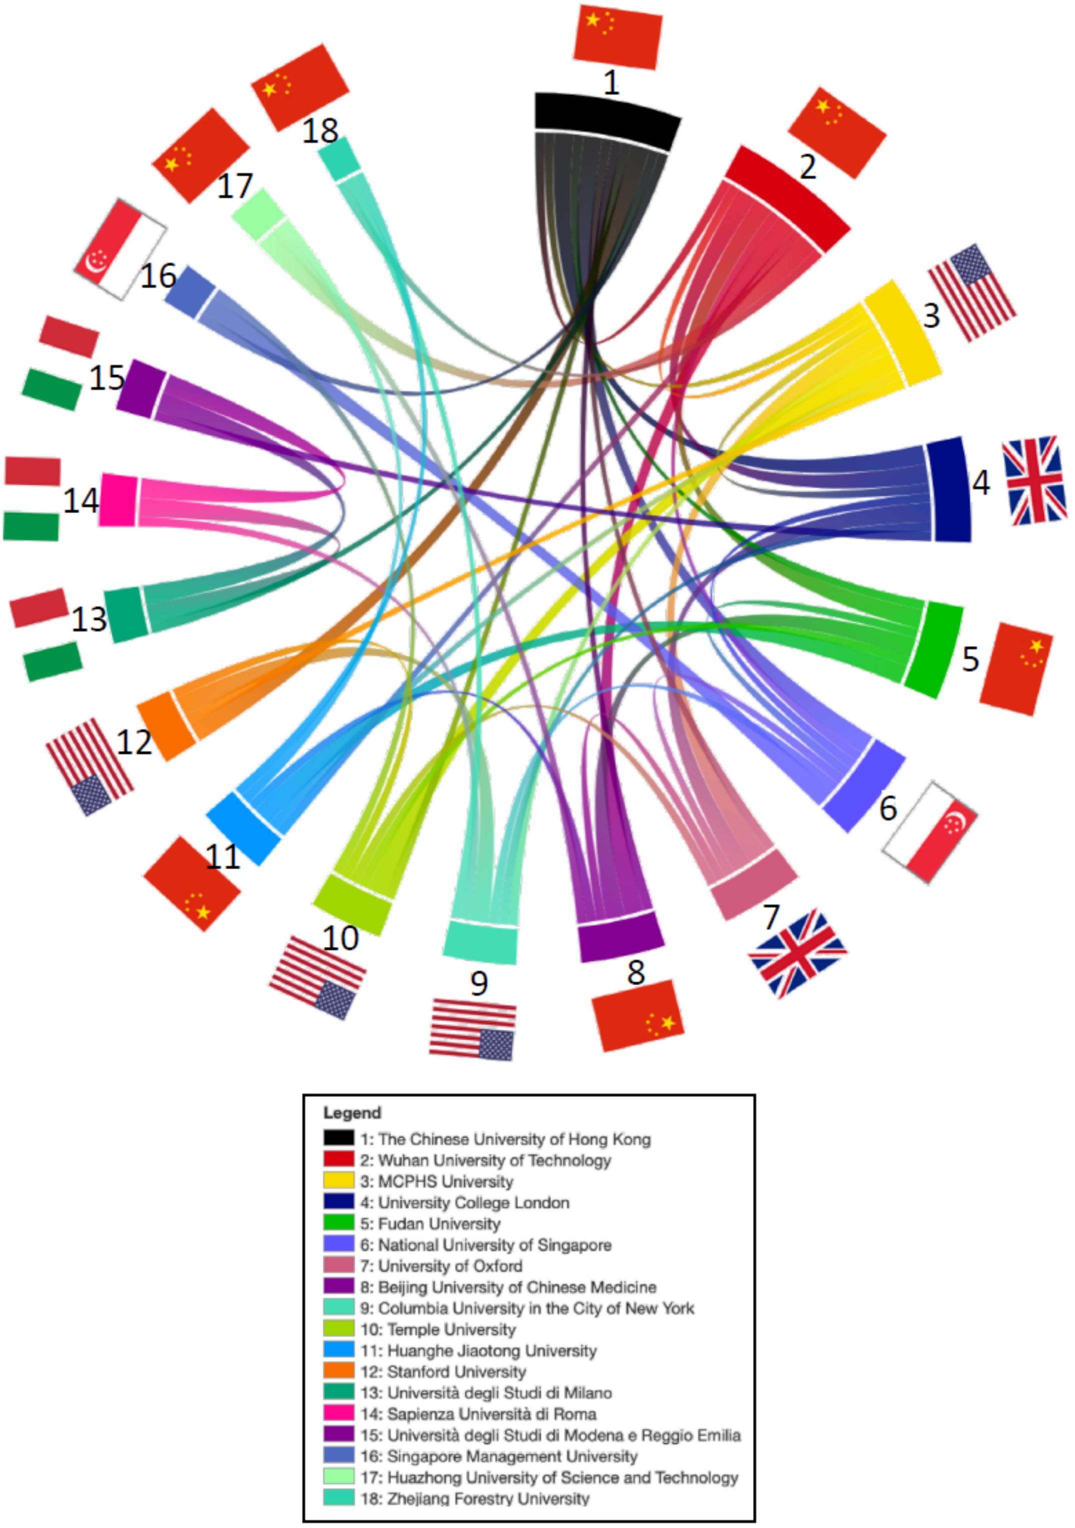

Research Topics

The majority of research items were published in the topic “general and internal; medicine” (Table 1), followed by “environmental and occupational health; public,” “nuclear medicine and medical imaging; radiology,” “infectious diseases,” “surgery,” “otorhinolaryngology; surgery,” and “dermatology.” The topic “virology” was found at position 8.

Table 1. Research categories of publications matched to their respective topics.

Topics	Publications, n (%)
General and internal; medicine	836 (11.64)
Environmental and occupational health; public	291 (4.0)
Nuclear medicine and medical imaging; radiology	194 (2.70)
Infectious diseases	171 (2.38)
Surgery	149 (2.07)
Otorhinolaryngology; surgery	146 (2.03)
Dermatology	143 (1.99)
Virology	139 (1.93)
Pharmacology and pharmacy	138 (1.92)
Cardiac and cardiovascular systems	123 (1.71)
Psychiatry	121 (1.68)
Anesthesiology	103 (1.43)
Critical care medicine	101 (1.41)
Oncology	98 (1.36)
Ophthalmology	91 (1.27)

Regional Differences in COVID-19 Research

With 1806 research items, the United States was the leading country in terms of COVID-19–related publications, followed by China (n=1306), Italy (n=856), and the United Kingdom (n=817). Spain and France, both of which were seriously affected European countries, were in positions 9 and 11, respectively. Focusing on the first or last author, the patterns were similar and the ranking of the top countries remained unchanged. In terms of continents, Europe, North America, and Asia published a similar number of research items (Figure 5). According to publications in relation to confirmed COVID-19 cases or related deaths and total population size, the United States had the highest number of both COVID-19 cases and related publications. In Europe, Italy was one of the leading countries. On the other hand, China had a lower number of cases and fewer deaths compared with the United States, although the population count was higher (Figure 6). Multimedia Appendices 5-8 visualize institution heatmaps for 4 highly affected countries, analyzing their research output per research institution. In Italy, Milano and Bergamo accounted for the highest number of COVID-19–related publications (n=131), followed by Rome (n=81) and Padua (n=78), as indicated by the numbers in the heatmap in Multimedia Appendix 5. Another highly represented region was Naples. In China, Wuhan led in terms of research volume, followed by Beijing, Shanghai, and Hong Kong/Shenzhen (Multimedia Appendix 6). In the United States, the east coast (Boston, New York, and Philadelphia) and California (Los Angeles and the San Francisco Bay area) had the highest output (Multimedia Appendix 7). Here, areas with a generally strong prepandemic research output that were highly affected by COVID-19 contributed the most amount of publications pertaining to the pandemic. Likewise, Detroit and Chicago were highly represented in the publication statistics. In France, Paris had the strongest research output while other French regions had no relevant manuscript numbers published to date (Multimedia Appendix 8).

Figure 5. Country coverage of publications. The donut chart represents continents (AS: Asia; EU: Europe; NA: North America; SA: South America; OC: Oceania; AF: Africa) and countries contributing to the publication output.

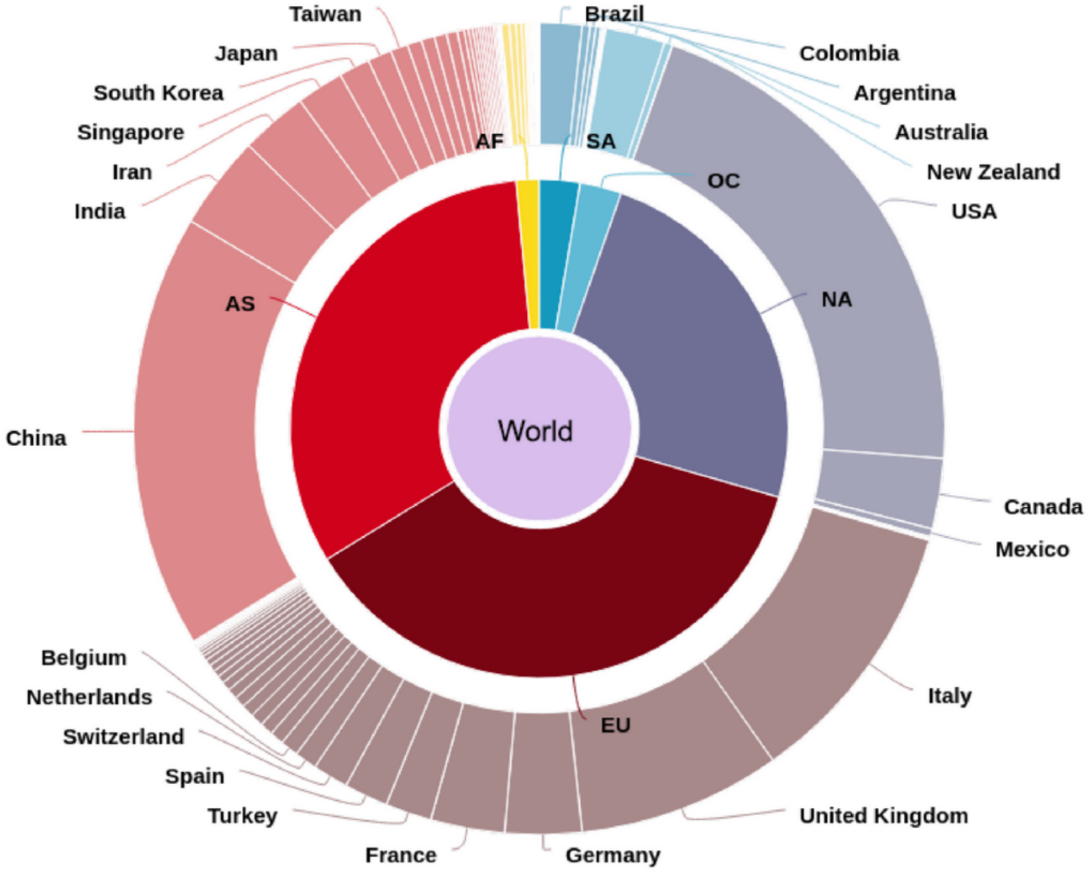

Figure 6. Population of countries versus the number of reported COVID-19 cases. Bubble sizes represent the number of publications; the color of the bubble represents the number of deaths. Data obtained from ourworldindata.org [12].

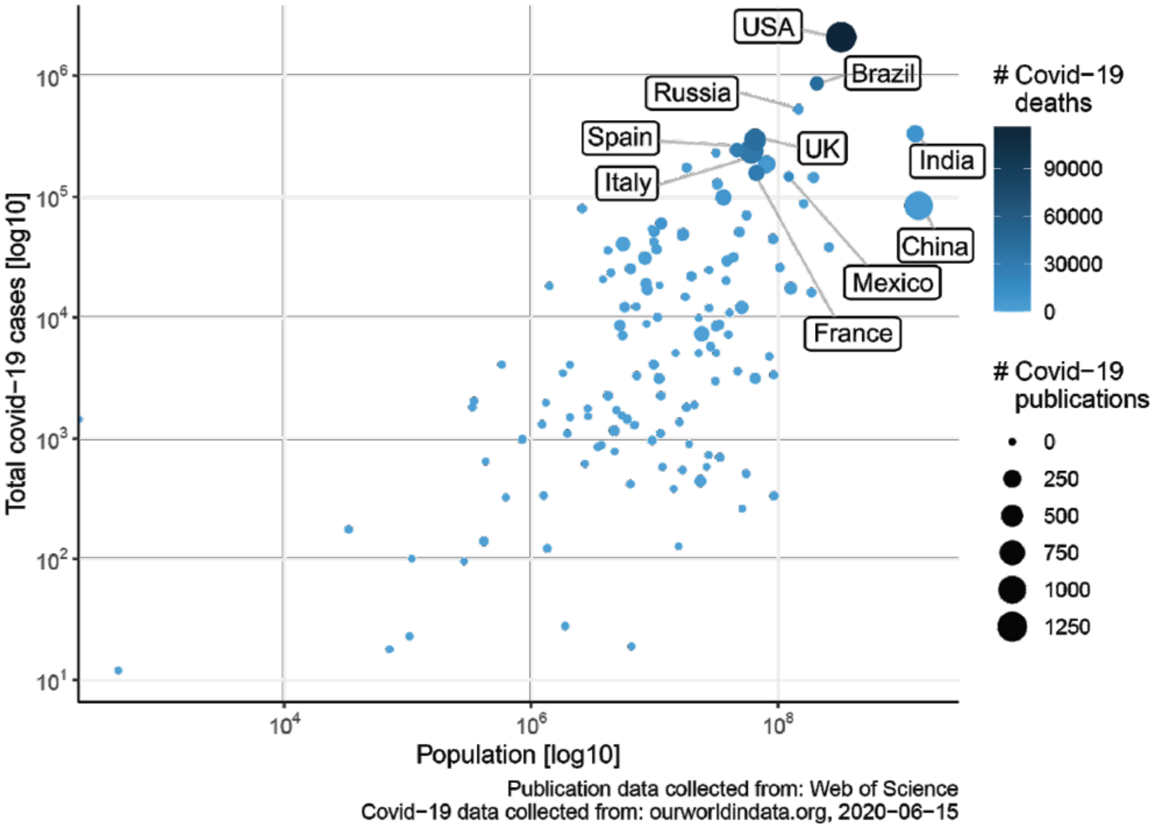

Publication data collected from: Web of Science
Covid−19 data collected from: ourworldindata.org, 2020−06−15

The leading 10 institutions were Wuhan University of Technology (Wuhan, China), Università degli Studi di Milano (Milano, Italy), Massachusetts College of Pharmacy and Health Sciences University (Boston, United States), The Chinese University of Hong Kong (Hong Kong, China), Fudan University (Shanghai, China), Columbia University in the City of New York (New York, United States), National University of Singapore (Singapore), Singapore Management University (Singapore), University of Oxford (Oxford, United Kingdom), and Ankara University (Ankara, Turkey).

Discussion

Principal Findings

This scientometric analysis provided profound insights into the publication landscape of COVID-19 research during the first months this disease was declared a pandemic. Countries severely affected by the pandemic such as Italy as well as those with a generally high research output such as the United States contributed significantly to the literature base. There were several retractions of published articles, indicating questionable peer-review processes and flawed data integrity. International collaborations were extensive, especially in countries with high numbers of COVID-19 cases, with an obvious underrepresentation of cooperation between China and Italy.

Considering the most active authors of COVID-19–related articles, some specifics must be acknowledged. The publications by the three most active authors were not original research articles but consisted mainly of letters. Interestingly, these journalistic articles providing news updates were indexed in WoS, PubMed, and other scientific databases along with other research work. As these articles play an important role in the visualization of the scientific landscape on COVID-19, these articles were included in our analysis for a more comprehensive picture. A recent study on coronavirus-related research in general revealed that medical journals have sped up their publication and production process during the pandemic. Indeed, the turnover time was reduced by 49% from submission to acceptance, which was mainly driven by a decrease in peer-review time [13]. One may speculate that this expedited review process was related to publication pressure by researchers submitting papers but also by journals aiming to publish articles with high-citation likelihood, which could enhance the relative importance of a journal within its field [4]. In line, a relatively large proportion of retractions and corrections of COVID-19–related articles was identified herein, adding up to 0.8% of all published materials, and was also found in high-impact journals [14,15]. A recent study on coronavirus research in the last decade found a large proportion of open access articles. From 2001-2020, 59.2% of all research articles on coronavirus research were provided free of charge. This number significantly increased in 2020 to 91.4%, mostly related to research on COVID-19 [16]. This high percentage of open access to scientific information and open data is crucial to facilitate better and faster research toward a vaccine and inform public health measures essential to contain the spread of the virus.

Interestingly, most articles were published in the topic “general and internal; medicine” as opposed to the topic “virology,” ranking at position 8. This may be driven by the overall higher aggregate impact factor (IF) in the category “general and internal; medicine” (aggregate IF 4.386) compared with “virology” (aggregate IF 3.731) [17], making the first mentioned journal category a generally more attractive option for article submissions.

Among the countries involved in COVID-19–related research, Italy played an exceptional role. Given the population and the general research output of Italy, it is disproportionately represented. Mapping the number of COVID-19 cases or COVID-19–associated deaths to countries, it becomes clear that Italy, as one of the most severely hit countries in Europe, also showed the largest scientific output. It is worth mentioning that the regions that suffered most from the pandemic (such as Milano, Bergamo, Bologna, and Padua) had an exceptional research output. In other countries, such as France, the majority of publications originated from the capital, whereas regions highly affected by the pandemic in peripheral areas were underrepresented.

Our analysis revealed a wide global collaboration network between several publishing countries. Here, the United States was a leading collaborator, sharing a significant amount of manuscript authorships with the United Kingdom, China, and Italy. Collaborations in medical research have been seen in other medical fields before [18]. This cooperation is often found between neighboring countries but also, as in the present case, between countries interested in similar research areas. It becomes obvious, however, that China and Italy, despite both being highly affected as well as productive in terms of research efforts, lack collaboration with one another. This analysis focused on the first wave of the COVID-19 pandemic; however, in a recent second analysis, the scientific landscape in this area including international collaborations remained similar.

Limitations

It is important to mention some limitations of our scientometric study. We rely on input from WoS, which is dependent on input query. Efforts were made to include as many specific publications as possible while simultaneously avoiding false positives, along with performing cross-checks with other medical databases to ensure a comprehensive data analysis. This scientometric analysis is of a quantitative, not qualitative, nature. One measure to assess the research quality would be to analyze citations, but given the comparably short time in which thousands of manuscripts have been published, a more comprehensive analysis can be expected in the future. If citation numbers grow, this will allow further analyses, according to three easily interpretable parameters: productivity, total impact, and how successful an author has been so far, as proposed in a recent study [19]. Regarding the number of COVID-19 cases and related deaths, we relied on published data from official authorities. However, this depends on both the integrity of these self-selected numbers as well as the extent of diagnostic testing in each country. Herein, we focused on COVID-19–associated death rates, as other variables such as the number of cases and hospitalizations provide only rough estimates based on the case fatality rate [20].

Conclusion

The publication landscape of COVID-19 is rapidly developing, making it challenging to identify high-quality research that substantially adds to the current knowledge base. Almost 1% of the literature considered in this study were corrections or retractions of articles, which challenges the quality and integrity of the expedited review process. The high number of publications is driven by countries with a generally strong research output in the past, but this also includes countries heavily affected by the pandemic such as Italy. In terms of international cooperation, the United States is most active while China is underrepresented. The most obvious finding is an underrepresentation of joint publications between China and Italy, despite both being strongly affected by the COVID-19 pandemic and producing a high research output.

Acknowledgments

This work was supported by the Deutsche Forschungsgemeinschaft (SFB TRR219) to MB and FM and by the Deutsche Gesellschaft für Kardiologie to MB and FM. The funders had no role in the design of this study, its execution, analyses, interpretation of the data, or decision to submit results for publication.

Authors' Contributions

NG and DM made substantial contributions to the conception of the work; both authors analyzed and interpreted the data, and drafted the manuscript. TF and FK made substantial contributions to data acquisition and revised the manuscript critically for important intellectual content. MB made substantial contributions to the concept of the work and revised the manuscript critically for important intellectual content. FM and AK made substantial contributions to the conception and design of the work as well as the interpretation of the data; both revised the manuscript critically for important intellectual content. All authors gave final approval of the version to be published and agreed to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Conflicts of Interest

Abstract

Surveys of the general population can provide crucial information for designing effective nonpharmaceutical interventions to tackle public health emergencies, such as the COVID-19 pandemic. Yet, conducting such surveys can be difficult, especially when timely data collection is required. In this viewpoint paper, we discuss our experiences with using targeted Facebook advertising campaigns to address these difficulties in relation to the COVID-19 pandemic. We describe central advantages, challenges, and practical considerations. This includes a discussion of potential sources of bias and how they can be addressed.

(J Med Internet Res 2020;22(12):e20653) doi:10.2196/20653

KEYWORDS

Facebook; web-based surveys; public health emergency; COVID-19

Introduction

As of September 9, 2020, the COVID-19 pandemic has caused over 27.4 million cases and over 894,000 deaths around the world [1]. To control the spread of COVID-19, national and local governments have implemented nonpharmaceutical interventions, including school closures, bans on large gatherings, mobility restrictions, and physical isolation, as well as unprecedented measures like local and nationwide lockdowns. Such measures have likely been critical in delaying and containing the COVID-19 pandemic [2]. However, individual behaviors, rather than governmental actions, may be crucial for controlling the spread of COVID-19 in the long run [3]. Timely and accurate data on human behaviors are thus of paramount importance in closely monitoring the adoption of preventive measures, emergence of symptoms, and changes in mobility and person-to-person contacts in the population.

In this context, surveys of the general population can provide central information needed to assess people's acceptance of and compliance with behavioral guidelines. Such surveys are also needed to capture spontaneous bottom-up behavioral changes. Yet, researchers who want to conduct surveys that directly address ongoing epidemics are faced with unique methodological challenges, as follows: (1) these surveys need to be designed, implemented, and conducted quickly, as epidemics spread rapidly and are difficult to predict, especially when they involve new emerging diseases (ie, timeliness); (2) they need to cover the entire population, and in the event of large-scale epidemics or pandemics, they need to be conducted simultaneously in multiple countries or regions, as regional differences could be relevant for designing effective interventions (ie, coverage); and (3) they should be cost-effective, as obtaining large research funds quickly for an ad hoc survey can be difficult (ie, cost-effectiveness). Furthermore, in the case of COVID-19, the nature of recommended social distancing measures may limit some traditional modes of data collection, such as face-to-face interviews and even phone interviews, to the extent that they rely on large call centers.

In this viewpoint, we discuss the use of Facebook as a recruitment tool to address these challenges. Our assessment is based on the COVID-19 Health Behavior Survey (CHBS) that we conducted between March 13 and August 12, 2020 in 8 countries (ie, Belgium, France, Germany, Italy, the Netherlands, Spain, the United Kingdom, and the United States). Participant recruitment took place on a daily basis via targeted advertisements on Facebook, resulting in a total of 144,034 completed questionnaires. In what follows, we first provide an overview of the most important design aspects of the survey, and then discuss some of the central advantages, challenges, and practical considerations related to using Facebook advertisements in surveys that address public health emergencies, such as the COVID-19 pandemic. This includes a discussion and empirical assessment of potential sources of bias and how they can be addressed. Additionally, we make recommendations for those who want to implement similar surveys in the near future, and we hope that this will facilitate timely data collection to address the current—and possibly future—public health and societal crises.

Methodological Approach

The CHBS is a web-based survey that focuses on people's reactions to the COVID-19 pandemic and targets individuals aged ≥18 years. The questionnaire has 4 sections, which encompass sociodemographic characteristics (eg, age, sex, and education), health indicators (eg, underlying medical conditions), behaviors and attitudes related to COVID-19 (eg, perceived threat level and preventive measures taken), and social contacts (ie, the number of interactions with other people).

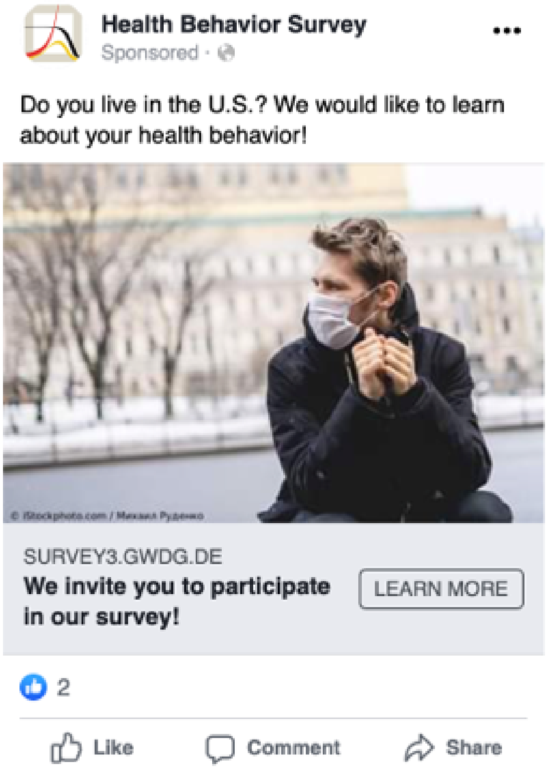
Recruitment took place via Facebook, by means of advertisement campaigns that we created with the Facebook Ads Manager (FAM). The Facebook business model centers on targeted advertisements, and the FAM enables advertisers to create campaigns that can be directed at specific user groups. Targeting can be based on both users' demographic characteristics and a set of characteristics that Facebook infers from users' behavior on the social network. Advertising campaigns consist of 3 levels. The highest level is the campaign level, at which the goals of the campaign are defined (eg, generating awareness or generating traffic). The second level is the ad set level, at which the target audience, budget, and schedule are defined. The third level includes the advertisements themselves, which can consist of multiple advertising materials (eg, images and videos), advertising text, and the link to the page where Facebook users should be directed when they click on the ad. More details on these levels can be found in the Pötzschke and Braun [4] study.

We created 1 campaign per country and stratified each campaign at the ad set level by users' sex (ie, male and female), age group (ie, 18-24, 25-44, 45-64, and ≥65 years), and region of residence. In the European countries, the region classification largely followed the NUTS (nomenclature of territorial units for statistics)-1 classification, which we aggregated into larger macro regions. In the United States, the region classification was based on census regions. More details on region stratification can be found in the Perrotta et al [5] study. Our study design resulted in 24-56 strata per country. Each ad set contained 6 different images, leading to a total of 1776 different ads. Figure 1 provides an example of the ads shown to Facebook users in the United States. We launched the campaigns between March 13, 2020 (ie, in Italy, the United Kingdom, and the United States) and April 4, 2020 (ie, in Belgium). This difference in the timing of the inclusion of countries is owed to a trade-off between the time needed to translate and technically implement country-specific surveys and the goal to start data collection in a timely manner. We concluded the survey on August 12, 2020.

Facebook advertising campaigns can have different goals, and the overall costs that are incurred will partly depend on the chosen goal. We chose the goal of generating traffic. This meant that the Facebook algorithms would optimize ad delivery to maximize the likelihood of people clicking on the ad when it is shown to them. Advertisers can choose and define how Facebook should use their budget to meet these goals. For example, advertisers can set a budget that is evenly spread over a fixed period, or they can define an average daily budget that Facebook would seek to meet weekly over an unspecified period. We opted for the latter, as the duration of the COVID-19 pandemic was uncertain. Based on these parameters, ad delivery was determined through an automated bidding process, in which a given ad competes for delivery with ads from other advertisers who are targeting the same user groups. In this process, Facebook considers the budget that can be afforded for delivering a given ad and the likelihood of the ad being of interest to users by comparing it to competing advertisements. Before an ad campaign is launched, the FAM provides an estimate of various parameters, such as the size of the target audience and daily reach, which makes it possible to gauge the likely performance of the advertising campaign.

It is important to note that our study is not the first to use targeted Facebook advertisements for participant recruitment in health research. Earlier research has used this approach to address topics such as smoking behavior [6], cannabis use [7], and mental health [8]. Furthermore, Whitaker et al [9] and Thornton et al [10] have performed systematic reviews of related literature. However, compared to these studies, our survey stands out because of its cross-national character, duration, and population coverage, given that we continuously collected data from 8 countries for 5 months and recruited more than 140,000 participants from most—if not all—parts of society and subnational regions.

Figure 1. Example of an advertisement in the Facebook advertising campaign in the United States.



Do you live in the U.S.? We would like to learn about your health behavior!

We invite you to participate in our survey!

Advantages

Our use of Facebook for participant recruitment enabled us to address the challenges of timeliness, coverage, and cost-effectiveness.

With regard to the advantages of our recruitment methodology, first, we were able to design, implement, and launch the survey in a timely manner. To summarize, preparing a Facebook advertising campaign involves creating an advertising account, a Facebook page that is associated with the advertisements/survey, and the ads themselves. Ad creation can be performed in bulk, by uploading a CSV (comma-separated values) file. Once the ads have been created, they need to be submitted for review, during which their compliance with Facebook advertising policies is assessed. This review can take between a couple of hours and a day, or longer. In our case, it was usually completed within 24 hours. However, it should be noted that in April/May 2020, Facebook warned advertisers that reviews could be delayed due to the COVID-19 pandemic [11]. Once reviewed, the ads can be delivered. Ads only need to be reviewed again when major changes are made (eg, changes to the advertising materials or ad text).

The second advantage is that our use of Facebook enabled us to draw multinational samples from diverse parts of the respective national populations. Facebook is the largest social media platform, with 2.45 billion monthly active users worldwide as of Fall 2019 [12]. In the United States, about 68% of adults used Facebook in 2018, whereas this percentage is 56% in Germany, 75% in Italy and Spain, 76% in France, 79% in the Netherlands, 85% in the United Kingdom, 89% in Belgium [13,14]. Compared to younger and middle-aged adults, older adults generally tend to be underrepresented on Facebook [15]. Nevertheless, the Facebook user population provides a cross section of the overall population with access to the internet. A comparison of different social media platforms (ie, Facebook, LinkedIn, Twitter, Tumblr, and Reddit) in the United States has suggested that Facebook is the most representative in terms of users' educational attainment and internet skills [16].

The third advantage is that our use of Facebook made participant recruitment comparatively cost-effective, even though it can be difficult to determine the exact costs in advance. This is partly due to the nature of the bidding process that determines ad delivery and variation in the competition for advertising space. A central performance measure of Facebook advertising campaigns is the cost per click (CPC) value. Whitaker et al [9] performed a review of studies that used Facebook for recruiting participants in health research, and they reported CPC values between €0.17 (US $0.20) and €1.46 (US $1.74). This variation is likely due to differences in the definitions of targeted user groups, the competition from other advertisers, and the likelihood of users clicking on the respective ad. Our costs were similar to those reported in earlier research. Between March 13 and August 12, 2020, we collected 144,034 questionnaires at an overall CPC of about €0.14 (US $0.17) and an overall cost per completed questionnaire (CPCQ) of about €1.05 (US $1.25), excluding the value-added tax. It should be noted that as a relief measure, the value-added tax in Germany was temporarily reduced from 19% to 16% on July 1, 2020. The difference between the CPC and CPCQ is due to Facebook users who clicked on one of our ads, but did not complete our questionnaire.

Thanks to these advantages, we were able to collect data that provided key insights into attitudes and behaviors that shape—and are shaped by—the COVID-19 pandemic. Figure

2 illustrates this by plotting the average number of face-to-face social contacts that respondents reported for the day before participating in the survey for the entire observation period. Face-to-face social contacts are the main vehicle for virus spread, given that the SARS-CoV-2 virus is mainly transmitted by infected secretions or respiratory droplets [17]. Figure 2 shows that there was great variation in the number of face-to-face contacts over time, especially in those that occurred outside the home. When paired with external information on the COVID-19 pandemic, such as lockdown measures and infection rates, these data provide valuable insights into the effectiveness of different policies. When the data is further broken down by respondents' demographic characteristics, it also becomes possible to assess whether different demographic groups respond differently to different policies. The data can also be used to calculate central epidemiological metrics (eg, the effective reproduction number, Rt) and design more realistic epidemiological models. More details on the contact patterns that we observed in the CHBS can be found in the Del Fava et al [18] study. Insights into other behaviors and attitudes toward the COVID-19 pandemic can be found in the Perrotta et al [5] study.

Figure 2. Average number of contacts at home and outside of home per week between March 13 and August 12, 2020 across the 8 countries. Lines show averages and shaded areas show 95% confidence intervals. Poststratification weighting has been applied.

To better illustrate the comparative strengths of our approach, it is helpful to contrast our work with similar ad hoc web-based survey efforts that also focus on COVID-19. A prominent example is the work of Fetzer et al [19], who used an open survey to recruit 108,075 participants from 58 countries between March 20 and April 7, 2020. In this study, recruitment took place via link sharing on social media and similar channels. Another prominent example is the work of De Coninck et al [20], who used an existing opt-in online panel that was maintained by a commercial polling company to recruit 1000 participants in the Flemish region of Belgium between March 17 and March 22, 2020. Both studies used web-based surveys to collect information about people's attitudes and behaviors toward COVID-19. Compared to Fetzer et al [19], our use of Facebook offered more control over the recruitment process, given that when a survey link is shared via social media, it is not possible to control who is invited to participate in the survey. Hence, our targeted advertising methodology made it arguably easier to ensure that our samples were demographically balanced. Compared to De Coninck et al [20], our use of Facebook arguably offered less control over the recruitment process, given that existing online panels typically offer more detailed information about prospective participants than the FAM. These panels make it easier to collect demographically balanced samples. However, our use of Facebook offered a larger reach in terms of the number of countries that could be included and the time frame that was covered. In terms of costs, the CPCQ that our paid advertisements incurred was higher than the CPCQ incurred by Fetzer et al [19], as their approach to link sharing did not incur any costs. However, based on our personal communication with De Coninck et al [20], the CPCQ we incurred was similar to that of De Coninck et al [20], who paid a commercial polling company for data collection.

Challenges

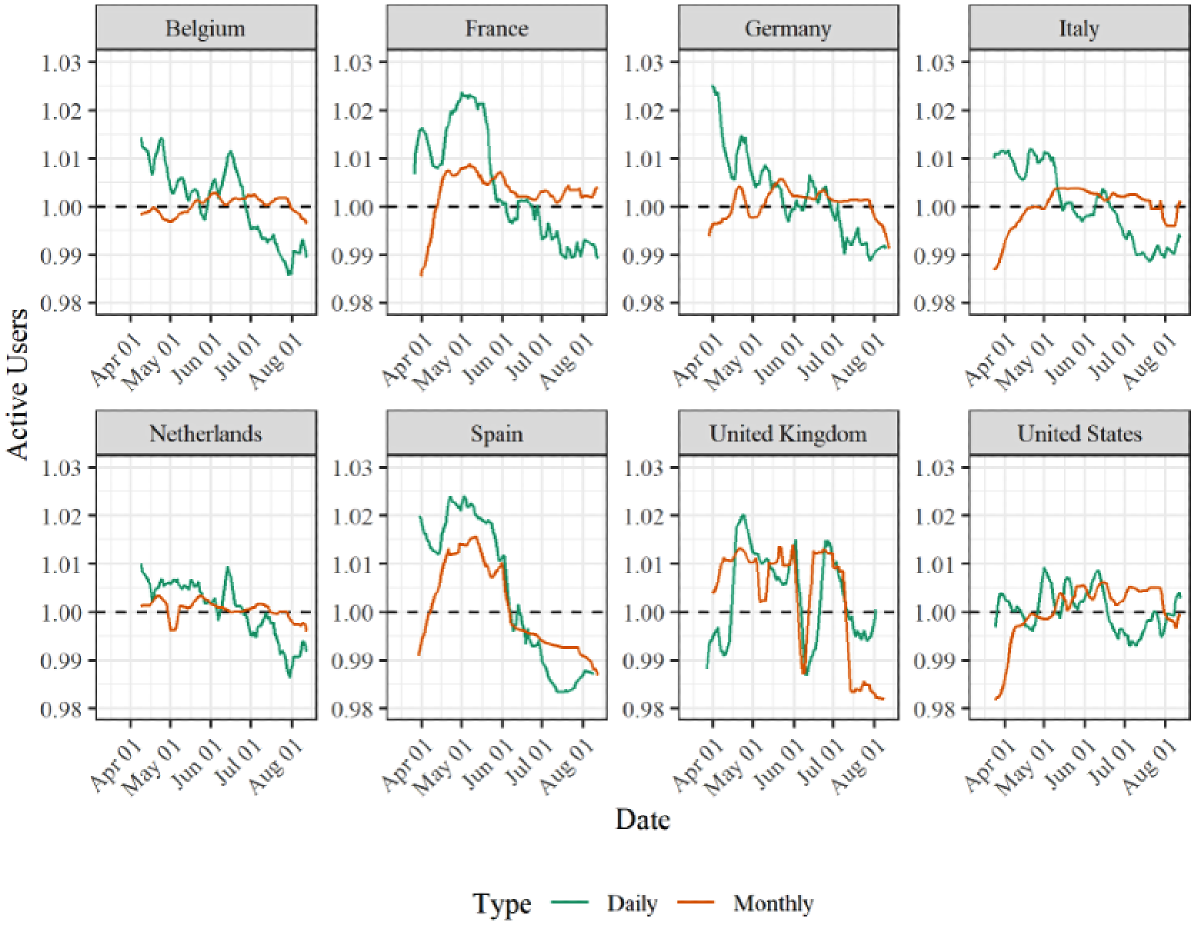
Eliciting information via self-administered web-based surveys involves several challenges. For example, issues with recall inaccuracy often occur when some time has elapsed between a specific event of interest and participation in the survey [21,22]. This puts limits on the information that can be collected, and such issues should therefore be considered in light of the goals of the respective study. If, for example, detailed and accurate medical information is essential (eg, exact blood pressure measurements), a web-based survey may not be the best choice, and an in-person assessment with medically trained personnel may be preferable. Discussing the methodological challenges of web-based surveys is out of the scope of this paper. Instead, we focus on the challenges that are specific to using Facebook for participant recruitment. A discussion on the methodological challenges of web-based surveys can be found in the Eysenbach and Wyatt [23] study.

The most important set of challenges relates to the issue of self-selection bias. The Facebook user base is a rough cross section of the overall population with internet access, but not all demographic groups are equally well represented [24]. Additionally, there may be variation in Facebook users' interest in the survey topic. Hence, there is no guarantee that the resulting samples will be representative in terms of central demographic characteristics (eg, age and sex) and important unobservable characteristics. This issue is potentially exacerbated by the algorithmic optimization that Facebook uses for ad delivery. If certain demographic groups are more likely to click on an ad than others, Facebook might increasingly deliver the ads to these groups, thereby reinforcing existing self-selection bias. This is particularly difficult to correct if survey participation and ad delivery are affected by user characteristics that cannot be easily considered when defining the relevant sampling strata.

It is important to note that if a survey is conducted over a long period of time, there may be changes in Facebook user activity. This may be due to seasonal variation in people's use of Facebook [25]. However, it seems possible that the development of the COVID-19 pandemic may have also led to changes in the composition of our samples over time. In the early days of the pandemic especially, the SARS-CoV-2 virus dominated the news, and lockdown measures were put in place to curb its spread. This may have increased participation in our survey in 2 ways. First, a lack of alternative activities due to lockdown measures may have led people from various sub-populations to spend more time on Facebook than normal, and this may have increased the likelihood of seeing our ads. Second, the salience of the pandemic may have increased the chance of people clicking on our ads when seeing them. Over time, as the number of infections decreased and lockdown measures eased, participation in the survey may have decreased, and the resulting samples may have become more selective.

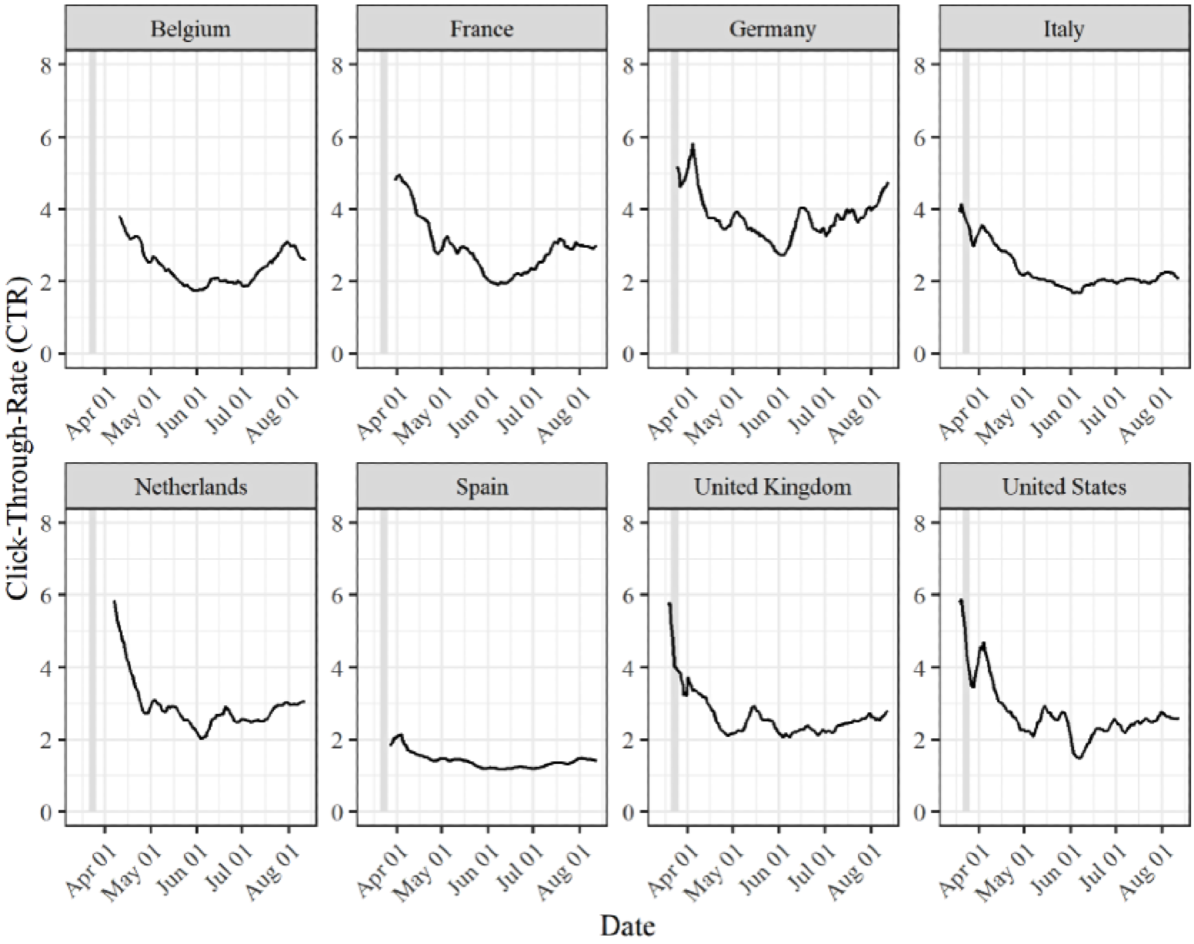
Figures 3 and 4 show changes in user behavior and survey participation over time. This was done by plotting the average number of daily active Facebook users (DAUs) and monthly active Facebook users (MAUs), as well as the click-through rates (CTRs), for all countries over the entire study period. All 3 measures are based on estimates from Facebook, which we obtained via the Facebook application programming interface. The number of DAUs is the number of unique active users on a given day, whereas the number of MAUs provides the number of unique users who have been active on Facebook within the last 30 days [26]. Both estimates are commonly used to assess the potential reach of advertising campaigns, and we systematically collected DAU and MAU estimates for all our strata over the entire study period. The CTR is defined as the number of people who click on an ad after seeing it, and CTRs become available after a campaign has been started and delivered to users [27]. Hence, changes in the number of DAUs and MAUs provide insights into changes in Facebook use, whereas changes in the CTR provide insights into topic salience/interest among Facebook users. It should be noted that between March 21 and March 26, 2020, we experienced technical problems with ad delivery across several countries, leading to a substantially lower number of participants than in the other weeks of our study. The CRT values for this period are therefore less reliable than those for the rest of the survey period.

Figure 3. Number of DAUs and MAUs between March 13 and August 12, 2020 across the 8 countries based on all ad sets. Numbers were standardized for each country by dividing the value for a given day by the average number of DAUs/MAUs over the entire observation period. Lines show 7-day moving averages. We collected DAU and MAU values every 6 hours, as these estimates can change within 1 day. We averaged these multiple observations to obtain 1 number per day. Data collection started between March 18 and April 4; no data was collected on April 11, April 12, and between August 3 and 6 due to technical issues. DAU: daily active Facebook user; MAU: monthly active Facebook user.



As shown in Figure 3, the number of DAUs was largest during the early weeks of the observation period for most countries. However, this number gradually decreased, usually by 3-5 percentage points. This means that the number of unique users who could have seen our ads on a given day decreased over time. The only exceptions to this were the United Kingdom and the United States, where changes in the number of DAUs were more erratic. The trends in the MAU values somewhat deviate from those in DAU values. Typically, there was an initial increase in the number of MAUs, but this number later decreased. Hence, while the number of individuals who may have seen our ads on a daily basis decreased over time, we may have reached users who we would not have reached in other months toward the middle of the observation period. Furthermore, in Figure 4, the CTR values show a clear trend over time. The CTR was initially high across all countries, and then it decreased before ultimately increasing again. This means that in the early phases of the survey, Facebook users were more likely to click on our ads than in later phases. Hence, our data suggest that over time, the process by which users selected themselves into the survey may have changed, but the data do not allow us to precisely assess why these changes occurred.

Figure 4. CTRs between March 13 and August 12, 2020 across the 8 countries. The line shows the 7-day moving average. The shaded area shows the period during which technical problems with ad delivery occurred. CTR: click-through rate.



How can the problem of self-selection be addressed? We suggest 4 methodological steps that can help alleviate this problem. First, in line with common approaches in traditional survey research, we suggest stratifying ad campaigns based on characteristics that are known to relate to survey participation and the outcome of interest, such as in the Pötzschke and Braun [4] study. Evidently, in the case of new emerging diseases, relevant individual characteristics are difficult to know in advance. Moreover, several relevant characteristics will not be available for creating strata in the FAM (eg, preexisting medical conditions). However, characteristics that are available (eg, age and sex) should be considered for stratifying advertising campaigns. We also suggest stratifying ads by region within countries, as people's responses might vary locally. With this approach, the bias that Facebook's ad delivery algorithms may generate is counteracted, leading to more balanced samples.

The second step we suggest, which is in line with the Zagheni and Weber [28] study, is applying poststratification techniques to the samples obtained from Facebook, to the extent that they deviate from the overall population in terms of important characteristics. In this regard, using Facebook offers distinct advantages over other, less controlled ways of recruiting online samples. As indicated previously, prior to launching a campaign, the FAM provides an estimate of the size of the audience with the characteristics of interest. Arguably, this feature is similar to a sampling plan and has been used in earlier research to conduct a "virtual census" of the overall population, such as in the Zagheni et al [29] study. Furthermore, the ad performance estimates that the FAM provides after a campaign has been launched (eg, the number of users to whom a given campaign, ad set, or ad has been delivered and the number of users who have clicked on the ad) can be paired with information about survey completion rates for each stratum. This makes it possible to calculate performance measures, such as approximate participation rates. However, it is important to keep in mind that many of the measures that Facebook reports are only estimates. The resulting indicators should thus be viewed as informed proxies.

As a complement to this approach, Zhang et al [30] recently reported that by selectively activating and deactivating ad sets over the course of the survey period, it is possible to obtain representative samples from Facebook that do not require poststratification. This approach is feasible if the specific timing of participation over the study period does not matter. However, this was not feasible in our case, as our goal was to obtain daily balanced samples. Selectively closing and opening ads over the course of a day or week would have implied that responses from certain subgroups may have been concentrated during a certain time of the day or certain days of the week. As an alternative, researchers may opt for dynamically adjusting the budget, so that more money is spent on strata that are underrepresented in the survey. With this approach, it is important to keep in mind that large changes in the budget allocated to an ad set may trigger the ad review process again, which can lead to a gap in data collection. As this would have undermined the goals of our study, we decided against this approach. Instead, we continuously recruited members of all strata using a stable budget.

With regard to the third step, we suggest that the issue of self-selection due to participant characteristics that are difficult to observe before people take part in the survey can be partly addressed by considering possible sources of bias in the design of the survey and advertising campaign. In the case of our study, we expected that individuals who are particularly concerned about COVID-19 might be more likely to participate, and such concerns might also be reflected in reported behaviors and attitudes. As it is not possible to stratify Facebook advertising campaigns based on such concerns, we considered this issue in 2 ways. First, in the survey, we directly assessed participants' concerns about COVID-19 and other factors that may raise such concerns. Second, when selecting the images for our ads, we aimed to create variation in how closely the images were linked to the topic of COVID-19. In our analyses, we were able to control the extent of how all these factors affected participation and answers to other questions.

Figure 5 shows the different images that we used in the ads. We considered images 1 and 2 to be the least strongly linked to COVID-19 and images 5 and 6 to be the most strongly linked to COVID-19. In total, 141,879 of the respondents arrived at the survey via one of the ads. Of these respondents, about 74% (104,292/141,879) arrived via image 5, about 16% arrived via image 6 (23,157/141,879), about 7% (9699/141,879) arrived via image 3, and the rest arrived via the remaining images. To assess whether the image through which participants arrived at the survey was related to their concerns about COVID-19, we conducted a Kruskal-Wallis test by rank. In this test, we assessed respondents' personal perceptions of how large a threat COVID-19 presented for themselves. This was determined using a 5-point Likert-type scale, in which a score of 1 represents very low threat and a score of 5 represents very high threat. These scores were associated with the picture through which participants arrived at the survey. Table 1 shows the number of respondents who selected 4 or 5 on the scale, which indicated a high or very high threat perception, respectively. The number of respondents who perceived COVID-19 as a high or very high threat was largest among those who arrived at the survey via image 3 (7178/9280, 77%) and lowest among those who arrived via image 2 (922/1461, 63%). The observed variation in threat perceptions across images was significant at the 1% level (χ^2_5=801, $P<.01$). A broader analysis of how the different images related to respondents' self-reported attitudes and behaviors would be important, but our assessment suggests that the inclusion of different images helped with recruiting more diverse samples in terms of concerns for COVID-19.

With regard to the fourth step, in recent years, the multilevel regression and poststratification approach to making inferences from highly selected survey data [31] has proved effective in producing unbiased population estimates [32,33]. In the first stage of multilevel regression and poststratification, the sample is partitioned into a large number of demographic strata (eg, each combination of age group, sex, and region), and a multilevel regression model is used to estimate the outcome of interest, such as the average number of contacts or the percentage of people wearing a face mask, in each stratum. In the second stage of multilevel regression, the stratum-level estimates are used to produce a final population-level estimate, and poststratification weights are used to account for the proportion of each stratum in the population. This approach combined with the previously mentioned steps, and a fine partition of the sample in demographic strata enables researchers to make proper inferences at the population level, even in presence of strong selection bias.

Table 1. The number of respondents who personally perceived COVID-19 as a high (score=4) or very high threat (score=5) to themselves based on a 5-point Likert-type scale for each ad image. No weighting has been applied.

Image number	Image name	Total, n/N (%)
1	Male athlete	422/586 (72%)
2	Group of athletes	922/1461 (63%)
3	Woman blowing nose	7178/9280 (77%)
4	Couple blowing noses	1819/2519 (72%)
5	Woman wearing mask	69,421/102,061 (68%)
6	Man wearing mask	16,882/22,451 (75%)

Another challenge relates to trust in web-based surveys. Web-based surveys may face suspicion, as they could be used to elicit personal information for nonresearch purposes (eg, marketing, identity theft, etc) [34]. In addition, over the last several years, there have been several incidents that may have negatively affected the trust that the public has in the data protection measures put in place by Facebook. A prominent example is the Cambridge Analytica scandal, in which the personal data of Facebook users was harvested without consent, with the goal of influencing the 2016 US presidential election through microtargeting [35]. When fielding our survey, we encountered such suspicions in the commenting sections of our ads, and 1 notable concern was that Facebook would transfer personal user information to us. We addressed this issue by highlighting that the survey was anonymous and that no personal information was exchanged with Facebook. We also provided additional information about our research institute, the research team, and the goals of our survey by providing a link to our data protection policy and providing information about preliminary results and reports as they became available. Despite these measures, it seems likely that Facebook users who are concerned about data privacy were less inclined to participate in our survey. Additionally, while anonymous web-based surveys have the potential to reduce the likelihood of respondents providing socially desirable answers compared to personal interviews [36], privacy concerns may have rendered them reluctant to answer questions that they perceive as sensitive. We addressed this issue by offering the possibility of not answering questions that they feel uncomfortable with, to avoid forcing answers on sensitive topics.

Practical Considerations

There are some practical aspects that need to be considered when using Facebook ads for survey research. First, the possibility of targeting certain user groups makes it easier to recruit members from certain subpopulations, even when they are underrepresented on Facebook. Yet, it is important to keep in mind that as the number of strata in the campaign increases, so will the selectivity and costs of the campaign. This is particularly true if the members of certain strata are less likely to participate than members of other strata. For example, if the goal is to stratify a campaign based on 5-year age groups, the number of strata will increase considerably compared to strata based on 10- or 20-year age groups. This means that overall, more responses will need to be collected to have enough observations per stratum to apply poststratification weighting. Furthermore, when the members of certain groups engage little with Facebook, a larger share of the budget needs to be devoted to recruiting them.

Second, both the advertisements and the study page to which these advertisements are linked need to be actively managed. Facebook advertisements are similar to user posts, meaning that users can react to them (eg, liking), comment on them, and share them with friends. Additionally, users can leave posts on the study page and review the page itself. In our experience, it is important to engage with user comments and provide additional information if needed, to maintain trust with current and prospective participants. The time investment that this requires should not be underestimated, especially for studies that run for a long period of time and are conducted in multiple languages. On average, our ads received about 19,300 impressions and about 135 comments per day, and it took us about 1 hour to manage 50-100 comments. The exact time it took to manage comments depended on the length of the comment and the complexity of the answer that was required. Over time, we became more experienced and efficient in managing comments. Based on these numbers, researchers who want to conduct a study on a similar topic and receive a similar number of impressions per day should expect to spend about 1-2.5 hours per day managing comments.

Third, the ad review process involves an automatic assessment of the links that are provided in the ads. In this process, the webpage to which the link leads is accessed. Hence, submitting ads for review can generate a large amount of traffic for a web-based survey, and it is important to keep in mind that the number of times that the survey page was accessed is not equivalent to the number of potential respondents who have accessed it, as some of the traffic may have been generated by the review process. It would therefore not be valid to approximate the survey completion rate by dividing the number of completed questionnaires by the number of page accesses. Furthermore, it is important to schedule sufficient time between submitting ads for review and launching the data collection. In our case, the review process was usually completed in a timely manner. However, there might be delays (eg, those predicted by Facebook due to COVID-19) and problems (eg, rejections due to violations of the Facebook advertising policies) that increase the time between review completion and delivery.

Conclusion

To conclude, we suggest that targeted advertisements on Facebook can be a powerful tool for recruiting participants in ad hoc surveys of the general population during a public health emergency, as long as certain methodological steps are taken to address the issue of self-selection. We hope that the experiences that we have described here, together with our recommendations, will make it easier for other researchers to implement similar surveys that tackle current and future pandemics.

Acknowledgments

We thank the editor and an anonymous reviewer for providing helpful comments on an earlier version of this paper. FR conducted most of his research for this article as a PhD student at the Department of Social Statistics and Demography of the University of Southampton with a scholarship from the Economic and Social Research Council (South Coast Doctoral Training Partnership; Project: ES/P000673/1).

Abstract

Background: The COVID-19 pandemic led to unprecedented mitigation efforts that disrupted the daily lives of millions. Beyond the general health repercussions of the pandemic itself, these measures also present a challenge to the world’s mental health and health care systems. Considering that traditional survey methods are time-consuming and expensive, we need timely and proactive data sources to respond to the rapidly evolving effects of health policy on our population’s mental health. Many people in the United States now use social media platforms such as Twitter to express the most minute details of their daily lives and social relations. This behavior is expected to increase during the COVID-19 pandemic, rendering social media data a rich field to understand personal well-being.

Objective: This study aims to answer three research questions: (1) What themes emerge from a corpus of US tweets about COVID-19? (2) To what extent did social media use increase during the onset of the COVID-19 pandemic? and (3) Does sentiment change in response to the COVID-19 pandemic?

Methods: We analyzed 86,581,237 public domain English language US tweets collected from an open-access public repository in three steps. First, we characterized the evolution of hashtags over time using latent Dirichlet allocation (LDA) topic modeling. Second, we increased the granularity of this analysis by downloading Twitter timelines of a large cohort of individuals (n=354,738) in 20 major US cities to assess changes in social media use. Finally, using this timeline data, we examined collective shifts in public mood in relation to evolving pandemic news cycles by analyzing the average daily sentiment of all timeline tweets with the Valence Aware Dictionary and Sentiment Reasoner (VADER) tool.

Results: LDA topics generated in the early months of the data set corresponded to major COVID-19–specific events. However, as state and municipal governments began issuing stay-at-home orders, latent themes shifted toward US-related lifestyle changes rather than global pandemic-related events. Social media volume also increased significantly, peaking during stay-at-home mandates. Finally, VADER sentiment analysis scores of user timelines were initially high and stable but decreased significantly, and continuously, by late March.

Conclusions: Our findings underscore the negative effects of the pandemic on overall population sentiment. Increased use rates suggest that, for some, social media may be a coping mechanism to combat feelings of isolation related to long-term social distancing. However, in light of the documented negative effect of heavy social media use on mental health, social media may further exacerbate negative feelings in the long-term for many individuals. Thus, considering the overburdened US mental health care structure, these findings have important implications for ongoing mitigation efforts.

Introduction

Beyond the obvious physical health ramifications of the COVID-19 pandemic, public health and the greater medical community is also bracing for a mental health crisis [1]. Within the span of 4 months, 45% of Americans indicated that the COVID-19 pandemic had taken a toll on their mental health, reporting higher levels of sadness and worsening of chronic psychiatric conditions [2]. Yet, despite an abundance of anecdotal evidence and peer-reviewed editorials that identify the potential mental health fallout of this public health crisis, the extent of these effects is empirically unknown.

Scientists mobilized quickly to measure many facets of the pandemic, including potential mental health effects. However, the time-consuming and costly nature of survey development [3] and instrument validation make it difficult to draw real-time conclusions [4], especially amid rapidly evolving news cycles that shift pandemic-related discourse. In the absence of survey data, social media represents a potentially valuable data source for studying emergent social issues, including the effect of those issues on behaviors and social mood [5]. Repeated tracking of social media data can provide a diachronic perspective on public morale and collective changes in sentiment, as participants voluntarily contribute to narratives, providing unprompted and diverse understandings of various issues [6-8]. Numerous scholars have successfully used social media data to identify trends and nuances in public mood using a combination of machine learning and artificial intelligence approaches. Some examples include comparing the happiness of users to their online social networks [9,10], identifying detailed predictors of mood through social media feeds [5], predicting cognitive distortions expressed among groups at risk of mental health disorders [11], tracking the emotions of social media users at high resolution [12,13], and mapping negative affectivity among users with internalizing disorders [14]. Collectively, these studies demonstrate the feasibility and value of using sentiment analysis on social media data to study societal mood and well-being, as well as biomedical signals among social media users that can provide useful proxies for mental health [12,15-17]. In fact, these approaches may be especially useful considering the speed that the pandemic became an acute socioeconomic phenomenon, the pervasiveness of COVID-19–related content available online, and the natural reaction of many to post on social media about pandemic-related events.

Indeed, throughout the COVID-19 pandemic, individuals have sought out crisis-related news at increased capacities [18], leading to a collective increase in global social media use [19]. This renders social media data about the COVID-19 pandemic a powerful source of information to draw real-time conclusions about aggregate social well-being during an unprecedented public health event. However, we must remember that, just as survey data are prone to biases, so are data derived from social media [20]. Therefore, to draw accurate inferences about mood, sentiment, and mental health, we must remain cognizant of the type of analysis performed, and what the analysis represents to measure nuanced aspects of sentiment. We contrasted topics discussed, topic-related sentiment, and personal sentiment to arrive at a more comprehensive and accurate assessment of changes in sentiments expressed through social media and their relevance to public health in the United States.

Broadly, this study answers the following three research questions (RQs):

- RQ1: What themes emerge from a corpus of US tweets about COVID-19?
- RQ2: To what extent did social media use increase during the onset of the COVID-19 pandemic?
- RQ3: What patterns emerge from longitudinal tracking of sentiment during the onset of the COVID-19 pandemic?

To address these RQs, we analyzed a large-scale set of Twitter data that are strictly relevant to the topic of COVID-19 in the United States from January 22, 2020, onward. Using this data, we also compiled a second corpus of individual geolocated social media timeline data from the same period to understand changes in personal sentiment as a proxy for mental health and evolving US perceptions of the COVID-19 pandemic.

Methods

Data

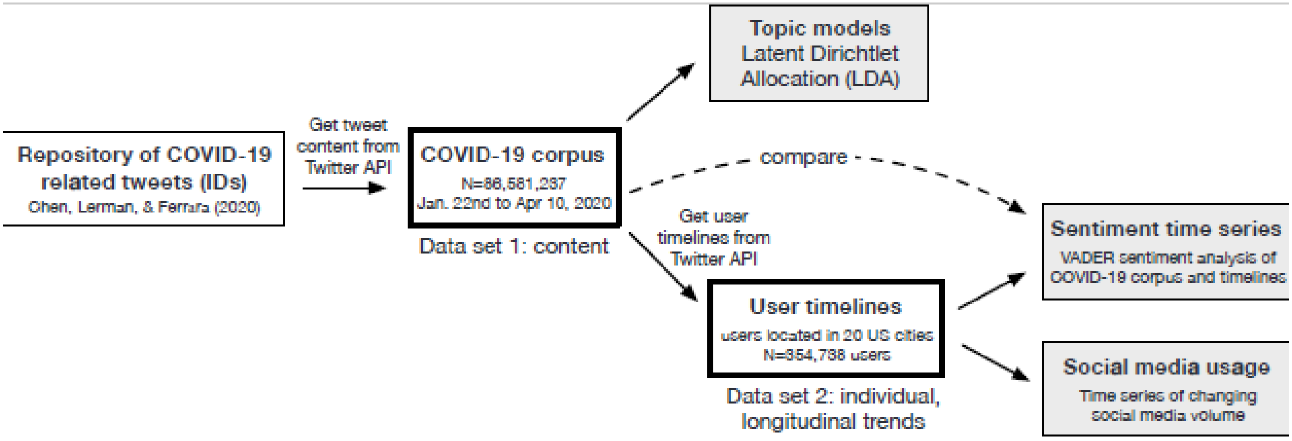
We collected two distinct data sets, each reflecting different aspects of changes in social media behavior before and during the COVID-19 pandemic. The first data set of tweets, collected from an open-access repository containing all COVID-19–related tweets published in the United States [21], was designed to capture *topical differences* (ie, themes) in the Twitter discussion during the events that marked the onset of the pandemic. The repository provides a list of tweet IDs, which we used to extract tweet content from Twitter's application programming interface (API; end point: GET statuses/show/id). We downloaded each tweet as well as the standard metadata provided by Twitter. Specifically, we retrieved COVID-19–related tweets posted between January 22, 2020 (first day of data collection and roughly 1 week prior to the first confirmed US COVID-19 case) through April 9, 2020 (the middle of social distancing efforts). Hereafter, we refer to this set of tweets as the "*COVID-19 corpus*" (n=86,581,237 tweets). Please refer to Figure 1 for a visual representation of this data set and how it was retrieved.

To gauge fluctuations of personal activity and mood at the individual (rather than topical) level, we downloaded the Twitter timelines (ie, the 3200 most recent tweets) of individual social media users who contributed to the COVID-19 corpus and resided within the 20 US cities with the most COVID-19 cases per 100,000 people from the Twitter API (end point: GET statuses/user_timeline). These timelines capture the changing behavior and emotions of individual Twitter users during the

COVID-19 pandemic but do not strictly pertain to tweets exclusively related to COVID-19. We referred to this data as *user timeline data* (n=354,738 users; n=69,349,479 tweets), as shown in Figure 1. All tweets in either data set were scrubbed of any personally identifiable information in accordance with ethical social media use practices.

To ensure that we were measuring expressed sentiment in our data, we excluded non-English tweets and, specifically within the user timeline data, retweets and biasing keywords including "coronavirus," "COVID-19," and "pandemic," among others. These words were removed because they inherently carry a negative connotation, and their inclusion would artificially decrease sentiment given that the corpus itself is composed of COVID-19–related content. In other words, because users are naturally tweeting about *coronavirus*, *virus*, and the *pandemic*, the inclusion of those words may not necessarily reflect the individual's well-being. Note, the resulting sample sizes for each corpora exceeded the mean observed in a recent scoping survey of the literature on social media analytics for public health (n=20,000) [22], resulting in ample representation to conduct our analyses. Additionally, previous studies have used large-scale sentiment analysis to accurately predict social mood [23] and how sentiment expressed on social media correlates with psychological well-being [24]. Thus, the use of sentiment analysis for this study was appropriate.

Figure 1. This diagram illustrates the procedure undertaken to procure Tweet IDs from an open-access COVID-19 repository. These tweet IDs were run through Twitter's API to create two distinct data sets. The COVID-19 corpus, which contains all COVID-19–related English language tweets published in the United States between January-April 2020. The user timeline data contains the 3200 most recent tweets of users residing in the 20 cities most affected by COVID-19. API: application programming interface; VADER: Valence Aware Dictionary for Sentiment Reasoning.



Analyses

Latent Dirichlet Allocation Topic Models

Latent Dirichlet allocation (LDA) topic models are unsupervised machine learning tools that perform probabilistic inferences to consolidate large volumes of text data into manageable themes [25]. Simply, words with high probabilities of association (ie, a high likelihood to appear in proximity with other words) are grouped together to form a latent theme, or topic, that qualitatively represents a content area within the collection of text. These methods have been applied in many ways such as to determine common themes in product reviews [26], to map themes within bodies of scientific literature [27], and to identify themes in social media data [28]. Thus, these tools are appropriate for exploratory analyses that seek to consolidate dense text data.

Sentiment Analysis

Sentiment analysis refers to a set of supervised or unsupervised machine learning and natural language processing techniques that extract affective or emotional indicators from text (eg, to determine whether a tweet expresses a negative or positive emotion about policy [23]). In this study, we used the Valence Aware Dictionary and Sentiment Reasoner (VADER) [29] to gauge the emotional valence of tweets. VADER is a rule-based open-source tool that recognizes common terms, idioms, abbreviations, and jargon while accounting for grammatical structures such as punctuation, negation, hedging, and magnification that are commonly employed in the vernacular of social media platforms. The VADER lexicon is one of the largest of its kind containing over 7500 common terms that are each rated for their emotional valence by 10 independent human raters. However, the word *virus* and its many variations (eg, viruses, viral) are not part of the VADER lexicon, meaning changes in the frequency of these words will not bias VADER scores. VADER has been extensively validated for Twitter content [30], showing some of the highest accuracy and coverage for tweets in a benchmark of more than 20 sentiment analysis tools [31].

Change-Point Detection

We applied the Pruned Exact Linear Time (PELT) change-point detection algorithm to identify significant changes in tweet volume and sentiment [32]. Change-point detection algorithms perform a set of mathematical operations over a time series (a series of time-based observations) to identify points in time where the statistical properties of the time series data changed significantly [33]. The PELT algorithm specifically attempts to find a set of change points for a given time series, such that their number and location in time minimizes a given segmentation cost. We chose the PELT algorithm over other similar change-detection algorithms because it is considered to be a more conservative estimate (preferring not to identify change points unless strict conditions are satisfied), thus yielding more accurate detection of statistical changes [34]. Additionally, PELT uses an offline approach to change detection [34], meaning it can consider all possible data points when identifying significant changes, regardless of the type of data, while maintaining high levels of performance.

Procedure

What Themes Emerge From a Corpus of US Tweets About COVID-19?

We divided the COVID-19 corpus into daily segments and generated one topic model per day consisting of 20 topics each. We chose this number to reflect the widest possible span of themes while summarizing the major themes of the online discussion, which is a process used in previous studies [28,35]. We then looked at the top 20 associated words per topic and collapsed similar words into general themes, taking into account similarities of words (eg, United States and US) and potential misspellings, which are common in social media posts. As an example, *Hubei* and *Wuhan* were collapsed into the theme *China*. We then found the frequency ratio (ie, the number of occurrences of a certain word divided by the total number of words) of COVID-19–related themes (China, United States, pandemic, social distancing, Trump, home, lockdown, and deaths) and plotted them on a daily basis to show the evolution of topics over time, indicating both the contribution of the theme to all content of that day and the relative ranking of these terms among these themes. We used intercoder agreement methods to arrive at mutually agreeable interpretations of collapsed themes [36].

To What Extent Did Social Media Use Increase During the Onset of the COVID-19 Pandemic?

For this analysis we used the user timeline data instead of the general COVID-19 corpus (see Figure 1) because within-subject individual posting frequency is a better marker for tracking changes in social media use behavior [37]. Since Twitter's API limits us to only the 3200 *most recent postings* per individual, we only selected individuals who posted on Twitter before January 22, 2020, retaining 354,738 users. This ensured that our analytic sample captured individual behavior in the 20 most-affected US cities throughout the interval of interest (January 22, 2020, to April 9, 2020). We performed a seasonal decomposition—a method that separates the baseline, trend, and seasonal components of a time series—to determine whether we can observe increased Twitter use during the pandemic relative to events just prior. We then detected significant points of change using the PELT algorithm [38].

What Patterns Emerge From Longitudinal Tracking of Sentiment During the Onset of the COVID-19 Pandemic?

Sentiment can change because individuals discuss different topics (eg, using pejorative terms such as "virus" more frequently) or because of personal, individual changes in how people actually feel. We therefore compared daily VADER sentiment scores for the COVID-19 corpus (to gauge topical sentiment) and the user timeline within-subjects data (to assess personal changes in sentiment) from January 22, 2020 (the first official day of data collection) through April 9, 2020. We determined change points in the time series of daily averaged VADER sentiment with the PELT detection algorithm to identify significant changes in sentiment throughout this time period.

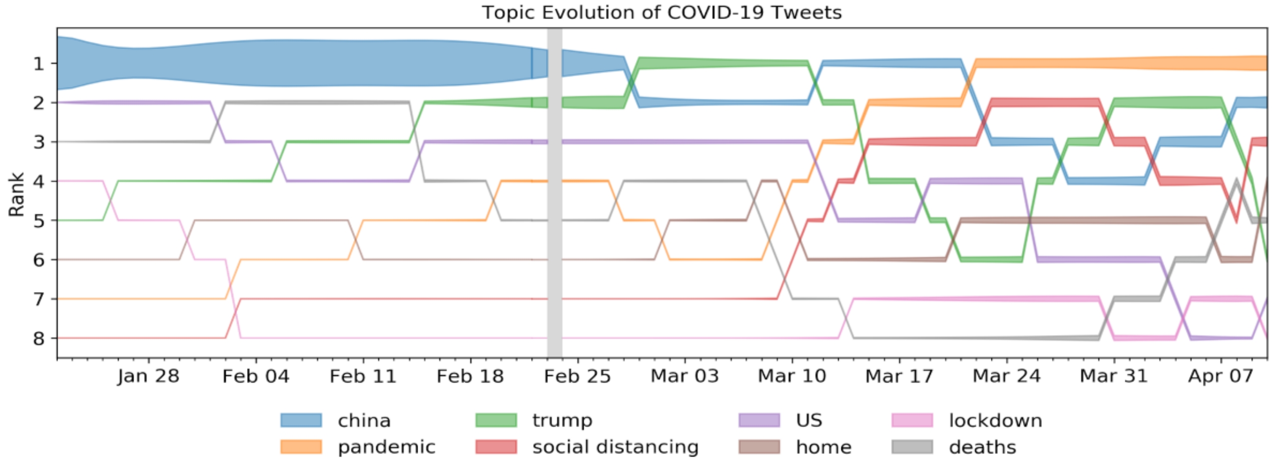
Results

What Themes Emerge From a Corpus of US Tweets About COVID-19?

We consolidated the COVID-19 corpus (n=86,581,237 tweets) into themes using LDA topic models. Figure 1 highlights the eight most salient topics and how their prominence (width of bars and rank) changed over time relative to major COVID-19–related milestones identified by the World Health Organization (WHO).

As shown in Figure 2, topics continued to rise and fall in prominence relative to emerging news cycles throughout the time period under consideration. Indeed, the majority of COVID-19–related Twitter activity focused on China in February 2020. However, from March to April, as the novel coronavirus increasingly began to affect the US population, *China* became less prominent as more US-centered topics such as "lockdown" and "social distancing" emerged. Although China remained a prominent theme throughout the duration of interest, US-centered topics gradually came to dominate social media spaces.

Figure 2. Topic group rankings over time in the COVID-19 corpus. Each topic is ranked by its frequency ratio. The width of the bars indicates the fraction of words in the topic on a given day. The colors of the areas indicate which theme the corresponding area belongs to.

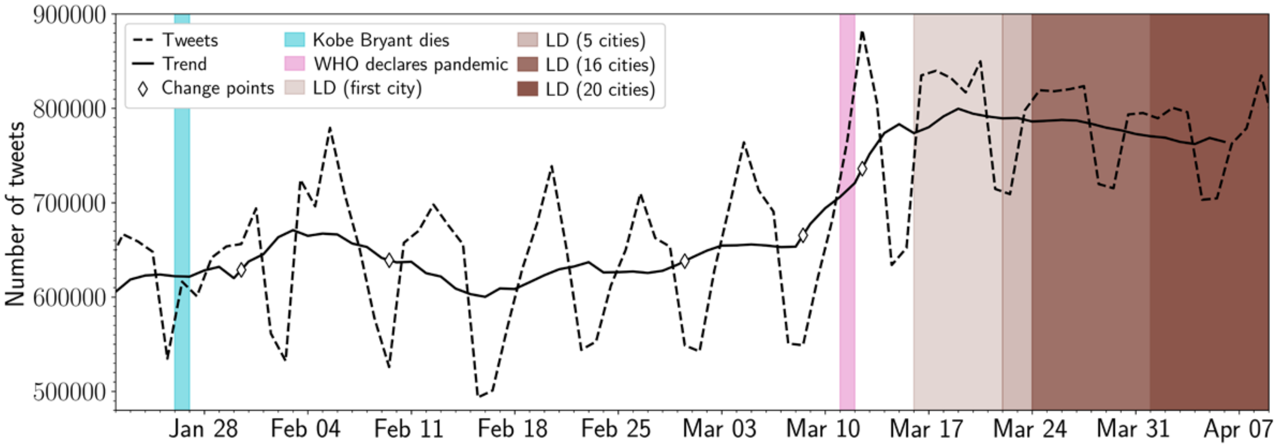


To What Extent Did Social Media Use Increase During the Onset of the COVID-19 Pandemic?

Using user timeline data, we compared the frequency of social media posts before and during the pandemic of 292,000 users (whose timelines span January 22 onwards) in the 20 most-affected metropolitan cities (n= 66,725,505 tweets). Figure 3 highlights changes in posting volume between January 22, 2020, and April 9, 2020. The peaks and troughs (dashed line) of this graph show how seasonal and weekly cycles shape tweet volume. The solid line plots the trend in the time series after removing cycles and seasonal effects (through seasonal decomposition), and the progressively darker shades of brown denote the number of cities that imposed mandatory lockdowns.

Generally, we observed a consistent upward trend in total Twitter volume from early to late March. The PELT change-point algorithm identified two significant volume changes on March 8 and 12, 2020—around the time COVID-19 was declared a global pandemic (March 11) and President Trump declared a national emergency in the United States (March 14). The upward trend stabilized thereafter, albeit at higher observed volumes than prior to the onset of the COVID-19 pandemic. This supports the notion that individuals in our sample were more engaged with social media and made more use of it, possibly to discuss or obtain further information relevant to the news cycle.

Figure 3. Number of daily tweets in a subsample of the user timeline data. The dashed line displays the daily number of tweets in the subsample of the user timeline data. The solid line indicates the underlying trend in the daily number of tweets (after removing its seasonal effects). The diamond markers indicate significant change points indicated by the Pruned Exact Linear Time algorithm. The light blue and pink annotations denote the death of Kobe Bryant (January 26, 2020) and the day when the WHO declared COVID-19 a global pandemic (March 11, 2020), respectively. The brown bars indicate the dates that lockdowns were enforced in the 20 considered cities (ranging from March 16 to April 1, 2020). The opacity of the brown bars indicates how many cities had enforced a lockdown at that date. LD: lockdown; WHO: World Health Organization.



What Patterns Emerge From Longitudinal Tracking of Sentiment During the Onset of the COVID-19 Pandemic?

We applied the VADER sentiment tool to the COVID-19 corpus (to assess sentiment of all US tweets about COVID-19) and the user timeline data (to track changes in user sentiment using their most recent 3200 tweets). Figure 4 tracks sentiment relative to major COVID-19–related milestones for both data sets, with the orange line tracking the COVID-19 corpus and the blue line tracking the user timeline data. In the COVID-19 corpus, there was an unmistakable increase in sentiment with two PELT-identified significant changes on March 9 (just before the WHO classified COVID-19 as a pandemic) and March 19, 2020 (shortly after President Donald Trump declared a national emergency). Figure 5 further shows that the percentage of positively scored COVID-19 tweets increased over time, reinforcing the positive trend.

Conversely, the user timeline data (which again contained the most recent 3200 tweets of a given user) showed decreases in sentiment over the same period. The user timeline data had one PELT-identified significant change in sentiment on January 28, 2020 (the day National Basketball Association [NBA] player Kobe Bryant died in a helicopter crash). There was a notable but short-lived drop in sentiment before March 9 (when the WHO classified COVID-19 as a pandemic).

Figure 4. Distribution of nonzero VADER sentiment in the COVID-19 corpus (orange) and user-timeline data (blue). The solid lines display the 14-day moving average, and orange crosses/blue triangles represent the actual daily average VADER sentiment value. The diamond markers show change points indicated by the Pruned Exact Linear Time algorithm; the color of the diamond's edge refers to the time series that this change point belongs. The light blue, gray, and pink annotations denote the day of Kobe Bryant’s death (January 26, 2020), the day of missing data in the COVID-19 corpus (February 23), and the WHO declaration of COVID-19 as a global pandemic (March 11), respectively. The brown bars indicate the dates that lockdowns were enforced in the 20 considered cities (ranging from March 16 to April 1, 2020). The opacity of the brown bars indicates how many cities had enforced a lockdown at that date. LD: lockdown; VADER: Valence Aware Dictionary for Sentiment Reasoning; WHO: World Health Organization.

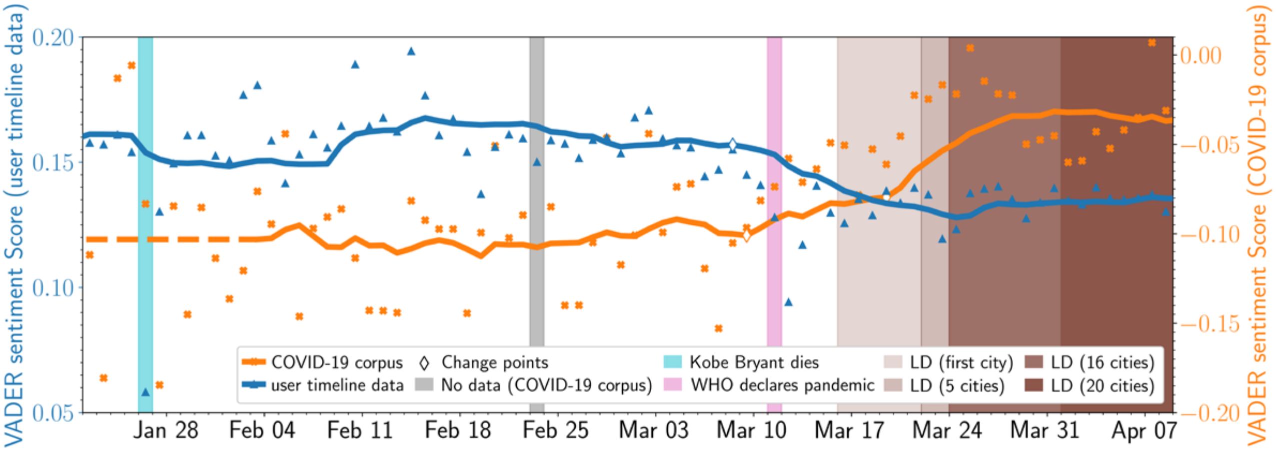


Figure 5. Distribution of positive and negative VADER sentiment in COVID-19 corpus. The solid line displays the fraction of tweets that hold positive or negative VADER sentiment in the user timeline data (colored green for positive and red for negative sentiment). The gray and pink annotations denote the day of missing data (February 23, 2020) and the WHO declaration of COVID-19 as a global pandemic (March 11), respectively. VADER: Valence Aware Dictionary for Sentiment Reasoning; WHO: World Health Organization.

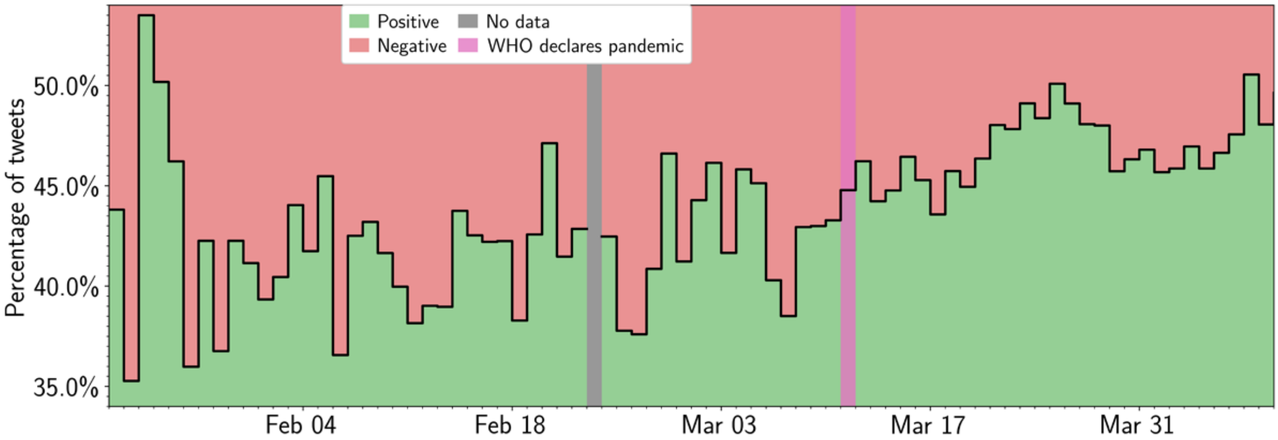

Discussion

Principal Findings

The purpose of this study is to draw conclusions about US mental health amid the COVID-19 pandemic using computational social media analytics of a publicly available repository containing all COVID-19–related tweets. Using the COVID-19 tweet repository released by Chen and colleagues [21], we expanded on their original topical analysis of COVID-19 content by examining both topics and sentiment specific to the US population to understand how the COVID-19 pandemic may be impacting social well-being. We used social media data as the medium for analysis for several reasons, in particular its usefulness to gauge real-time changes in mental health and social well-being before, during, and after rapid socioeconomic changes [15]. In this section, we discuss the findings of this study in detail and highlight public health implications about social well-being during the onset of the COVID-19 pandemic.

COVID-19 Social Media Themes: Content Is Reactionary to News Cycles

Bento and colleagues [18] predicted that crisis-related information seeking would increase during the COVID-19 pandemic. Numerous studies have supported that prediction by identifying increased panic within social media spaces as users react to COVID-19 news–related content on their feeds [39,40]. Through our LDA topic modeling analysis, we echo much of those findings as well; the topics uncovered by LDA frequently corresponded to the life cycles of COVID-19–related news and current events. For example, the name used to identify the virus on social media evolved to match changes in viral terminology as presented on news outlets (eg, the *novel coronavirus* became *coronavirus*, *COVID-19*, and *COVID-19 pandemic*). The locations that emerged within the topics also corresponded to the movement of COVID-19 from mainland China to the United States. For example, in late January, *China* was a dominant theme in Twitter content (shown by the width of the bars in Figure 2), indicating the US public may have considered the then-classified epidemic a foreign matter (eg, tweet: “OMG China just shut down trading...Still think it's just a flu?”). However, in later weeks and months, US-centered topics and tweets replaced *China* in prominence as more Americans became preoccupied with pandemic control measures at home (eg, tweet: “lol it’s wild seeing every single other country grappling with this virus in ways we KNOW the US will never do”). These findings suggest that, as the COVID-19 pandemic became more prominent in the United States, social media content changed to topics of more direct impact to the United States and with greater frequency of use (evidenced by a PELT-identified significant increase in Twitter volume during that time). This volume increase remained consistently above levels observed prior to the COVID-19 pandemic, which is possibly explained by several factors including increased anxiety as the COVID-19 pandemic reached the United States, the isolating effects of statewide stay-at-home orders, or other social fallouts driven by the pandemic. These findings collectively support those of Castillo and colleagues [41], who contend that social media content follows the life cycle of news stories. Thus, news, as a vehicle for crisis-related social media communication, should be studied more intently.

COVID-19 Topical Sentiment: Increased Sentiment May Indicate a Priming Effect

Given the expected negative physical and emotional outcomes of a major pandemic, we were surprised to observe that the sentiment of the COVID-19 corpus trended positively. However, this increase in sentiment is likely not indicative of actual changes in population sentiment but rather the effect of a common *topical* bias in social media analytics [42]. Our COVID-19 data set was specifically selected to contain tweets that related to the topic of COVID-19. Hence, its sentiment scores will reflect the language used to discuss this particular topic and not necessarily the underlying emotion of the population. Topically selected social media posts are likely primed by news cycles [43] and show false optimism—a phenomena where individuals tend to post content that is more positive or optimistic than their true emotions [44]. Previous research has further shown that language in general is biased toward positivity, especially when posts are collected for a random topic [30]. For example, language used to compose a post about COVID-19 may contain trending verbiage or framing devices, including showcasing support of groups frequently part of news cycles (eg, tweet: “Great news...it’s a welcome burden lifted off our incredible nurses and medical first responders”). Similarly, users may just be conveying positivity through carefully selected *popular* words around a trending topic (eg, tweet: “No matter how hard the situation nowadays during the pandemic outbreak, we should keep being positive and optimistic”). Within the VADER lexicon, many of the words commonly used in this context are scored positively (great, welcome, incredible, positive, optimistic), which also artificially inflates sentiment ratings. Thus, we posit that topically driven tweet samples may not validly reflect actual changes in population mood but rather topic-driven language sentiment. This justifies our approach to analyze within-subject timelines of individual posts that are not necessarily bound by the criterion of strictly being COVID-19–related, thereby increasing the odds of reflecting personal changes in mood trajectories.

User Timeline Sentiment: Lower Timeline Sentiment May Indicate Decreased Social Well-being

By contrast, we found a negative trajectory in sentiment scores for the user timeline data. This means that, although content in the COVID-19 corpus trended positively (possibly due to priming), relative to the totality of their timelines, our sample mood was *lower* than it once was. Thus, this comparison gives us deeper insight into *underlying* mood and sentiment. This finding further supports the assertion that the positivity conveyed in social media posts may not validly reflect what people are feeling at a given moment. Indeed, that positivity may be serving as a veneer posted *in the moment* to convey positivity during a time of uncertainty. To obtain an accurate assessment of mood and well-being, other reference points (in this case, social media posts prior to the pandemic) are needed to examine in-the-moment sentiment relative to their prior histories. Within our timeline data, we captured one event that occurred prior to the pandemic that also affected sentiment scores relative to timeline histories—the passing of NBA basketball player Kobe Bryant. The effect of Bryant’s passing led to a sharp decline in sentiment, which lasted approximately 24 hours before returning to levels observed previously. Regarding the pandemic, after the PELT-identified shift on March 8, 2020, sentiment scores (relative to timelines) became not only lower but also consistently lower and did not return to levels observed before the pandemic reached the United States. This trend may hold implications into the longitudinal effects of the pandemic and subsequent impacts on US mood and social sentiment, as this continued trend may be indicative of a long-lasting shift in mood and well-being.

Social Media Use in Times of Crisis

Analyses of aggregated social media feeds are shown to adequately predict other phenomena including the stock market [45]; political leanings [46]; and, when analyzed through a time series, collective shifts in general mood [47]. Our study contributes to this body of literature by highlighting the disparity between how Americans portray themselves on social media versus the latent sentiment they may be experiencing during times of crisis. Generally, Americans were not posting social media content about COVID-19 prior to the first documented US case. Once COVID-19 became a reality in the United States, however, there was a continued increase in the total number of US-based tweets about the novel coronavirus, indicative of growing social media use in our sample. By analyzing the COVID-19 corpus and user timeline data separately, but with the same analytic procedures, we saw divergent findings that reinforced the difference between in-the-moment portrayals versus the longitudinal information that can be gleaned from individual timeline analyses. For example, tweets and posts about COVID-19 may attempt to be lighthearted or convey optimism; however, individually, social media users may not be as optimistic as they were prior to the pandemic. During an unprecedented public health crisis, it is therefore important to look beyond the topical focus of messages on social media that reference the crisis itself as a proxy of public mood, as they are likely to be affected by other influences (eg, political framing and projecting hope). Ultimately, our findings exemplify COVID-19 as a case study in social media behavior, whose outcomes should be generalized to other crisis-related events.

Concluding Remarks and Implications

At the time of writing, the US COVID-19 death toll was just over 136,000, with the lives of millions of people disrupted by the various effects of the pandemic. This study elucidates the possible mental health effects of the COVID-19 pandemic among Twitter users using a computational approach to analyze a corpus of all archived US-based COVID-19 tweets from January to April 2020. These analyses revealed, to varying extents, how the pervasiveness of COVID-19 content available on social media and abrupt shift in lifestyles may be negatively affecting social sentiment relative to points just prior to the pandemic. Given that sentiments expressed on social media have been used as a proxy for mental well-being [48], these findings support calls from public health and medical scholars who contend that mental health is an urgent concern during the COVID-19 pandemic, especially as our findings illustrate a declining trend in sentiment. Thus, we encourage further research on US mental health status amid the pandemic using survey methods or other primary data collections to substantiate our findings with testable outcomes. We also call for more research on mental health interventions amid the COVID-19 pandemic, with particular attention to modality (ie, in person vs virtual), and the efficacy of those efforts.

Limitations

Our study is subject to limitations. Twitter requires users to opt in to geotagging features. Consequently, any information inferred about the user's city of residence is often limited to self-reported data as specified on profile pages. This means that some of our timeline data may not originate from the city specified by a user, as this information can easily be misrepresented [49] (eg, stating they live in New York, NY, but actually residing in Newark, NJ). We also acknowledge a likely bias regarding key demographic information, including age, gender, and socioeconomic status among social media users [50], in addition to the temporal, spatial, and geographic patterns that may affect how sentiment is expressed on social media (eg, older adults posting early in the morning vs younger adults posting late at night or urban vs rural users) [51]. It is also, as of yet, not possible to accurately diagnose someone with a mental health condition through social media feeds alone, although research has shown that social media content contains important indicators with respect to mental health and biomedical signals. Thus, we relied on trend data to draw inferences about the *possibility* of mental health decline based on average sentiment scores [52]. However, these limitations do not diminish the importance or validity of this study. Rather, they create avenues for additional research that expand on the findings of this paper and leverage the limitations inherent to social media data, such as measuring cognitive distortions on Twitter based on posting time or approaches that measure diagnosable mental health conditions through social media data, particularly during times of increased panic and crisis. In addition, because social media has been widely used to draw conclusions about public mood through large-scale sentiment analysis procedures [10,18], we contend our approach is appropriate to draw the conclusions discussed herein. Abstract

Background: The COVID-19 pandemic has led to an increase in the use of and demand for telehealth services.

Objective: Here, we describe the utilization of telehealth services provided by Doctor On Demand, Inc., a well-known telehealth company in the United States, before and during the COVID-19 pandemic. We also explore how the number of virtual visits, reasons for visits, and patients served changed over time.

Methods: We reported data as a percentage change from the baseline week during 2 distinct time periods: February-June 2019 and February-June 2020 based on 4 categories of visits: respiratory illness, unscheduled behavioral health, scheduled behavioral health, and chronic illness.

Results: In 2020, the total visit volume increased considerably from March through April 7, 2020 (59% above the baseline) and then declined through the week of June 2 (15% above the baseline). Visits for respiratory illnesses increased through the week of March 24 (30% above the baseline) and then steadily declined through the week of June 2 (65% below the baseline). Higher relative increases were observed for unscheduled behavioral health and chronic illness visits through April (109% and 131% above the baseline, respectively) before a decline through the week of June 2 (69% and 37% above the baseline, respectively). Increases in visit volume among rural residents were slightly higher than those among urban residents (peak at 64% vs 58% above the baseline, respectively).

Conclusions: Although this telehealth service provider observed a substantial increase in the volume of visits during the COVID-19 pandemic, it is interesting to note that this growth was not fueled by COVID-19 concerns but by visits for behavioral health and chronic illness. Telehealth services may play a role as a “safety valve” for patients who have difficulty accessing care during a public health emergency.

KEYWORDS

telehealth; telemedicine; COVID-19; pandemic; infectious disease; virus; United States

Introduction

In response to the COVID-19 pandemic, health care delivery in the United States has changed dramatically since March 2020. As a result of stay-at-home orders, many physicians who had limited prior experience with telehealth started offering telehealth visits to support social distancing, conserve the use of personal protective equipment, and safeguard vulnerable patients from exposure to COVID-19. This transformation in health care delivery was unprecedented, and evidence about clinicians' experiences transitioning to and maintaining telehealth services during the pandemic is still emerging.

However, when COVID-19 outbreaks emerged, many organizations were already conducting telehealth visits in high volumes. Prior to 2020, large telehealth service providers were providing millions of telehealth visits per year, offering patients immediate access to clinicians via videoconferencing visits from personal electronic devices [1].

To date, research on telehealth implementation during the COVID-19 pandemic has focused on the experiences of professionals new to telehealth [2]. Little is known about the impact of COVID-19 among telehealth services that were functional prior to the pandemic. To address this gap in the literature, we collaborated with a prominent telehealth service provider, Doctor On Demand, Inc., to describe their experience during the ongoing pandemic and to explore how the number of telehealth visits, reasons for visits, and patients served have changed over time.

Methods

Services Offered

Doctor On Demand is a telehealth company that provides services across all 50 US states. It delivers urgent care, behavioral health, preventive care, and chronic care services directly to consumers through its affiliations with self-insured employers and health plans. In March 2020, the company observed an increase in requests for visits and pursued several strategies to increase its capacity. They launched an online COVID-19 assessment tool and information center for mobile devices. The assessment tool, which was developed in collaboration with the Centers for Disease Control and Prevention, allowed patients to compare their symptoms to those suggestive of COVID-19 and provided recommendations regarding whether they need to seek care. The company also hired additional providers and increased the working hours of existing providers. Visits during the study period were delivered by board-certified primary care physicians, board-certified psychiatrists, and doctoral-level psychologists.

Data Analysis

The company generated data in an aggregate form, as a percentage change from the baseline over 2 distinct time periods: February-June 2019 and February-June 2020. The baseline week was defined as February 25 to March 3 for 2019 and February 24 to March 1 for 2020. We selected this specific week-long period because it represented the tail end of the influenza season and, in 2020, it occurred before significant community transmission of COVID-19 was reported in the United States.

We plotted weekly changes in the visit volume from the baseline for all virtual visits and 4 specific categories of visits: respiratory illness (including acute respiratory infection, influenza-like illness, and potential COVID-19), unscheduled behavioral health services offered within the urgent care service staffed by primary care providers, scheduled behavioral health services (including therapy and psychiatry) offered within the behavioral health service staffed by specialty behavioral health providers, and chronic illness.

In the respiratory illness category, we combined acute respiratory infection, influenza-like illness, and suspected COVID-19 given the similarities in their presentation with fever and potential cough. Respiratory illness visits included visits for the following diagnoses: coronavirus infection; viral infection, unspecified; SARS-associated coronavirus; other coronavirus; acute nasopharyngitis; acute maxillary sinusitis; acute frontal sinusitis; acute pansinusitis; acute sinusitis; acute recurrent sinusitis; streptococcal pharyngitis; acute pharyngitis; acute tonsillitis; acute laryngitis; acute obstructive laryngitis (croup); acute upper respiratory infection, unspecified; influenza; viral pneumonia, unspecified; pneumonia; acute bronchitis; acute bronchiolitis; acute lower respiratory infection, unspecified; allergic rhinitis; chronic rhinitis; bronchitis; chronic bronchitis, unspecified; asthma, unspecified; acute bronchospasm; cough; dyspnea; shortness of breath; wheezing; nasal congestion; other disturbances of smell or taste; fever, unspecified; headache; other fatigue; and COVID-19 acute respiratory disease.

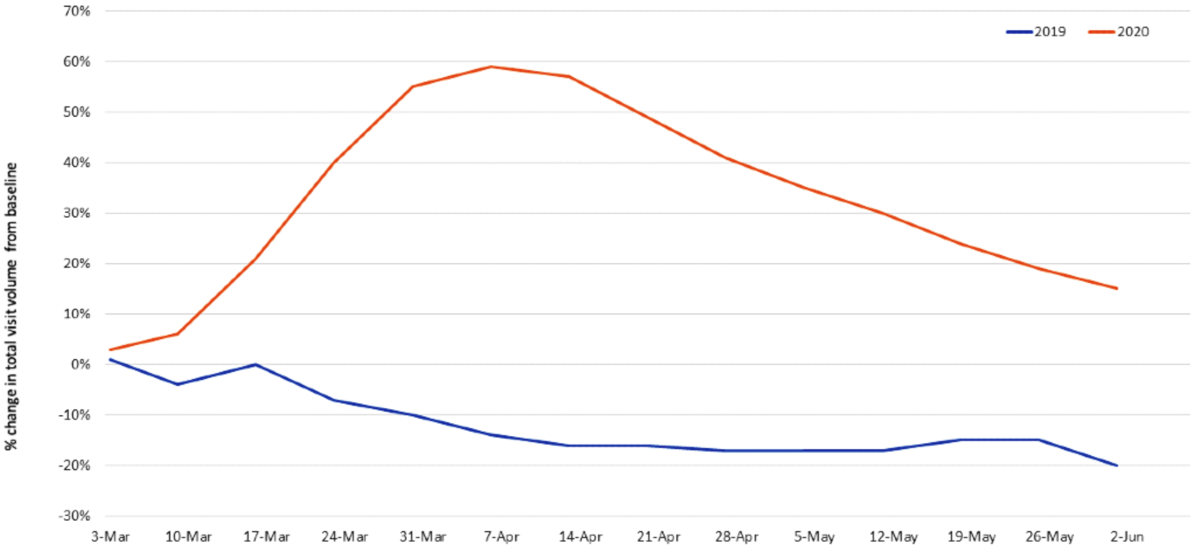
Chronic illness visits included visits for the following diagnoses: asthma, low back pain, hypertension, thyroid disorders, obesity, hypercholesterolemia/hyperlipidemia, chronic obstructive pulmonary disease, type 2 diabetes, complex diabetes, osteoarthritis, iron deficiency anemia, rheumatoid arthritis, fibromyalgia, prediabetes, lupus, ulcerative colitis, heart disease, Crohn disease, HIV, cancer, emphysema, sleep apnea, glaucoma, hemophilia, falls, hepatitis C, chronic kidney disease, end-stage liver disease, scleroderma, stroke, severe chronic kidney disease, hepatitis B, hemochromatosis, macrocytic anemia, macrocytosis, polymyalgia rheumatica, hepatitis A, joint replacement, and interstitial lung disease.

Results

Visit Volume

Compared to the baseline week, in 2019, total visit volume declined from March through June 2019 (Figure 1). In contrast, in 2020, total visit volume increased sharply from March to April 7, 2020 (59% above the baseline) and then steadily declined through the week of June 2, 2020 (15% above the baseline).

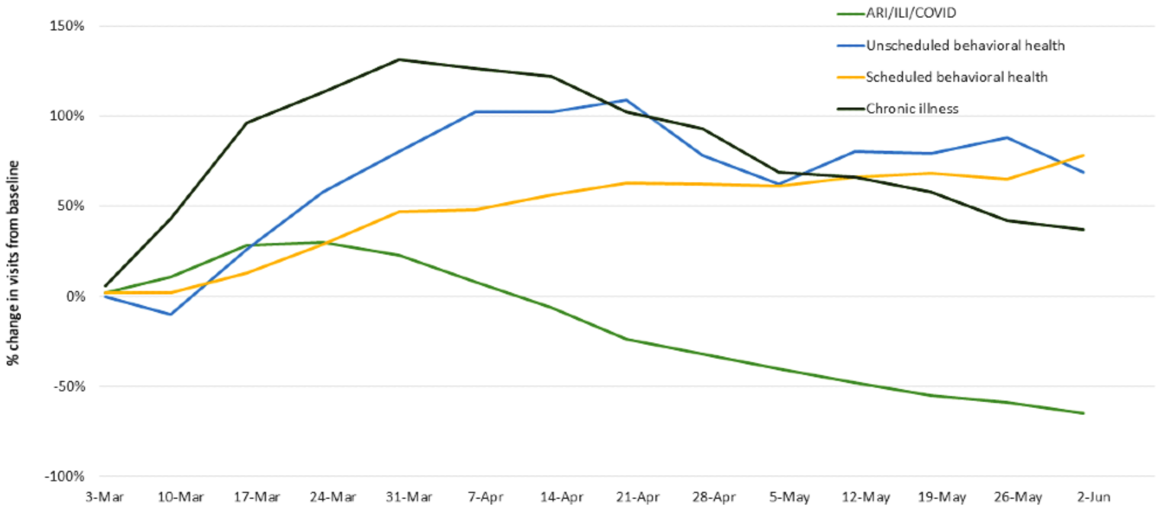
Figure 1. Percentage change in the total volume of virtual visits from the baseline week in 2019 and 2020. Baseline weeks: February 25 to March 3, 2019, and February 24 to March 1, 2020.



In 2020, during the baseline week starting February 24, respiratory illness visits represented 45% of the total visit volume, whereas the total number of visits for behavioral health (scheduled and unscheduled) and chronic illness comprised 20% and 5% of the total visit volume, respectively.

Moreover, in 2020, visits for respiratory illnesses modestly increased initially (peak at 30% above the baseline in the week of March 24) and then steadily declined (65% below the baseline in the week of June 2; Figure 2). In contrast, unscheduled behavioral health and chronic illness visits increased across this period, peaking at 109% in the week of April 21 and at 131% in the week of March 31, before declining to 69% and 37%, respectively—levels that were still above the baseline. In the week of June 2, 2020, respiratory illness visits represented 14% of the total visit volume, whereas behavioral health (scheduled and unscheduled) and chronic illness visits comprised 31% and 5%, respectively.

Figure 2. Percentage change in the total volume of virtual visits by type of visit from the baseline week in 2020. ARI: acute respiratory infection, ILI: influenza-like illness.



Patients Served

In 2020, differences in visit trends by patient location were observed. All visits among urban residents peaked at 58% above baseline, whereas visits among rural residents peaked at 64% above baseline.

Individuals residing in low-income regions (mean per capita income of <US $20,000) accounted for 47% of all visits in January and February 2020 and 50% of all visits in April 2020. The proportion of patients new to the telehealth platform increased from 40% in February 2020 to 53% in April 2020.

Discussion

Consistent with health care providers who were not focused on telehealth prior to the COVID-19 pandemic [2], the telehealth provider Doctor On Demand experienced a substantial increase in the total visit volume during the ongoing pandemic. It is noteworthy that this growth is not attributed to COVID-19 concerns; instead, behavioral health and chronic illness visits seemed to have contributed to the growth.

Although the overall growth of 59% above the baseline is substantial and similar to that reported by other telehealth services [3], it is significantly lower than the telehealth growth rate reported among in-person providers during the pandemic. For In-person providers, telehealth grew from <1% of visits to 14%-43% of visits, which corresponds to growth of >1000% [2,4]. The differences in relative growth likely suggest that the use of telehealth services among in-person providers was very low at baseline.

The overall number of telehealth visits on the Doctor On Demand platform peaked at approximately the same time as emergency department visits in the USA were at their lowest point [5]. This finding suggests that the demand for telehealth in April 2020 may have been driven in part by patient hesitation to seek in-person care. Increasing comfort with in-person care may result in a reduced demand for telehealth services as the pandemic progresses. Studies have also found that the use of telehealth services has reduced as in-person visits have rebounded [6]. However, the exposure to telehealth in the spring of 2020 may result in an increased use of these services over the long-term.

It is unclear whether the increased demand for behavioral health visits during the study period was driven by a higher incidence of mental health concerns due to pandemic-related stressors (eg, increased isolation and financial hardship) or was attributed to the reduced capacity of health care providers practicing in the community. Telehealth services may serve as a “safety valve” for patients, addressing gaps in access to the traditional (in-person) health care delivery system. Previous studies have highlighted the important role that telehealth plays during a pandemic, helping protect patients and clinicians from exposure to disease and maintaining continuity of care [7,8]. National telehealth services are especially well positioned to respond to local or regional emergencies given they have large panels of providers who are spread out geographically, and as such they can support load balancing across their networks [7]. However, in a nation affected by a pandemic, the capacity of these telehealth services is somewhat constrained by the fact that they need to hire and train additional providers to meet unexpected surges in the demand for health care. To increase the preparedness of telehealth services to scale up quickly in a national emergency, it may be necessary to maintain “reserve” providers who can be activated on a short notice.

There has been substantial discussion about the “digital divide” in health care and concerns that patients from lower-income communities may not have the necessary technology or digital literacy to participate in video-based visits. Nevertheless, it is reassuring that the proportion of telehealth visits by patients from lower-income communities was stable during the early weeks of the COVID-19 pandemic.

Conclusions

In summary, we observed that the substantial growth in the use of telehealth services of Doctor On Demand, during the pandemic was surprisingly driven by the increase in visits for behavioral health and chronic illness. Future studies should continue to describe changes in the volume of telehealth visits and reasons for their use as the current COVID-19 pandemic progresses.

Conflicts of Interest

JT, PT, KD, TY, and IT are all employees of Doctor on Demand. PT is also a small shareholder in the company, and IT is the Chief Medical Officer of Doctor on Demand and also a stock holder. All other authors declare no conflict of interest.

Abstract

Background: Assigning meaningful probabilities of SARS-CoV-2 infection risk presents a diagnostic challenge across the continuum of care.

Objective: The aim of this study was to develop and clinically validate an adaptable, personalized diagnostic model to assist clinicians in ruling in and ruling out COVID-19 in potential patients. We compared the diagnostic performance of probabilistic, graphical, and machine learning models against a previously published benchmark model.

Methods: We integrated patient symptoms and test data using machine learning and Bayesian inference to quantify individual patient risk of SARS-CoV-2 infection. We trained models with 100,000 simulated patient profiles based on 13 symptoms and estimated local prevalence, imaging, and molecular diagnostic performance from published reports. We tested these models with consecutive patients who presented with a COVID-19–compatible illness at the University of California San Diego Medical Center over the course of 14 days starting in March 2020.

Results: We included 55 consecutive patients with fever (n=43, 78%) or cough (n=42, 77%) presenting for ambulatory (n=11, 20%) or hospital care (n=44, 80%). In total, 51% (n=28) were female and 49% (n=27) were aged <60 years. Common comorbidities included diabetes (n=12, 22%), hypertension (n=15, 27%), cancer (n=9, 16%), and cardiovascular disease (n=7, 13%). Of these, 69% (n=38) were confirmed via reverse transcription-polymerase chain reaction (RT-PCR) to be positive for SARS-CoV-2 infection, and 20% (n=11) had repeated negative nucleic acid testing and an alternate diagnosis. Bayesian inference network, distance metric learning, and ensemble models discriminated between patients with SARS-CoV-2 infection and alternate diagnoses with sensitivities of 81.6%-84.2%, specificities of 58.8%-70.6%, and accuracies of 61.4%-71.8%. After integrating imaging and laboratory test statistics with the predictions of the Bayesian inference network, changes in diagnostic uncertainty at each step in the simulated clinical evaluation process were highly sensitive to location, symptom, and diagnostic test choices.

Conclusions: Decision support models that incorporate symptoms and available test results can help providers diagnose SARS-CoV-2 infection in real-world settings.

Introduction

Despite advances in molecular diagnostics and imaging, ruling in or ruling out COVID-19 infection in an individual patient remains a significant challenge [1]. Current guidelines from the Centers for Disease Control and Prevention (CDC) recommend providers to determine whether signs or symptoms are compatible with COVID-19 infection and to test appropriate patients using nucleic acid amplification tests (NAATs) or antigen detection assays [2]. However, the diverse clinical presentations of COVID-19 infection may mimic those of common infections, potentially confounding the diagnostic value of presenting symptoms [3]. Moreover, significant and evolving differences in estimated local disease prevalence for both COVID-19 infection and seasonal respiratory illnesses meaningfully impact differential diagnostic probabilities. Despite the uncertain utility of this symptom and local prevalence information, in low-resource and community settings such as ambulatory clinics, nursing homes, and telemedicine, these may be the only sources of data. In higher-resource settings, NAATs [4], antibody based lateral flow assays [5], chest radiography (CXR) [6], and computed tomography (CT) [7] may be available, yet published literature notes varied performance. Despite these limitations, clinicians with access to any imaging and testing modalities must optimize diagnostic imaging and testing sequences to appropriately reduce diagnostic uncertainty in a given setting.

This complexity highlights the need for reliable and user-friendly clinical decision support systems (CDSS) that suggest optimal testing strategies and quantify SARS-CoV-2 infection risk for patients across the continuum of care. Prior research has demonstrated the potential utility of Bayesian inference [8,9] and machine learning [10,11] methods in diagnostic decision making, but computational clinical decision support has often been underutilized due to a lack of accessibility, transparency, workflow integration, and most importantly, the flexibility to incorporate local provider beliefs into the diagnostic model [12,13].

A robust diagnostic risk model should be built on individualized patient data that is easily obtained by patients and health care workers. Menni et al [14] analyzed a large database of smartphone-enabled, self-reported symptom tracker records to predict potential COVID-19 cases using logistic regression models. In the US test set, this approach had a reported sensitivity of 66% and a specificity of 83%. Ahsan et al [15] used deep learning techniques to differentiate between COVID-19 and non–COVID-19 patients based on open-source imaging and clinical data. However, the performance of this or other machine learning models in clinical settings has not yet been examined.

Moreover, in evolving contexts where illness presentation may change depending on host and viral characteristics, large databases of individual patient records may not be available or locally relevant. Constructing inflexible predictive algorithms, such as logistic regression models, based on out-of-date and locally irrelevant data sets would significantly compromise diagnostic accuracy. Addressing these issues, Chishti et al [16] demonstrated the advantages of using flexible probabilistic frameworks built without large-scale clinical data sets to generate ranked differential diagnoses that are more accurate that those developed by physicians.

Combining the approaches of this prior work suggests that an appropriate diagnostic support model should rely on easily obtained symptom data, probabilistic frameworks to avoid the need for large-scale data sets, and most importantly, a flexible schema to refine predictions based on provider judgment and the ability to adapt to changes in local prevalence and current diagnostic test performance. To this end, we present a comparison and clinical validation of 3 such quantitative models as well as an ensemble approach to the diagnosis of COVID-19 in ambulatory and acute care settings. We then illustrate how this approach can be employed to help providers optimally reduce diagnostic uncertainty through appropriate diagnostic test choices and update predictions based on local clinical context and test results as that are obtained. Finally, we provide an interactive, online resource to assess COVID-19 infection probability based on user-defined parameters such as local disease prevalence, imaging, and testing performance [17].

Methods

Data Acquisition

National and state-specific confirmed cases of COVID-19 as of July 2, 2020, were acquired from the Center for Systems Science and Engineering at Johns Hopkins University [18]. During our model training, validation, and testing process, we assumed a national SARS-CoV-2 infection prevalence of 11.1% based on the total confirmed count of 5,438,325 in the United States as of August 17, 2020 [18], a population estimate of 328,239,523 [19], and an estimated reporting rate of 14.9% [20-22]. Prevalence and conditional symptom probabilities for diseases in the differential diagnosis were collected from the CDC and literature estimates (Multimedia Appendix 1, Table S1). COVID-19 symptom probabilities were developed primarily from a 393-person consecutive patient series [23] and supplemented by 3 meta-analyses, which included 3062 [24], 49,504 [25], and 53,000 patients [26]. Where conditional symptom probabilities have not been described in the literature, we used a symptom probability of 1.0% based on our assumption that a higher conditional symptom probability would have been discussed in the literature.

To incorporate location and diagnostic test results into risk predictions, we used state-level case figures [18], state-level population data [19], and the estimated reporting rate [20-22] to compute an estimated SARS-CoV-2 infection prevalence for each state. We sourced imaging diagnostic accuracies from existing literature [6,7] and laboratory test accuracies from the Johns Hopkins Center for Health Security. The reverse transcription-polymerase chain reaction (RT-PCR) sensitivity of 70% is based on published estimates [4] that take into account operator dependency and variability in viral load across upper respiratory tract sites [27]. The RT-PCR specificity of 99.8% is based on published data from Abbott Molecular [28]. Antibody test sensitivity and specificity are based on published figures [5] for electro-chemiluminescence immunoassay completed between 0-6 days of infection. We computed likelihood ratios and prevalence-adjusted predictive values based on sensitivity, specificity, and our estimated national COVID-19 prevalence of 11.1% (Table 1).

Table 1. Imaging and laboratory diagnostic test statistics for SARS-CoV-2 infection.

Diagnostic test	Sensitivity (%)	Specificity (%)	Likelihood ratio (%)		Predictive value[a] (%)	
			Positive	Negative	PPV[b]	NPV[c]
Chest radiography	69.0 [6]	50.0[d]	1.4	0.6	14.7	92.8
Computed tomography [7]	97.0	57.3	2.3	0.1	22.1	99.3
RT-PCR[e]	70.0 [4]	97.0 [28]	23.3	0.3	74.5	96.3
Antibody (0-6 days) [5]	65.5	99.8	327.5	0.3	97.6	95.9

[a] Prevalence-adjusted predictive values assume a prevalence of 11.1%.

[b] PPV: positive predictive value.

[c] NPV: negative predictive value.

[d] No published figures available.

[e] RT-PCR: reverse transcription-polymerase chain reaction.

Training

We developed Bayesian inference network (BN) and set-cover (SC) models from published disease prevalence and conditional symptom probabilities (see Multimedia Appendix 1, Table S1). We simulated symptom profiles and diagnoses for 100,000 patients using the published aggregate diagnosis prevalence and conditional symptom probabilities. Of the 100,000 simulated patients, the number of patients assigned to each mutually exclusive diagnosis was proportional to diagnosis prevalence. Within each diagnostic class, we simulated a joint symptom distribution by randomly assigning the presence or absence of each symptom to every patient. The number of patients with a positive symptom within each diagnostic class was proportional to the conditional symptom probability for that symptom and diagnosis. We trained our distance metric learning (DML) and ensemble models on this simulated data.

Study Design

We analyzed consecutive ambulatory and hospitalized patients with COVID-19–compatible syndromes presenting to University of California San Diego Medical Center over 14 days in March and April 2020, with institutional review board approval (#200498). Patients were included if they had a recorded presenting illness including fever or cough, and at least a single NAAT in the electronic health record. Patients were labeled “positive” if they had one or more positive RT-PCR tests and a compatible syndrome or findings on radiographic imaging. Patients were labeled “negative” if they had 2 or more consecutive negative NAAT tests (>72 hours apart) or a single negative RT-PCR and a negative antibody test within 14-21 days of symptom onset. Chart review was performed manually by an infectious disease specialist with an anonymized and blinded data set presented for analysis (see Multimedia Appendix 1 for additional details).

Data Analysis

We calculated the sensitivity, specificity, and prevalence-adjusted accuracy as well as the prevalence-adjusted negative predictive value (NPV) and positive predictive value (PPV) of each model on the clinical test data using standard Wald-type CIs [29]. We estimated the 95% CIs for sensitivity and specificity using Clopper-Pearson exact binomial proportion CIs [29]. We estimated 95% CIs for accuracy using the normal approximation method [29]. For the imaging and laboratory tests, we computed likelihood ratios based on sensitivity and specificity; and prevalence-adjusted predictive values based on sensitivity, specificity, and an assumed national COVID-19 prevalence of 11.1%.

Results

Patient Characteristics

In total, 55 individuals and the presence or absence of 13 symptoms at initial presentation were included in our clinical test data set. Of this, 38 patients (69.1%) were confirmed SARS-CoV-2 infection positive by RT-PCR; 44 subjects were seen via inpatient services, and 11 were seen as outpatients. The majority of subjects (n=43, 78.2%) presented with fever, 63.6% (n=35) with shortness of breath or dyspnea, 54.5% (n=30) with nonproductive cough, 21.8% (n=12) with productive cough, 50.9% (n=28) with fatigue or exhaustion, 9.1% (n=5) with loss of smell, 7.3% (n=4) with sore throat or pharyngalgia, 18.2% (n=10) with body or muscle aches, 16.4% (n=9) with headaches, 16.4% (n=9) with diarrhea, 14.5% (n=8) with nausea, 5.5% (n=3) with vomiting, and 3.6% (n=2) with nasal congestion or rhinorrhea (Table 2; Multimedia Appendix 1, Table S2).

Table 2. Clinical test data set: patient characteristics.

Characteristic	Total, n (%)	SARS-CoV-2 test result	
		Positive, n (%)	Negative, n (%)
Patients	55 (100)	38 (69)	17 (31)

Classification Performance in the Clinical Test Data Set

Base models classified SARS-CoV-2 infection in the clinical test data set with sensitivities and specificities of 81.6% (95% CI 65.7 to 92.3) and 58.8% (95% CI 32.9 to 81.6) for the BN model; 0.0% (95% CI 0.0 to 9.3) and 100.0% (95% CI 80.5 to 100.0) for the SC model; 84.2% (95% CI 68.7 to 94.0) and 64.7% (95% CI 38.3 to 85.8) for the DML model; and 81.6% (95% CI 65.7 to 92.3) and 70.6% (95% CI 44.0 to 89.7) for the ensemble model. The overall accuracy of each of these models was 61.4% (95% CI 48.5 to 74.2) for the BN model; 88.9% (95% CI 80.6 to 97.2) for the SC model; 66.9% (95% CI 54.4 to 79.3) for the DML model; and 71.8% (95% CI 59.9 to 83.7) for the ensemble model. The prevalence-adjusted positive and negative predictive values for each model were 19.9% (95% CI 10.5 to 29.2) and 96.2% (95% CI 92.5 to 100.0) for the BN model; 0.0% and 88.9% for the SC model; 23.0% (95% CI 11.3 to 34.7) and 97.0% (95% CI 93.8 to 100.0) for the DML model; and 25.8% (95% CI 11.4 to 40.2) and 96.8% (95% CI 93.7 to 100.0) for the ensemble model (Table 3).

Table 3. Classification performance on the clinical test data set for the developed base and ensemble models compared to a logistic regression model reported in the literature.

Model	Sensitivity (95% CI) (%)	Specificity (95% CI) (%)	Accuracy[a] (95% CI) (%)	Predictive value[a] (%)	
				PPV[b] (95% CI)	NPV[c] (95% CI)
Bayesian inference network	81.6 (65.7-92.3)	58.8 (32.9-81.6)	61.4 (48.5-74.2)	19.9 (10.5-29.2)	96.2 (92.5-100.0)
Information-theoretic set cover	0.0 (0.0-9.3)	100.0 (80.5-100.0)	88.9 (80.6-97.2)	0.0	88.9
Distance metric learning	84.2 (68.7-94.0)	64.7 (38.3-85.8)	66.9 (54.4-79.3)	23.0 (11.3-34.7)	97.0 (93.8-100.0)
Multinomial logistic regression ensemble	81.6 (65.7-92.3)	70.6 (44.0-89.7)	71.8 (59.9-83.7)	25.8 (11.4-40.2)	96.8 (93.7-100.0)
Logistic regression (Menni et al [14])	15.8 (6.0-31.3)	100.0 (80.5-100.0)	90.6 (82.9-98.3)	100.0	90.5 (88.7-92.2)

[a] Prevalence-adjusted metrics assume a COVID-19 prevalence of 11.1%.

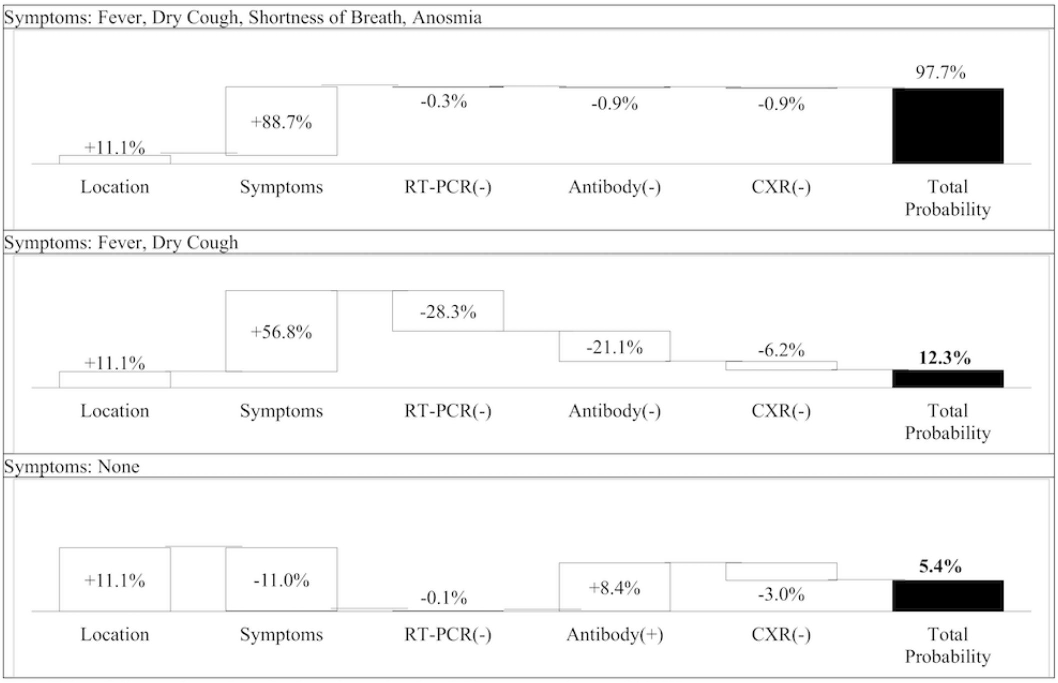
[b] PPV: positive predictive value.

[c] NPV: negative predictive value.

Incorporation of Location and Diagnostic Test Sequences

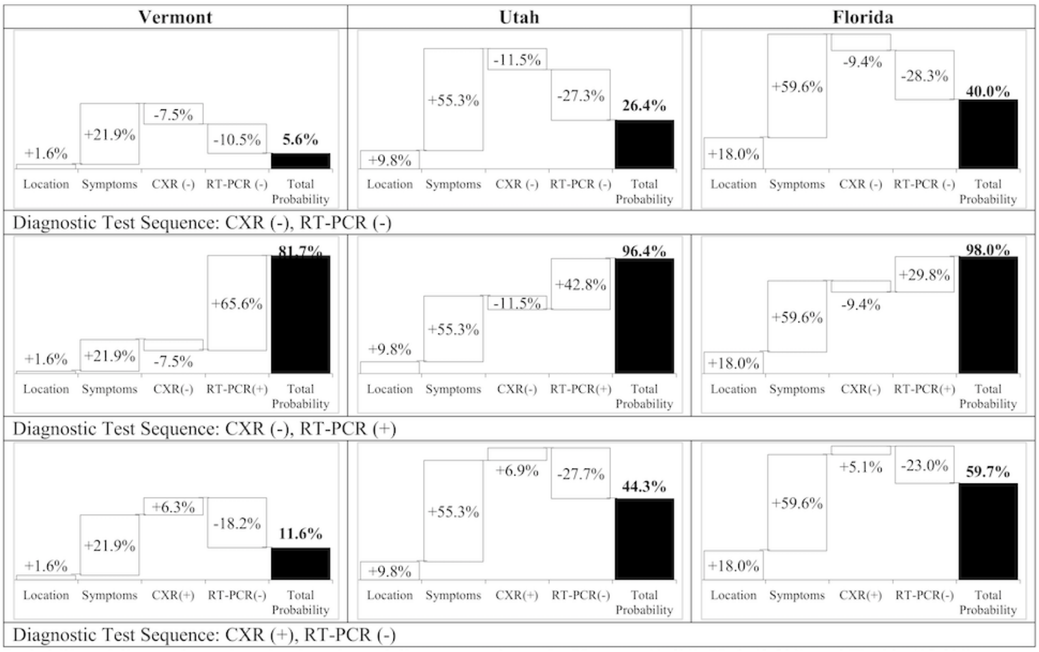
We then employed the BN model to evaluate 3 hypothetical patients with 3 different presentations: (1) fever, dry cough, shortness of breath, and anosmia; (2) fever and dry cough; and (3) asymptomatic. We assumed all of these patients presented for care in an area with a local disease prevalence equivalent to the national disease prevalence of 11.1%. For patient 1, we simulated a clinically plausible imaging and test result sequence of negative RT-PCR, negative antibody, and negative CXR. The probability of a COVID-19 diagnosis following symptom collection was 99.8%. Despite negative test results, residual risk due to local disease prevalence and symptoms remained at 97.7%. The change in diagnosis probability, or the reduction in diagnostic uncertainty, was only 2.1% following all 3 negative tests. For patient 2, we simulated the same negative test sequence. In this scenario, the combination of negative test results with nonspecific symptom information resulted in a decrease in residual risk to 12.3%. The reduction in diagnostic uncertainty due to test results was 55.6%, primarily due to negative RT-PCR and negative antibody test results. The negative CXR provided less information as the reduction in diagnostic uncertainty following negative RT-PCR and antibody tests was only 6.2%. For patient 3, we simulated an imaging and test result sequence of negative RT-PCR, positive antibody, and negative CXR. The negative RT-PCR test reduced disease probability by only 0.1%, and the positive antibody test increased the probability of a COVID-19 diagnosis by 8.4%. The CXR results reduced diagnostic uncertainty by 3.0% (Figure 1).

Figure 1. Probability of SARS-CoV-2 infection for common patient presentations and clinical test sequences. Probability of disease due to location is the estimated national disease prevalence of 11.1%. RT-PCR: reverse transcription-polymerase chain reaction; CXR: chest radiography.



To illustrate the dependence of risk assessment on local disease prevalence, we simulated a patient with symptoms of only fever and dry cough presenting in 3 locations with significantly different COVID-19 prevalence estimates: Vermont with an estimated statewide prevalence of 1.6%, Utah with an estimated statewide prevalence of 9.8%, and Florida with an estimated statewide prevalence of 18.0% at the time of the simulation. We combined results from 3 common test sequences with our BN pretest probabilities to compute location-dependent risk trajectories. The test sequences included: (1) negative CXR and negative RT-PCR; (2) negative CXR and positive RT-PCR; and (3) positive CXR and negative RT-PCR. Our results indicate that for a pauci-symptomatic patient presenting with identical symptoms in states with significantly different disease prevalence, the posttest probabilities of SARS-CoV-2 infection following common diagnostic test sequences demonstrate marked variation. Moreover, changes in diagnostic probability or reductions in diagnostic uncertainty are highly context and test dependent (Figure 2).

Figure 2. Impact of patient location and diagnostic test results on probability of SARS-CoV-2 infection. Prior probability of disease due to location is the estimated disease prevalence for Vermont (1.6%), Utah (9.8%), and Florida (18.0%). Incremental probability due to symptoms assumes the patient presents with only fever and dry cough. RT-PCR: reverse transcription-polymerase chain reaction; CXR: chest radiography.



Discussion

Principal Findings

Our results suggest simple computable models that quantify patient risk of SARS-CoV-2 infection based on key elements of the clinical case can reduce diagnostic uncertainty for providers attempting to rule in or rule out disease with limited or conflicting information.

Building on work by Chishti et al [16], we chose probabilistic models considering the scarcity of detailed, individual patient data and to take advantage of the depth of published literature on aggregate symptom probabilities. Clinicians are trained in evidence-based medicine, and Bayesian reasoning provides a natural framework to understand the impact of incremental information on diagnosis probabilities. Our approaches to making stepwise diagnostic assessments with incremental information mimic clinical workflows and reflect the need for transparency and accommodation of new information critical to clinical decision making. As in Menni et al [14], we chose clinical indicators that would be easily obtained by patients and providers as well as predictive models that are easily computed and transparent to all users. While other machine learning approaches, such as generative adversarial networks, transfer learning, n-shot learning, and prototypical networks, are also robust for limited data, these methods can be opaque and inaccessible to providers and may be inflexible and fragile in an evolving clinical context.

Our most simple model, the Bayesian inference network, is transparent, easily interpreted, and highly modifiable depending on the user’s prior beliefs about location-based prevalence, conditional symptom probabilities, and imaging and laboratory test accuracy. Clinicians, educated in evidence-based medicine and often familiar with Bayesian decision making in diagnostic testing, are ideal users of this model. By developing base models that do not require access to large amounts of patient-level data and can accommodate changes in local provider beliefs and new sources of information, we alert physicians to the utility of using Bayesian reasoning to not only combine multiple data streams in order to make more informed diagnostic decisions but also to guide decisions about use of imaging and testing that will most effectively reduce diagnostic uncertainty.

Limitations

Our study has limitations. First, we used simulated patient data based on prevalence and conditional symptom probabilities to train and validate our DML and ensemble models that biased the ensemble model to heavily weight the DML model predictions. Second, the number of patients in our clinical test data set was relatively small, and this data set was enriched for SARS-CoV-2–positive patients due to the cancellation of all elective procedures and the use of telemedicine for almost all patient visits during the study period, leaving clinics and hospitals open primarily for COVID-19 patients and the acutely ill. Third, 80% of the patients in our clinical test data set were from inpatient services, potentially biasing model accuracy by disease severity. Fourth, we chose as a reference standard the RT-PCR test results for SARS-CoV-2 infection despite outstanding questions about false negative rates in NAAT tests due to operator dependency and patient-level differences in viral loads across upper respiratory tract sites [4,27].

Conclusions

Overall, we found that the Bayesian inference network, the metric learning model, and ensemble models trained and validated on a simulated patient data set had sensitivities (81.6%-84.2%) and specificities (58.8%-70.6%) for discriminating between COVID-19 infection and other potential diagnoses in real clinical settings. These models had higher sensitivities than reported for most commonly used diagnostics, and model specificities were higher than those of both imaging modalities. For purposes of comparison, the logistic regression model proposed by Menni et al [14], when applied to our clinical test data set, had a sensitivity of 15.8% and a specificity of 100.0%. Finally, our BN model shows that information acquired by imaging and testing choices is highly dependent on location and symptoms, and emphasizes the utility of a quantitative framework to guide clinical decision making in rapidly changing local environments with potentially unreliable diagnostic tests.

Abstract

Background: During the COVID-19 pandemic, residential lockdowns were implemented in numerous cities in China to contain the rapid spread of the disease. Although these stringent regulations effectively slowed the spread of COVID-19, they may have posed challenges to the well-being of residents.

Objective: This study aims to explore the effects of residential lockdown on the subjective well-being (SWB) of individuals in China during the COVID-19 pandemic.

Methods: The sample consisted of 1790 Sina Weibo users who were residents of cities that imposed residential lockdowns, of which 1310 users (73.18%) were female, and 3580 users who were residents of cities that were not locked down (gender-matched with the 1790 lockdown residents). In both the lockdown and nonlockdown groups, we calculated SWB indicators during the 2 weeks before and after the enforcement date of the residential lockdown using individuals' original posts on Sina Weibo. SWB was calculated via online ecological recognition, which is based on established machine learning predictive models.

Results: The interactions of time (before the residential lockdown or after the residential lockdown) × area (lockdown or nonlockdown) in the integral analysis (N=5370) showed that after the residential lockdown, compared with the nonlockdown group, the lockdown group scored lower in some negative SWB indicators, including somatization ($F_{1,5368}$=13.593, P<.001) and paranoid ideation ($F_{1,5368}$=14.333, P<.001). The interactions of time (before the residential lockdown or after the residential lockdown) × area (developed or underdeveloped) in the comparison of residential lockdown areas with different levels of economic development (N=1790) indicated that the SWB of residents in underdeveloped areas showed no significant change after the residential lockdown (P>.05), while that of residents in developed areas changed.

Conclusions: These findings increase our understanding of the psychological impact and cost of residential lockdown during an epidemic. The more negative changes in the SWB of residents in developed areas imply a greater need for psychological intervention under residential lockdown in such areas.

KEYWORDS

COVID-19; residential lockdown; subjective well-being; online ecological recognition

Introduction

Since the outbreak of COVID-19, therapeutic options to treat the disease have been limited, although research to produce an effective and safe vaccine is quickly progressing. Varying degrees of travel limitations on citizens, such as residential lockdowns, were enforced across China to contain the epidemic. Residential lockdown is a type of home quarantine during which residents are not allowed to go out unnecessarily and each family can only appoint a relatively fixed family member to purchase living supplies every 2-3 days. These vigorous actions played a key role in containing the spread of COVID-19 [1,2]; however, they have also had some effects on residents' mental health, including their subjective well-being (SWB) [3,4]. In psychology, the concepts of well-being, mental health, and happiness are often used as synonyms [5]. The World Health Organization (WHO) defined mental health as a "state of well-being whereby individuals recognize their abilities, are able to cope with the normal stresses of life, work productively and fruitfully, and make a contribution to their communities" [6].

As a comprehensive psychological indicator, SWB describes an individual's subjective evaluation of their living quality and happiness [7]. It focuses on personal experience in a specific social context to reflect individuals' mental health [8-11]. As a social group experience [11], SWB has also become a surveying mark of government action, governance capability, and social development trends [12,13]. During the COVID-19 crisis, the loss or significant reduction of SWB may not only increase the incidence of panic disorder, anxiety, depression, and other mental health issues [14] but also cause a series of problems at the social level, such as social hindrance, unstable social environment, and decline of trust in the government [15]. To adequately and effectively prepare for the psychological impact and cost of residential lockdown (eg, targeted psychological crisis intervention), it is necessary to examine the mental health of residents from the SWB perspective.

At present, the assessment of positive SWB indicators mainly relies on self-report inventories such as the Psychological Well-Being (PWB) scale [16]. In addition, because mental health is the crucial element or is even considered to be a synonym of SWB [5,6], some psychiatric status rating scales are widely used to assess negative SWB indicators [17,18], such as the Symptom Checklist 90 (SCL-90), with good reliability and validity [19-21].

However, it is almost impossible to conduct a SWB survey measuring the immediate psychological impact of residential lockdown without delay, as it is difficult to anticipate whether and when a residential lockdown will start, and a questionnaire cannot be used for ecological momentary assessment [22,23]. On the other hand, retrospective measurement is also unsuitable for this aim because individuals' recall bias may result in inability to accurately trace back to the original baseline state [24]. Facing these challenges in conducting an accurate pre-post comparative analysis during unexpected residential lockdown, it is necessary to develop a new method to capture the SWB status of a large number of individuals in a timely fashion.

With the rise of interdisciplinary research, information technology and computing models are increasingly being used in the evaluation of psychological characteristics, and the popularity of web-based social media provides a new platform for such research. Information collected from these social media platforms can clarify the public's response and can be mapped to psychological indices [25]. For example, Kosinski et al [26] used digital records on Facebook to automatically and accurately predict users' personal attributes. Qiu et al [27] also showed that users' personalities manifested on web-based social media. In China, Sina Weibo is a leading social media platform; by March 2020, it comprised more than 550 million monthly active users. By using machine learning–trained predictive models, users' ecological behavior on Sina Weibo can be tracked to identify their psychological traits, such as their mental health status [28]. Based on web-based big data, these prediction models provided a rationale for our research. According to previous studies, online ecological recognition (OER) can be defined as the method of acquiring users' psychological characteristics by machine learning models based on ecological web-based social media data [29,30]. Therefore, in this study, to effectively examine the impact of the residential lockdown on SWB, we conducted OER on publicly available Sina Weibo data to identify users' SWB with high ecological validity on a large scale.

In the present study, we aimed to explore the impact of the residential lockdown on SWB of individuals during the COVID-19 pandemic. To examine individuals' SWB before and after the residential lockdown, we used data from posts by active Sina Weibo users to calculate SWB indicators through OER based on trained predictive models [5]. The main purpose of this study was to obtain empirical evidence to provide deep insight into the psychological impact and cost of the residential lockdown. This will in turn form the basis for a concrete plan to develop and implement targeted intervention policies to cope with the COVID-19 pandemic efficiently and effectively.

Methods

Sampling

We searched for the following keywords on Baidu (baidu.com): *residential lockdown* (居民出行管控) + *city* or *211 measure* (211举措; the abbreviation of the residential lockdown policy) + *city*. After locating the cities that had issued residential lockdowns from January 20 to February 20, 2020, we finally obtained 17 prefecture-level cities in which local governments implemented the same residential lockdown policy. Then, we identified the specific time period for the implementation of the residential lockdown from the announcement released by the local COVID-19 Prevention and Control Headquarters, and we took the enforcement date as the demarcation point of this study. The residential lockdown cities and the enforcement and ending dates of their residential lockdowns are shown in Table 1. Given that the lockdown enforcement durations of Ningbo, Taizhou, and Yiwu were all <2 weeks, we excluded these three residential lockdown cities from the subsequent analysis.

Table 1. Residential lockdown cities and their enforcement and ending dates (in 2020).

Residential lockdown city	Province	Enforcement date	Ending date
Bengbu	Anhui	February 3	March 22
Ezhou	Hubei	February 4	March 25
Fangchenggang	Guangxi Zhuang Autonomous Region	February 2	March 6
Fuyang	Anhui	February 5	March 9
Guigang	Guangxi Zhuang Autonomous Region	February 3	February 24
Huaibei	Anhui	February 3	March 20
Huanggang	Hubei	February 1	March 22
Huangshi	Hubei	February 17	March 23
Nanyang	Henan	February 4	March 11
Ningbo[a]	Zhejiang	February 4	February 10
Songyuan	Jilin	February 4	March 20
Taizhou[a]	Zhejiang	February 2	February 13
Wenzhou	Zhejiang	February 1	February 19
Wuhan	Hubei	February 11	April 8
Xiaogan	Hubei	February 14	March 14
Yiwu[a]	Zhejiang	February 4	February 12
Zhongshan	Guangdong	February 7	March 27

[a] Ningbo, Taizhou, and Yiwu were not included in subsequent analyses because the enforcement duration in these cities was less than 2 weeks.

Participants and Data Collection

The sample in this study was obtained from the original Sina Weibo data pool [30] containing more than 1.16 million active users. The retrieved data included users' account profiles and posts. Privacy was strictly protected during this process, referring to the ethical principles listed by Kosinski et al [31]. This study was approved by the Review Board of Institute of Psychology, Chinese Academy of Sciences (ethical code H15009).

From the data pool, we selected Sina Weibo users who met the following criteria: (1) Published at least one original Weibo post per day on average within 2 weeks before and after the corresponding enforcement date of the residential lockdown (see Table 2); (2) authentication type was no-institutional, such as individual user; (3) the geolocation of the user's account profile was in China, not "overseas" or "others."

Lockdown Group

We combined all the residential lockdown cities mentioned in Table 1 except Ningbo, Taizhou, and Yiwu as the lockdown group. Then, we downloaded each user's original posts during the 2 weeks before and after the enforcement date of the residential lockdown in their city of residence for analysis in this study.

Nonlockdown Group

We combined users who did not live in the abovementioned 17 residential lockdown cities as the entire nonlockdown sample group. Because cities under residential lockdown are a minority among all the cities in China, to increase the generalizability of the results and reduce sampling error, we built the nonlockdown group at twice the sample size of the lockdown group in each of the 14 residential lockdown cities by random sampling without replacement of users in the whole nonlockdown sample group. The male-female ratio of the nonlockdown group was same as that of the lockdown group. Finally, we downloaded each user's original posts during the 2 weeks before and after the enforcement date from the paired residential lockdown city for analysis in this study.

The final sample contained 5370 users, among whom the male-female ratio was 1:2.7 (see Table 2 for details).

Table 2. Numbers of users in each group in the final sample and corresponding time periods of data extraction (N=5370).

Residential lockdown city	Time period (in 2020)		Lockdown group	Nonlockdown group
	Before the residential lockdown	After the residential lockdown		
Bengbu	January 21 to February 3	February 4-17	25	50
Ezhou	January 21 to February 3	February 4-17	16	32
Fangchenggang	January 19 to February 1	February 2-15	18	36
Fuyang	January 22 to February 4	February 5-18	14	28
Guigang	January 20 to February 2	February 3-16	32	64
Huaibei	January 20 to February 2	February 3-16	25	50
Huanggang	January 18-31	February 1-14	28	56
Huangshi	February 3-16	February 17 to March 1	11	22
Nanyang	January 21 to February 3	February 4-17	42	84
Songyuan	January 21 to February 3	February 4-17	16	32
Wenzhou	January 19 to February 1	February 2-15	235	470
Wuhan	January 28 to February 10	February 11-24	1084	2168
Xiaogan	January 31 to February 13	February 14-27	10	20
Zhongshan	January 24 to February 6	February 7-20	234	468

Compartmentalization by Economic Development Level

SWB is influenced by various factors in the long term [32-35], and there is an inevitable connection between the level of economic development and SWB. Clark and Senik [36] reported that economic development was generally identified with growth in gross domestic product (GDP) per capita, which improved residents' welfare [37]. Therefore, differentiating the lockdown group by GDP per capita could clarify the impact of the residential lockdown under different economic development conditions.

We took the GDP per capita published by the Municipal Bureau of Statistics of each residential lockdown city in 2017 as the indicator of economic development level. Using between-groups linkage and taking the squared Euclidean distance as the measurement standard, we applied a hierarchical clustering analysis on the 14 residential lockdown cities included in our study. The dendrogram of the whole process of clustering indicated that when the 14 residential lockdown cities were divided into 2 categories, the distance between the categories was relatively large and the characteristics of each category were relatively prominent; therefore, the categories could be readily defined. We applied an additional hierarchical clustering analysis with a cluster number of 2 on the 14 residential lockdown cities. The results suggested that the first category included Wuhan, Ezhou, Zhongshan, and Fangchenggang, and the second category included the remaining 10 residential lockdown cities. Based on this result, in this study, we grouped Wuhan, Ezhou, Zhongshan, and Fangchenggang into developed areas with residential lockdowns and grouped the remaining 10 residential lockdown cities into underdeveloped areas with residential lockdowns. All analyses were performed using SPSS Statistics 26 (IBM Corporation).

Measurement of SWB and Procedure

We applied OER by employing established machine learning models [28,38] to calculate the SWB indicators of the users in the final sample before and after the corresponding enforcement date of the residential lockdown. First, we used the TextMind system [39], a Chinese language psychological analysis system, to extract psycholinguistic features from active Sina Weibo users' original posts. This system first segmented the users' original Weibo posts and extracted independent and linguistically labeled words [40]; then, it used the Simplified Chinese Language Inquiry and Word Count (SCLIWC) to determine the word frequency statistics [41].

Next, we used these extracted psycholinguistic features as the input of established machine learning models to calculate the SWB indicators. The SWB indicators in our research included both positive and negative indicators, which are depicted in Table 3. Because the SCL-90 is also widely used in the assessment of negative SWB indicators [17], we used factors of the SCL-90 as our negative SWB indicators.

Table 3. Positive and negative SWB indicators.

SWB[a] indicator	Definition
Positive[b]	
Self-acceptance	Possession of a positive attitude toward the self
Environmental mastery	Sense of mastery and competence in managing the environment
Positive relations	Warm, satisfying, trusting relationships with others
Purpose in life	Goals in life and a sense of directedness
Personal growth	Feeling of continued development
Autonomy	Self-determining and independent
Negative[c]	
Somatization	Distress arising from perceptions of bodily disfunction
Obsessive-compulsive	Thoughts, impulses, and actions that are experienced as unremitting and irresistible by the individual, but are of an ego-alien or unwanted nature
Interpersonal sensitivity	Feelings of personal inadequacy and inferiority, particularly in comparison to other persons
Depression	Withdrawal of life interest, lack of motivation, and loss of vital energy
Anxiety	Restlessness, nervousness, and tension
Hostility	Thoughts, feelings, or actions that are characteristics of the negative affect state of anger
Phobic anxiety	Persistent fear response to a specific person, place, object, or situation which is characterized as being irrational and disproportionate to the stimulus, and which leads to avoidance or escape behavior
Paranoid Ideation	Paranoid behavior fundamentally as a disordered mode of thinking
Psychoticism	Withdrawn, isolated, schizoid lifestyle, and first-rank symptoms of schizophrenia.

[a] SWB: subjective well-being.

[b] Source: Psychological Well-Being scale [42].

[c] Source: Symptom Checklist 90 [19].

We used Li, Hao, Bai, and Zhu's machine learning model [28] to calculate the positive SWB indicators. To establish this predictive model, 1785 active Sina Weibo users were invited to complete Scales of PWB on the internet [42] and were asked for approval to access their Weibo data. Then, we used multivariate adaptive regression splines and other algorithms to fit the relationship between the psycholinguistic features and self-report scores, and the evaluation was conducted by 10-fold cross-validation. To predict the negative SWB indicators, we used Hao et al's [38] machine-learning model to predict them. To establish this model, we used Weibo data of 448 active Sina Weibo users and their SCL-90 scores [19]. We used a linear regression algorithm to fit the relationship between the psycholinguistic features and self-report scores and conducted 10-fold cross-validation. For most SWB indicators, the Pearson correlation coefficient between the predicted and self-report scores achieved a moderate level (≥.30) [28,38]. For more details about the established SWB models, please see [28,38].

To explore the overall impact of the residential lockdown on SWB, we conducted 2 (times: before the residential lockdown, after the residential lockdown) × 2 (areas: lockdown, nonlockdown) repeated measures analysis of variance (RM ANOVA) on all our samples. In this analysis, time was the within-subject factor, while area was the between-subject factor. Moreover, to explore the impact of the residential lockdown on the SWB of residents at different economic development levels, we applied 2 (times: before the residential lockdown, after the residential lockdown) × 2 (areas: developed, underdeveloped) RM ANOVA on the residential lockdown cities. All these analyses were performed using SPSS 26.

Results

Demographics

Among the 5370 active Sina Weibo users, 1790 were in the lockdown group (1310 female, 73.18%) and 3580 were in the non-lockdown group (gender matched with the lockdown group). According to the birthdates the users registered in their account profiles (1160/5370, 21.60%), the users' ages ranged from 21 to 83 years, with a median age of 29.95 (SD 6.30) years. Table 4 features the demographic profiles of these users.

Table 4. Demographic characteristics of users in the lockdown group and nonlockdown group (N=5370), n (%).

Characteristic	Developed areas with residential lockdown (n=1352)	Underdeveloped areas with residential lockdown (n=438)	Lockdown group (n=1790)	Nonlockdown group (n=3580)
Gender				
Male	348 (25.74)	132 (30.14)	480 (26.82)	960 (26.82)
Female	1004 (74.26)	306 (69.86)	1310 (73.18)	2620 (73.18)
Age (years)				
18-30	198 (14.64)	57 (13.01)	255 (14.25)	464 (12.96)
31-40	92 (6.80)	36 (8.22)	128 (7.15)	249 (6.96)
≥41	11 (0.81)	7 (1.60)	18 (1.01)	46 (1.28)
Missing data	1051 (77.74)	338 (77.17)	1389 (77.60)	2821 (78.80)

All Residential Lockdown Cities

In this analysis, we compared the SWB scores of residents of different areas across the country during different periods. As shown in Table 5, there were significant (including marginally significant) interactions of area and time on 2 negative SWB indicators.

Table 5. Repeated measures analysis of variance on subjective well-being across China.

Indicator	Residential lockdown area, mean (SD)				Area		Time		Area × Time	
	Lockdown group (n=1790)		Nonlockdown group (n=3580)		$F_{1,5368}$	*P* value	$F_{1,5368}$	*P* value	$F_{1,5368}$	*P* value
	T-before[a]	T-after[b]	T-before	T-after						
Somatization	8.38 (2.94)	8.64 (3.04)	8.56 (3.25)	8.98 (3.30)	10.457	.001	56.414	<.001	3.430	.06
Paranoid Ideation	5.46 (1.46)	5.61 (1.45)	5.58 (1.85)	5.82 (2.11)	12.418	<.001	66.862	<.001	3.405	.07

[a] T-before: the period before the residential lockdown.

[b] T-after: the period after the residential lockdown.

Somatization

The main effect of the area was significant ($F_{1,5368}$=10.457, P=.001, η_p^2=0.002). The main effect of time was significant ($F_{1,5368}$=56.414, P<.001, η_p^2=0.010. The interaction of area and time was marginally significant ($F_{1,5368}$=3.430, P=.06, η_p^2=0.001. After simple effect analysis, our findings were as follows:

Area: In the T-before period, there was no significant difference between the lockdown group and the nonlockdown group; in the T-after period, the somatization of residents in the lockdown group was significantly lower than that of residents in the non-lockdown group ($F_{1,5368}$=13.593, P<.001, η_p^2=0.003).

Time: After the implementation of the residential lockdown, somatization of the residents in both groups increased significantly (lockdown group: $F_{1,5368}$=12.009, P=.001, η_p^2=0.002; nonlockdown group: $F_{1,5368}$=65.748, P<.001, η_p^2=0.012).

Paranoid Ideation

The main effect of area was significant ($F_{1,5368}$=12.418, P<.001, η_p^2=0.002). The main effect of time was significant ($F_{1,5368}$=66.862, P<.001, η_p^2=0.012). The interaction of area and time was marginally significant ($F_{1,5368}$=3.405, P=.07, η_p^2=0.001). After simple effect analysis, our findings were as follows:

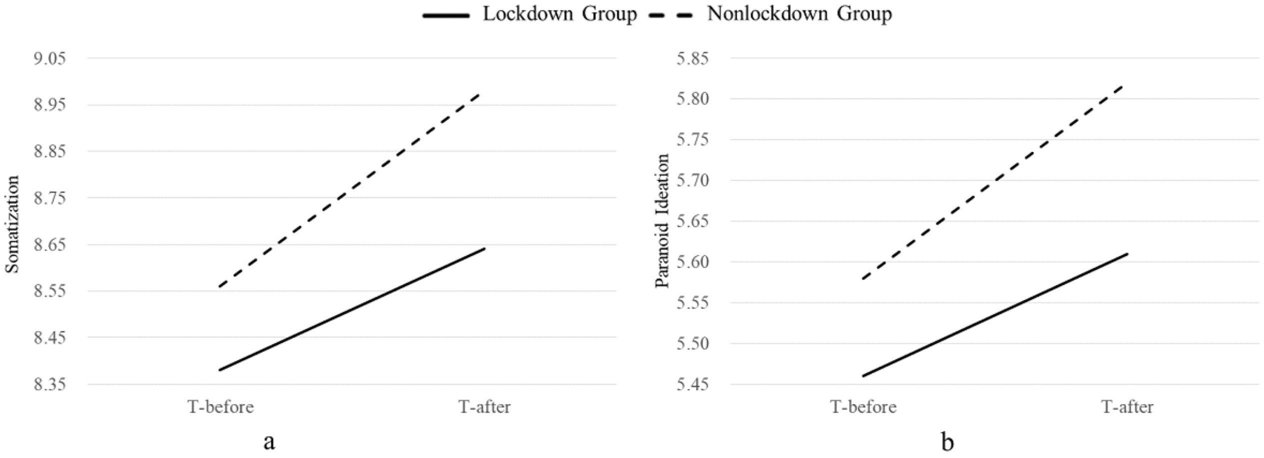
Area: In both periods, the paranoid ideation of residents in the lockdown group was significantly lower than that of residents in the nonlockdown group (T-before: $F_{1,5368}$=6.008, P=.01, η_p^2=0.001; T-after: $F_{1,5368}$=14.333, P<.001, η_p^2=0.003).

Time: After the implementation of the residential lockdown, the paranoid ideation of residents in both groups increased significantly (lockdown group: $F_{1,5368}$=15.033, P<.001, η_p^2=0.003; non-lockdown group: $F_{1,5368}$=75.334, P<.001, η_p^2=0.014).

However, for self-acceptance, environmental mastery, positive relations, purpose in life, personal growth, autonomy, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, and psychoticism, the interactions of area and time were not significant (all *P* values >.10).

The interactions of somatization and paranoid ideation are presented in Figure 1.

Figure 1. Interactions of area and time on (a) somatization and (b) paranoid ideation across China. T-after: the period after the residential lockdown; T-before: the period before the residential lockdown.



Residential Lockdown Areas at Different Economic Development Levels

According to the clustering analysis above, we grouped Wuhan, Ezhou, Zhongshan, and Fangchenggang into developed areas with residential lockdowns, and we grouped the remaining 10 residential lockdown cities into underdeveloped areas with residential lockdowns. To further explore the different effects of residential lockdown on the SWB of residents of areas with different economic development, we compared the SWB scores of residents of developed areas and underdeveloped areas during the different periods.

As shown in Table 6, there were significant (including marginally significant) interactions of area and time on 2 positive SWB indicators and 5 negative SWB indicators.

Table 6. Repeated measures analysis of variance on subjective well-being in the residential lockdown areas.

Indicator	Residential lockdown area, mean (SD)				Area		Time		Area × Time

[a] T-before: the period before the residential lockdown.

[b] T-after: the period after the residential lockdown.

Purpose in Life

The main effect of area was significant ($F_{1,1788}$=5.548, P=.02, η_p^2=0.003). The main effect of time was not significant ($F_{1,1788}$=0.698, P=.40, η_p^2=0.000). The interaction of area and time was significant ($F_{1,1788}$=5.057, P=.03, η_p^2=0.003). After simple effect analysis, our findings were as follows:

Area: In the T-before period, the purpose in life of residents of developed areas with residential lockdowns was significantly higher than that of residents of underdeveloped areas with residential lockdowns ($F_{1,1788}$=11.363, P=.001, η_p^2=0.006); in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of the residential lockdown, there were no significant changes in either developed or underdeveloped areas with residential lockdowns.

Autonomy

The main effect of area was significant ($F_{1,1788}$=8.351, P=.004, η_p^2=0.005). The main effect of time was not significant ($F_{1,1788}$=.099, P=.75, η_p^2=0.000). The interaction of area and time was significant ($F_{1,1788}$=4.984, P=.03, η_p^2=0.003). After simple effect analysis, our findings were as follows:

Area: In the T-before period, the autonomy of residents of developed areas with residential lockdowns was significantly higher than that of residents of under-developed areas with residential lockdowns ($F_{1,1788}$=12.229, P<.001, η_p^2=0.007; in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdown.

Time: After the implementation of residential lockdown, there were no significant changes in either developed or underdeveloped areas with residential lockdowns.

Interpersonal Sensitivity

The main effect of area was significant ($F_{1,1788}$=4.342, P=.04, η_p^2=0.002). The main effect of time was not significant ($F_{1,1788}$=0.248, P=.62, η_p^2=0.000). The interaction of area and time was significant ($F_{1,1788}$= 9.850, P=.002, η_p^2=0.005). After simple effect analysis, our findings were as follows:

Area: In the T-before period, the interpersonal sensitivity of residents of developed areas with residential lockdowns was significantly lower than that of residents of underdeveloped areas with residential lockdowns ($F_{1,1788}$=10.643, P=.001, η_p^2=0.006); in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of residential lockdown, the interpersonal sensitivity of residents in developed areas with residential lockdowns increased significantly ($F_{1,1788}$=13.514, P<.001, η_p^2=0.008); meanwhile, there was no significant change in underdeveloped areas with residential lockdowns.

Anxiety

The main effect of area was not significant ($F_{1,1788}$=1.880, P=.17, η_p^2=0.001). The main effect of time was significant ($F_{1,1788}$=9.527, P=.002, η_p^2=0.005). The interaction of area and time was significant ($F_{1,1788}$=7.273, P=.007, η_p^2=0.004). After simple effect analysis, our findings were as follows:

Area: In the T-before period, the anxiety of residents of developed areas with residential lockdowns was significantly lower than that of residents of underdeveloped areas with residential lockdowns ($F_{1,1788}$=5.923, P=.02, η_p^2=0.003); in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of residential lockdown, the anxiety of residents of developed areas with residential lockdowns increased significantly ($F_{1,1788}$=34.173, P<.001, η_p^2=.019); meanwhile, there was no significant change in underdeveloped areas with residential lockdowns.

Hostility

The main effect of area was marginally significant ($F_{1,1788}$=3.382, P=.07, η_p^2=0.002). The main effect of time was not significant ($F_{1,1788}$=0.466, P=.50, η_p^2=0.000). The interaction of area and time was significant ($F_{1,1788}$=5.202, P=.02, η_p^2=0.003). After simple effect analysis, our findings were as follows:

Area: In the T-before period, the hostility of residents of developed areas with residential lockdowns was significantly lower than that of residents of underdeveloped areas with residential lockdowns ($F_{1,1788}$=7.487, P=.006, η_p^2=0.004); in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of residential lockdown, the hostility of residents of developed areas with residential lockdowns increased significantly ($F_{1,1788}$=8.974, P=.003, η_p^2=0.005); meanwhile, there was no significant change in underdeveloped areas with residential lockdowns.

Paranoid Ideation

The main effect of area was not significant ($F_{1,1788}$=1.155, P=.28, η_p^2=0.001). The main effect of time was significant ($F_{1,1788}$=7.822, P=.005, η_p^2=0.004). The interaction of area and time was marginally significant ($F_{1,1788}$=3.083, P=.08, η_p^2=0.002). After simple effect analysis, our findings were as follows:

Area: In both periods, there were no significant differences between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of residential lockdown, the paranoid ideation of residents of developed areas with residential lockdowns increased significantly ($F_{1,1788}$=21.177, P<.001, η_p^2=0.012); meanwhile, there was no significant change in underdeveloped areas with residential lockdowns.

Psychoticism

The main effect of area was significant ($F_{1,1788}$=4.251, P=.04, η_p^2=.002). The main effect of time was not significant ($F_{1,1788}$=1.074, P=.30, η_p^2=0.001). The interaction of area and time was marginally significant ($F_{1,1788}$=3.584, P=.06, η_p^2=0.002). After simple effect analysis, our findings were as follows:

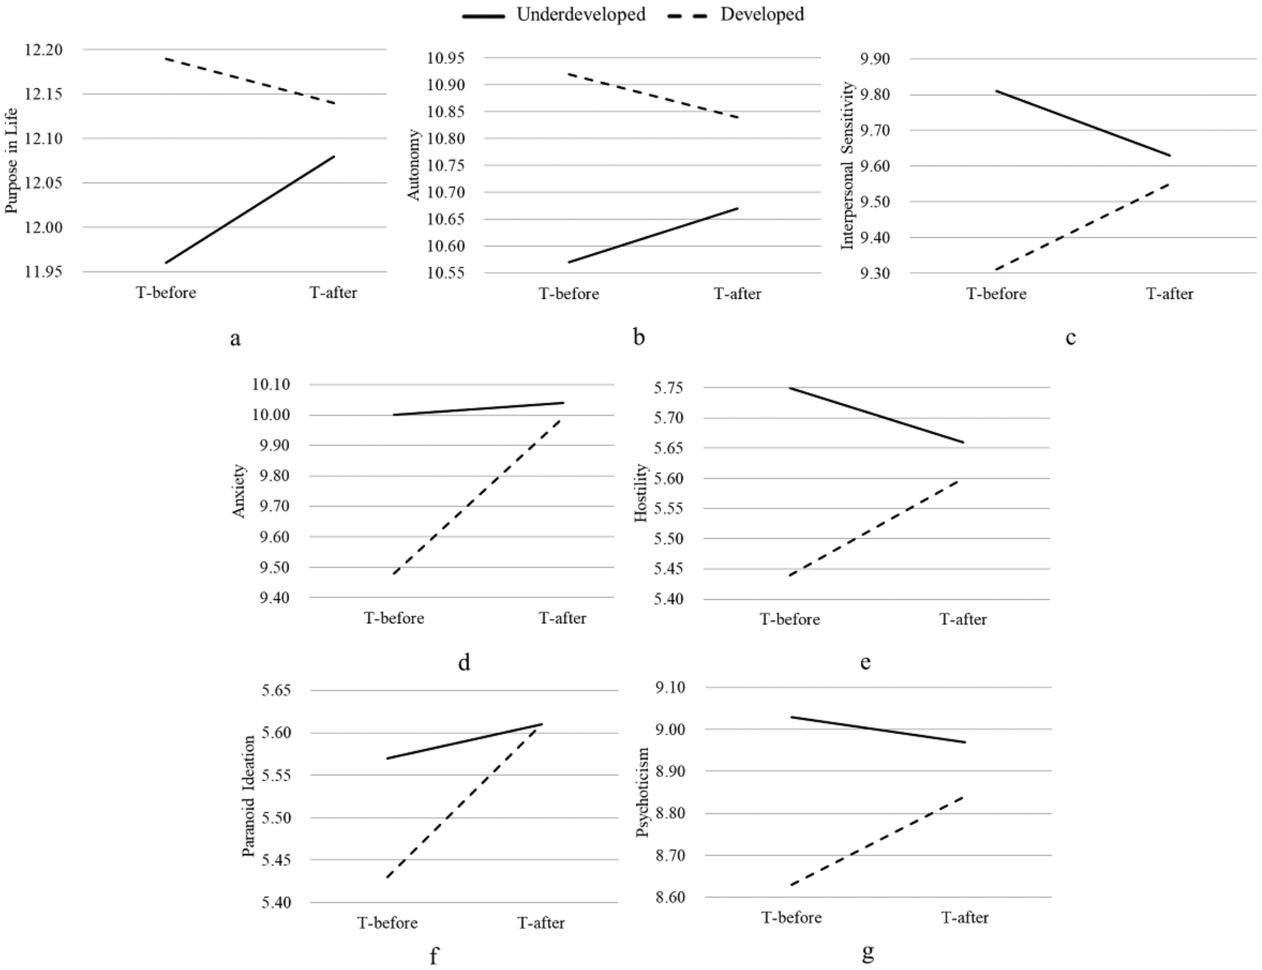
Area: In the T-before period, the psychoticism of residents of developed areas with residential lockdowns was significantly lower than that of residents of underdeveloped areas with residential lockdowns ($F_{1,1788}$=7.822, P=.005, η_p^2=0.004); in the T-after period, there was no significant difference between developed and underdeveloped areas with residential lockdowns.

Time: After the implementation of residential lockdown, the psychoticism of residents of developed areas with residential lockdowns increased significantly ($F_{1,1788}$=8.768, P=.003, η_p^2=0.005); meanwhile, there was no significant change in underdeveloped areas with residential lockdowns.

However, for self-acceptance, environmental mastery, positive relations, personal growth, somatization, obsessive-compulsive, depression, and phobic anxiety, the interactions of area and time were not significant (all *P* values >.10).

The interactions of purpose in life, autonomy, interpersonal sensitivity, anxiety, hostility, paranoid ideation, and psychoticism are presented in Figure 2.

Figure 2. Interactions of area and time on (a) purpose in life, (b) autonomy, (c) interpersonal sensitivity, (d) anxiety, (e) hostility, (f) paranoid ideation, and (g) psychoticism in the residential lockdown areas. T-after: the period after the residential lockdown; T-before: the period before the residential lockdown.



Discussion

Principal Findings

This study aimed to investigate the impact of the residential lockdown on SWB. We obtained the SWB indices of residents inside and outside cities with residential lockdown before and after the enforcement of the residential lockdown policy through OER. In addition, by introducing economic factors, we also made a transverse comparison of SWB in residential lockdown cities divided by economic development level. The results of the RM ANOVAs revealed that the lockdown group scored lower on negative SWB indicators than the nonlockdown group. Moreover, the SWB of residents in underdeveloped areas remained relatively stable after the implementation of the residential lockdown. On the whole, the strict regulations of the residential lockdown and the limitation on residents' travel did have an impact on SWB; however, this impact was positive, and the degree of positivity was greater in underdeveloped areas.

By comparing the residential lockdown cities with corresponding cities without residential lockdowns all over China, the main effect of time from RM ANOVA indicated that as time progressed, the overall SWB of the residents was adversely affected to some degree by the epidemic. This impact was mainly manifested by a general decrease in the scores of positive SWB indicators and an increase in the scores of negative SWB indicators. These results are consistent with previous studies: COVID-19 has caused public pressure and panic owing to the high degree of uncertainty and infectivity of the disease, which has had a deleterious effect on people's mental health [4,14].

However, it is worth mentioning that the simple effect of the interaction in the integral analysis indicated that the implementation of the residential lockdown had a positive influence on the control of residents' negative mental states. Specifically, compared with the nonlockdown group, residents in the lockdown group scored lower on negative SWB indicators. This finding also suggests that stringent residential lockdowns during a pandemic will not only ensure residents' health and life but will also effectively control the prevailing negative mental states of residents. Our findings are in keeping with those of Suryawanshi and More [43], who reported that the positive impact of the lockdown was far greater than the negative impact. Two factors may explain the above results. First, because the residential lockdowns were implemented only after the outbreak of COVID-19, people had a full understanding of the epidemic and were aware that only residential lockdown could effectively stop the spread of the virus by cutting off the transmission route. Therefore, on balance, because the powerful residential lockdown slowed the spread of the virus and curbed the rapid deterioration of the epidemic, it provided greater psychological comfort to the residents compared with the discomfort caused by restriction of personal freedom [43]. Second, the residential lockdown offered family members an opportunity to reevaluate and improve their family relations [43], which could effectively relieve their state of mind.

Furthermore, we used GDP per capita as an indicator of economic development level to classify the cities under residential lockdown. After performing RM ANOVA, we found that the positive impact of the residential lockdown was different in areas with different economic development levels. The SWB of residents in underdeveloped areas with residential lockdown (eg, Huanggang, Huangshi) was found to be relatively stable over time. In contrast, the results showed that during the lockdown in developed areas (eg, Wuhan, Zhongshan), the SWB of the residents generally changed significantly for the worse, although two SWB indicators did not show significant changes (ie, purpose in life and autonomy). The difference in the stability of residents' mental states between the residential lockdown areas at high and low economic development levels can mainly be explained by the following reasons.

Urban and Rural Population Ratio

Economists generally believe that regional economic growth is related to population structure (eg, urban and rural population ratio), among which GDP per capita is positively associated with urban population size [44]. In the residential lockdown areas with higher economic development, the urban population size is larger, and the problems produced by the residential lockdown (eg, unemployment) had a strong impact on urban commuters, which posed great risks to local residents' SWB.

Communication and Transportation

The statistical yearbooks of the residential lockdown cities reported that in the more economically developed areas, key indicators (eg, passenger traffic, number of civil vehicles) would score higher. For example, in 2017, the passenger traffic of Wuhan was 299.5 million, and the number of civil vehicles was 2.75 million [45]. These figures show that residents of more economically developed areas may have had greater transport demand and therefore were more affected by stringent residential lockdown due to the restrictions on their travel.

Floating Population

Economic development is the decisive factor in the formation of population flow. The population usually flows to developed areas with better economic development [46]. During the residential lockdown, the original pattern of life was disrupted, face-to-face association outside home was cut off, and residents mainly obtained social support from family members [47]. However, most members of the floating population make their living without the company of family. Hence, in more economically developed areas, the size of the floating population without family is larger, and the psychological impact of the residential lockdown on residents was more significant.

With the fast rise in the number of confirmed cases, COVID-19 has become a global pandemic. The decision of whether to enforce residential lockdowns is a difficult challenge faced by governments worldwide. The above results indicate that residential lockdowns not only have important medical value in protecting public health and life safety but may also have psychological value in maintaining SWB in China. Furthermore, in developed areas, the urban and floating populations are larger, and the relationship between transportation and life is more important; thus, the SWB of local residents is more likely to be affected by the residential lockdown and fluctuate greatly. These findings provide new references for local governments of areas at different economic development levels to consider the benefit and cost of residential lockdown and to prepare for the possible risks. For example, local governments in developed areas should make more preparations for psychological interventions and associated costs during and following residential lockdown.

To date, Britain, America, and many other countries have adopted lockdowns that are similar to those in China to some extent. Despite cultural differences, the effectiveness of residential lockdown in stopping disease spread is obvious [48]. However, the positive and negative psychological effects of the lockdown are complicated. These effects will also be influenced by the enforcement time, the effects of lockdown, and other factors mentioned above. In addition, in view of the fact that the level of economic development is a common indicator, different regions of the world will also have differences in urban and rural population ratios, floating population, communication and transportation, etc, which may influence the psychological effects caused by residential lockdown. Our findings with regard to the overall effect of the residential lockdown on SWB and the differences in the impact on mental states under different economic development conditions are instructive to analogous policies around the world.

Limitations

Although this study reveals changes in SWB caused by residential lockdown, there are some limitations to be highlighted. First, considering that most of the respondents in our sample are female, there may be some bias in the results. Second, more than 70% of our sample did not provide age information on the internet, which prevented us from evaluating the possible influence of age. In future studies, obtaining more age information and expanding the ranges of age and gender could be helpful. Third, in this study, transverse comparison of SWB in cities divided by economic development level only targeted residential lockdown areas; therefore, in future studies, this comparison can be extended to areas without residential lockdowns. Fourth, in light of the fact that not only economic factors but other factors such as social environment and cultural background may affect SWB, future studies could consider more factors to obtain a more comprehensive understanding of the lockdown effect. Additionally, it should be noted that the patterns we observed may be largely determined by the Chinese culture, and any application of our conclusions to a different culture should be made very carefully.

Conclusion

In this study, to explore the impact of residential lockdown during the COVID-19 pandemic on individual SWB in China, we predicted residents' SWB by OER and compared the SWB of residents of different areas with different economic development levels. The results demonstrated that in China and in the context of the COVID-19 pandemic, the residential lockdown alleviated the negative psychological changes caused by the epidemic to a certain extent. In addition, compared with developed areas, the psychological benefit of the residential lockdown was more obvious in underdeveloped areas. This study sheds light on the psychological effects of strict residential lockdown during pandemics and provides new clues for epidemic prevention in areas with different socioeconomic situations.

Abstract

Background: The COVID-19 crisis and consequent confinement restrictions have caused significant psychosocial stress and reports of sleep complaints, which require early management, have increased during recent months. To help individuals concerned about their sleep, we developed a smartphone-based app called KANOPEE that allows users to interact with a virtual agent dedicated to autonomous screening and delivering digital behavioral interventions.

Objective: Our objective was to assess the feasibility of this app, in terms of inclusion rate, follow-up rate, perceived trust and acceptance of the virtual agent, and effects of the intervention program, in the context of COVID-19 confinement in France.

Methods: The virtual agent is an artificial intelligence program using decision tree architecture and interacting through natural body motion and natural voice. A total of 2069 users aged 18 years and above downloaded the free app during the study period (April 22 to May 5, 2020). These users first completed a screening interview based on the Insomnia Severity Index (ISI) conducted by the virtual agent. If the users were positive for insomnia complaints (ISI score >14), they were eligible to join the 2-stage intervention program: (1) complete an electronic sleep diary for 1 week and (2) follow personalized sleep recommendations for 10 days. We collected and analyzed the following measures: sociodemographic information, ISI scores and sleep/wake schedules, and acceptance and trust of the agent.

Results: Approximately 76% (1574/2069) of the app users completed the screening interview with the virtual agent. The virtual agent was well accepted by 27.4% (431/1574) of the users who answered the acceptance and trust questionnaires on its usability, satisfaction, benevolence, and credibility. Of the 773 screened users who reported sleep complaints (ISI score >14), 166 (21.5%) followed Step 1 of the intervention, and only 47 of those (28.3%) followed Step 2. Users who completed Step 1 found that their insomnia complaints (baseline mean ISI score 18.56, mean ISI score after Step 1 15.99; $P<.001$) and nocturnal sleep quality improved significantly after 1 week. Users who completed Step 2 also showed an improvement compared to the initial measures (baseline mean ISI score 18.87, mean ISI score after Step 2 14.68; $P<.001$). Users that were most severely affected (ISI score >21) did not respond to either intervention.

Conclusions: These preliminary results suggest that the KANOPEE app is a promising solution to screen populations for sleep complaints and that it provides acceptable and practical behavioral advice for individuals reporting moderately severe insomnia.

Introduction

The current COVID-19 crisis has led to massive public health interventions, resulting in the confinement of almost the entire human population worldwide [1]. However, recent studies suggest that confinement may induce several negative psychological effects, including post-traumatic stress symptoms, anxiety, depression, anger, and insomnia [2,3]. Notably, Voitsidis et al [4] showed that in a study comprising 2363 Greek subjects, almost 38% of them reported insomnia complaints during the confinement due to COVID-19, and these complaints were associated with a higher rate of depression. The use of tobacco and alcohol in association with depression and stress symptoms has also increased during the COVID-19 pandemic [5].

These findings confirm that the COVID-19 crisis has caused major psychosocial stress and that prolonged confinement is potentially an aggravating factor for sleep complaints and insomnia. Therefore, given the large number of individuals affected and the limited number of health care professionals available during the crisis, there is a need for innovative solutions to track and help individuals at risk of psychosocial stress.

Digital technologies play a significant role in the context of the ongoing pandemic and overwhelmed health care services. As suggested by many researchers [6,7] and governmental authorities [1], technologies such as social media, smartphone apps, telehealth, and big data have great potential to disseminate information as well as screen and remotely monitor the general population, including patients with COVID-19. Several apps have been deployed in recent times to assist with COVID-19 management (eg, STOP COVID in France [8]). However, only a few apps and technologies specifically address psychosocial stress induced by the COVID-19 crisis and confinement [9-11]. To our knowledge, no study has focused on insomnia complaints, despite the evidence that digital behavioral therapies are effective to treat insomnia [12-14].

Soon after confinement measures were effective in France on March 17, 2020, we launched the first social media campaign in affiliation with our hospital and university through major national radios and newspapers. This campaign focused on the risk of insomnia and the measures to evaluate and correct inappropriate sleep hygiene practices among people during the COVID-19 confinement. In addition to social media campaigns, we developed a free smartphone app to help individuals with sleep concerns in the context of the COVID-19 pandemic. Named KANOPEE, the program is based on our previous research on embodied conversational agents (ECAs), also called virtual agents, which may be defined as animated characters that can engage in face-to-face dialogue through verbal and nonverbal behaviors. We previously demonstrated that ECAs can deliver a clinical interview to diagnose not only sleep complaints but also addiction and depression in an autonomous, reliable, valid, and acceptable way [15-19], by fostering empathy and facilitating disclosure of negatively connoted topics. In addition, based on the existing tools and knowledge on digital therapies for insomnia [14], we developed a digital sleep diary to automatically quantify the user's daily sleep patterns and sleep duration, and to establish personalized sleep interventions guided by the data collected through the app.

We hypothesized that a virtual agent made available via a smartphone app would be efficient and acceptable not only in providing autonomous screening for insomnia complaints but also in establishing digital behavioral interventions to help the population during the COVID-19 crisis. Therefore, to test our hypothesis, we launched a proof-of-concept study during the COVID-19 confinement.

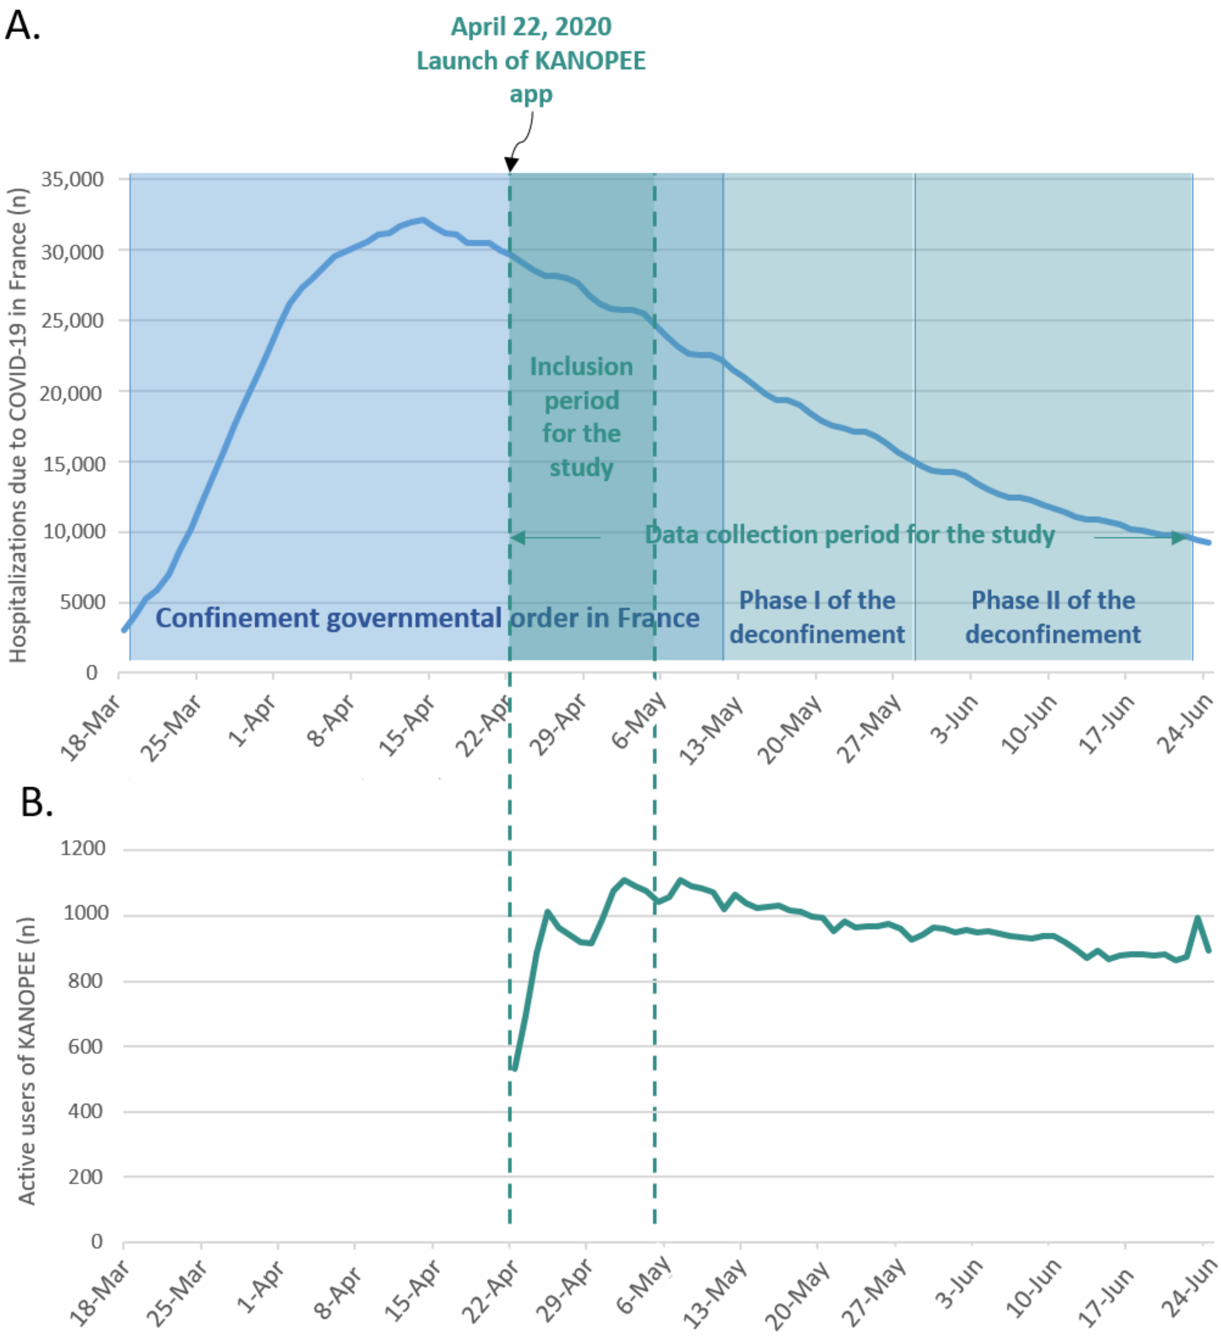
Methods

Description and Implementation of KANOPEE

KANOPEE was implemented using the same architecture as our previous ECAs [15-19], with C# programming language in Unity 3D software (Unity Technologies). The virtual agent, named Louise, interacts through natural voice and body motion, as recorded by a professional artist by using motion capture technologies (Optitrack suit for 3D animations of Louise's body and GoPro for 3D animations of Louise's face and her voice). The interaction scenario is predefined, using decision trees to adapt to the user's answers.

The app was made freely available on Google Play Store on April 22, 2020 (see Figure 1). After its launch, we organized a second media campaign presenting KANOPEE and showing how the app could help the French population to self-evaluate their sleep quality and provide practical solutions to manage insomnia. We analyzed the number of active app users across the confinement and deconfinement stages in France as well as hospitalizations due to COVID-19 during this time (Figure 1, [20])

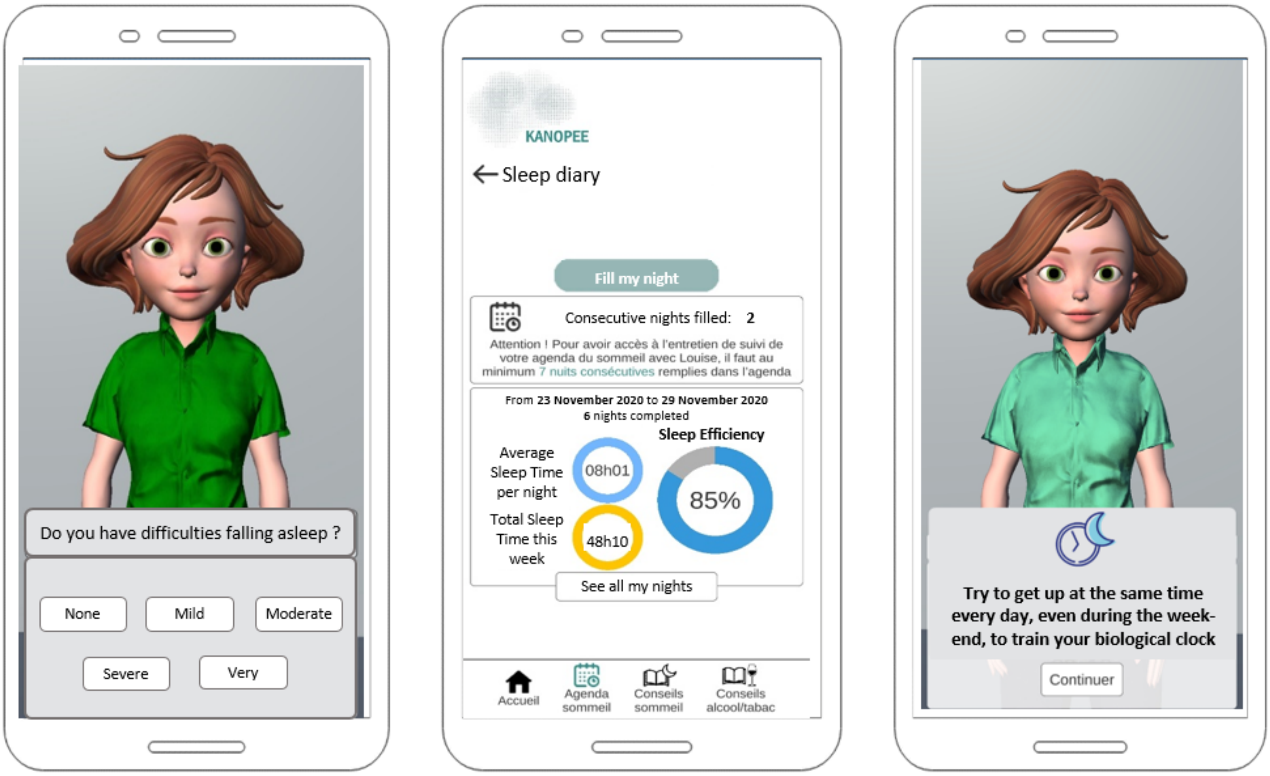
Figure 1. Conception and use of KANOPEE app. Chronological evolution of (A) the number of hospitalizations due to COVID-19 in France [20] and (B) the number of active users after the launch of the app across the confinement and deconfinement stages in France (based on data sourced from the Statistics page of the Google Play Store developer console for the app).



User Interaction

The interaction scenario comprises of the following steps: first, during the screening interview (Interview 1), Louise introduces herself and administers the Insomnia Severity Index (ISI) [21] (see Figure 2, leftmost screen capture). Then, depending on the score, users are either provided with simple sleep hygiene recommendations (eg, follow usual wake up time, get exposed to sunlight in the morning, sleep in a quiet and dark room) if ISI score ≤14, or they are considered eligible to enter the intervention program if ISI score >14 [22]. Initially, users enter the "first step" of the intervention program, wherein they receive instructions to complete a sleep diary for 1 week in order to have a better understanding of their sleep patterns and to collect data about sleep indicators. Every morning, after filling in their sleep schedule, these users receive visual feedback on their sleep (eg, time spent in bed, total sleep time, and sleep efficiency; see Figure 2, middle screen capture). After completing the sleep diary for 7 days, they receive a follow-up interview request with Louise (Interview 2) wherein they learn about their sleep indicators from the previous week. At this point, they receive an ISI score for the second time. Next, the users can enter the "second step," during which they are provided with personalized sleep recommendations for 10 days based on the sleep diary data and their answers on the ISI (see Figure 2, rightmost screen capture). Details of the conditions for providing personalized recommendations are listed in Textbox S1 (Multimedia Appendix 1). Thereafter, they can access another follow-up interview (Interview 3) and take the ISI a third time. Depending on the third ISI score, users can continue to use the app autonomously or, if their sleep complaints persisted (ie, ISI score >21), be referred to a sleep specialist in our hospital.

Figure 2. Illustrative references of KANOPEE app interfaces. From left to right, screenshot of (1) virtual agent Louise conducting an interview based on the Insomnia Severity Index, (2) sleep diary and visual feedbacks regarding user's sleep patterns, and (3) a personalized sleep recommendation given by Louise during Interview 3.



Do you have difficulties falling asleep ?

Consecutive nights filled: 2

Attention ! Pour avoir accès à l'entretien de suivi de votre agenda du sommeil avec Louise, il faut au minimum 7 nuits consécutives remplies dans l'agenda

From 23 November 2020 to 29 November 2020
6 nights completed

Average Sleep Time per night: 08h01

Total Sleep Time this week: 48h10

Sleep Efficiency: 85%

Try to get up at the same time every day, even during the week-end, to train your biological clock

Throughout the process, all procedures and tools (ie, questionnaires and sleep diary) are introduced by the virtual agent in order to facilitate understanding among the users and increase their engagement. A demo video of the user interaction by Louise has been hosted on YouTube [23].

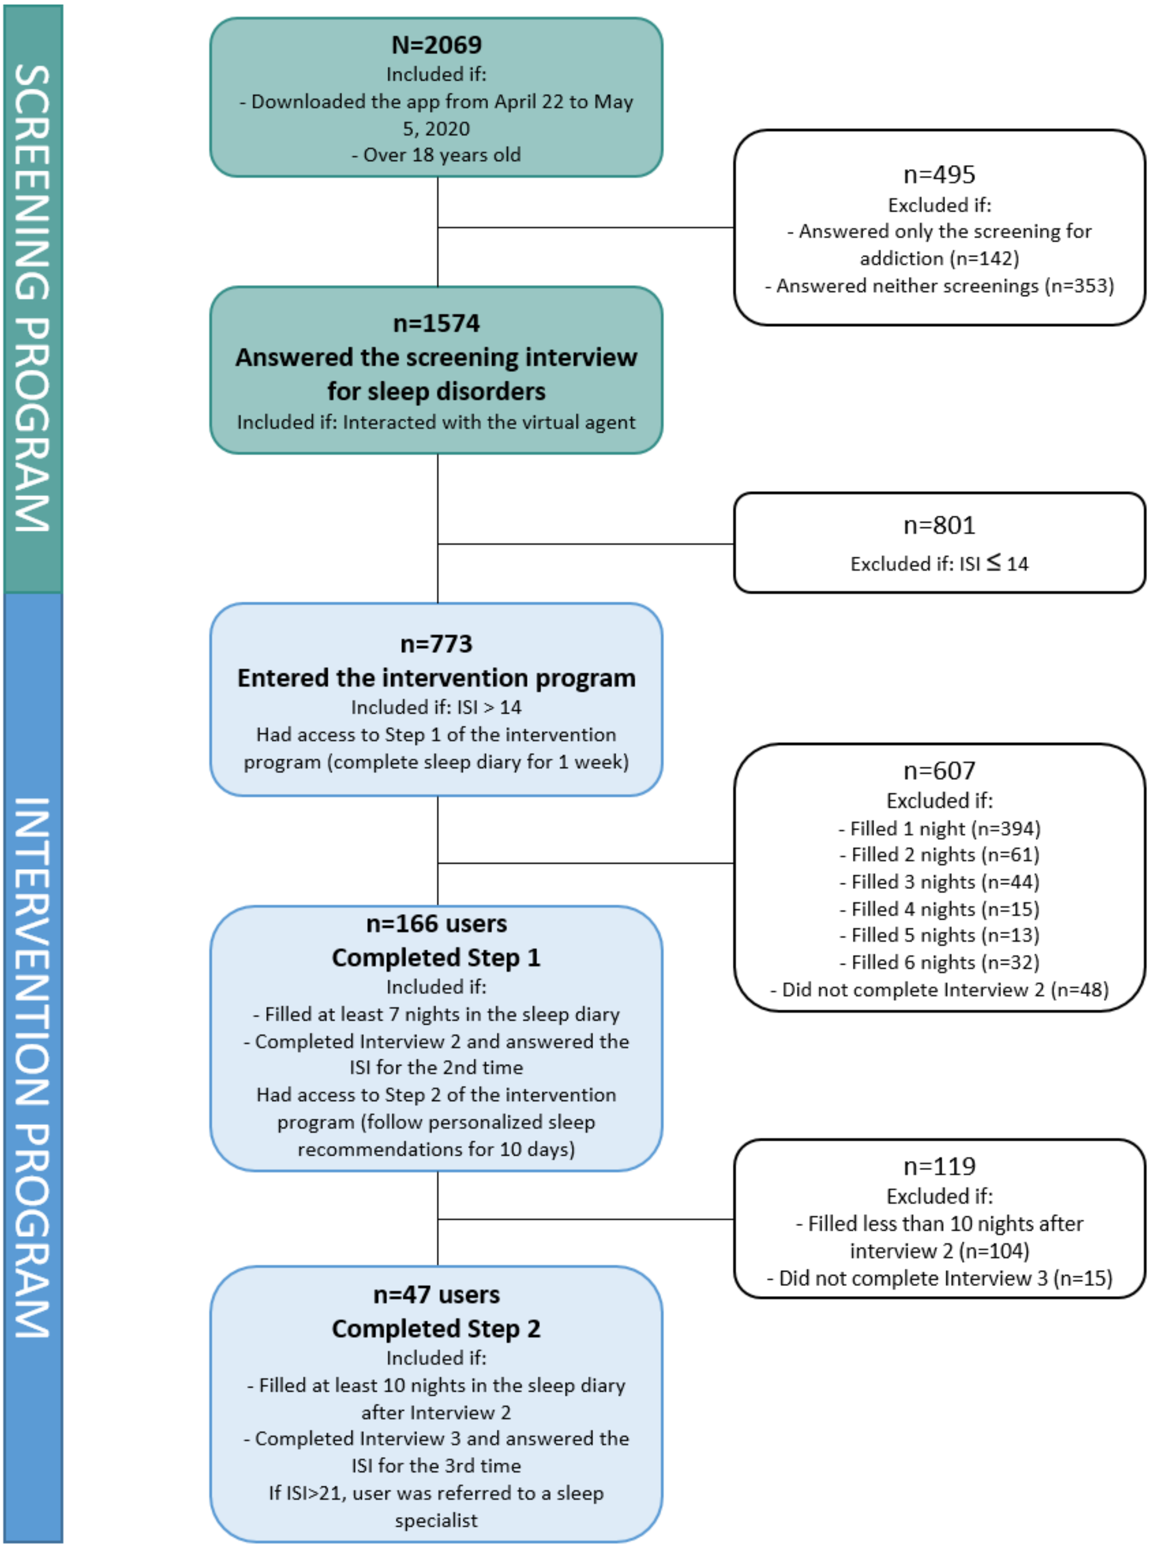
Sociodemographics and Clinical Characteristics of Users

For the purpose of this study, users were selected for the analysis if they met the following inclusion criteria: (1) aged 18 years old and above and (2) had downloaded KANOPEE app before May 5, 2020, such that they had access to the 1-week intervention before the end of confinement period in France (ie, May 11, 2020). Their use of the app was recorded from April 22 until May 26.

After getting approval by the University and Hospital scientific committees, we obtained authorizations to be registered on the University Hospital register for General Data Protection Regulation (GDPR) approval by the French authorities—Commission nationale de l'informatique et des libertés (CNIL). Informed consent was obtained from all users downloading the app according to the GDPR and CNIL regulations.

Subgroups of users were then selected for more detailed analyses (see Figure 3). Specifically, users who answered the screening interview for sleep disorders were further examined to determine their eligibility for the next step of daily sleep monitoring, and users who reported insomnia complaints (ie, ISI score >14) entered the intervention program and were included in the analyses of outcomes and feasibility.

Figure 3. Flowchart of users included in the different steps of analyses.



Measures

Clinical Measures

The ISI [21] is a 7-item self-report questionnaire that provides a global measure of perceived insomnia severity, with scores ranging from 0 to 28 (0-7: no clinical insomnia, 8-14: subthreshold insomnia, 15-21: insomnia of moderate severity, and 22-28: severe insomnia). The ISI has been previously validated and proven sensitive to changes in insomnia severity with treatment [22]. The ISI was used as a screening tool for assessing insomnia severity and as the primary outcome measure of treatment efficacy after the intervention.

Users who had an ISI score >14 were asked to complete a daily sleep diary in the app [24,25] throughout the intervention program. The following dependent variables were derived from users' daily sleep diary entries: sleep onset latency (SOL, ie, how many minutes it takes to fall asleep, starting from the moment of intention to fall asleep), number of awakenings

(NWAK), terminal wakefulness (TWAK, ie, the amount of awake time between the final wakefulness awakening and the time of getting out of bed), wake after initial sleep onset (WASO, ie, total amount of time awake during the night, excluding SOL and TWAK), total time spent in bed (TIB, ie, time starting from the moment of intention to fall asleep and concluding with the final arising), total sleep time (TST, ie, time actually spent sleeping) that was calculated from other self-reported variables (TIB−SOL− WASO−TWAK), and sleep efficiency (ie, percentage of time in bed spent asleep) that was calculated from other self-reported variables (TST/TIB × 100).

Addictive behaviors (ie, alcohol and cigarette consumption) of users were evaluated through a clinical interview based on the CAGE (Cut down, Annoyed, Guilty, and Eye-opener) [26] and CDS-5 (Cigarette Dependence Scale, 5-item) questionnaires [27].

Acceptance and Trust Questionnaires

After the interviews with the virtual agent, users could complete 2 assessments on the app. The first assessment was the French version of the Acceptability E-scale (AES) [28,29] to measure acceptance of the KANOPEE app based on 2 subscores: usability (ie, the perceived ease of using the system or app) and satisfaction (ie, the perceived enjoyment of the use and usefulness of the system or app). The second assessment was the ECA trust questionnaire (ETQ) [18] that measures a user's trust in a virtual agent based on 2 subdimensions: perceived credibility (ie, perception that the agent has the ability and the expertise to conduct a medical intervention) and benevolence (ie, perception that the agent is well-intentioned and will accurately take the user's interests into account). Familiarity with technologies was also evaluated by a single question: “Are you familiar with computer technologies?” with the following 3 choices: “No,” “Moderately,” and “Yes,” which were scored as 0, 1, and 2, respectively.

Statistical Analyses

Quantitative variables were expressed as means and SD, and qualitative variables were expressed as percentages. To compare 2 groups of users (eg, subclinical insomnia vs with moderate-to-severe insomnia), we performed 2-tailed Student *t* tests for continuous variables (eg, age, CDS score, and cigarettes smoked), and χ^2 tests for categorical variables (eg, gender, educational level, health care professional, and users adhering to the confinement). The data collected during the program were described using mean and SD values, and evolution of the measures over time was analyzed using repeated *t* tests. Acceptance (ie, usability and satisfaction subscores of the AES) and trust (ie, credibility and benevolence subscores of the ETQ) data were expressed using distributions and percentages. To investigate factors associated with acceptance and trust, we conducted univariate analyses with Pearson correlation analyses between 2 continuous variables (age, insomnia severity, and familiarity with technologies) and performed mean comparisons (*t* test or analysis of variance) to analyze the variation in AES and ETQ scores regarding categorical variables (gender and educational level). All analyses were performed using SPSS software (version 26; IBM Corp).

Results

Characteristics of App Users

A total of 2069 users aged ≥18 years downloaded KANOPEE app and answered sociodemographic information (Table 1). Of these, 76% (1574/2069) of the users answered the screening interview for insomnia disorders. Most of these users were between 31 and 50 years old (mean 43.52, SD 13.94) and had a university degree. Furthermore, most users were in confinement due to the COVID-19 lockdown, and 5.6% (89/1574) were front-line health care professionals involved in the fight against COVID-19. Approximately half of the users (773/2069, 49.1%) who answered the screening interview for sleep disorders obtained an ISI score over the clinical threshold for insomnia (ie, ISI score >14). Compared to the users who answered the screening interview for sleep, those who chose not to were significantly older (P=.016) and predominantly male users (P=.001). Other factors remained nonsignificant between the 2 groups (see Table 1).

Table 1. Characteristics of KANOPEE users depending on their use of the app.

Characteristics	Values		Group comparison		*P* value
	Answered screening interview for sleep (n=1574)	Did not answer screening interview for sleep (n=495)	*t* test (*df*)	Chi-square (*df*)

Users who answered the screening interview for sleep disorders (n=1574) were divided into 2 subgroups based on their performance on the ISI: scores ≤14 considered “with subclinical insomnia” and scores >14 considered “with moderate-to-severe insomnia” (Table 2).

Compared to users with subclinical insomnia, users with moderate-to-severe insomnia were younger ($t_{1576}=-3.03$; *P*=.002), more educated ($\chi^2_2=12.14$; *P*=.007), and more likely to be female ($\chi^2_1=31.91$; *P*<.001). Interestingly, more users in confinement were found in the moderate-to-severe insomnia group ($\chi^2_1=8.86$; *P*=.003), but we did not find evidence of a higher prevalence of insomnia among health care professionals. Users with moderate-to-severe insomnia smoked more cigarettes ($t_{734}=-4.03$; *P*<.001) and obtained a higher score on the screening questionnaire for addiction to cigarettes ($t_{734}=3.41$; *P*=.001) than those in the other groups.

Table 2. Characteristics of users depending on their sleep complaints.

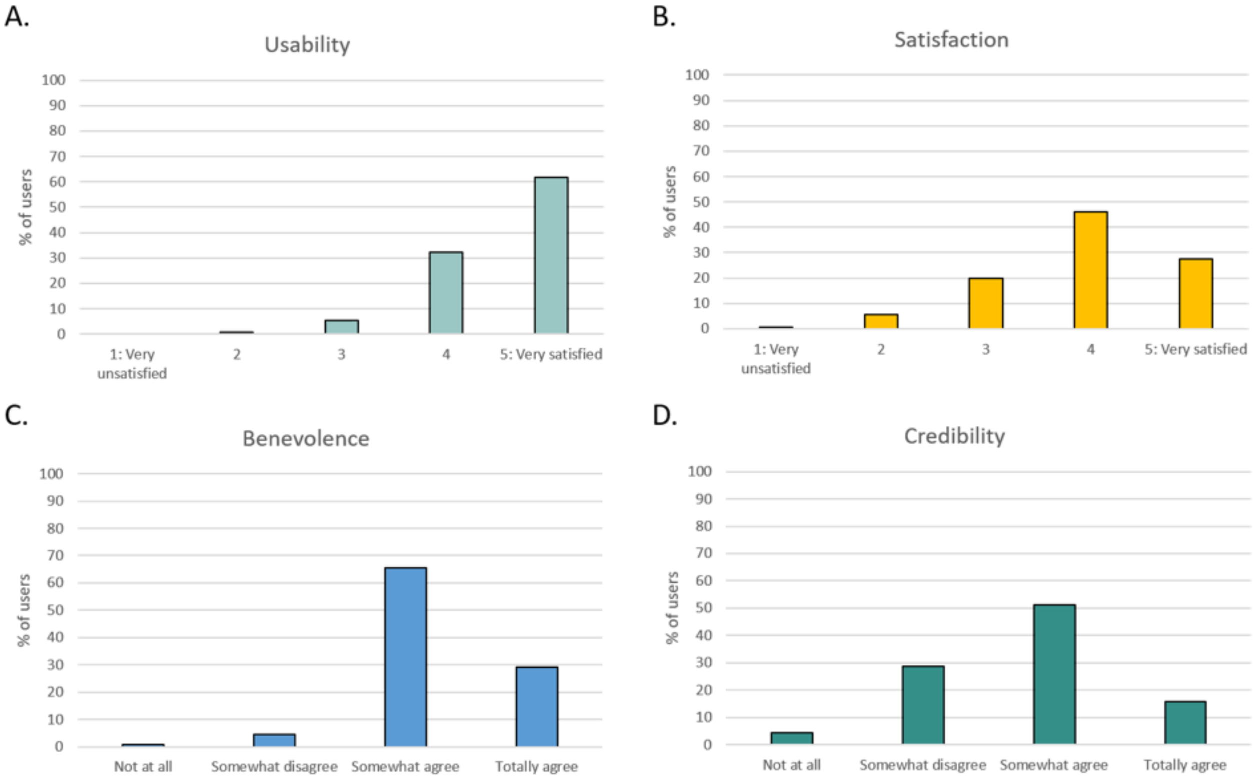
Trust and Acceptance of Virtual Agents

In all, 431 of 1574 (27.4%) users answered the acceptance and trust questionnaires (Figure 4). Acceptance of the overall system (AES score) was rated very positively, with 61.7% (266/431) of users being “very satisfied” with the usability of the system, and 91.6% (395/431) of users rating the virtual agent more than 3 out of 5 for satisfaction. Regarding trust (ETQ score), Louise was perceived as trustworthy to perform medical interviews. Indeed, 94.6% (408/431) of users “somewhat agreed” or “totally agreed” that she was benevolent, and 67.05% (289/431) of users had a positive attitude towards her credibility (ie, rating of more than 1 out of 3).

Figure 4. Distribution of usability, satisfaction, benevolence, and credibility perception of the virtual companion for sleep disorders (Louise). (A) Percentage of users' rating for usability dimension (AES subscore), (B) percentage of users' rating for satisfaction dimension (AES subscore), (C) percentage of users' rating for benevolence dimension (ETQ subscore), and (D) percentage of users' rating for credibility dimension (ETQ subscore).

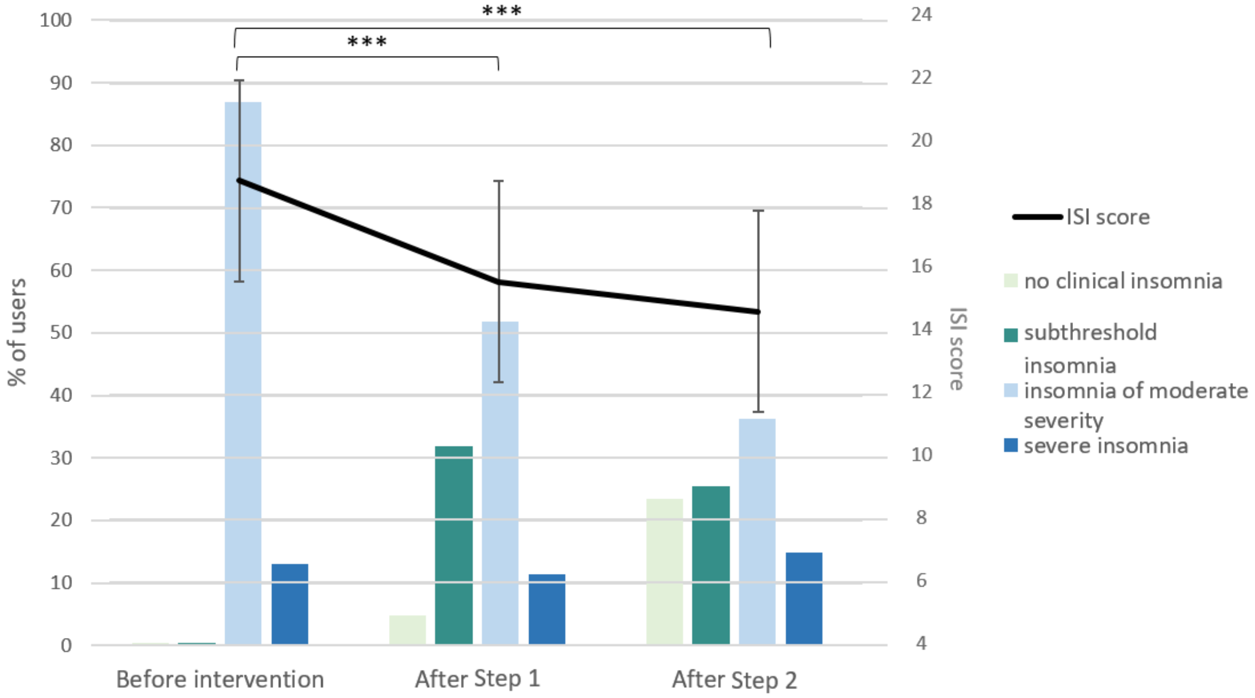


We found a negative correlation between age and credibility subscore on the ETQ (r=−.102; *P*=.034), suggesting that older individuals found Louise less credible than the younger ones. Age was not correlated with other dimensions of trust and acceptance. Similarly, gender and educational level of the users were not correlated with their attitude towards Louise. Regarding insomnia severity, there was a positive relationship between the severity and credibility of Louise (r=.125; *P*=.009), indicating that users with more severe insomnia complaints found her more credible. Lastly, we found significant correlations between users' familiarity with technologies and their attitudes towards Louise: users more familiar with technologies found her more usable (r=.109; *P*=.024), more satisfactory (r=.128; *P*=.008), and more benevolent (r=.117; *P*=.015).

Evolution of ISI Score and Nocturnal Sleep Indicators During the Intervention Program

Among the 166 users who completed Step 1 of the intervention (ie, fill a sleep diary for 1 week and answer the ISI for the second time), the total ISI score (Figure 5) decreased compared to the baseline (baseline mean ISI score 18.56, mean ISI score after Step 1 15.99; t_{165}=7.88; *P*<.001), with 36.7% (61/166) of users obtaining an ISI score below a clinically significant level (ie, ≤14) either corresponding to "no insomnia" (8/166, 4.8%) or to "subthreshold insomnia" (53/166, 31.9%). For the 47 users who completed Step 2 of the intervention, their ISI scores continued to decrease but did not reach a significant threshold (mean ISI score after Step 1 15.64, mean ISI score after Step 2 14.68; t_{46}=1.42; *P*=.162). However, compared to the initial measure, a significant decrease was observed (baseline mean ISI score 18.87, mean ISI score after Step 2 14.68; t_{46}=4.85; *P*<.001). Moreover, the proportion of users reporting low insomnia complaints increased, with a total of 48.9% (23/47) of users below a clinically significant level. Of note, 14.9% (7/47) of users still reported "severe insomnia" after Step 2, so they were referred to a sleep specialist.

Figure 5. Distribution of users depending on the severity of their insomnia complaints (based on ISI scores) along the intervention program: Step 1: completed sleep diary; Step 2: followed personalized sleep recommendations. ISI: Insomnia Severity Index. Significance: *$P<.05$, **$P<.001$.



Regarding nocturnal sleep patterns, we computed the mean scores of the first 2 nights filled in the sleep diary and the last 2 nights before receiving step 2 intervention in order to evaluate the evolution of sleep indicators during completion of Step 1 of the intervention program among the 166 users who completed the Step 1 (ie, filling in the sleep diary). Analyses of mean and SD values (see Table 3) suggest a reduction in TIB, SOL, and TWAK, and an increased sleep efficiency among this subgroup.

Table 3. Nocturnal sleep indicators of users completing Step 1 (n=166).

Sleep indicator	Value, mean (SD)		*t* test (*df*)	*P* value
	First 2 nights (1 & 2)	Last 2 nights (6 & 7)		
Time in bed, hh:mm:ss	08:56:45 (01:34:22)	08:40:27 (01:29:27)	*2.17 (165)*[a]	*.03*
Total sleep time, hh:mm:ss	06:04:32 (01:56:47)	06:21:30 (01:37:33)	−1.88 (165)	.06
Sleep efficiency, %	67.60 (20.25)	73.82 (17.33)	*−4.25 (165)*	*.001*
Sleep onset latency, hh:mm:ss	01:31:38 (02:39:11)	00:58:37 (01:26.00)	*2.78 (165)*	*.006*
Nocturnal awakenings, n	1.89 (1.57)	1.67 (1.32)	1.81 (165)	.07
Wake after initial sleep onset, hh:mm:ss	00:48:57 (00:55:48)	00:42:01 (00:52:58)	1.27 (165)	.21
Terminal wakefulness, hh:mm:ss	00:58:11 (01:09:42)	00:39:43 (0:39:57)	*3.31 (165)*	*.001*

[a] Italicized values indicate they are statistically significant.

To measure the effect of completing Step 2 on sleep indicators, we computed the mean scores of the 7 nights before the users received personalized sleep recommendations and compared it to the mean scores of the 7 nights after they started Step 2. Mean and SD analyses among the 47 users who completed Step 2 suggest that WASO, NWAK, and TWAK decreased after Step 2, whereas TIB, TST, and sleep efficiency increased (see Table 4).

Table 4. Nocturnal sleep indicators of users completing Step 2 (n=47).

Sleep indicator	Value, mean (SD)		*t* test (*df*)	*P* value
	7 nights before Step 2	7 nights after Step 2		
Time in bed, hh:mm:ss	07:56:45 (01:18:51)	08:37:45 (00:50:21)	−5.35 (*46*)	.001
Total sleep time, hh:mm:ss	06:00:05 (01:24:29)	06:13:26 (01:30:16)	−2.02 (*46*)	.047
Sleep efficiency, %	68.47 (14.75)	72.36 (16.76)	−3.18 (*46*)	.002
Sleep onset latency, hh:mm:ss	00:59:22 (00:53:41)	01:08:50 (01:25:02)	−1.01 (*46*)	.32
Nocturnal awakenings, n	1.77 (1.24)	1.35 (0.97)	5.24 (*46*)	.001
Wake after initial sleep onset, hh:mm:ss	00:55:26 (00:52:03)	00:35:58 (00:32:57)	3.57 (*46*)	.001
Terminal wakefulness, hh:mm:ss	00:51:59 (00:42:15)	00:41:17 (00:32:22)	3.04 (*46*)	.003

Discussion

Principal Findings

Our results show, for the first time, the feasibility of using virtual agents in the context of a major health crisis to monitor insomnia symptoms and deliver assistance to the users through behavioral interventions. eHealth is a very rapidly growing field, and numerous solutions are particularly adapted to conditions such as confinement where human contacts must be limited. Several mobile apps use text-based chatbots for medical interviews, but the use of virtual agents (interacting through natural body motion and natural voice) is still sparse. We believe that these new empathic human-machine interfaces can reinforce acceptance of eHealth solutions.

More than 2000 people downloaded the KANOPEE app over the 11-day study period, with no technical errors reported by Google Play Store, indicating a higher inclusion rate than that reported in a previous study proposing digital cognitive behavioral therapy for insomnia [30]. This confirms the potential of digital technologies to provide access to clinical screening and behavioral intervention for insomnia for the general population [31]. Out of the 2069 users who downloaded KANOPEE, 1574 (76%) used it to self-evaluate their sleep. We noted that users who decided not to answer the screening interview for sleep were older and more likely to be male. This result might reflect more specific target populations such as young women—a group that is well known to report high levels of sleep complaints [32]. While the stress related to the COVID-19 confinement could explain why we obtained such a high app download rate, another potential explanation is the visual appeal of virtual agents to engage in digital interactions. Even individuals without significant sleep complaints (about 50% of the study sample) used our app and were interested in completing a sleep evaluation; this finding strongly indicates the need to develop apps for normal sleepers who want to improve their sleep hygiene and should be interpreted as a positive indicator for future sleep health campaigns.

Acceptance of the virtual agent was a major challenge in this specific context, and we obtained very good results, similar to those reported previously with outpatients in a hospital [18]. Usability and benevolence were very well ranked by the app users, which confirms the empathic dimension of our virtual agents, even on smaller devices like smartphones. This is also a positive message to reinforce the use of virtual agents in eHealth technologies, which is a growing field of interest for medicine.

In the intervention program, 21.5% of the users reporting significant sleep complaints (ie, ISI score >14) completed a daily sleep diary for more than 7 days and consented to participate in Interview 2 (ie, they completed Step 1), and 28.3% of users followed behavioral interventions and completed the sleep diary for 10 more days. Interestingly, subjects completing Step 1 significantly improved their sleep over a brief period of time (ie, 7 days). We hypothesize that filling in the sleep diary and receiving daily feedback on their sleep efficiency score helped users to adjust their sleep schedule autonomously. Another possible explanation is that their insomnia symptoms decreased naturally over time, even though a reduction of time in bed for about half an hour suggests an active change. These findings are very encouraging for the use of electronic sleep diaries to promote sleep hygiene practices, a form of low-intensity sleep health intervention that could be beneficial at the more global population level. Users who completed their personalized intervention reported an improvement in nocturnal sleep, with a reduction of nocturnal awakenings and insomnia complaints, which suggests Step 2 was beneficial for a subgroup of individuals with more significant sleep complaints. Altogether, with completion rates of 76% for the initial evaluation and 28.3% for the personalized interventions in a selected population, we believe that our results open interesting perspectives for populational interventions and mirror the proposal of Berry et al [33] to set up trials in which large-scale interventions are offered simultaneously to different subgroups of patients.

Study Limitations

Nevertheless, this study has a few limitations. First, the very peculiar period of recruitment, during the COVID-19 confinement, makes our results preliminary. Future work needs to confirm, in a more “normal period of time,” the fact that KANOPEE can help individuals improve their insomnia complaints and sleep hygiene. Second, the drop-out rate was quite high. We were unable to determine why users did not follow the program until the end, and further study is therefore needed for a precise examination of usage (eg, frequency of use and errors made) and qualitative interviews with app users to unveil the reasons why they decided to drop out of KANOPEE.

Another limitation of our study is related to the fact that we did not note an improvement among the most severe users, which shows the limitations of nonhuman interventions. Because we did not explore all the possible comorbidities, we might have proposed to some users a solution that may be unsuitable to their health problems. Future studies could use detailed interviews that could help precisely select the ideal population to receive the interventions and refer the other users directly to sleep centers.

Conclusions

Considering the above limitations, we believe that KANOPEE is a new promising tool in the field of eHhealth that could limit the number of individuals asking for consultations by general practitioners for moderate sleep complaints. Indeed, we believe this app can help in both ways: identifying individuals with insomnia complaints and providing brief and practical behavioral interventions. Further research is needed to test this app apart from the COVID-19 confinement period and on more specifically selected users.

Acknowledgments

We thank Yannick Levavasseur and Emeric Labbé for developing the app. This project was supported by the grants LABEX BRAIN (ANR-10-LABX-43), EQUIPEX PHENOVIRT (ANR-10-EQPX-12-01), and funding from the Region Nouvelle-Aquitaine (IS-OSA project, Contract No.: 18000389).

Conflicts of Interest

Abstract

Background: Worldwide, nonpharmacologic interventions (NPIs) have been the main tool used to mitigate the COVID-19 pandemic. This includes social distancing measures (closing businesses, closing schools, and quarantining symptomatic persons) and contact tracing (tracking and following exposed individuals). While preliminary research across the globe has shown these policies to be effective, there is currently a lack of information on the effectiveness of NPIs in the United States.

Objective: The purpose of this study was to create a granular NPI data set at the county level and then analyze the relationship between NPI policies and changes in reported COVID-19 cases.

Methods: Using a standardized crowdsourcing methodology, we collected time-series data on 7 key NPIs for 1320 US counties.

Results: This open-source data set is the largest and most comprehensive collection of county NPI policy data and meets the need for higher-resolution COVID-19 policy data. Our analysis revealed a wide variation in county-level policies both within and among states ($P<.001$). We identified a correlation between workplace closures and lower growth rates of COVID-19 cases ($P=.004$). We found weak correlations between shelter-in-place enforcement and measures of Democratic local voter proportion (R=0.21) and elected leadership (R=0.22).

Conclusions: This study is the first large-scale NPI analysis at the county level demonstrating a correlation between NPIs and decreased rates of COVID-19. Future work using this data set will explore the relationship between county-level policies and COVID-19 transmission to optimize real-time policy formulation.

Introduction

In the absence of effective vaccines or therapeutics targeting SARS-CoV-2, nonpharmacologic interventions (NPIs) have been the only effective measures for containing the current COVID-19 pandemic [1-4]. NPIs are grouped into social distancing measures and contact tracing measures [5]. Examples of social distancing measures include closing businesses, closing schools, and quarantining symptomatic persons [6]. Contact tracing involves tracking and following exposed individuals, which requires both testing capabilities and infrastructure to execute [7]. Systematic reviews and modeling studies have demonstrated that each of these NPIs have a variable impact on respiratory virus transmission, depending on how and when they are deployed [1,5,7].

While China was initially slow to implement NPIs, models have shown that China’s social distancing measures were sufficient to control COVID-19 [1,2]. Local governments across China were integral in the successful implementation of NPIs, including diagnostic testing and enforcing social distancing [2]. NPIs have similarly been found to effectively limit COVID-19 across 11 countries in Europe [4], especially Italy [3]. However, the United States has implemented NPIs more variably, which may be related to the higher rates of transmission [8].

In the United States, the first known cases of COVID-19 were reported on January 20, 2020 [9]. However, it was not until March 2020 that individual states responded with NPI policies, and as of April 20, 2020, multiple states still had not implemented stay-at-home orders [10,11]. The limited coordination of national, state, and local responses to COVID-19 led to substantial variation in NPIs at the county level across the United States. As the pandemic continued into late May and early June, states began to roll back measures with incongruent reopening plans. These reopening plans again differed by location and by NPI policy type [9]. As a result, the United States has uniquely experienced wide variations in NPI policy, both geographically and temporally. County-level political party alignments may be relevant to the formulation of local COVID-19 NPI policies; this question has not yet been rigorously assessed. Partisanship in county-level policy has significant ramifications for how policymakers engage stakeholders to realistically implement local policy.

As of November 25, 2020, there are 12,838,102 confirmed COVID-19 cases and 262,847 deaths in the United States [8], both higher totals than those of any other country in the world [8,12]. Preliminary data on social distancing at the state level [13] and limited data on shelter-in-place orders at the county level from bordering communities in Illinois and Iowa [14] have shown that NPIs can be effective, particularly when implemented in a timely manner. However, there remains a need to better understand the effects of NPIs on COVID-19 transmission dynamics at a national scale on the granular county level.

The first objective of this study was to describe the motivation and novel methodology for creating the first large-scale county-level NPI policy data set in the United States. The second objective was to highlight initial findings from this data set to demonstrate its utility for much-needed local NPI analyses. A unique standardized crowdsourcing methodology was deployed to collect time-series data on 7 key NPIs for 1320 US counties. This novel data set was then mined for correlations in combination with publicly available COVID-19 case data, reproduction number (R_t) estimates, and political demographics at the county level. This exploratory analysis illustrates the utility of county-level NPI implementation and analysis in the United States, particularly with the novel data set described herein.

Methods

Data Collection

A novel crowdsourcing methodology was implemented by Hikma Health to collect COVID-19 policy data for 1320 US counties from March to July 2020. The data set covers 7 distinct NPI policies, including the most widely deployed and accepted NPIs. For each county, trained volunteers reported a binarized policy status for each NPI policy indicating if/when the following NPI policies were first implemented in each county, along with a timestamp and a reference URL: (1) closure of nonessential workplaces, (2) shelter-in-place/stay-at-home orders, (3) enforcement of shelter-in-place/stay-at-home orders, (4) size restrictions on public gatherings, (5) school closures, (6) public transit closures, and (7) publicly available testing. Table 1 provides a full description of the variables included in the data set. The data set also includes a second timestamp and reference URL for if/when each of the same 1320 US counties terminated the following 2 NPI policies: nonessential workplace closures and shelter-in-place/stay-at-home orders. Given the limits in data collection capacity, these 2 NPI policies were prioritized over the other 5 NPI policies for observation at a second timepoint, as we hypothesized they had a relatively higher likelihood of changing in May-July 2020.

Table 1. Variables in the Hikma Health data set of county-level nonpharmacologic intervention policies.

Variable name	Description
fips	County FIPS[a] geographic code (unique identifier)
testing	Binary coding whether COVID-19 testing is publicly available in the county to any resident without physician referral needed
school	Binary coding whether all schools are closed in the county
shelter	Binary coding whether the county has an active shelter-in-place order, publicly announced by any county official
shelter_enforcement	Binary coding whether the shelter-in-place order is being enforced in the county with fines or other penalties
work	Binary coding whether all "nonessential workplaces" are closed in the county, with any local definition of "nonessential"
event	Binary coding whether public events and gatherings larger than a particular size N are restricted, for any N>1
transport	Binary coding whether any public transportation has been closed down for any public bus, train, shuttle, or ferry routes
X_date	For each policy binary X, the date on which it was first implemented
X_URL	For each policy binary X, the source URL with evidence of the nature and date of the policy
updated	The timestamp for when this data was entered

[a] FIPS: Federal Information Processing Standard.

Because each US county reports its standing COVID-19 NPI policies differently—from county websites to local news outlets and official social media channels—the data collection process cannot be automated and instead requires human review and discernment. From March to July of 2020, 104 volunteers, consisting mostly of health-related graduate degree students and medical professionals, were recruited through COVID-19 project postings, outreach groups, and institutional listservs. Each volunteer was remotely trained to use the same 7-step standard operating procedure to research and collect the aforementioned NPI data on 1320 US counties through standardized online forms, effectively transforming the convoluted county policy landscape into an organized NPI data set with binary yes/no and interval date variables. The free and open-source data set contains corresponding URL references on all counties for quality assurance [15].

In assigning counties to volunteers, we initially prioritized population and then transitioned to COVID-19 incidence as the pandemic unfolded. Specifically, we sourced data for the 500 most populous US counties and then used dynamic 4-day incidence rate calculations to prioritize the remaining counties in real time. For the first 100 counties, every policy and its implementation date was validated manually by double-checking the website URL from which the information was sourced. The same extraction process was repeated for the subsequent 1220 counties, with validation of URLs for an additional randomly selected 10% of completed counties, rendering a volunteer coding accuracy rate over 99%.

Statistical Analysis

In this study, we conducted time-series correlational analyses combining our county-level NPI data for 1320 US counties with multiple data sources, including daily county COVID-19 cases and deaths sourced from The New York Times. We also assessed correlations with COVID-19 effective R_t estimates from the RT Live project, and political demographics at the county level from the Kaiser Family Foundation and the MIT Election Data and Science Lab.

For optimal visualization and temporally focused analysis on current policies, we constructed a consolidated version of the data set as follows: for each NPI policy in each county, all observations within the last 24 hours were pooled; the mean was calculated for each binary, and binaries above 0.5 were considered positive, while binaries less than or equal to 0.5 were considered negative; the latest date and URL reported were chosen to represent that policy; lastly, a Policy Strength Index (PSI) was calculated as a linear sum of all 7 NPI policy binary variables, with 7 being the maximum and 0 being the minimum possible value.

We then mined this consolidated data set for correlations and distribution differences using standard statistical tests including *T* tests and chi-square tests with a Bonferroni correction applied for multiple hypothesis testing. All analyses were conducted in Python notebooks that are available open source for review and global use under the Apache 2.0 license.

Results

Data Set Construction and Access

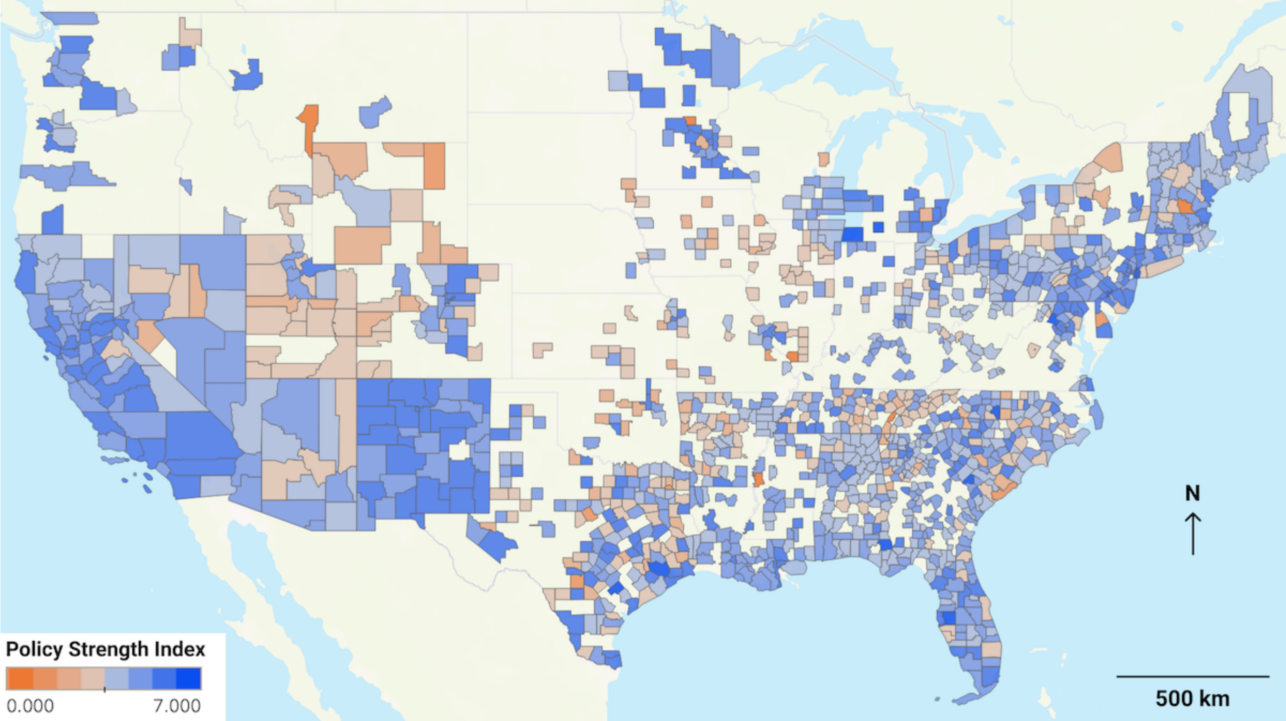
The full county NPI data set, hereon referred to as the "all policies" data set, yielded 2704 observations of NPI policies described in Table 1 in 1320 counties from all 50 states in the United States. We analyzed the all policies data set (n=2704) as well as the consolidated current version of the data set, hereon referred to as the "current policies" data set (n=1320), containing only the most recent timestamp for county NPIs as described in the *Methods* section. These versions are referred to as the "all_county_ policies" and "county_policies" files, respectively, on GitHub, where they can be freely accessed by the global public, along with reference documentation [15]. The data set is available as both CSV (comma-separated values) and JSON (JavaScript Object Notation) files, indexed by US county FIPS (Federal Information Processing Standard) geographic codes. Each of these files include the binary NPI variables with accompanying interval date variables, corresponding reference URLs, and the timestamps of when the data were collected. The

CSV files used for all analyses presented in this paper are included in Multimedia Appendix 1.

Policy and Case Correlations

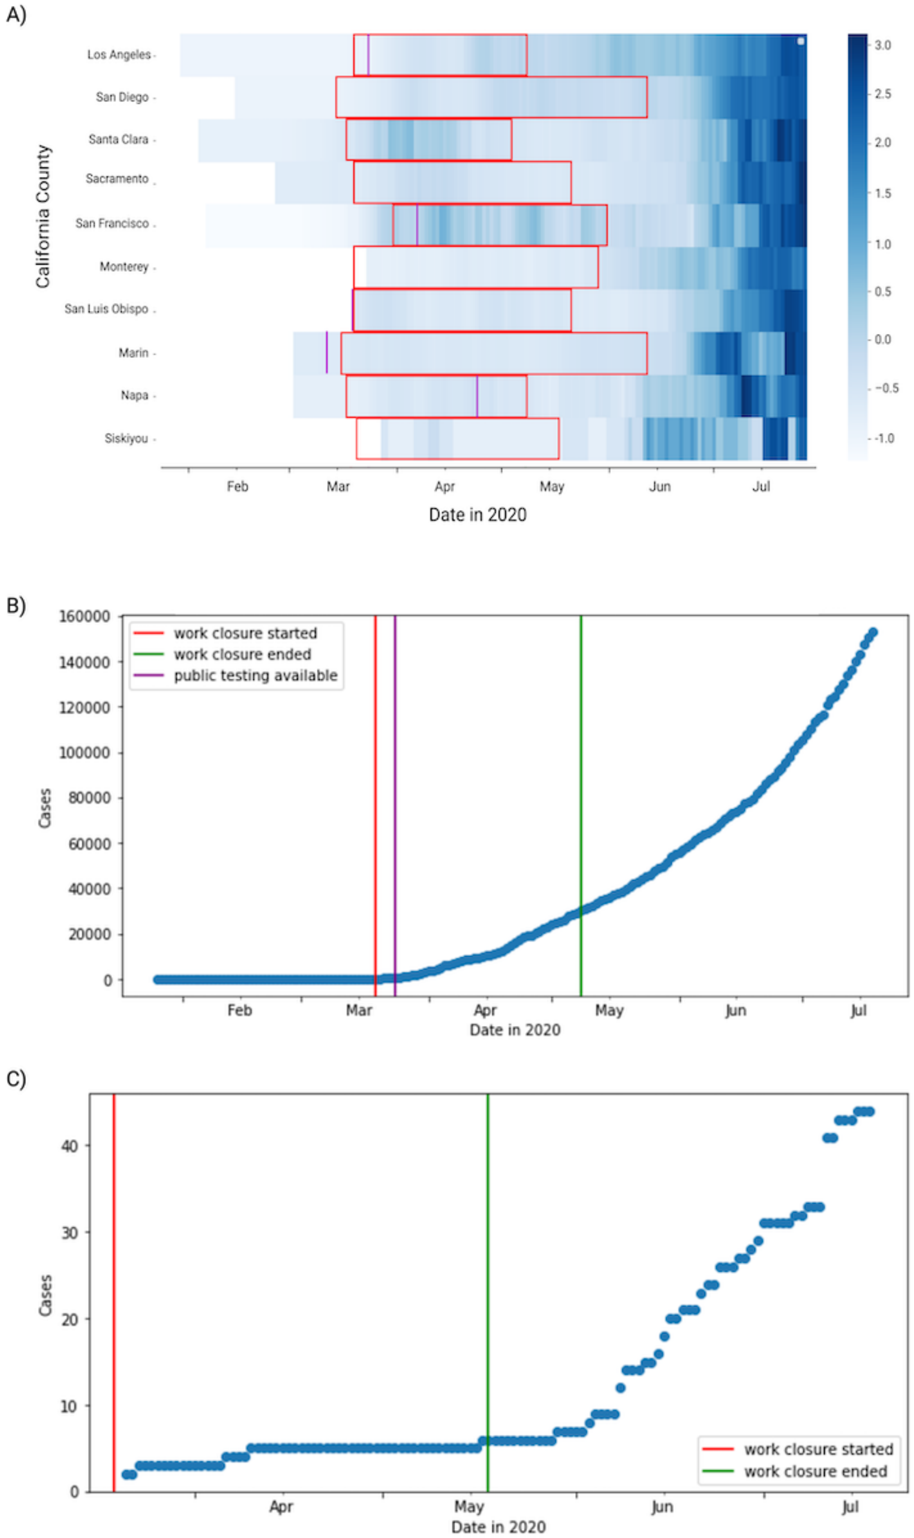
In the all policies data set, there was a strong positive correlation between nonessential workplace closure and shelter-in-place orders at the county level with a Pearson R of 0.835. All other correlations between individual policies were weak in the all policies data set, with an absolute value of R<0.3. In the current policies data set, the correlation between nonessential workplace closure and shelter-in-place orders weakened to a Pearson R of 0.144, generally in association with the reopening of workplaces without lifting shelter-in-place orders in May-June 2020. In the current policies data set, all other correlations were less than 0.1. Of all policies tested for interstate differences by a one-way ANOVA (analysis of variance), only school closure was not significantly different at a Bonferroni corrected α level of .0071 (*P*=.06); for all other policies *P*<.001. States also exhibited varying degrees of overall intrastate/intercounty variability in PSI, as illustrated in Figure 1.

Figure 1. Map showing that county policies are uncorrelated and highly variable between and within states. Policy Strength Index (PSI) for the current policies data set mapped by county indicates that across states, there was wide variability in policy implementation on July 15, 2020. The PSI is calculated as the linear sum of the 7 binary nonpharmacologic intervention policy variables in each county as described in the Methods section.



We also observed that within states the variability in county NPIs informs the visualization of case growth rates, as shown in Figure 2. For example, in California, the variability in county NPI policies informed the interpretation of timelines showing the 7-day simple moving averages of new cases in each county (Figure 2A). As a general trend, case growth was minimal during the period of workplace closure, highlighted for each county in Figure 2A in the red window, while case growth increased significantly 2-8 weeks after the end of workplace closure. For example, in Los Angeles County, California (shown in Figure 2B), case growth accelerated following the end of the work closure policy; additionally, the start of public testing coincided with the inflection point of case growth. In Siskiyou County, California (shown in Figure 2C), case growth similarly accelerated following the end of workplace closure.

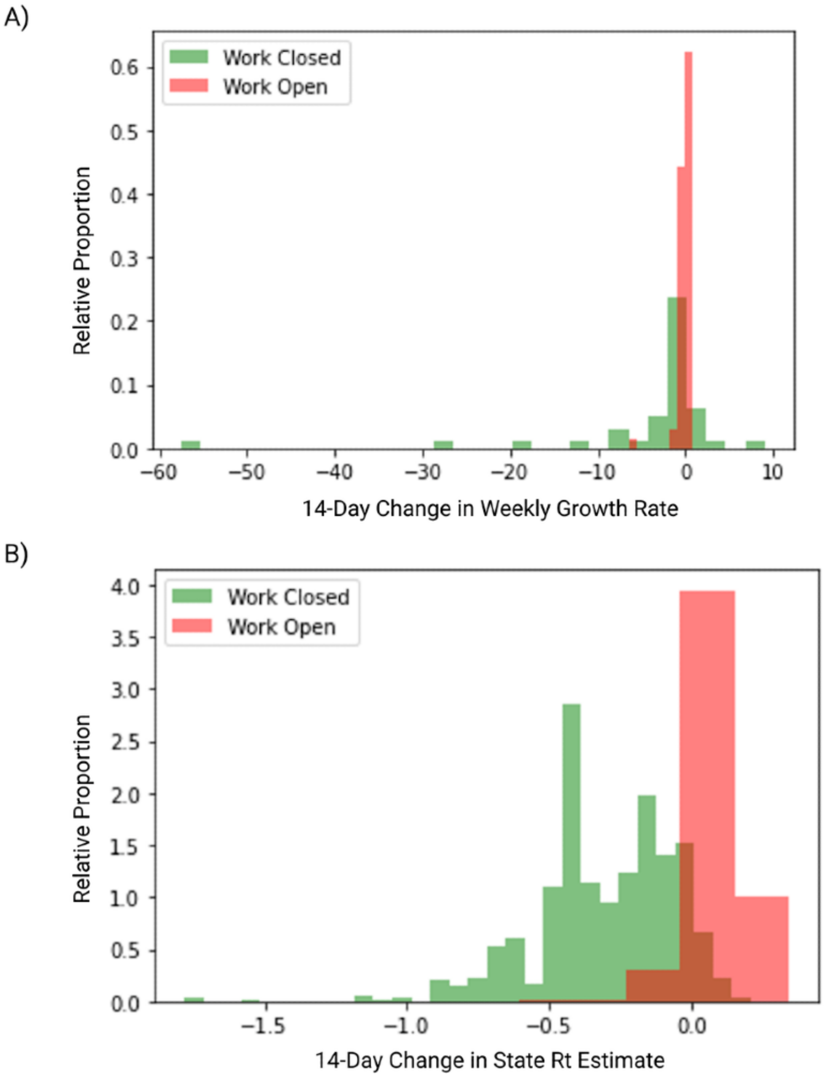
Figure 2. Variability in California county policies in time and in relation to caseloads. (A) Time-series heatmap of the 7-day simple moving average of daily cases plotted for 10 representative California counties in order of descending population, all normalized by county. The red rectangle demarcates the period for which the county had nonessential workplaces closed. The purple line indicates if and when public testing became available. (B) Plot of the total number of county cases as a timeline with county-level nonessential work closure policy and public testing times labeled for Los Angeles County. (C) Plot of the total number of county cases as a timeline with county-level nonessential work closure policy times labeled for Siskiyou County.



Policies and Case Growth

As summarized in Figure 3, we assessed whether there are significant differences in the change in weekly case growth in counties where workplaces closed versus those that remained open in the all policies data set. Figure 3A shows a histogram illustrating change in weekly case growth rate from the week preceding the date of workplace closure to 14 days later for counties with open versus closed nonessential workplaces. Weekly case growth rates decreased over the 14 days following a workplace NPI by larger magnitudes for counties that had such nonessential workplace closure policies as compared to those that had openings (*P*=.004; Figure 3A). We also assessed whether there was a significant difference in statewide R_t. This effect of decreasing case propagation following workplace closure was similarly observed in state-level estimates of R_t 14 days after the workplace policy (from RT Live) (*P*<.001; Figure 3B). The effect for R_t was recapitulated at 28 days after the workplace policy (*P*<.001). These effects are statistically significant at our Bonferroni corrected α level of .0071.

Figure 3. Counties with closed nonessential workplaces and significant declines in growth rate and reproduction number (R_t) following workplace closure. (A) A histogram of the change in weekly case growth rate from the week preceding the date of workplace closure to 14 days later for counties with open versus closed nonessential workplaces. (B) A histogram of the change in RT Live estimates of R_t by state from the date of the workplace policy to 14 days later for counties with open versus closed nonessential workplaces.

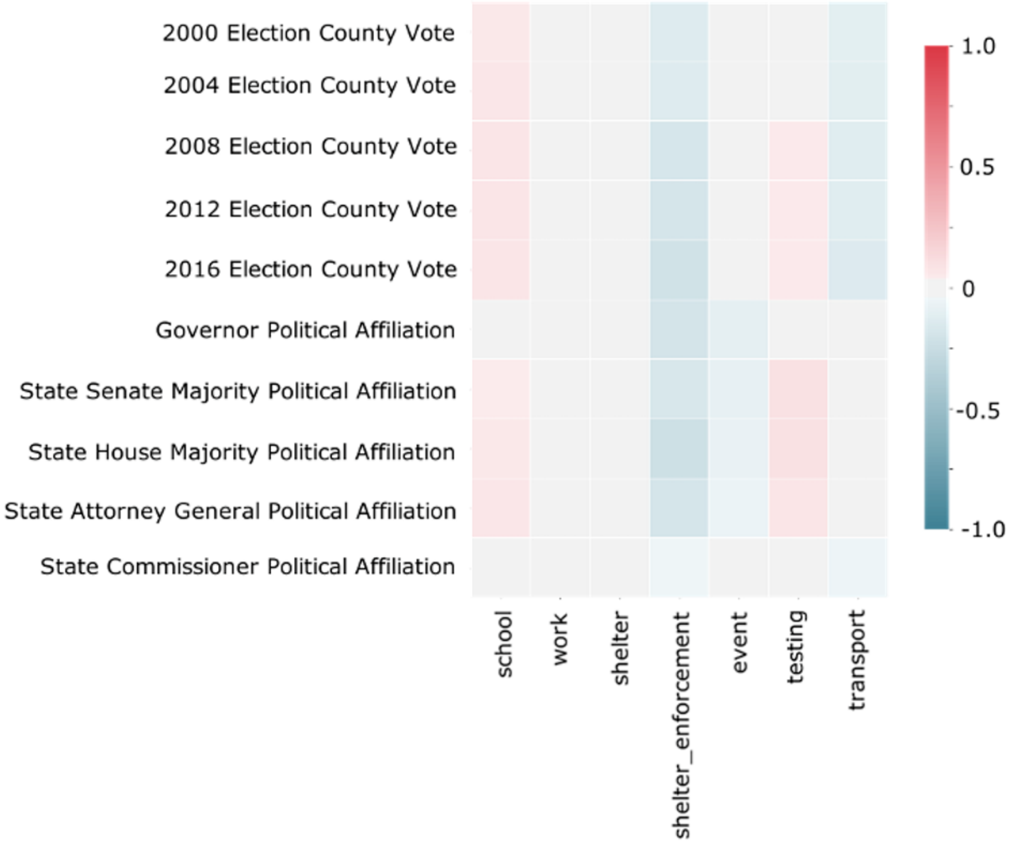


The start date of public testing varied in each county both on the absolute date timeline and the timeline relative to other NPIs. To assess whether counties that had free public testing before a workplace policy observation were more likely to have had a workplace closure for that observation, counties were grouped based on their timelines into the categories of no testing, testing after workplace closure, and testing before workplace closure. A chi-square test for significance found no significant difference in workplace openings versus workplace closures for these categories (*P*=.08).

Policies and Political Alignment Correlations

We observed weak correlations between the political parties of local leadership and electorate and the policy of shelter-in-place enforcement. In the all policies data set, shelter-in-place enforcement was weakly correlated with Democratic party State House leadership (R=0.22) and Democratic voting proportion in the 2016 presidential election (R=0.21); all other correlations had an absolute value of R<0.2 (Figure 4). No correlations greater than 0.2 were observed between county political parties and the dates at which a positive intervention was initially made for a particular NPI policy.

Figure 4. Weak correlation between county policies and county political parties. Correlogram of county-level nonpharmacologic interventions (NPIs) and political election patterns for state and national government for the all policies data set. A positive correlation shown in red indicates a positive correlation between a Republican-oriented election pattern and an NPI.



Discussion

Principal Results

The most effective measures for countries around the world preventing COVID-19 have been NPIs [1-4]. However, due to policy variations across levels of government, the United States has not demonstrated the same success with NPIs [8]. While some research has been published looking at small collections of neighboring counties, there has not been a comprehensive analysis of NPIs across a wider range of counties or any local level more granular than the state level in the United States [14]. In this study, we identify associations between county level NPI policies and COVID-19 transmission from March 1 to July 20, 2020, using a novel crowdsourced county NPI policy data set.

The first objective of this project was to construct a comprehensive data set that has a broad representation of different NPI policies; has a diverse representation of counties both in geographic distribution and population; and incorporates changes in NPIs over time. Overall, this study rendered a highly granular NPI policy data set with time-series data for 1320 counties from all 50 states in the United States. While there have been comprehensive data sets reviewing NPI policies at the state level [10,11] and some data generated for small clusters of neighboring counties (<100 counties) [14], this novel data set is the most comprehensive publicly available county data set to date. We have openly shared this data set with the aim that it be used by researchers around the United States and the world to further analyze the correlates of NPIs and various COVID-19 epidemiological outcomes. Future research could include a finer-grained analysis and modeling of the relationships between COVID-19 cases, deaths, and NPI policies, as well as the explorations of the relationship between NPIs and outcomes including economic status, health care utilization, and social inequities.

The second objective of this project was to analyze this data set and report preliminary findings. We found that across the United States, there was significant variability in NPI policy implementation among counties, both within and among states. NPI policies themselves for any given county are largely uncorrelated, with the singular exception of workplace closure and shelter-in-place NPIs. This finding supports previous research that has also found wide variation in policies across states, which was associated with statistically significant differences in rates of COVID-19 transmission [13]. While no causal link has been demonstrated, these strong correlations are further supported by international studies that have compared similarly sized territories within countries [2,3].

We also found that there was significant variation in NPI policies across counties within states. We displayed 10 representative California counties as an example, which show the relationship between the rate of COVID-19 cases and timing of when individual California counties closed workplaces, reopened workplaces, and started public testing. These results show that the implementation of NPI policies varied when they were enacted in response to COVID-19 case rates across counties. As a consistent trend, we observed that for both heavily populated urban counties like Los Angeles County (10 million residents) and sparsely populated rural counties like Siskiyou County (44,000 residents), the end of a workplace closure appears to precede an increase in cases by 2-6 weeks. This heatmap timeline could be confounded by when public testing started in each county and the rate at which counties were able to test. While we have recorded the date at which public testing became available in each county, as displayed in Figure 2, the rate of testing by county remains generally unknown.

The final and most notable finding of this analysis is that there are statistically significant positive correlations between county workplace closures and decreases in subsequent COVID-19 case growth, as shown in Figure 3. We found that across all counties, those with work closures had significantly lower rates of subsequent COVID-19 case growth compared to counties that did not. We emphasize that these results do not in any way demonstrate causation but rather a temporally informative correlation between NPI policy and COVID-19 rates. Nevertheless, these findings align with others highlighting the relationship between increased NPI policies and subsequently declining growth rates of COVID-19 at the county level [14]. Our Hikma Health data set also has the potential to be used in further temporal modeling, particularly to predict R_t for counties across the United States. Our data set particularly lends itself to a clustering analysis to assess the relationship between NPI policies and cases in demographically similar counties, which will be helpful to local policymakers.

Current research on political affiliation and attitudes toward COVID-19 policies has shown that differences between Democrats and Republicans are more significant than differences across race or gender [16]. Reports from the Pew Research Center have shown that Democrats are more likely to see COVID-19 as a serious threat [17]. In order to understand the political landscape in which these policies are being implemented, we analyzed both the political parties in charge of counties and the political electorate in each county. As shown in Figure 4, we found a relatively weak correlation between Democratic county governments and electorates and shelter-in-place policy enforcement (no significant correlations). However, our finding of relatively limited differences by political party is consistent with a generally high public support across the political spectrum for NPI policies to reduce COVID-19 spread [18]. These preliminary results should be further analyzed to understand the relationship between political party and NPI policy choices.

Limitations

There are a number of important limitations to note about our study. Firstly, our data collection, while rigorous, is affected by a number of factors both inherent to the study and external that could skew outcomes. Even though data collectors were well trained and used standardized methods, the estimated date of policy changes could be highly variable, particularly for counties with limited or conflicting information available online. Thus, an important next step will be to fully validate this Hikma Health data set by double coding all 1320 counties and subsequent reconciliation of discordant datapoints. In addition, external and contemporaneous factors such as rates of testing and the degree to which the public actually adhere to NPI guidelines are not addressed by our binarized data set. In subsequent analyses to address these factors, we aim to integrate testing rates and mobility data as these data sets become available.

Secondly, the Hikma Health data set comprises 2 timepoints for 2 of the 7 NPI policies originally assessed. The analyses presented in Figures 2 and 3 are subject to the caveat that changes in the other 5 unrecorded NPI policies may theoretically confound any associations. Of these NPI policies, enforcement of shelter-in-place/stay-at-home orders, school closures, and publicly available testing were unlikely to change before August 2020, whereas size restrictions on public gatherings and public transit closures may have been reversed and therefore might be more significant confounds.

Finally, our analysis identifies correlations in the data set without any implication of causality. In order to establish causation, NPI policies would have to be implemented as a coordinated randomized controlled trial across counties, which is unlikely. In lieu of such a study, our group and others will build temporal predictive models using this data set to test the potential effects of NPI policies.

Despite these limitations, our study is the first to identify correlations between county-level NPI policies and subsequent COVID-19 growth rates across the United States, including over 1000 counties from all 50 states. Our novel data set enabled us to consistently describe correlations for counties across the United States, compared to previous studies conducted on a more limited and thus less representative scale [13,14]. Our data collection methodology allowed for the evaluation and validation of data across geography and time. As the pandemic continues, future research should continue to investigate the relationship between NPI policies, COVID-19 case rates, and the factors that may influence implementation such as political affiliation, culture, and social structures.

Conclusion

As COVID-19 cases continue to climb across the United States, we anticipate that local leadership at the state and county levels will need to devise informed and relevant policies to limit local spread. Our findings suggest that there is substantial variation in NPI implementation and termination at the county level, both between and within states, reflecting an inconsistent policy approach. We also found positive correlations between implementing a workplace closure NPI and lower future rates of COVID-19, supporting previous national and international studies suggesting that NPI policies like workplace closure reduce COVID-19 transmission [1-4,13,14]. Taken together, this growing body of literature suggests that NPI policies at multiple levels, and especially at the local level of the county, play a role in limiting the effects of the COVID-19 pandemic.

Abstract

Background: COVID-19 has spread like wildfire across the globe, prompting many governments to impose unprecedented stay-at-home orders to limit its transmission. During an extended stay-at-home period, individuals may engage in more online leisure activities. Internet use is a double-edged sword that may have both desirable and undesirable effects on psychological well-being, and this study sought to disentangle adaptive from maladaptive internet use amidst this unusual health crisis.

Objective: The objectives of this study were to assess the prevalence of probable depression during the COVID-19 stay-at-home period and to test three hypothesized risk reduction or risk elevation mechanisms, namely social capital–accrual, escape-from-self, and time-displacement effects.

Methods: This study took place from March to May 2020 at the early stage of the pandemic. The study adopted a prospective design, with an online survey administered to 573 UK and 474 US adult residents at two assessment points 2 months apart.

Results: The prevalence of moderate to severe depression was 36% (bootstrap bias-corrected and accelerated [BCa] 95% CI 33%-39%) at Time 1 (ie, initial time point) and 27% (bootstrap BCa 95% CI 25%-30%) at Time 2 (ie, follow-up time point). The results supported the social capital–accrual hypothesis by showing that the approach coping style was inversely associated with Time 2 depression through its positive associations with both social networking and perceived family support. The results also supported the escape-from-self hypothesis by revealing that the avoidant coping style was positively associated with Time 2 depression through its positive associations with both gaming and cyberbullying victimization, but the serial mediation model was no longer significant after Time 1 depression and some demographic risk factors had been controlled for. Finally, the results supported the time-displacement hypothesis by showing that gaming was positively associated with Time 2 depression through its inverse associations with social networking and perceived family support.

Conclusions: During the extended stay-at-home period in the early stages of the COVID-19 pandemic, the prevalence of probable depression during the 2-month study period was high among the UK and US residents. Individuals with distinct coping styles may engage in different types of online leisure activities and perceive varying levels of social support, which are associated with risks of probable depression.

Introduction

Background Context

COVID-19 is an infectious disease caused by a novel strain of coronavirus known as SARS-CoV-2, which is deadly and highly transmissible [1,2]. Since the World Health Organization (WHO) reported the initial batch of confirmed COVID-19 cases on January 11, 2020, the disease has affected more than 68 million people and caused more than 1.6 million deaths in 191 countries and regions, globally, as of December 9, 2020 [3].

In response to the massive threat posed by COVID-19, numerous governments around the world have imposed a series of community-control measures in an attempt to curb its rapid transmission. For instance, the UK government implemented self-quarantine orders and school closures in March 2020 that lasted for around two months. During the same period, the majority of US states imposed similar stay-at-home orders. The residents of both countries were urged to avoid social gatherings and to stay at home, although they were allowed to go out for essential errands, such as buying groceries and attending medical appointments [4]. A US household survey revealed that the prevalence of probable depression during the early stage of the pandemic was 3 times higher than the prepandemic rate [5]. Systematic and meta-analytic reviews similarly showed that probable depression was prevalent (overall effect size of 34%, 95% CI 28%-41%) across the globe during the early stage of the pandemic [6,7] and that such alarming rates were 3-fold higher than the lifetime prevalence of depression from 1994 to 2014 (11%) [8]. Besides, sleep disturbance was also prevalent among the general public during the pandemic [9,10]. Apart from demographic factors such as gender and age, it is noteworthy that frequent social networking site (SNS) use was identified as a risk factor that heightened mental health problems [6,10].

Internet Use and Mental Health Issues

This study examined major online leisure activities that people engaged in during the stay-at-home period and, more importantly, the problems related to such activities. With rapid advances in information and communication technology and the emergence of affordable mobile devices (eg, smartphones and tablets), people are increasingly reliant on the internet for social networking, entertainment, information, and online purchases. Among the array of online leisure activities, social networking is the most popular, as reflected in the escalation of the number of SNS users over the past two decades [11]. Facebook, the most widely used SNS, has more than 2.7 billion active users worldwide as of August 2020 [12]. Another highly popular online leisure activity is gaming; there were more than 2.3 billion active video gamers all around the world in 2019 [13].

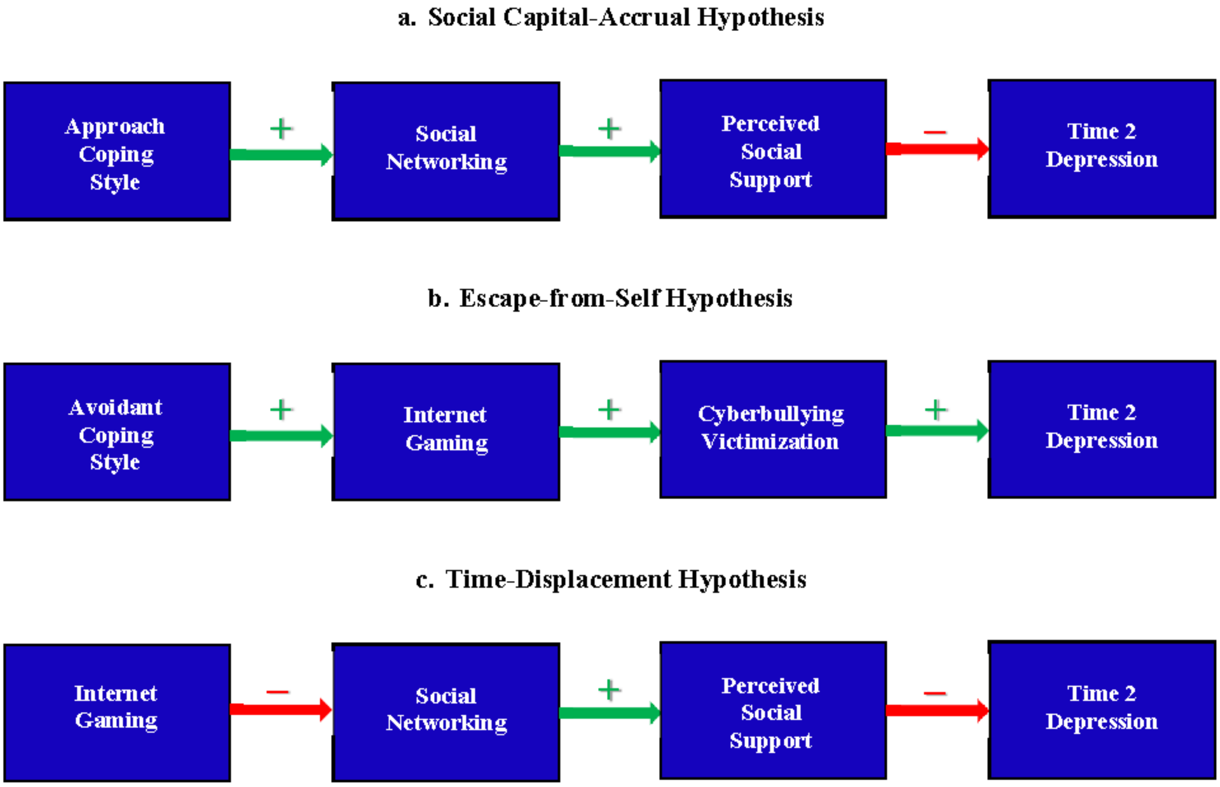
The use of the internet can be beneficial, allowing connections with other people without geographical or time constraints [14]. Support from social network members rendered online has been reported to alleviate depressive symptoms [15,16]. However, certain problems brought about by internet use also merit attention [17]. For instance, internet use may increase the likelihood of cybervictimization, such as impersonation and social exclusion, which in turn increases the risk of depression [18,19]. Moreover, excessive engagement in online games may disrupt daily functioning [20,21]. Internet use is, thus, a double-edged sword that can enhance and compromise mental health.

Risk Reduction and Elevation Mechanisms Underlying Internet Use

This study aimed at unveiling both risk reduction and risk elevation mechanisms underlying leisure-time internet use and depression during the COVID-19 pandemic. Figure 1 depicts the conceptual models that illustrate three hypothesized mechanisms. According to the conservation of resources theory [22,23], individuals strive to obtain and retain resources that facilitate goal attainment, and they feel distressed when such resources are lost or unavailable after making significant effort. Since the onset of the ongoing pandemic, the social resources of many people had been severely depleted while the stay-at-home orders were in place. As face-to-face interactions were not feasible, people attempted to regain their reduced social resources through the internet. SNS has emerged as a popular venue for rendering and gaining social support in the cyber era [15,24], and users' social support and subjective well-being were found to be increased after social networking [25,26].

A meta-analysis revealed considerable individual differences in the beneficial role of social networking in facilitating the accrual of online social capital [27]. Specifically, the meta-analytic findings showed that individuals who are motivated to use SNS to maintain contacts with members of their existing social networks tend to accrue more social capital that mitigates depressive symptoms. In a stressful encounter, an individual's coping style plays a pivotal role in influencing the display of cognitive and behavioral responses, which, in turn, have mental health implications [28,29]. In the coping literature, a broad conceptualization has been widely adopted to dichotomize these psychological responses into two general coping styles: approach versus avoidant [29,30]. Approach coping refers to a tendency to undertake direct actions as an attempt to confront or change a stressful event, whereas avoidant coping refers to a tendency to retreat or divert attention away from a stressful event [31,32]. As individuals characterized by an approach coping style tend to face the stressful encounter and take proactive actions to tackle problems [33,34], we predict that these individuals may actively utilize SNS to accrue more support from members of their social network and may, thus, be less vulnerable to depression (see Figure 1a).

Figure 1. Conceptual models summarizing three hypotheses tested in this study. Time 2 is the follow-up time point.



The meta-analytic findings further revealed that such mental health benefits, however, were absent among those who were motivated to use the internet as a refuge to avoid facing problems in the real world. According to the escaping-the-self theory [35], individuals tend to feel distressed when they realize that real-life outcomes are falling short of their expectations; they are motivated to evade such psychological discomfort by engaging in avoidant behaviors to divert their attention from existing problems. Their avoidant responses may elicit greater distress in the long run because the real-life problems remain intact [36,37]. Previous studies have consistently shown escapism as a major motivation of gaming that elicits adverse outcomes, such as cyberbullying victimization [38]. In the digital age, cyberbullying victimization is prevalent [39,40], and frequent such experiences enhance mental health risks [41,42]. In light of these theories and findings, we predict that individuals characterized by an avoidant coping style will tend to rely on gaming in an attempt to handle stress; however, their gaming behavior may increase their exposure to cyberbullying victimization, which may, in turn, enhance their susceptibility to depression (see Figure 1b).

It is noteworthy that investing more leisure time in gaming may reduce time spent social networking and, thus, the opportunities of reaping support from social network members. This notion stems from displacement theory [43], whose underlying assumption is that the total time spent on daily activities is constant. Hence, spending more time on a particular online activity results in less time on another. In light of the time-displacement theory, we predict that more time spent on gaming may be associated with less time spent on social networking and lower levels of social support, thus enhancing the risk of depression (see Figure 1c).

Study Setting and Aims

This study was conducted at an early stage of the COVID-19 pandemic, when stay-at-home orders were in effect in many countries, including the United Kingdom and the United States. The study aimed at assessing the prevalence of probable depression and testing three hypothesized mechanisms that would reduce or enhance risks of depression: social capital–accrual, escape-from-self, and time-displacement effects (see Figure 1).

Methods

Study Design and Settings

A prospective design with a quantitative approach was adopted in this study, which comprised two assessment points. Initial (Time 1) data collection took place from March 16 to 22, 2020, the week after the WHO declared the COVID-19 outbreak a global pandemic and stay-at-home orders were first implemented in various countries. Follow-up (Time 2) data collection then took place from May 18 to 24, 2020, during which stay-at-home orders were gradually lifted in some regions of the United Kingdom and the United States.

Study Sample and Eligibility Criteria

The participants were recruited through Prolific [44], a crowdsourcing platform for participant recruitment. Studies have shown that data generated via the crowdsourcing method were as reliable and valid as those obtained by offline methods, with participants reporting that they felt more comfortable sharing their personal data in crowdsourcing research than with other types of research [45,46]. Prolific was chosen because its participants were reported to have the most diverse demographic characteristics and to generate the highest data quality among popular crowdsourcing platforms [47,48].

Eligible participants were adults between the ages of 18 and 65 years who were living in the United Kingdom or the United States at the time of the study. Participants from other countries, those who did not take part in the follow-up assessment, and those who did not give informed consent were excluded. Data were collected from 1086 eligible participants, but 16 of them did not submit the survey, while 23 were timed out before they completed or submitted the survey (completion rate 96.4%). The final sample contained 1047 community adults.

Measures

Overview

The online survey contained a set of validated measures, all of which were chosen because they were short and designed for use in surveys administered in general populations. All of the measures were administered at Time 1; the measure assessing depression was administered at both time points. The measures were arranged in a randomized order to counterbalance potential order effects. Participants were prompted if there were missing responses.

Coping Style

Both approach and avoidant coping styles were measured by the Coping Strategies Inventory–Short Form [49]. Each of the coping subscales included four items, each of which was rated on a 5-point scale, ranging from 1 (*never*) to 5 (*almost always*). A higher composite score (Cronbach α=.79 for the approach coping style subscale and .89 for the avoidant coping style subscale) indicates the endorsement of a particular coping style.

Cyberbullying Victimization

Cyberbullying victimization was assessed by the cybervictimization subscale of the Cyber-Aggression and Cyber-Victimization Scale [50]. The subscale contained eight items, each of which was rated on a 5-point scale, ranging from 1 (*never*) to 5 (*very often*). A composite score (Cronbach α=.88 in this sample) was derived by aggregating the scores for all items, with a higher score representing a greater degree of cyberbullying victimization.

Perceived Social Support

Perceived family support and friend support were measured by the family and friend subscales of the Multidimensional Scale of Perceived Social Support [51]. Each subscale had four items, each of which was rated on a 7-point scale, ranging from 1 (*very strongly disagree*) to 7 (*very strongly agree*). A subscale score (Cronbach α=.94 for the family subscale and .95 for the friend subscale) was derived from the sum of all item scores, with a higher score representing the subjective appraisals of greater perceived support from a particular social group.

Depression

Each participant's level of depression was assessed by the Center for Epidemiological Studies–Depression Scale [52]. This depression scale comprised 20 items, each of which was rated on a 4-point scale, ranging from 0 (*rarely or none of the time*) to 3 (*all of the time*). A total depressive symptom score (Cronbach α=.84 and .80 at Time 1 and Time 2, respectively) was computed by summing all of the item scores, with a higher score representing a greater frequency and severity of depression. The conventional cutoff scores were 16 and over for mild depression and 23 and over for moderate to severe depression [52].

Time Allocated to Social Networking and Internet Gaming During the COVID-19 Pandemic

The participants reported the amount of leisure time (hours) they had dedicated on a typical day within the past week to two highly popular internet activities: social networking and gaming. Both of these items were found valid for assessing these online leisure activities [53,54].

Demographic Variables

At the end of the survey, the participants were asked to provide the following demographic information: age, sex, educational qualifications (ie, undergraduate degree holder or not), employment status (ie, employed, no need to work [ie, student, homemaker, or retired], or unemployed), marital status (ie, married or partnered or not), and ethnicity (ie, White or non-White). For conducting statistical analyses, the three-level employment status was recoded as a pair of dummy variables: employed (ie, 1=employed, 0=no need to work, 0=unemployed) and unemployed (ie, 0=employed, 0=no need to work, 1=unemployed). Age was recorded as a continuous variable, whereas all of the other demographic variables were dummy coded.

Study Procedures

Survey invitations were sent by Prolific to its members who met the demographic criteria. The survey was distributed through the Qualtrics survey system. Participation was entirely voluntary. Potential participants were told the survey aim and length, payment rate for completion (ie, £7.80 [US $10.50] per hour), and the ethical approval number and agent. They were also assured that all data collected would be anonymous and kept in strict confidentiality in the investigators' laboratory. All of the participants were requested to give informed consent prior to their participation at both time points, and were paid upon the completion of each survey. The data collected at the two time points were matched according to a unique code assigned to each participant by the survey platform.

Strategy of Analysis

All statistical analyses were performed with SPSS, version 26 (IBM Corp). Independent-samples *t* tests were conducted to examine whether there were any between-country differences (ie, United Kingdom vs United States) in the study variable. To test the three hypothesized mechanisms underlying the experience of Time 2 depression during the early stage of the COVID-19 pandemic, serial mediation analysis was performed using Model 6 of the SPSS macro PROCESS, version 3.5 [55], which used ordinary least squares procedures to estimate the hypothesized effects. Three sets of analyses were performed. First, initial tests for all three hypothesized serial mediation effects were conducted without any covariates. Second, the hypothesized effects were then tested with Time 1 depression as a covariate in order to capture temporal changes in depression level. Third, both Time 1 depression and relevant demographic variables were included as covariates to rule out any additional confounding factors. Recent reviews on depression assessed during the COVID-19 pandemic revealed some demographic characteristics (ie, age, gender, country, and finance-related factors) as risk factors that enhanced susceptibility to depression [5,6]. In addition, marital status was identified to be crucial for social connectedness [56]. Taken together, the following demographic risk factors were included as covariates in the third set of model testing: age; gender; country; employment status, which was represented by a pair of dummy variables (ie, employed or unemployed); and marital status.

In all of the mediation analyses, the scores on the predictor variables were centered to reduce multicollinearity [57]. Bootstrapping was conducted with 10,000 iterations (2-tailed significance), with the bootstrap bias-corrected and accelerated (BCa) interval employed to estimate the CIs. The hypothesized effects were deemed statistically significant if zero was excluded in the bootstrapped CIs.

Ethical Considerations

The research protocol was reviewed and approved by the human research ethics committee of the University of Hong Kong (approval No. EA2002033) prior to Time 1 data collection. All study procedures were carried out in accordance with the ethical rules of the Declaration of Helsinki of 1975, as revised in 2008.

Results

Sample Characteristics

The sample from this study consisted of 1047 adults residing in the United Kingdom and the United States at the time of the study. Participants from the two countries did not differ significantly in terms of the study variables (*P* values were above .14), except for Time 1 depression (t_{1043}=11.91, *P*<.001). The UK participants (mean score 22.32, SD 13.24) reported higher levels of depression at Time 1 than their US counterparts (mean score 18.11, SD 11.08). The two groups were pooled to enhance statistical power, but the demographic variable of country was included as a covariate in model testing.

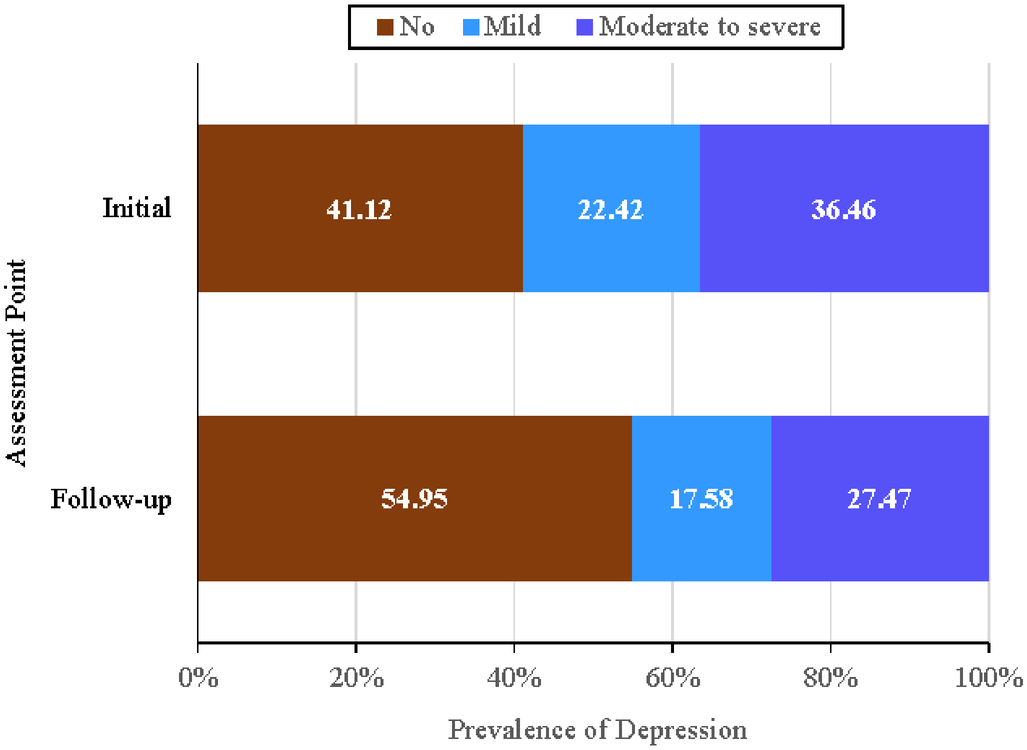
The pooled sample of 1047 participants comprised 481 men (45.9%) and 563 women (53.8%), as well as 3 participants (0.3%) who did not indicate their sex. The average age was 44.10 years (SD 12.59). Slightly more than half of the participants were undergraduate degree holders or above (596/1044, 57.1%) and were married or partnered (569/1036, 54.9%). Most participants were ethnically White (887/1041, 85.2%).

On average, the participants spent 1.35 hours (bootstrap BCa 95% CI 1.28-1.42) on social networking and 1.70 hours (bootstrap BCa 95% CI 1.59-1.81) on gaming.

Prevalence of Probable Depression at the Early Stage of the COVID-19 Pandemic

The average depression scores at the initial and follow-up time points were 20.41 (bootstrap BCa 95% CI 19.60-21.12) and 16.74 (bootstrap BCa 95% CI 16.06-17.42), respectively. Figure 2 illustrates the proportion of participants categorized as having no, mild, and moderate to severe depression. According to the standard cutoff scheme, the prevalence of moderate to severe depression was quite high: 36% (bootstrap BCa 95% CI 33%-39%) at Time 1 and 27% (bootstrap BCa 95% CI 25%-30%) at Time 2.

Figure 2. Prevalence of depression at the initial (March 16-22, 2020) and follow-up (May 18-24, 2020) assessment points during the COVID-19 pandemic.



Mediation Analyses Unveiling Risk Reduction and Elevation Mechanisms

The results of serial mediation analysis for testing the various hypotheses are summarized in Table 1. The various serial mediation models were first tested without any covariates entered (see the upper panel of Table 1). Consistent with the social capital–accrual hypothesis, the results showed that the indirect effects of the approach coping style on Time 2 depression via social networking and perceived social support—both family and peer support—were significant. In line with the escape-from-self hypothesis, the indirect effect of the avoidant coping style on Time 2 depression via gaming and cyberbullying was significant. Consistent with the time-displacement hypothesis, the indirect effects of gaming on Time 2 depression via social networking and perceived social support—both family and peer support—were significant.

A highly similar pattern of findings was obtained after controlling for Time 1 depression (see the middle panel of Table 1), except for the set of findings for testing the escape-from-self hypothesis. Specifically, this particular serial mediation model was no longer significant. We then performed post hoc tests for simple mediation effects (ie, PROCESS Model 4), and gaming was found to mediate the positive association between the avoidant coping style and Time 2 depression after the baseline depression level had been controlled for.

In the final set of models, Time 1 depression and some demographic risk factors of depression were included as covariates (see the lower panel of Table 1). Similar to the previous set of analyses, only the simple mediation effect of gaming between the avoidant coping style and Time 2 depression was significant. In addition, the two serial mediation effects with perceived peer support as a mediator became nonsignificant when the cluster of demographic risk factors had been entered. In summary, this final set of analyses showed strong support for both social capital–accrual and time-displacement hypotheses when perceived family support was a mediator.

Table 1. Summary of model testing for three hypotheses (N=1047).

[a] Bias-corrected and accelerated (BCa) bootstrapped CIs, computed based on 10,000 bootstrap samples, were employed to interpret the significance of results for indirect effects instead of inferential tests [55].

[b] H1: social capital–accrual hypothesis, with either perceived family support (a) or perceived peer support (b).

[c] APC: approach coping style.

[d] SNW: social networking.

[e] PFS: perceived family support.

[f] PPS: perceived peer support.

[g] H2: escape-from-self hypothesis.

[h] AVC: avoidant coping style.

[i] CBV: cyberbullying victimization.

[j] H3: time-displacement hypothesis, with either perceived family support (a) or perceived peer support (b).

[k] This model resulted in nonsignificant findings.

[l] Demographic risk factor covariates include gender, age, country, employment status (ie, employed or unemployed), and marital status.

Discussion

Principal Findings

This study was conducted at a time when stay-at-home orders were in effect during the early stage of the COVID-19 pandemic. The findings indicate a high prevalence of probable depression immediately after the WHO's designation of the novel disease as a global pandemic. Specifically, more than one-third of our participants reported moderate to severe depression in the initial assessment period. Although the prevalence rate was lower at the second assessment that took place 2 months later, it remained at a relatively high level, with around one-quarter of the sample reporting moderate to severe depression at the follow-up period. These findings indicate that it was quite common for UK and US residents to experience some forms of depression when self-quarantining in their respective countries. The prevalence of probable depression obtained at both time points was about 3 times higher than the prepandemic prevalence [5]. Similarly, the prevalence of probable depression obtained at the initial time point was 3 times higher, and that obtained at the follow-up time point was about 2.5 times higher, than the lifetime prevalence of depression from 1994 to 2014 reported in a review [8].

Consistent with the social capital–accrual hypothesis, the findings show that individuals who report higher levels of approach coping tend to spend more leisure time on social networking and perceive a higher level of family support, which is related to lower subsequent levels of depression during the extended stay-at-home period. In contrast, individuals who report higher levels of avoidant coping tend to spend more time gaming, which is related to higher subsequent levels of depression. In line with the time-displacement hypothesis, gaming time is inversely associated with both social networking time and perceived family support, which is inversely associated with subsequent levels of depression.

Recommendations

These findings highlight the mental health implications of leisure-time internet use during the extended stay-at-home period at the early stage of the COVID-19 pandemic. Clinicians should be aware of individual differences in coping styles and assess whether the amount and type of internet use may increase or decrease risk for depression. Online professional support may be helpful to maintain psychological well-being if support from one's social network is unavailable or perceived to be scant during social isolation. If in-person appointments for mental health services cannot be made, the use of telemedicine can bridge this gap by strengthening adaptive coping with various types of stressors during the pandemic [58]. Further, the general public may benefit from increased awareness about mental health issues during the extended stay-at-home period and acquire practical strategies to reduce risk of depression, such as limiting sources of stress, social support seeking, and maintaining a regular routine [59].

As excessive leisure-time internet use, especially for gaming, can heighten risks of depression, clinicians are advised to expend more effort probing into the amount of leisure time their clients spend on the internet as part of a comprehensive mental health assessment, as well as to evaluate their clients' engagement in specific leisure activities (eg, social networking and gaming) that are likely to enhance or mitigate depression risk [60]. For instance, limiting the amount of time devoted to unconfirmed or questionable sources of COVID-19–related information, as well as maintaining a routine that does not involve excessive internet use, could reduce depressive symptoms [59].

The identification of mechanistic pathways leading to psychological issues during the pandemic has been proposed as a research priority owing to its relevance to refining interventions [61]. This study indicates that depression experienced during the extended stay-at-home period is a function of three crucial factors: coping style, the type of leisure-time internet use, and the type of social support. The three pathways identified in our study have practical implications. Firstly, the social capital–accrual pathway highlights the importance of the approach coping style and social networking in an attempt to elicit greater social support from family members. Secondly, the escape-from-self pathway specifies the maladaptive role of the avoidant coping style and gaming. Finally, the time-displacement pathway indicates that more time spent on gaming may reduce time spent on social networking and perceptions of family support. Clinicians who deliver psychological interventions to clients who lack family support should evaluate their clients' patterns of leisure-time internet use as a potential contributor to depression.

Study Limitations and Future Research Directions

Prior to concluding, several study limitations and directions for future research should be noted. First, the participants in this study were residents of the United Kingdom or the United States, both with some of the highest internet penetration rates in the world [62]. Accordingly, our findings may not be applicable to other COVID-19 hard-hit countries, particularly those with low internet penetration rates. Moreover, the participants were all residents of individualist countries, whose cultural values differ considerably from those shared by members of collectivist countries, such as Brazil and India [63-65]. Studies have shown considerable cultural differences in the motivation of social networking [66] and in the prevalence of internet addiction and internet gaming disorder [67,68]. Although the prevalence rates of probable depression of our two samples were comparable to those reported in a systematic review during the COVID-19 pandemic in eight countries across four continents [6], future studies should expand the scope of our research by recruiting participants from an array of countries with varying levels of internet penetration and cultural values to allow for more extensive multinational and cross-cultural comparisons.

Second, the prospective study was conducted during an early stage of the COVID-19 pandemic when unprecedented stay-at-home orders were in place. It is noteworthy that the findings reflect the participants' initial psychological responses to the pandemic and may, thus, not be generalizable to other waves of the pandemic or to the postpandemic period. Previous studies have shown social isolation for extended periods to have long-term undesirable psychological impacts [69,70], and mental health issues fluctuated drastically across various waves of a disease outbreak [71]. Follow-up studies with a longer time horizon should be conducted to examine the potential chronic impact once the current drastic control measures have been lifted.

Finally, our study focused on the two most popular online leisure activities, namely social networking and gaming, because validated measures are only available for assessing time spent on these two types of activities. Nowadays, individuals also browse the internet for other purposes (eg, watching videos and movies and shopping), and it is worthwhile to expand the scope of internet use if validated measures are available for tapping these activities as well. As interpersonal interactions are minimal in many of these alternative activities, the pattern of findings may differ from those yielded in this study. Also, studies have demonstrated that interpersonal behaviors tend to differ among players of distinct game genres (eg, single-player vs multiplayer and cooperative vs competitive gamers) [72-75], and the pattern of findings may vary according to the type of games played on a regular basis. Future research may benefit from a nuanced analysis that takes the game genre and type of internet activity into consideration to enhance explanatory and predictive utility.

Conclusions

During the extended stay-at-home period mandated to deal with COVID-19 transmission, depression was found to be prevalent. The findings reported herein indicate that leisure-time internet use can reduce or increase risks of depression, depending largely on the coping style of the users. As increasing numbers of people worldwide are being required to stay at home, additional studies should be conducted to obtain a more nuanced picture of the impacts of coping style, engagement in online leisure activities, and family dynamics on mental health.

Abstract

Background: The COVID-19 pandemic has negatively affected the mental health of university students.

Objective: This study examined the psychological responses toward COVID-19 among university students from 3 countries—Indonesia, Taiwan, and Thailand.

Methods: We used a web-based, cross-sectional survey to recruit 1985 university students from 5 public universities (2 in Indonesia, 1 in Thailand, and 1 in Taiwan) via popular social media platforms such as Facebook, LINE, WhatsApp, and broadcast. All students (n=938 in Indonesia, n=734 in Thailand, and n=313 in Taiwan) answered questions concerning their anxiety, suicidal thoughts (or sadness), confidence in pandemic control, risk perception of susceptibility to infection, perceived support, resources for fighting infection, and sources of information in the context of the COVID-19 pandemic.

Results: Among the 3 student groups, Thai students had the highest levels of anxiety but the lowest levels of confidence in pandemic control and available resources for fighting COVID-19. Factors associated with higher anxiety differed across countries. Less perceived satisfactory support was associated with more suicidal thoughts among Indonesian students. On the other hand, Taiwanese students were more negatively affected by information gathered from the internet and from medical staff than were Indonesian or Thai students.

Conclusions: Our findings suggest that health care providers in Thailand may need to pay special attention to Thai university students given that high levels of anxiety were observed in this study population. In addition, health care providers should establish a good support system for university students, as the results of this study indicate a negative association between support and suicidal thoughts.

KEYWORDS
anxiety; COVID-19; cross-country; suicidal thoughts; university students

Introduction

The COVID-19 outbreak was declared as a pandemic on March 11, 2020, by the World Health Organization [1]. It has affected over 100 countries worldwide, including many countries in the Asia-Pacific region. As of October 20, 2020, nearly 40 million confirmed cases of COVID-19 were reported globally, with over 9 million cases reported in the Asia-Pacific region [1]. In Indonesia, Thailand, and Taiwan, in particular, the total number of confirmed COVID-19 cases was over 137,000; 3300; and 480, respectively, as of August 16, 2020 [1-3].

With increasing numbers of COVID-19 infections and associated deaths, psychological responses toward COVID-19 have become an important topic for health care providers [4,5]. Indeed, studies on different populations (including pregnant women and their husbands, general population, and children) have reported increased psychological problems during the COVID-19 pandemic [6-8]. Moreover, instruments assessing psychological responses specifically designed in relation to COVID-19 have been developed and validated [9-14]. Therefore, the importance of assessing psychological responses toward COVID-19 and their associated factors has been highlighted in the extant literature. More specifically, adverse effects of elevated psychological distress may trigger reassurance-seeking and compulsive-checking behaviors in response to potential threats of COVID-19 infection, which, in turn, may have an impact on the daily lives of individuals who impede preventive behaviors [15,16].

Although university students worldwide are affected by the COVID-19 pandemic, their psychological responses may be different because of cultural differences and varying levels of the COVID-19 crisis across countries. For example, Taiwan undertook early action to prevent COVID-19 transmission and maintained an almost normal living state without having to implement a national lockdown [10,15,17]. Such a situation may have mitigated negative psychological responses among Taiwanese university students. On the other hand, COVID-19–related fatality rate in Indonesia was found to be relatively high (8.9%), and it may have more negatively affected university students than other countries [18].

This study examined university students' psychological responses toward COVID-19 for the following reasons. First, the COVID-19 pandemic has become a major life stressor that has direct and indirect influences on students' psychological well-being. The direct influences include the students' emotional feelings toward COVID-19 (eg, fear of being infected) [19-21], and the indirect influences include the government's reaction in relation to transmission control (eg, feeling depressed when receiving threatening COVID-19 news or feeling lonely because of social distancing) [7]. Second, university students are at a critical life-transition period (ie, school-to-work transition [22]). Most of them are expected to begin their careers after graduation by applying the skills they have learned at the university [23]. However, the COVID-19 pandemic may interfere with their plans and, subsequently, affect their future careers. Therefore, university students need support in maintaining good mental health conditions in order to deal with the COVID-19 pandemic, as well as avoid any negative consequences later in life.

Therefore, in this study, we applied a combination of the health belief model (HBM) [24] and protection motivation theory (PMT) [25], to examine potential independent variables for explaining psychological responses among university students. The HBM posits that perceived susceptibility, perceived severity, and perceived benefits are the major contributors enabling individuals to take specific health behavioral actions. Moreover, the PMT posits that individuals' health-related behaviors are triggered by their psychological distress (eg, anxiety and fear). Therefore, the factors proposed by the HBM are potential independent variables that help explain the psychological responses of individuals. In this study, we assessed the factors proposed by the HBM as follows: perceived susceptibility and perceived severity were assessed using risk perception of susceptibility to COVID-19; perceived benefits were assessed using confidence in pandemic control (ie, controlling the pandemic is a benefit for the individual to fight COVID-19), perceived support (ie, having support is a benefit for the individual to fight COVID-19), and perceived sufficiency of resources (ie, having sufficient resources is a benefit for the individual to fight COVID-19).

In addition to applying the HBM [24] and PMT [25], the existing literature on COVID-19 also suggests that these independent variables could contribute to an individual's psychological responses. For instance, a higher confidence in fighting COVID-19 may be associated with more adaptive psychological responses when dealing with COVID-19 [17,26]. Fear of COVID-19 was found to be lower when the country had better control of COVID-19 cases. As people are known to have fear of COVID-19 [27] and being stigmatized if they are infected [28], they may have more negative psychological responses when they perceive higher risk of having COVID-19. In addition, previous studies have made recommendations to provide sufficient resources such as personal protective equipment (PPE) and support to assist individuals in combating psychological problems during the COVID-19 outbreak [29,30].

Apart from the HBM and PMT, the literature proposes the importance of obtaining accurate COVID-19 information from trusted sources. Indeed, misinformation concerning COVID-19 is associated with a greater fear of the disease [15,16]. Hou et al [31] reported that rumors and misinformation shared on the internet may induce panic behaviors such as purchasing herbal remedies via web-based shopping and storing them. Based on the HBM, PMT, and the existing literature, we hypothesized that confidence in COVID-19 pandemic control, risk perception of susceptibility to COVID-19, perceived satisfactory support, perceived sufficiency of resources for fighting COVID-19, and sources of obtaining COVID-19 information are all potential factors that may be associated with psychological responses to COVID-19.

To the best of our knowledge, there have been few cross-country comparisons concerning psychological responses among university students. In order address this gap in the literature, we compared the psychological responses toward COVID-19 and its related factors among university students in 3 different countries—Indonesia, Thailand, and Taiwan. These 3 countries were selected for the comparative study because they are all East Asian countries that share similar cultures and values (ie, Confucianism) [32]. In addition, a previous study on country variations concerning depression symptoms found similar prevalence of low self-confidence in these 3 countries [33]. However, the 3 countries had different outcomes and policies in minimizing the impact of the COVID-19 pandemic. Therefore, it would be useful to apply the same model to 3 countries that have similar cultures and values but had implemented different measures in combating COVID-19.

The primary outcomes of this study were different psychological responses such as anxiety and suicidal thoughts. Moreover, we examined other related factors (ie, confidence in COVID-19 pandemic control, risk perception of susceptibility to COVID-19, perceived satisfactory support, perceived sufficiency of resources for fighting COVID-19, and sources of obtaining COVID-19 information) to understand their associations with psychological responses among different university student groups from different countries.

Methods

Study Design, Participants, and Data Collection

A multicountry, web-based cross-sectional study was conducted in 5 public universities. The sample comprised students in Indonesia (2 universities), Taiwan (1 university), and Thailand (1 university). Participants were recruited through popular social media platforms operational in these countries, including Facebook, LINE, WhatsApp, and Broadcast, from April 10 to June 30, 2020. Only participants aged 20 years and above were eligible for this study. Before beginning the survey, the participants were asked to log in with their personal email addresses in order to avoid having participants repeat the survey more than once.

We obtained approvals from the Research Ethics Committee in each of the 3 countries studied (ie, University of Indonesia [SK-139/UN2.F12.D1.2.1/ETIK 2020] for Indonesia, National Cheng Kung University Hospital [A-EX-109-019] for Taiwan, and Mahidol University [COA No. MU-COVID 2020.006/1205] for Thailand). Thereafter, data collection was initiated. Participation in the survey was voluntary, and survey responses were anonymously collected. Study participants were given no incentive for participation. Participants who agreed to participate in the study completed the web-based survey in their native languages: Bahasa (Indonesian students), Mandarin (Taiwanese students), and Thai (Thai students).

Measures

Outcome Variables: Anxiety and Suicidal Thoughts (or Sadness)

The State-Trait Anxiety Inventory (STAI) was used to assess the anxiety levels of the participants toward the COVID-19 pandemic. The STAI comprises 10 items rated on a 4-point Likert scale ("not at all," "a little," "somewhat," and "very much"). A lower score on the STAI indicates a lower level of anxiety [34]. Suicidal thoughts in the past week were assessed for Taiwanese and Indonesian students on a 5-point Likert scale ("not at all," "mild," "moderate," "severe," and "very severe"). A lower score on this scale indicates a lower level of suicidal ideation. Similarly, sadness experienced in the past week was assessed for Thai students on the same 5-point Likert scale. Although sadness is not a direct concept of suicidal thoughts, it can be viewed as a proxy of suicidal thoughts for Thai students. More specifically, we considered that when a Thai student feels sad for a prolonged period, their physiological and psychological functions will be disturbed and may further lead to depressive symptoms with a high risk of suicidal ideation.

Independent Variables

Confidence in Pandemic Control

Confidence in pandemic control included confidence concerning personal, city, and the university in handling the pandemic situation. This variable was rated on a 5-point Likert scale from 1 ("not confident at all") to 5 ("very confident") [35]. The Cronbach alpha of the 3 items concerning confidence in pandemic control indicated very good internal reliability (Cronbach α=.83).

Risk Perception of Susceptibility to COVID-19

Risk perception of susceptibility to COVID-19 included both absolute susceptibility and relative susceptibility, both of which were rated on a 7-point Likert scale from 1 ("not at all susceptible") to 7 ("very susceptible") [36]. The Cronbach alpha value of the 2 items concerning risk perception of susceptibility to COVID-19 indicated very good internal reliability (Cronbach α=.80).

Perceived Support

Perceived support assesses support received from families, classmates, and faculties. The 3 items were rated on a 5-point Likert scale from 1 ("not satisfied at all") to 5 ("very satisfied") [37]. The Cronbach alpha value of the 3 items concerning perceived support indicated acceptable internal reliability (Cronbach α=.69).

Perceived Sufficiency of Resources for Fighting COVID-19

Perceived sufficiency of resources included perceived sufficiency of PPE, COVID-19 information, money, medical resources, and psychological support. All items were rated on a 3-point Likert scale from 1 ("insufficient") to 3 ("sufficient") [38]. The Cronbach alpha value of the 5 items concerning perceived sufficiency of resources for fight COVID-19 indicated very good internal reliability (Cronbach α=.76).

Sources of COVID-19 Information

Seeking information from various sources included information from the internet, medical staff, and family [39]. All items were rated on a 3-point Likert scale from 1 (“never”) to 3 (“always”).

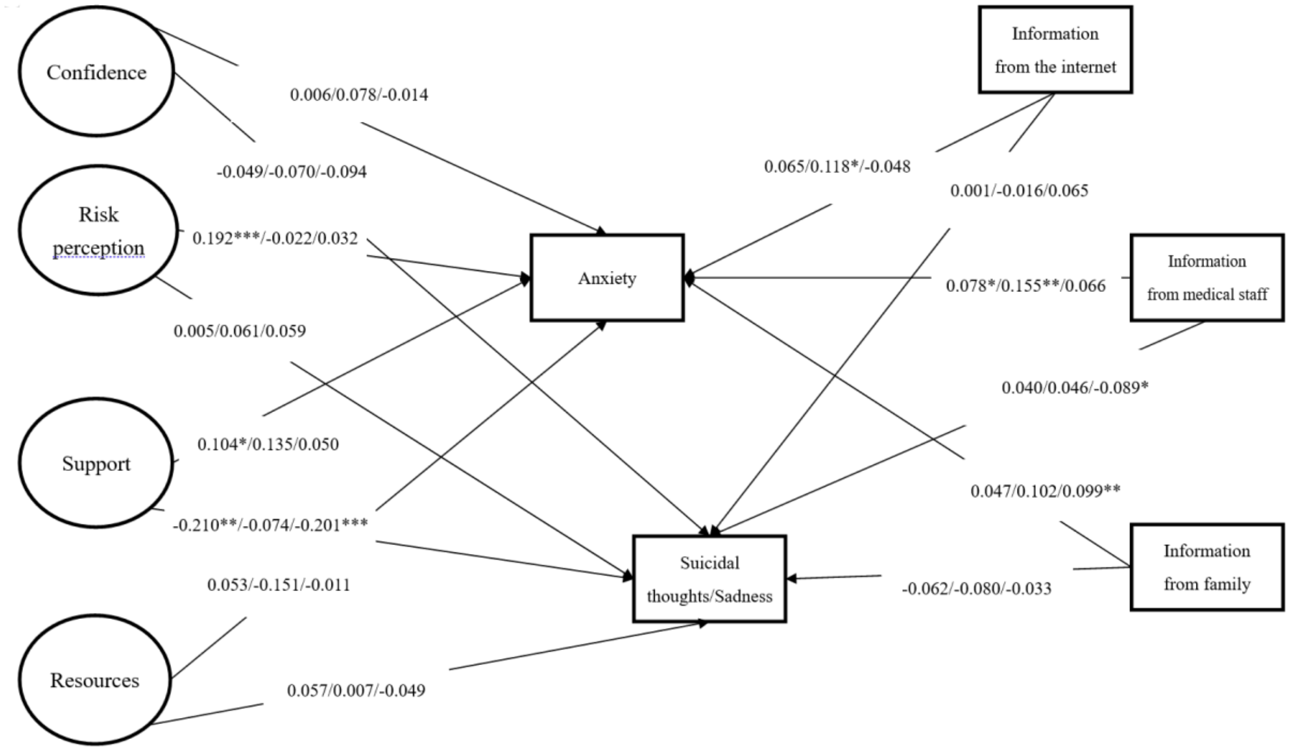
Demographic Information

Sociodemographic data such as gender, age, and education level were collected from the survey responses. Students with a Bachelor’s qualification were classified as undergraduates, and those with a Master’s qualification or above were classified as postgraduates. Students were also asked whether their major subjects of study were health-related or not.

Statistical Analysis

Analyses of variance (ANOVA) and χ^2 tests were used to examine the differences concerning dependent variables, independent variables, and controlled variables. Posthoc comparisons with Bonferroni adjustments were used when an overall statistical significance was observed in ANOVAs or χ^2 tests. Pearson correlations were then used to understand the bivariate correlations between the studied variables for all participants. Multigroup structural equation modeling (SEM) was then applied to examine how the independent variables explained anxiety and suicidal thoughts (for Taiwanese and Indonesian students) or anxiety and sadness (for Thai students; see Figure 1). In the multigroup SEM, confidence in fighting COVID-19, risk perception of susceptibility to COVID-19, perceived satisfactory support, and perceived sufficiency of resources were latent variables, whereas anxiety, suicidal thoughts (or sadness), sources of COVID-19 information (internet, medical staff, and family), and gender were manifest variables. Weighted least squares mean and variance adjusted estimator was used in the multigroup SEM to address the nature of Likert-type scales used in the study measures. Fit indices such as comparative fit index (CFI), Tucker-Lewis index (TLI), root mean square error of approximation (RMSEA), and standardized root mean square residual (SRMR) were used to determine whether the multigroup SEM is supported (CFI and TLI should be 0.9 or above; RMSEA and SRMR should 0.08 or less [40,41]).

Figure 1. Results of the proposed model showing standardized coefficients among Indonesian, Taiwanese, and Thai students. **P*<.05, ***P*<.01, ****P*<.001. Gender was controlled for in the model. Suicidal thoughts were assessed for Taiwanese and Indonesian students; sadness was assessed for Thai students. Confidence was constructed using (1) confidence to deal with the pandemic, (2) confidence of the city to deal with the pandemic, and (3) confidence of students to deal with the pandemic. Risk perception was constructed using (1) perceived absolute susceptibility to COVID-19 and (2) perceived relative susceptibility to COVID-19. Support was constructed using (1) satisfaction with family support, (2) satisfaction with friend support, and (3) satisfaction with university support. Resource was constructed using (1) sufficiency of personal protective equipment, (2) sufficiency of information, (3) sufficiency of money, (4) sufficiency of medical resources, and (5) sufficiency of psychological support. Fit indices: χ2378=1035.12; *P*<.001; comparative fit index=0.92; Tucker-Lewis index=0.90; root mean square error of approximation=0.051 (90% CI 0.048-0.055); standardized root mean square residual index=0.053.



Results

Among the 1985 university students, 938 (47.2%) were Indonesian, 734 (37%) were Thai, and 313 (15.8%) were Taiwanese. Approximately 80% (1588/1985) of all study participants were female, with 82.2% of the participants majoring in medical-related programs (1631/1985) and 80.9% studying at the undergraduate level (1605/1985). The compositions of these aforementioned demographics were significantly different among the 3 groups. More specifically, the Taiwanese student sample comprised more males, the Indonesian student sample comprised more medical students, and the Thai student sample comprised more postgraduates (Table 1).

Table 1. Participant characteristics in different groups (N=1985).

Characteristic	Value			*F* test (*df1*, *df2*)	Chi-square (*df*)	*P* value	Post-hoc comparison
	Indonesian students (n=938)	Taiwanese students (n=313)	Thai students (n=734)				
Gender, male, n (%)	134 (14.3)	117 (37.4)	146 (19.9)	N/A[a]	78.76 (*2*)	<.001	2>3>1
Medical student, yes, n (%)	841 (89.7)	233 (74.4)	557 (75.9)	N/A	565.21 (*2*)	<.001	1>2,3
Postgraduate, yes, n (%)	125 (13.3)	37 (11.8)	218 (29.7)	N/A	92.65 (*2*)	<.001	3>1,2

[a] N/A: not applicable.

[b] Confidence: confidence in pandemic control.

[c] Perceived risk: risk perception of susceptibility to COVID-19.

[d] Support: perceived satisfactory support from family, friends, or university.

[e] Resources: sufficiency of resources.

[f] Internet: COVID-19 information received from the internet.

[g] Medical staff: COVID-19 information received from medical staff.

[h] Family: COVID-19 information received from family.

The differences in independent and outcome variables across the 3 student groups are also shown in Table 1. Our results showed that Thai students had the highest levels of anxiety, the lowest levels of confidence in fighting COVID-19, and the least sufficient resources among the 3 student groups. On the other hand, Indonesian students had the highest levels of risk perception of susceptibility to COVID-19 and perceived satisfactory support from different sources among the 3 student groups. Moreover, compared to the other groups, Thai students received more COVID-19 information from the internet, and

Indonesian students received more information from medical staff and family (Table 1).

Correlations between independent variables, outcome variables, and controlled variables are presented in Table 2. We found that anxiety was significantly associated with confidence in pandemic control (r=−.08; *P*<.001); risk perception of susceptibility to COVID-19 (r=.07; *P*=.003); sufficiency of resources (r=.08; *P*<.001); and receiving information from the internet (r=.10; *P*<.001), medical staff (r=.11; *P*<.001), and family (r=.08; *P*<.001). Suicidal thoughts were significantly associated with confidence in pandemic control (r=-.28; *P*<.001), perceived satisfactory support (r=-.36; *P*<.001), sufficient resources (r=-.21; *P*<.001), and receiving information from the internet (r=.06; *P*=.006) and family (r=-.12; *P*<.001).

Multigroup SEM showed satisfactory fit indices (CFI=0.92; TLI=0.90; RMSEA=0.051; SRMR=0.053). Regarding the path coefficients for Indonesian students, higher risk perception of susceptibility to COVID-19, greater perceived satisfactory support, and receiving more information from medical staff significantly explained higher levels of anxiety. Less perceived satisfactory support was the only independent variable that significantly explained more frequent suicidal thoughts among the Indonesian students.

Regarding the path coefficients for Taiwanese students, receiving more information from the internet and medical staff significantly explained the higher levels of anxiety observed in this study group. No independent variables significantly explained suicidal thoughts among Taiwanese students.

Finally, regarding the path coefficients for Thai students, only receiving more information from family significantly explained the higher levels of anxiety observed in this study group. Less perceived satisfactory support and receiving less information from medical staff significantly explained the more frequent sadness reported by Thai students (Figure 1).

[a] Not applicable.

[b] Confidence: confidence in pandemic control.

[c] Perceived risk: risk perception of susceptibility to COVID-19.

[d] Support: perceived satisfactory support from family, friends, or university.

[e] Resources: sufficiency of resources.

[f] Internet: COVID-19 information received from the internet.

[g] Medical staff: COVID-19 information received from medical staff.

[h] Family: COVID-19 information received from family.

Discussion

Principal Findings

This study showed that, among the 3 student groups compared, Thai university students had the greatest negative psychological responses (ie, the highest level of anxiety), whereas Taiwanese students had the lowest negative psychological responses. Confidence in pandemic control, sufficiency of resources, and receiving COVID-19 information from the internet and family were all factors associated with both anxiety and suicidal thoughts in the overall study population. Moreover, factors associated with higher levels of psychological responses considerably differed across the 3 countries. For example, less perceived satisfactory support was associated with more suicidal thoughts among Indonesian students and more sadness among Thai students.

Thai students had the highest levels of anxiety among the 3 study groups, which may be attributed to the low confidence they expressed in pandemic control and the lack of resources for fighting COVID-19. Indeed, the correlation results indicated that anxiety and suicidal thoughts were negatively associated with confidence in pandemic control and sufficiency of resources. The main reason for the lowest levels of anxiety and suicidal thoughts among Taiwanese students could be the early reaction by the Taiwan government to control COVID-19 infection [17,42], which substantially decreased disease transmission rate. Consequently, the effects of COVID-19 on daily life were less substantial in Taiwan than in Indonesia and Thailand.

When comparing the various sources of COVID-19 information in relation to anxiety, we found that Taiwanese students were highly affected by COVID-19 information gathered from the internet and from medical staff. This finding was similar to that of another study on the general population in Taiwan, which found that receiving COVID-19 information from the internet was associated with poorer psychological well-being [43,44]. Previous research has indicated that the more an individual gathers internet-based COVID-19 information, the higher is the impact on the individual's anxiety level, a phenomenon termed "cyberchondria" [43,44]. Seeking health information on the internet has been the most common method to obtain health information even before the COVID-19 pandemic [45]. However, the content and quality of health information available on the internet regarding COVID-19 can vary depending on the region. For example, frequencies of recommendations regarding COVID-19 prevention, such as "wash your hands frequently" or "stay home if you feel unwell," appearing on the internet were significantly different between Spain and the United States [46].

The proposed model in this study was partially supported because confidence in pandemic control and sufficiency of resources were both associated with more positive psychological responses to the pandemic. This finding indicates that perceived benefits in the HBM is important for university students in overcoming their psychological challenges during the COVID-19 pandemic period. Moreover, the benefits concerning COVID-19 control (ie, confidence in COVID-19 control and resource sufficiency) appeared to be more important than the benefits of others' emotional support (ie, perceived support). Moreover, perceived satisfactory support appeared to be an important factor in our study given the contrasting findings concerning anxiety and suicidal thoughts in some cultures. Lower perceived satisfactory support was associated with greater suicidal thoughts among Indonesian students and more sadness among Thai students, but more perceived support was associated with higher anxiety among Indonesian students. Perceived support may prevent individuals from having suicidal thoughts or sadness, but it may result in increased anxiety due to sharing of COVID-19 information repeatedly in a smaller social network. Moreover, information on the internet may even contain misinformation concerning COVID-19 [47]. The general public needs to know where on the internet to seek accurate information related to COVID-19 and not to constantly check for new information, as this could negatively affect their psychological health. However, individuals are still encouraged to seek information because accurate information can help them to engage in appropriate preventive behaviors. Therefore, we recommend that the public should seek information moderately. In some cultures, such as among the Thai university students in this study, receiving more COVID-19 information from medical staff was associated with less sadness. This finding suggests that a more reliable source of COVID-19 information may subsequently reduce suicidal thoughts among Thai students, given that feeling sad or experiencing a low mood is one of the depressive symptoms that could lead to suicide. Future studies should also analyze the content, frequency, and the various types of COVID-19 information available online that may be directly associated with anxiety. This knowledge could be used to promote additional sources on COVID-19 information for the general population such that they can find reliable and accurate information.

The amount of information may be amplified due to echo chamber effects, wherein information is disseminated among those who know each other very well, and individuals believe and trust in the information shared because they are very familiar with each other [48]. Thus, if misinformation was spread and exacerbated in their networks, it is likely that their anxiety levels will increase. However, if individuals can obtain accurate COVID-19 information through their close social network, it could lead to a reduction in suicidal thoughts. The findings of our study also highlight that the risks of university students having suicidal thoughts during the COVID-19 pandemic should not be overlooked.

Based on the findings of this study, there are several implications. First, these findings suggest there is a need for health care providers to help improve the psychological health of university students by providing them with reliable information to increase their confidence in COVID-19 pandemic control and provide sufficient resources in dealing with the resulting psychological impact. More specifically, psychoeducation to assist university students in understanding how the city and university are controlling and minimizing the spread of COVID-19 may be one method for improving students' confidence in COVID-19 control. Additionally, programs highlighting preventive COVID-19 behaviors may also increase students' confidence in controlling COVID-19 at an individual level. Second, health care providers need to provide sufficient PPE, accurate COVID-19 information, monetary and medical resources, and psychological support to students. This would help students perceive the benefits of these resources in minimizing the impact of COVID-19 and decreasing their psychological distress. Third, health care providers should encourage students to obtain COVID-19 information from reputable and trusted sources, such as from medical staff, rather than from the internet and social media, as misinformation on the internet may be difficult to identify and may have a negative impact on the students' psychological health. In addition, health care providers also need to be proactive in correcting misinformation spread among university students.

Study Limitations

There are some limitations to this study. First, the majority of the university students in the present study were female majoring in medical-related programs. Therefore, the generalizability of the findings is restricted. Future studies with university students majoring in other programs (eg, social science and engineering) are therefore needed. Moreover, the present findings are arguably biased because, in general, medical professionals are subject to experiencing more psychological impacts due to the nature of their work requiring them to be at the frontline, especially during the ongoing COVID-19 pandemic. Second, although the present study recruited participants from different East Asian countries, the sample representativeness is restricted due to the sample sizes being different in the 3 countries studied. More specifically, the Taiwanese sample was relatively smaller (15.8%) than the other two samples. Therefore, the country comparisons are limited. Third, all the measures were assessed using self-reports received via a web-based survey. The biases of social desirability and common method variance may therefore influence these results. Fourth, confidence in pandemic control was assessed by combining 3 different domains (ie, personal, university, and city). Given that confidence in oneself can considerably differ from that in how a university or city handles a public health emergency situation, the confidence in pandemic control examined in the present study was not specific. Therefore, future studies should consider separating the confidence in different domains and examining the effects of each type of confidence. Finally, the response scales used in the present study were different for different variables (eg, the items concerning confidence in pandemic control used a 5-point scale, and items concerning risk perception of susceptibility to COVID-19 used a 7-point scale). The use of different response scales may have affected instrument reliability and validity. However, this may not be a serious problem because instruments using different response scales within the same measure (eg, Short-Form 36) have been shown to have good psychometric properties [49].

Conclusions

In conclusion, this study demonstrated that university students from different countries had different levels of psychological responses relating to the COVID-19 pandemic. Moreover, receiving more COVID-19 information appears to increase the anxiety levels among university students, but not in relation to suicidal thoughts. Receiving less satisfactory support was found to be associated with more suicidal thoughts among Indonesian students and greater sadness among Thai students. Therefore, health care providers need to establish a good support system for university students to get through the current pandemic.

Acknowledgments

We acknowledge financial support received from the Ministry of Science and Technology (MOST109-2327-B-006-005) and National Health Research Institute, Taiwan (NHRI-EX108-10625EI), and Southeast and South Asia and Taiwan Universities Joint Research Scheme (NCKU 33).

Authors' Contributions

IP, CS, C-FY, C-YL, and N-YK conceptualized the study. IP, CS, C-YL, and N-YK wrote the first draft. IP, YS, AS, MP, C-FY, and N-YK designed the online survey and collected data. C-YL analyzed the data. CS, C-YL, MDG, and N-YK interpreted the data. IP, CS, YS, AS, MP, C-FY, MDG, and N-YK critically reviewed the manuscript. MDG was responsible for the final editing. IP and CS contributed equally to the study; N-YK and C-YL contributed equally to the study. All the authors have read and approved the final version of the manuscript.

Abstract

Background: The COVID-19 pandemic has resulted in profound mental health impacts among the general population worldwide. As many in-person mental health support services have been suspended or transitioned online to facilitate physical distancing, there have been numerous calls for the rapid expansion of asynchronous virtual mental health (AVMH) resources. These AVMH resources have great potential to provide support for people coping with negative mental health impacts associated with the pandemic; however, literature examining use prior to COVID-19 illustrates that the uptake of these resources is consistently low.

Objective: The aim of this paper is to examine the use of AVMH resources in Canada during the COVID-19 pandemic among the general population and among a participant subgroup classified as experiencing an adverse mental health impact related to the pandemic.

Methods: Data from this study were drawn from the first wave of a large multiwave cross-sectional monitoring survey, distributed from May 14 to 29, 2020. Participants (N=3000) were adults living in Canada. Descriptive statistics were used to characterize the sample, and bivariate cross-tabulations were used to examine the relationships between the use of AVMH resources and self-reported indicators of mental health that included a range of emotional and coping-related responses to the pandemic. Univariate and fully adjusted multivariate logistic regression models were used to examine associations between sociodemographic and health-related characteristics and use of AVMH resources in the subgroup of participants who reported experiencing one or more adverse mental health impacts identified in the set of self-reported mental health indicators.

Results: Among the total sample, 2.0% (n=59) of participants reported accessing AVMH resources in the prior 2 weeks to cope with stress related to the COVID-19 pandemic, with the highest rates of use among individuals who reported self-harm (n=5, 10.4%) and those who reported coping "not well" with COVID-19–related stress (n=22, 5.5%). Within the subgroup of 1954 participants (65.1% of the total sample) who reported an adverse mental health impact related to COVID-19, 54 (2.8%) reported use of AVMH resources. Individuals were more likely to have used AVMH resources if they had reported receiving in-person mental health supports, were connecting virtually with a mental health worker or counselor, or belonged to a visible minority group.

Conclusions: Despite substantial government investment into AVMH resources, uptake is low among both the general population and individuals who may benefit from the use of these resources as a means of coping with the adverse mental health impacts of the COVID-19 pandemic. Further research is needed to improve our understanding of the barriers to use.

Introduction

With growing global access to the internet [1], the World Health Organization [2] has identified digital health as a key health promotion strategy that can “benefit people in a way that is ethical, safe, secure, reliable, equitable and sustainable." Broadly, digital mental health comprises health care activities that are not carried out in traditional face-to-face format and may include synchronous (ie, in real time) video visits with mental health care providers or asynchronous (ie, not in real time) use of online self-management skill-building programs [3]. As a core aspect of the growth in digital health, there has been a recent surge in free, publicly available virtual mental health resources, including online programs and smartphone apps. In this paper, we use the term *asynchronous virtual mental health* (AVMH) *resources* to refer to any app, website, online tool, or other online support that does *not* involve synchronous direct contact with a mental health care provider. Although many of these publicly available mental health apps and online programs have been endorsed by users with generally high ratings and positive review comments [4], most are lacking direct scientific evidence of their effectiveness [5]. While not a replacement for professional decision making, AVMH resources nonetheless offer an alternative to in-person engagement with a mental health clinician, and aim to support people coping with symptoms related to a wide range of mental health conditions and challenges, including mild to moderate depression and anxiety, trauma, substance use, and other psychosocial stressors [6,7]. While limited, the research that has been conducted on smartphone and internet-based resources has demonstrated that AVMH resources can be effective in supporting people to manage their symptoms [8,9] and may reduce the need for clinical care [6].

The COVID-19 pandemic presents a heightened opportunity for AVMH resources to support mental well-being. The mental health impacts of COVID-19 are profound, including significant increases in depression, anxiety, and stress among the general population [10-13]. Public health measures, such as lockdown and quarantine, are necessary for reducing the spread of the virus but are also associated with negative psychological effects [14,15]. Loss of employment, anxiety about physical health and COVID-19 exposure, and social isolation are additional stressors that can contribute to poor mental health during the pandemic and beyond [16-18]. Further, researchers have warned of a likely increase in self-harm and suicide related to COVID-19 stressors [19,20]. In May 2020, many in-person mental health supports were reduced, suspended, or transitioned to online services in Canada, amid numerous reports from researchers around the globe calling for the rapid expansion of AVMH resources to address the mental health impact of the pandemic [21-24]. In the context of limited in-person services, AVMH resources represent a scalable means of promoting coping among those experiencing mental health challenges, including members of the general population who have not engaged with the mental health system but would likely benefit from these resources as a means of managing the mental health impacts of the COVID-19 pandemic [8,9,23].

Despite the potential for AVMH resources to support coping with COVID-19–related stressors, research suggests that uptake has been consistently low. While research examining AVMH resources in the context of COVID-19 is still emerging and no Canadian data are currently available, Yao and colleagues [25] reported results from a survey in China indicating that only 3.7% of respondents experiencing high levels of acute stress had used mental health services in any form in the early months of the COVID-19 outbreak. To our knowledge, few, if any, studies have examined the uptake of AVMH resources in the COVID-19 context. Prior to COVID-19, AVMH uptake and retention have been a perpetual challenge, with many internet-based resources and apps having very low use among the general population [26,27]. Moreover, use of AVMH resources tends to decline sharply in the first week following initial use; for example, Baumel and colleagues [28] found that as few as 4% of users of mental health apps continued to access the resource 15 days after initial installation.

In Canada, various AVMH programs have been promoted to support individuals’ mental health during the COVID-19 pandemic, including BounceBack [29], Wellness Together Canada [30], WellCan [31], and MindBeacon [32]. Free and available to the public, these resources hold promise for improving mental health and well-being at a time when in-person services are reduced and travel for services is limited, particularly for individuals in rural and remote areas. While a digital divide persists, particularly among low-income and rural populations [33], internet access is widespread in Canada, supporting the uptake of AVMH resources. In 2018, 94% of Canadians reported home internet access, and 88% of internet users had a smartphone [34]. AVMH resources have great potential to promote mental health and coping with stressors during the COVID-19 pandemic, given their demonstrated efficacy in supporting individuals’ self-management of a variety of mental health challenges [8,35]; however, little is known about the uptake of these resources among the general public in Canada in the pandemic context. Further, as mentioned, the global evidence on the use of similar virtual resources remains extremely limited. The aim of this investigation is to examine the use of AVMH resources during the COVID-19 pandemic among the general population in Canada to inform intervention research, development, and refinement of asynchronous virtual public health solutions related to mental health service delivery.

Methods

Overview

Data for this analysis were drawn from the first wave of a large multiwave cross-sectional monitoring survey, *Assessing the Impacts of COVID-19 on Mental Health*. This study utilizes a nationally representative sample of people aged ≥18 years living in Canada with the aim to examine mental health, stress, and coping during the COVID-19 pandemic. This project involves a unique partnership between academic researchers and 2 not-for-profit mental health organizations, the Canadian Mental Health Association (CMHA) and the Mental Health Foundation in the United Kingdom. Survey items were largely drawn from a repeated cross-sectional survey first commissioned by the Mental Health Foundation for COVID-19. Adaptations were made for the Canadian context.

Data Collection

Wave 1 of the survey was distributed from May 14 to 29, 2020, by Maru/Matchbox, a national polling vendor that maintains the online Maru Voice Panel of 125,000 Canadian adults. Members of the panel were randomly invited to participate in the survey from national census–informed stratifications defined by sociodemographic characteristics (age, gender, household income, and region), with adjustments for response propensity. Maru/Matchbox utilized target sampling to ensure inclusion of populations that may be difficult to reach via the internet, including older adults and racialized populations. In total, 3558 participants were invited by email to complete the survey to yield a total of 3000 respondents (84% invitation-to-response rate). The survey was available in English and French, Canada’s two official languages. The data collection time period was chosen to correspond with the beginning phases of the reopening of many of Canada’s provinces and territories, following approximately 2 months of public health orders that resulted in closures and physical distancing after COVID-19 was declared a pandemic by the World Health Organization on March 11, 2020 [36]. Additional details on the survey development and implementation have recently been published [13].

Measures and Analysis

Participants reported on their sociodemographic information as well as their mental health during the COVID-19 pandemic. Participants were asked to rate their mental health *now* compared to *before* the COVID-19 pandemic and related restrictions. Participants also reported on their overall coping and emotional responses to the COVID-19 pandemic in the past 2 weeks, including feeling depressed, stressed, hopeless, and anxious. Finally, participants reported if they had experienced suicidal thoughts/feelings or deliberate self-harm as a result of the COVID-19 pandemic in the past 2 weeks. These indicators were informed by research on previous pandemics with further refinement carried out via a citizen’s jury participatory methodology process involving people with lived experience of mental health conditions [37].

To assess the use of AVMH resources during COVID-19, participants responded to the survey item, “Which of the following have helped you cope with stress related to the COVID-19 pandemic in the past 2 weeks?” Participants were asked to select all that apply from a checklist of items that included three mental health strategies: (1) accessing virtual mental health resources (eg, online cognitive behavioral therapy, etc); (2) connecting with a mental health worker or counselor virtually (eg, via phone, video chat, etc); and (3) receiving in-person mental health supports. Study participants who endorsed the first option were classified as having used AVMH resources for this investigation.

Descriptive statistics were used to characterize the sample, and bivariate cross-tabulations were used to examine the relationships between self-reported indicators of mental health and the use of AVMH resources. Any participant who reported experiencing a negative impact of the pandemic on one or more of the self-reported mental health indictors was classified as experiencing an adverse mental health impact. The subgroup of participants who reported experiencing an adverse mental health impact included participants who reported that their mental health was now “slightly worse” or “significantly worse” compared to before the COVID-19 pandemic; participants who indicated that their level of coping with the stress of the COVID-19 pandemic was “not very well” or “not well at all”; and participants who reported feeling panicked, anxious or worried, hopeless, stressed, or depressed as a result of the COVID-19 pandemic. Additionally, respondents who reported experiencing suicidal thoughts/feelings as a result of the COVID-19 pandemic in the past 2 weeks and those who reported deliberately hurting themselves as a result of the COVID-19 pandemic in the past 2 weeks were also classified as experiencing an adverse mental health impact. Univariate and fully adjusted multivariate logistic regression models were then used to examine the associations between a set of a priori specified sociodemographic and health-related characteristics and use of AVMH resources in the subgroup of participants classified as experiencing an adverse mental health impact.

Ethics

Ethical approval for this study was provided by the Behavioural Research Ethics Board at the University of British Columbia (H20-01273). Participants provided consent online prior to beginning the survey. Maru/Matchbox provided all participants with a small honorarium for completing the survey.

Results

The sample comprised 3000 participants; detailed sociodemographic characteristics are presented in Table 1.

Table 1. Sociodemographic characteristics of the sample.

Characteristic	Total respondents (N=3000), n (%)[a]
Gender[b]	
Male	1467 (48.9)
Female	1533 (51.1)
Age group (years)	
Youth (18-24)	62 (2.1)
Adult (25-64)	2145 (71.5)
Senior (≥65)	793 (26.4)
Household income ($CAD)	
<$25,000	234 (7.8)
$25,000-$50,000	504 (16.8)
$50,000-$100,000	992 (33.1)
>$100,000	1270 (42.3)
Education	
High school or less	431 (14.4)
Some university or college	1139 (38.0)
University or college degree (diploma, undergraduate, and/or graduate degree)	1430 (47.7)
Employment (multiple responses permitted)	
Working full time (≥30 hours per week)	1225 (40.8)
Working part time (<30 hours per week)	286 (9.5)
Retired	882 (29.4)
Full-time student (eg, school, college, university, job training)	50 (1.7)
Part-time student (eg, school, college, university, job training)	16 (0.5)
Unemployed (due to COVID-19)	284 (9.5)
Unemployed (prior to COVID-19)	103 (3.4)
Ethnic minority[c]	
Not a visible minority	2128 (70.9)
Visible minority	389 (13.0)
Indigenous (eg, First Nations, Inuit, Métis)	87 (2.9)
Province	
British Columbia/territories	440 (14.7)
Alberta	333 (11.1)
Ontario	1140 (38.0)
Quebec	658 (21.9)
Manitoba/Saskatchewan	194 (6.5)
Atlantic provinces	235 (7.8)
Location	
Urban	2516 (83.9)
Rural	484 (16.1)
Self-reported prior mental health condition (yes)	546 (18.2)
Accessed virtual mental health resources in the past 2 weeks (yes)	59 (2.0)

[a] Note that some category percentages do not add up to 100 due to missing responses.

[b] Maru/Matchbox, the polling vendor that distributed this survey, provides demographic data for each panel member collected prior to survey completion. Though this binary variable was used in this analysis, the research team recognizes that binary gender identities do not accurately reflect many individuals' self-identified gender.

[c] Visible minority and non–visible minority categories were constructed by the research team based on participants' self-reported ethnicity (eg, South Asian, Middle Eastern, European origins).

Among the total sample, 59 (2.0%) participants reported accessing AVMH resources in the prior 2 weeks to cope with stress related to the COVID-19 pandemic. Table 2 presents rates of self-reported AVMH resource use or nonuse across various self-reported mental health indicators. The highest rate of access was among individuals who reported having deliberately hurt themselves (n=5, 10.4%), those who reported coping “not well” with stress related to the COVID-19 pandemic (n=22, 5.5%), those who experienced suicidal thoughts/feelings (n=14, 8.0%), and those who reported having “worse” mental health compared to before the COVID-19 pandemic (n=40, 3.6%). There was also significant overlap across these subgroups in that 74.3% (n=130) of participants who reported experiencing suicidal thoughts/feelings and 54.2% (n=26) of participants who reported deliberately hurting themselves also reported having worse mental health now compared to before the pandemic. Though higher than the sample average, accessing AVMH resources remained low among those who experienced negative emotions related to COVID-19, including individuals who felt hopeless (n=16, 4.5%), depressed (n=29, 4.3%), panicked (n=10, 4.3%), stressed (n=32, 2.9%), and anxious (n=38, 2.8%).

To identify sociodemographic and health-related characteristics associated with reported use of AVMH resources, a subgroup was created that contained any participant who reported experiencing one or more adverse mental health impacts on the mental health indicators listed in Table 2. This subgroup comprised 1954 participants, of which 54 (2.8%) reported use of AVMH resources. Table 3 presents the results of a multivariate logistic regression model examining the association between sociodemographic characteristics and the use of AVMH resources within this subsample of participants who reported adverse mental health outcomes due to the COVID-19 pandemic.

Results of the fully adjusted multivariate logistic regression model indicate that, among the subsample who reported adverse mental health impacts due to COVID-19, those who reported receiving in-person mental health supports or connecting virtually with a mental health worker or counselor were significantly more likely to report accessing AVMH resources (odds ratio [OR] 6.05, 95% CI 1.35-27.17 and OR 8.96, 95% CI 4.36-18.42, respectively). Additionally, individuals belonging to visible minority groups were more likely to report accessing AVMH resources (OR 3.79, 95% CI 1.83-7.86).

Table 2. Accessing asynchronous virtual mental health (AVMH) resources across indicators of self-reported mental health impact.

Mental health indicator	Used AVMH resource, n (%)	Did not use AVMH resource, n (%)
Compared to before the COVID-19 pandemic and related restrictions in Canada, how would you say your mental health is now?[a]		
About the same or better (n=1874)	19 (1.0)	1855 (99.0)
Worse (n=1121)	40 (3.6)	1081 (96.4)
Overall, how well do you think you are coping with stress related to the COVID-19 pandemic?[a]		
Fairly or very well (n=2439)	36 (1.5)	2403 (98.5)
Not well (n=400)	22 (5.5)	378 (94.5)
Felt panicked as a result of the COVID-19 pandemic in the past 2 weeks[b]		
Yes (n=231)	10 (4.3)	221 (95.7)
No (n=2769)	49 (1.8)	2720 (98.2)
Felt anxious or worried as a result of the COVID-19 pandemic in the past 2 weeks[a]		
Yes (n=1361)	38 (2.8)	1323 (97.2)
No (n=1639)	21 (1.3)	1618 (98.7)
Felt hopeless as a result of the COVID-19 pandemic in the past 2 weeks[a]		
Yes (n=353)	16 (4.5)	337 (95.5)
No (n=2647)	43 (1.6)	2604 (98.4)
Felt stressed as a result of the COVID-19 pandemic in the past 2 weeks[a]		
Yes (n=1103)	32 (2.9)	1071 (97.1)
No (n=1897)	27 (1.4)	1870 (98.6)
Felt depressed as a result of the COVID-19 pandemic in the past 2 weeks[a]		
Yes (n=676)	29 (4.3)	647 (95.7)
No (n=2324)	30 (1.3)	2294 (98.7)
Experienced suicidal thoughts/feelings in the past 2 weeks[a]		
Yes (n=176)	14 (8)	162 (92)
No (n=2792)	43 (1.5)	2749 (98.5)
Deliberately hurt myself in the past 2 weeks[a]		
Yes (n=48)	5 (10.4)	43 (89.6)
No (n=2936)	52 (1.8)	2884 (98.2)

Discussion

Principal Findings

Findings from this study illustrate that the reported uptake of AVMH resources was extremely low (2.0%) among the general population in Canada in the context of the first 3 months of the COVID-19 pandemic. A similarly low level of use (2.8%) was observed in the subgroup of participants who reported an adverse mental health impact related to COVID-19. While utilization of these resources was higher among particular groups experiencing mental health challenges as a result of the pandemic, including those who had engaged in self-harm behaviors, experienced suicidal thoughts, or reported poor coping, uptake remained low even among these groups. While representing a different national context for mental health care, these findings are consistent with Yao and colleagues' [25] report of very low use of any mental health services among adults in China experiencing high levels of acute stress during COVID-19. Despite evidence indicating efficacy of select resources [38,39], promotion of existing AVMH resources (eg, [40]), and numerous calls for the expansion of these resources among researchers and public health officials, there is a dearth of evidence regarding the uptake of AVMH resources among the general public and population subgroups experiencing adverse mental health impacts during the current pandemic. This study is among the first to present data regarding the extent to which members of the general public report accessing AVMH resources during the COVID-19 pandemic, while also examining access among a subgroup of individuals experiencing adverse mental health impacts related to the pandemic. In this section, we discuss key findings from this study: the low uptake of AVMH resources within the sample, higher use among the visible ethnic minority subgroup and those who accessed other forms of mental health support, and limited use of AVMH resources among those who reported self-harm or suicidal thoughts.

COVID-19 has presented unexpected and significant stressors that have been demonstrated to negatively impact mental health worldwide [10,12]. While for some individuals, the mental health impacts are considerable, including posttraumatic stress disorder, self-harm, and suicidal ideation [20,41], most people will experience mild to moderate symptoms of stress, anxiety, and low mood [11,42,43]. Such subclinical symptoms have been shown to be particularly responsive to self-directed mental health interventions, including virtual resources [44]. Research also indicates that accessing internet-based cognitive behavioral therapy for depression is associated with reductions in suicidal ideation [45], suggesting that use of AVMH resources can also contribute to reductions in these adverse mental health experiences. In the context of COVID-19 public health measures, including lockdown and physical distancing, mental health apps and online programs are particularly important public resources that are free or low cost, widely available, and can support mental health without additional risks for spreading the virus. However, research demonstrates that prior to COVID-19, uptake of AVMH resources was consistently low [26,28]. Our findings illustrate that despite the increased value of virtual supports during the pandemic and promotion of AVMH resources in Canada, use of these resources remains extremely limited within the general population. Concerningly, use remains low (<10.5%) among population subgroups who would appear to benefit from their use, including those experiencing suicidal thoughts, anxiety, hopelessness, stress, and depression related to COVID-19. While many companies and organizations are producing AVMH resources, there is an expectation of “build it and they will come,” but that does not appear to be the case.

Previous literature on the challenges of AVMH resources sheds light on potential reasons for poor uptake in the context of COVID-19. Many users have reported technological issues that hinder the usability of the apps, including poor speed or stability of their internet connection [46]. Additionally, potential users may be deterred by privacy and confidentiality concerns [6,47] or by a lack of comfort and familiarity with the internet and smartphone devices, such as among older adults [48]. While the AVMH resources promoted by governments and public health officials in Canada to support mental health during COVID-19 are evidence based and reputable, many apps advertised online or through app stores are not grounded in evidence or validated through research and may not actually be effective for managing mental health challenges [6,22]. Further research is needed to examine the barriers to widespread uptake of AVMH resources, particularly among individuals experiencing mental health impacts due to the COVID-19 pandemic. Such research can guide refinement of existing AVMH resources and promotion strategies for these resources among the general public and those experiencing mental health challenges.

In addition to presenting findings on accessing of virtual mental health supports among the general population, findings from this study illustrate that a higher proportion of specific population subgroups reported using these resources. We found that belonging to a visible minority ethnic group was associated with an increased likelihood of accessing AVMH resources, even after adjusting for age, income, and education. A potential factor in increased use among these populations may be heightened stigma toward mental health challenges within certain cultures. For example, cultural values held by some individuals of Asian descent have contributed to higher stigma about mental health challenges and reduced help seeking for in-person mental health supports [49,50]. Research has further suggested that while individuals of Asian descent may exhibit fewer mental health help-seeking behaviors overall, there is evidence of an increased preference among Asian American college students (compared to Caucasian students) for online-only supports versus face-to-face services [51]. It is possible that the anonymity of virtual mental health supports may therefore facilitate increased use among particular visible minority populations, as a preferred alternative to seeking one-on-one or group support from a mental health clinician.

Additionally, individuals who were either receiving in-person mental health supports or connecting virtually with a mental health worker or counselor were significantly more likely to report having accessed AVMH supports. This suggests that those who seek support may be motivated to try multiple strategies for supporting their own mental health, or that mental health clinicians may be directing clients toward AVMH resources to augment individual therapy. Previous literature demonstrates that integrating the use of virtual resources with other forms of mental health care, such as discussing trends from a mental health app with a clinician during an in-person appointment, can lead to improved outcomes [52]. As such, enhancing clinicians’ awareness of AVMH resources and providing training specifically for clinicians on how to integrate these resources into mental health care, may increase uptake among individuals who may benefit from the support they provide. Research has further demonstrated that while most users do not sustain engagement after initial sign-up [27], supports built into the system to facilitate engagement can be effective. Specifically, uptake and retention are significantly higher among users of AVMH resources who receive peer support [27], and automated conversational agents such as chatbots have been shown to effectively support sustained engagement [53]. While clinician and peer support may be logistically challenging and costly, Burger and colleagues [54] note that current AVMH resources “do not get close to the full technological potential of e-mental health” and that enhancing the available features of these resources may lead to greater uptake and retention of users.

While AVMH resources were underutilized across the entire sample, including among those experiencing mental health challenges, what was particularly concerning was the relatively low uptake among those who had deliberately self-harmed or had suicidal thoughts/feelings in the past 2 weeks. While specific AVMH resources related to suicide are fewer compared to those addressing mental health challenges such as low mood and anxiety [55], many resources address a broad range of mental health concerns that may underlie self-harm or suicidal ideation. Although a recent systematic review and meta-analysis concluded that internet-based interventions directly targeting suicidal ideation using cognitive behavioral therapy represent a promising means of providing low-threshold support to address suicidal ideation [56], researchers have suggested that AVMH resources may not represent the most appropriate form of mental health support for individuals with this experience given the severity of symptoms and degree of risk involved [57]. Despite relatively low uptake, use of mental health resources among individuals who reported self-harm or suicidal ideation was significantly higher compared to the general population, suggesting a desire for support seeking in this population. As Frost and Casey [58] suggest, utilizing virtual resources may be a critical stepping stone toward engaging in more intensive in-person clinical support.

Limitations

The sampling approach used in this study aimed to generate a large nationally representative sample of individuals living in Canada. The representativeness of the sample was supported since, according to the results from the 2016 Canadian census [59], 77.7% of the population did not belong to a visible minority (versus 70.9% in our sample), and 18.7% of the population was considered rural (versus 16.1% in our sample). In terms of household income, 57.7% of individuals reported an annual household income that was less than $100,000, which is consistent with recent data from Statistics Canada indicating that the average household income in Canada in 2017 was $93,300 [60]. However, while the sample was representative in these ways, there are other ways in which it did not reflect the overall population of Canada. For example, because it was an online survey, only individuals with internet access were able to participate. Individuals who were unable to afford the cost of internet service or equipment, or those living in rural "blackout zones" are therefore not represented in our sample [34,61]. As such, the actual use of AVMH resources among the general population may be even lower than that reflected in our findings.

The indicators of mental health used in the survey did not include clinical assessments of mental illness nor did it include prepandemic measures of baseline mental health. However, as noted in the description of study methods, the selection of items was informed by research on previous pandemics and the items were refined in consultation with people with lived experience of mental health conditions through a citizen's jury participatory methodology process [37]. Additionally, accessing AVMH resources was assessed in this survey through a single item measure. We are therefore unable to present data on which AVMH resources were used (eg, websites, apps, podcasts), participants' perceptions of the effectiveness of the resources, length of use, or why they may have stopped using these resources. Additionally, our survey asked participants about accessing AVMH resources to cope with COVID-19 stress and may not have captured use of these resources for other reasons, such as to help manage other mental health challenges. To further examine the use of AVMH resources among people living in Canada, we have expanded our survey content for subsequent waves of data collection to add further depth and nuance to the results presented in this investigation. It is also important to note that the cross-sectional design of this study prevents us from making causal conclusions. However, we will be conducting future waves of data collection over the course of the pandemic that will help address this limitation.

Comparison With Prior Work

While multiple researchers have highlighted the importance of virtual resources to address the significant mental health impacts of the COVID-19 pandemic, there remains a paucity of data on their use, uptake, and retention. However, previous research suggests that these resources may be underutilized [28], and emerging data within the COVID-19 context suggest low uptake among acutely stressed members of the general population [25]. Our examination of the use of AVMH resources related to COVID-19 stressors among people living in Canada is one of the first to provide empirical evidence on trends in accessing AVMH resources among the general population, with particular attention to their uptake among people experiencing adverse mental health impacts related to the current COVID-19 pandemic. Our analysis illustrates that not only is overall use of AVMH resources low, but use remains low even among individuals who would be predicted to benefit from these resources, such as individuals experiencing negative emotions (eg, anxiety) related to COVID-19 and individuals experiencing worsening mental health and difficulty coping.

Conclusions

AVMH resources hold great promise to support mental well-being during the COVID-19 pandemic by helping individuals cope with stressors and negative mental health impacts. However, despite efforts to promote AVMH resources within Canada, the results from this study suggest that many individuals who may benefit from these resources are not accessing them to help manage mental health challenges. Further research that examines the barriers and facilitators to AVMH resource use is needed to enhance uptake and impact.

Acknowledgments

The authors thank the CMHA and the Mental Health Foundation for supporting this monitoring study. We are grateful to the CMHA for funding Maru/Matchbox to deploy the survey. Special thanks to Jonathan Morris, Katherine Janson, Andrew Galley, and Margaret Eaton (CMHA) for assisting with study communications and government relations outreach, and to Neesha Mathew and Jacqueline Campbell (Maru/Matchbox) for managing survey deployment and data preparation.

EJ and AG both hold Scholar Awards from the Michael Smith Foundation for Health Research, which has supported their time contributions to the study. JM, employed by the CMHA, contributed to the development of survey content. The CMHA had no further role in the study design, data collection, data analysis, or interpretation.

Conflicts of Interest

CR reports receiving personal fees from the University of British Columbia during the conduct of this study. All other authors report no competing interests.

Abstract

A common development observed during the COVID-19 pandemic is the renewed reliance on digital health technologies. Prior to the pandemic, the uptake of digital health technologies to directly strengthen public health systems had been unsatisfactory; however, a relentless acceleration took place within health care systems during the COVID-19 pandemic. Therefore, digital health technologies could not be prescinded from the organizational and institutional merits of the systems in which they were introduced. The Italian National Health Service is strongly decentralized, with the national government exercising general stewardship and regions responsible for the delivery of health care services. Together with the substantial lack of digital efforts previously, these institutional characteristics resulted in delays in the uptake of appropriate solutions, territorial differences, and issues in engaging the appropriate health care professionals during the pandemic. An in-depth analysis of the organizational context is instrumental in fully interpreting the contribution of digital health during the pandemic and providing the foundation for the digital reconstruction of what is to come after.

The Unparalleled Surge in Digital Health Adoption

The COVID-19 pandemic has presented governments, managers, and professionals worldwide with unprecedented challenges, highlighting the limitations of analog health care systems that have long reinforced face-to-face models of care and congregation of individuals [1]. Regardless of the diverse containment and mitigation strategies implemented across countries, a common development observed during the pandemic is the renewed reliance on digital health, with efficient strategies implemented at various levels and directed at different stakeholders [2,3].

Rapid implementation of social distancing measures and rescheduling of elective procedures have led health care providers to resort to digital health applications for granting access to virtual consultations and remote visits and monitoring [4]. In short, health care has come to patients rather than the other way round.

As a result, during the first 3 months of the pandemic, an unparalleled surge in digital health adoption was observed, with a general scale-up of telemedicine [5] and a substantial shift to telehealth visits in some clinics [6], as confirmed by the increased number of telehealth services and e-consultations reported in several jurisdictions [6-8].

The fact that these technologies were available and ready for use should not have come as a surprise. However, before the COVID-19 outbreak, the uptake of digital health technologies to strengthen public health systems had been unsatisfactory, and the scholarly debate had rather focused on the barriers to adoption of digital health solutions [9,10] and difficulties in governing mobile apps [11]. Nonetheless, the adoption of digital health solutions, regardless of whether it occurred during or after the pandemic, cannot be prescinded from the organizational and institutional merits of the systems in which they are introduced. The full potential of technological innovation can be realized only by way of heightened attention to context.

COVID-19 Digital Health Experience in the Italian National Health Service

Italy was among the first and most significantly hit countries by SARS-CoV-2. As of July 21, 2020, Italy reported a total of 244,708 confirmed cases, over 34,000 COVID-19–related deaths, and the highest deaths per million inhabitants and case fatality rates worldwide [12-14].

In terms of institutional composition, the Italian National Health Service (SSN) is strongly decentralized and based on universal access to care. The central government exercises general stewardship, whereas 21 regions—each considerably different in size and economic development and autonomous in their health care management decisions—are responsible for the organization and delivery of primary, secondary, tertiary, and preventive health care services through local health authorities (LHAs) [15].

Before the COVID-19 emergency, adoption of digital health was a challenge in Italy, as elsewhere. By analyzing the distinctive digital health experiences during the first wave of the pandemic in Italy—a country that was on the front line of the pandemic [16,17], we aimed to showcase the best practices, open questions, and barriers encountered. Systems, institutions, and organizations who have attempted to embrace digital health in the past months and are looking to maintain the momentum after COVID-19 have experienced similar challenges. Some of these challenges are related to issues such as reimbursement of digital health services, experience of using contact tracing apps, the search for balance between local experiences and national stewardship, arduous involvement of all health care professionals, and the coexistence of digital and analog pathways.

Reimbursement Schemes

Appropriate reimbursement schemes are essential to expanding the role of digital technologies. During the current public health crisis, telemedicine services promptly seemed to be vital to support remote monitoring of less severe cases and ensure continuity of care for vulnerable, typically chronic patients, whose needs were overshadowed by the surge in patients with COVID-19 seeking assistance. However, telemedicine services in Italy have traditionally been scattered across a number of different applications, with poor interconnection and inconsistent local and regional reimbursement practices, since they are not specifically covered by the guaranteed health basket of the Italian SSN [18]. No extensive, nationwide input was provided by health authorities during the pandemic, as has been the case of France, where the Ministry of Health allowed the reimbursement of teleconsultations for suspected and confirmed COVID-19 cases [6]. The Italian National Institute of Health (Istituto Superiore di Sanità) proposed a temporary model to ease the implementation of telemedicine services during the emergency, but this essentially focused on the organizational requirements for telemedicine services and did not tackle the reimbursement domain [19]. The delay in the adoption of national guidance and specific reimbursement codes for telemedicine services resulted in inter-regional differences: jurisdictions such as Veneto, the Autonomous Province of Trento, and Tuscany promptly introduced digital health services as part of their discretionary guaranteed health benefits packages, and were followed by other pioneering regions in the following months. These packages are now being managed online with dedicated tariffs for the citizens of the above regions. Conversely, the remaining regions could only fund telemedicine services by implicitly allowing payment parity with standard outpatient procedures through regional discretionary spending. While the lack of a framework to pay for telehealth services hindered wider-scale adoption by public institutions, private telemonitoring service providers reported a marked increase in the use of direct-to-consumer services [18].

Contact Tracing Apps

Use of contact tracing techniques and apps during the pandemic exposed the challenges of safeguarding privacy in the development of prompt digital responses to address current and future needs. National contact tracing apps were identified as a key tool to tackle the epidemic and facilitate reopening of the economy. However, unsurprisingly, the design and adoption of these applications, along with associated evaluation timelines, have raised significant privacy and security concerns and resulted in considerable delays in their deployment during the pandemic. Like most European countries, Italy initially backed the adoption of centralized management and maintenance of contact tracing data, including the "social graph" of individuals a person has physically met over a given period [20]. This practice was in contrast with the view of the European Commission, which supported anonymous, aggregated, and decentralized approaches to contact tracing to preserve privacy [21]. Meanwhile, Apple and Google had collaborated in a novel partnership to develop a safe infrastructure and privacy protection standards to specifically tackle these operations [22]. However, voluntary, data minimization systems are considered the sole option to build acceptance and maximize the uptake of these solutions [23]. These systems preserve user anonymity while providing useful warnings to other users who may have recently come into close physical proximity of a certain individual who subsequently tested positive for COVID-19. Eventually, together with several other European countries [24], the Italian government shifted focus towards these types of

Bluetooth Low Energy apps that interfere as little as possible with users' privacy rights.

Collectively, lengthy negotiations on privacy standards and relatively scarce previous attempts to evaluate these technologies have delayed the widespread roll-out of functional contact-tracing apps.

Immuni, an app selected by an adhoc task force of the Italian Ministry of Health [25], was launched nationwide on June 15, 2020, that is, 6 weeks after the first lockdown in Italy was lifted (May 4, 2020). Despite significant setbacks that delayed the app deployment, Italy was still among the first European countries to roll-out a contact-tracing solution, as proof of the broad-based intricacy of this matter. Nonetheless, the number of app downloads (4.3 million) for Immuni has been disappointingly low so far and is insufficient to guarantee the effectiveness of the tool [26].

Balancing Local Experiences and National Responsibilities

Leveraging local experiences with digital health projects in response to the crisis must be balanced with the national governments' global policy-setting responsibilities. Highly regionalized health systems, such as the Italian SSN, can generate both significant opportunities for innovation as well as threats to national public health initiatives. Moreover, territorial differences in digital response to the COVID-19 crisis that have emerged could provide a basis for mutual learning. For instance, some regional health care systems were better prepared than others, not just in terms of telemedicine policies. In addition, in territories where large-scale digital health projects were ongoing, LHAs were able to rapidly apply them to the needs of the COVID-19 pandemic. For example, in 2015, the LHA of the Autonomous Province of Trento adopted TreC, a patient monitoring system that includes a mobile diary app and a web-based dashboard to facilitate patient-physician interaction and reduce direct access to hospitals. This system was designed to be interoperable with various electronic health records and was tested in several chronic populations [27-29]. After the COVID-19 outbreak in February 2020, the LHA, together with the research entity Fondazione Bruno Kessler, launched TreCovid19—an app built on the same infrastructure designed to inform citizens and enforce remote symptom monitoring. By the end of the pandemic peak, more than 9400 infected or quarantined cases from the province of Trento were actively monitored through this platform, with over 40,000 single parameters directly reported via the chatbot and approximately 700,000 individuals' information accessed via personal interviews with a local executive (data not reported elsewhere).

In the Puglia region in Southern Italy, similar work was being carried out for years on remote follow-up management of chronic patients through several pilot projects. This enabled the implementation of a remote monitoring system based on a web-based application for citizens, a web portal for health care professionals, and a telemedicine kit. The platform, called #Accasa, was implemented on April 22, 2020, for individuals under quarantine or those who have tested positive for COVID-19 [30]. Conversely, boundaries are sometimes blurred in decentralized systems when close cooperation among different institutional levels is required. Several related apps have proliferated in the market during the COVID-19 pandemic, often without the necessary interoperability described above and with overlapping or even hindering features concerning their proposed nationwide application. Although the central government was working on selecting and deploying the most appropriate solutions, all Italian regional systems have worked on their own apps. Initially, these apps only provided information to local communities; however, over time, extra functionalities were added, some of which were slated for inclusion in the design of the national contact-tracing app. For example, Friuli–Venezia Giulia in Northeast Italy had successfully completed the testing of the same app used for contact tracing in Singapore [31], whereas the island of Sardinia had actively sought solutions to track tourists in view of the upcoming summer holiday season. Both attempts were set aside, as contact-tracing needed to be managed nationally. Given that there was no guarantee that the regional apps would be interoperable with the national app, it was fundamental, but not trivial, to ensure that widespread adoption of the national contact-tracing app was not hampered by local and regional initiatives that had been in use for weeks before the national app was launched.

Involvement of Health Care Professionals

Designing a successful digital health solution requires advanced alignment of the interests of all health care professionals and stakeholders involved. Management of the COVID-19 pandemic is challenging for the health care systems in many ways, including maintaining a balance and relative responsibilities of hospital vis-à-vis community care. It has become clear over time that primary care professionals should play a central role in managing less severe COVID-19 cases via home-based monitoring, possibly by using digital solutions. However, in Italy, general practitioners are contracted professionals. Therefore, it has been much more complex to extend institutionally sponsored digital tools to these third parties and guarantee the necessary system interoperability between services deployed in primary care clinics and all others provided by LHAs. Elsewhere, however, this has been pivotal in implementing a successful digital strategy during the pandemic [7].

Coexistence of Digital and Analog Pathways for Health Care

The analog approach is not going away any time soon, so analog and digital health systems will need to coexist. Although digital health applications have spread in parallel to the virus, they have rarely been proposed as the only available option. None of the digital solutions implemented in the Italian SSN have been imposed as a mandatory alternative; rather, they have been added to the mix of traditional in-person and telephone-based services to maximize coverage for the entire population. Despite the increased adoption of smartphone use, Italy's overall population and health care workforce are among the "oldest" in the world [32]. The digital divide is still an issue, and COVID-19 has taught us that digital health is an important option to have in place, but it is no panacea.

Building on the Momentum

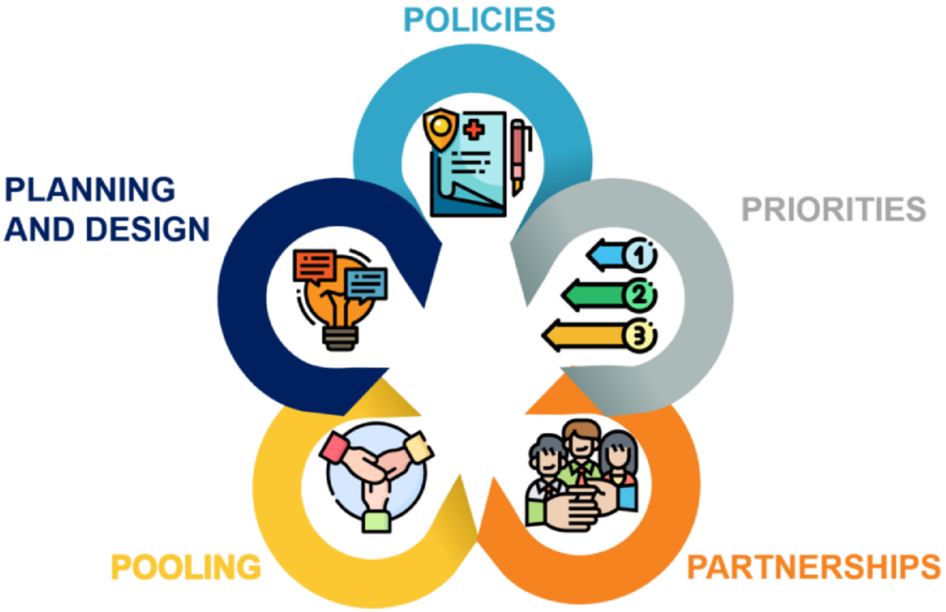
Despite the unprecedented expansion in the utilization of digital health tools during the COVID-19 pandemic, Italy, like many other countries worldwide, was not sufficiently equipped to harness the full potential of these tools. The urgency of the current public health emergency may have set the grounds for making exceptions [33], but the acceleration could not bypass the institutional and organizational elements that characterize national health care systems.

If we intend to maintain the momentum in expanding the digital health services that have resulted from the COVID-19 pandemic, now is the time to effectively plan for the future and to follow a new path, distinct from the pre-pandemic models [33]. The path must be selected by paying particular attention to avoid disparities in access to care. In theory, telemedicine can mitigate this issue but, if not carefully planned, it could also exacerbate it [34].

Achieving Sustained Benefits

No single best recipe exists, but a list of ingredients may help Italy, and other health care systems worldwide, focus their proposals to achieve sustained benefits (Figure 1):

Figure 1. Ingredients to achieve sustained benefits through digital health.



Policies

The COVID-19 crisis has reinforced the need to define and uphold appropriate policy standards. Long-standing digital health issues (reimbursement, regulatory framework, evidence generation, privacy, and security concerns) will still be unresolved by the end of this pandemic. Decisive and comprehensive action is thus needed from a policy standpoint, and several extensive proposals have been suggested in other contributions [1,4,18,23,33,35].

Priorities

The combination of the widespread availability of digital health solutions, their poor uptake before the pandemic, and the confidence gained during the recent expansion may push countries to aim too high. Governments should act promptly, but pragmatically, in adopting a stepped-wedge approach based on their health care system needs and organizational characteristics.

Partnerships

Digital transformation is bringing in new players with different backgrounds, expertise, and logic compared to the players that have typically populated the health care industry. Public institutions need to welcome innovation and be open to interorganizational relationships and trust. During a public health emergency, occasional, hastily generated partnerships may proliferate. Governments must adopt a strategic approach to partnerships and actively pursue the necessary competencies to harness these opportunities.

Pooling

The pre-pandemic digital health environment was characterized by a predominance of scattered experiences and the inability to adequately value existing best practices. Higher interinstitutional coordination should be assured by stewardship at the central level to take charge of streamlining the process, identifying parameters and conditions conducive to transferability, and ensuring no one is left behind—all without stifling local innovation.

Planning and Design

Digital health introduction should be complemented by an in-depth service redesign. The organizational implications of digital health have been largely neglected to date, but they need to be addressed now to exploit the complete potential of digital tools, integrate solutions in current care pathways, and pave the way for new models of care. Any digital technology is only as good as the response it gets from its end-users in terms of acceptability, continuity, and engagement. Hence, new, digitally enriched organizational processes should be planned and designed by all relevant stakeholders, directing patient-provider interactions to the channels generating the most value [36]. Irrespective of the cultural or contract issues, all health care professionals should be involved to steer change processes. Likewise, health care systems should flexibly partner with patients by enacting a mutual learning space and blurring the boundary between producers and consumers [37]. This shared effort at the system level should be pursued in the awareness that digital health literacy, among both citizens and health care professionals, still carries significant weight in influencing the uptake of digital solutions [38]. Although health care systems tackle this issue to grant the benefits of technological advancements to all users, the service redesign should be oriented by process of segmentation that will ideally result in a more tailored response to each individual’s needs through a combination of traditional and digital solutions.

Unprecedented times call for unprecedented decisions. It is time for policymakers to step up and make timely valiant choices about the use of telemedicine and digital health to permanently integrate them into the health care systems for the good of the public health and, ultimately, of the people. This will be extremely helpful now, during the COVID-19 crisis, and even more as we head toward the post-pandemic world.

Acknowledgments

We would like to warmly thank Ettore Turra for his contribution regarding the digital health solutions implemented in APSS Trento before and during the COVID-19 outbreak. The authors received no specific funding for this work.

Conflicts of Interest

FP, OC, MC, and RT all reported grants from the European Union’s Horizon 2020 research and innovation program under grant agreement no. 779306. FP, OC, MC, and RT are also involved in an RCT to evaluate a mobile supportive care app for patients with metastatic lung cancer.

Abstract

Background: The COVID-19 pandemic continues to pose an international public health threat. Prevention is of paramount importance to protect the high-risk group of older adults until specific treatments for COVID-19 become available; however, little work has been done to explore factors that promote preventive behaviors among this population.

Objective: This study aims to investigate the knowledge, perceived beliefs, and preventive behaviors towards COVID-19 of older adults in China and determine the factors that influence their practice of preventive behaviors.

Methods: From February 19 to March 19, 2020, a cross-sectional, web-based survey was administered to Chinese older adults in all 31 provinces of mainland China using a convenience sampling method to assess the respondents’ knowledge, perceived beliefs, and preventive behaviors towards COVID-19. Standard descriptive statistics and hierarchical linear regression analyses were conducted to analyze the data.

Results: A total of 1501 participants responded to the survey, and 1263 valid responses (84.1%) were obtained for further analysis. The overall correct rate on the knowledge questionnaire was 87%, overall positive beliefs regarding COVID-19 were found, and the mean behavior score was 13.73/15 (SD 1.62, range 5-15). The hierarchical linear regression showed that respondents who were married or cohabitating and who lived in areas with community-level control measures were more likely to practice preventive behaviors ($P<.01$). Knowledge ($\beta=0.198$, $P<.001$), perceived susceptibility ($\beta=0.263$, $P=.03$), perceived benefits ($\beta=0.643$, $P<.001$), and self-efficacy in preventing COVID-19 ($\beta=0.468$, $P<.001$) were also found to be significantly associated with preventive behaviors.

Conclusions: Most older residents had adequate knowledge and positive beliefs regarding COVID-19 and engaged in proactive behaviors to prevent the disease. Knowledge and beliefs were confirmed to be significantly associated with behavior responses. Our findings have significant implications in enhancing the effectiveness of COVID-19 prevention programs targeting the older population; these programs must be continued and strengthened as the epidemic continues.

KEYWORDS

COVID-19; knowledge; perceived beliefs; behaviors; elderly; China

Introduction

COVID-19, which was first detected in Wuhan, China, in December 2019, is an emerging infectious disease caused by a novel coronavirus (SARS-CoV-2). The crude case fatality rate of COVID-19 was 3.7% worldwide as of August 9, 2020 [1], which is much lower than that of severe acute respiratory syndrome (SARS, 9.5%), Middle East respiratory syndrome (MERS, 34.4%), or H7N9 (39.0%) [2]; however, evidence has shown that SARS-CoV-2 is more contagious than the viruses that cause the latter diseases [3,4]. Considering its extensive spread scope, COVID-19 was declared a public health emergency of international concern on January 30, 2020 [5] and was declared a pandemic on March 11, 2020 [6] by the World Health Organization (WHO). As of August 9, 2020, the virus had reached 215 countries and regions, resulting in over 19 million confirmed infections and more than 700,000 deaths [1].

Older people are especially susceptible to infectious diseases due to decreased immunity [7], the presence of underlying chronic illnesses [8], and cognitive impairment, which causes difficulty in their participating in proper prevention activities [9]. In the case of COVID-19, older people are also at significantly higher risk of morbidity and mortality [10-12]. According to an epidemiological study on COVID-19 in China, people aged >60 years comprised 31.2% of the 44,672 confirmed cases and 81% of the total number of deaths [13].

To date, no specific treatments or vaccines for COVID-19 have been made available; thus, it is of great importance for older people to engage in preventive behaviors, which has been proved to be effective in preventing respiratory infectious diseases and controlling their transmission [14,15]. It is believed that the transmission route of COVID-19 is human-to-human via respiratory droplets or direct contacts [16] and that the average infected person can spread the disease to up to 3 other people [17]; thus, effective preventive measures, including handwashing, mask-wearing, household ventilation and disinfection, and reduction of interpersonal contacts by avoiding visiting crowded spaces [18], have been recommended to older people by local Chinese authorities. However, these guidelines would severely hamper many daily activities if implemented at a high level of fidelity; therefore, voluntary compliance is likely to be uneven at best.

In fact, in the early stage of the COVID-19 epidemic, older people underestimated the severity of the epidemic, as it affected a relatively small population. They were reluctant to listen to the authorities, believing that there was no need to practice the suggested preventive behaviors for COVID-19. A recent study found that compared with younger adults, older men were less worried about COVID-19 and adopted fewer preventive behaviors [19]. Hence, special efforts should be made to enhance older people's protection against this new infectious disease.

A good understanding of underlying factors that encourage older people to adopt particular preventive behaviors is significant to provide necessary strategies to implement. A higher level of knowledge has been proved to be associated with positive behavior changes [20,21]. In addition, studies on individuals' behavior changes toward infectious diseases have suggested that perceptions or beliefs about an outbreak are important in determining the adoption of particular preventive behaviors [22-24]. In particular, the health belief model (HBM) [25] has provided a theoretical framework in previous research for understanding and explaining various health-promoting behaviors [26-28], including preventive behaviors during global pandemics [29-31]. The HBM model reveals that significant perception factors include perceived severity, perceived susceptibility, and perceived benefits. Additionally, previous literature has suggested that self-efficacy in preventing disease [32] and belief in the ability of the government to contain the spread of the epidemic [33] are significantly associated with the practice of preventive measures.

Studies have investigated behavioral responses toward COVID-19 among the general population [34,35] and in specific populations such as health care workers [36] and college students [37,38]; however, literature reports focusing on behavior changes in older people remain scant in spite of the detection of increased vulnerability among this population. Therefore, this paper aims to assess the knowledge, perceived beliefs, and preventive behaviors of older Chinese residents toward COVID-19 and to explore the knowledge, perceived beliefs, and other relevant factors that influence behavior changes. Our findings may help enhance the effectiveness of intervention programs targeting the older population.

Methods

Study Design

This cross-sectional study was conducted using an anonymous web-based questionnaire between February 19 and March 19, 2020. A convenience sampling method was used to recruit participants. Chinese residents aged ≥60 years without intellectual or cognitive impairment who agreed to participate in our survey were considered eligible. Those who were illiterate or unable to use electronic devices could ask others to help them fill out the questionnaire; however, it was emphasized that the answers must always reflect the older person's own opinions. The link to the web-based questionnaire was sent through WeChat (which is similar to WhatsApp) and other social media platforms to the contacts of potential respondents. A brief introduction was presented at the beginning of the survey to inform the respondents of the purpose and content of this study and to instruct them on how to complete the questionnaire. Respondents who completed the questionnaire were entered in a draw for a monetary incentive of approximately ¥1-5 (US $0.15-0.76).

Sampling

According to Kendall, multiple regression analysis demands a sample size of at least 5 to 10 times the number of independent variables. Thus, we required a maximum sample size of 670 cases, as 67 independent variables were included in this study. Returned surveys with unreasonably short answer times, incomplete information, or logic problems were deemed invalid. The effective sample size estimated for the study was 957 cases, with an invalid response rate of 30%. Finally, a total of 1501 questionnaires were returned in the study duration; after excluding 212 invalid questionnaires and 26 participants who reported having never heard about COVID-19, a total of 1263 surveys (84.1%) from all of the 31 provinces, municipalities, and autonomous regions in mainland China remained for statistical analysis.

Measures

Dependent Variable (Practice of Preventive Behaviors)

The questionnaire on the practice of COVID-19 preventive behaviors was developed based on the guidelines from the Chinese Center for Disease Control and Prevention (CDC). This section contained 5 items, including washing hands frequently, wearing a face mask in public areas, disinfecting one's household, ventilating one's household, and avoiding crowds (P1-P5). Answers of “more,” “as usual,” and “less” were rated as 3, 2, and 1, respectively. Therefore, the total behavior score could range from 5 to 15, with a higher score indicating better adherence to preventive behaviors.

Independent Variables

Background Variables

Sociodemographic characteristics were surveyed in this section of the survey, including gender, age, marital status, education level, registered residential area, and monthly household income per capita. Additionally, the respondents' self-perceived health status, current addresses at the district level, and local community-level control measures (free entry/exit as usual, entry/exit control exercised, and lockdown) in their residential areas were surveyed. The provinces of the respondents' current addresses were divided into eastern, central, and western regions according to the National Bureau of Statistics of China and were also categorized into three levels according to their numbers of confirmed COVID-19 cases; provinces with <100 cumulative confirmed cases, 100-1000 cases, and >1000 cases were rated as low, medium, and high-risk areas, respectively.

COVID-19–Related Knowledge

The participants' levels of knowledge about COVID-19 were assessed by 7 questions (K1-K7): 1 regarding the province in which the first COVID-19 cases were reported, 1 regarding the incubation period, 1 regarding the source of infection, 2 regarding transmission modes, 1 regarding susceptible populations, and 1 regarding the availability of a vaccine for COVID-19. The answers were judged according to the guidelines for clinical management of COVID-19 by the National Health Commission of the People's Republic of China [39]. A correct answer was assigned 1 point, and an incorrect or unknown answer was assigned 0 points. The total knowledge score thus ranged from 0 to 7, with a higher score representing better knowledge of COVID-19.

Perceived Beliefs Regarding COVID-19

Based on the HBM and previous studies, the perceived beliefs measured in our study included constructs of HBM (perceived severity, perceived susceptibility, and perceived benefits), self-efficacy in preventing the disease, and belief that the government can contain the spread of the epidemic (B1-B5). Perceived severity of COVID-19 was assessed by 1 item asking the respondents whether they would suffer from more severe symptoms if they contracted the disease; an answer of “yes” was coded as 1, while other answers were coded as 0. One item assessed perceived susceptibility by measuring the degree to which the respondents perceived themselves to be vulnerable to COVID-19; the responses were coded into two groups (1: high/very high; 0: low/very low/I don't know). Perceived benefits were assessed by three items measuring the respondent's belief in the effectiveness of COVID-19–related preventive measures of mask wearing in public areas, handwashing, and avoidance of visiting crowded places, respectively; answers of “yes” were considered appropriate (1: yes; 0: others), and the perceived benefits indicator was established by counting the number of appropriate answers (values of 0-3). The respondents' self-efficacy in preventing the disease and confidence in the government to contain the spread of the epidemic were assessed by asking “Are you confident that you can protect yourself from contracting COVID-19?” and “Do you believe that the government can win the battle against COVID-19?” Answers of “yes” were considered positive and were given 1 point, while 0 points were given for choosing other answers.

Statistical Analysis

Descriptive statistics were used to summarize the background factors and COVID-19 knowledge, perceived beliefs, and behaviors; the results are presented as frequencies (n) and percentages (%) or as means and SDs. Associations between background variables and behavior scores were examined by one-way analysis of variance (ANOVA) or independent sample *t* tests as appropriate. A multiple linear regression model using statistically significant background variables, knowledge scores, and factors of perceived beliefs as independent variables and scores of preventive behavior as outcome variables was applied to identify factors associated with preventive behaviors. The demographic variables of the respondents were entered in the regression model first to control for their effects. Then, the knowledge score was entered in the next block of the regression, and factors of perceived beliefs were simultaneously entered in the last block. Unstandardized regression coefficients (β) and 95% CIs are reported. All statistical analyses were performed in SPSS version 21.0 (IBM Corporation), and a *P* value <.05 was considered statistically significant.

Ethics Statement

The study protocol was approved by the Ethics Committee of School of Public Health, Zhejiang University (approval number: ZGL202002-2) before the formal survey. The questionnaire was designed to be anonymous and voluntary, and respondents were informed that submission of the questionnaire implied informed consent. The data were kept confidential, and the results did not identify the respondents personally.

Results

Background Characteristics

Of the 1263 participants, 730 (57.8%) completed the questionnaire with the help of others, and 687 (54.4%) were registered permanent residents of rural areas. The mean age was 69.48 years (SD 6.72), over half of the respondents were female (697/1263, 55.2%), and approximately three-fourths were married or cohabitating (941/1263, 74.5%). Of the 1263 participants, 586 (46.4%) had an education level of primary school or below, and most respondents (844, 66.8%) had an average household income of between ¥600 and ¥6000 per month (US $91.61-$916.07). Moreover, 564/1263 participants (44.7%) self-reported their physical health status to be fair; 613 (48.5%) of the 1263 respondents lived in the eastern region, and nearly half of the participants (591/1263, 46.8%) lived in areas with medium risk of COVID-19. The majority of respondents (1050/1263, 83.1%) reported that entry and exit control was exercised in their community or village.

Levels of COVID-19–Related Knowledge, Perceived Beliefs, and Behaviors

Knowledge

The mean knowledge score was 6.06 (SD 0.03, range 1-7), suggesting an overall 87% (6.06/7*100) correct rate on this knowledge test (Table 1). Of the 1263 respondents, 85.4% (n=1078) agreed that the current main source of infection was patients with COVID-19. In terms of modes of transmission, 98.1% of respondents (1239/1263) thought that COVID-19 can be transmitted by droplets emitted by patients; however, less than 80% (960/1263, 76.0%) were aware that it can also be transmitted through virus-contaminated objects. Approximately 90% of respondents (1165/1263, 92.2%) correctly stated that the population is generally susceptible to the virus regardless of age. However, only 64.1% of the respondents (809/1263) knew that effective vaccines for COVID-19 were not yet available.

Table 1. Participants' knowledge and perceived beliefs regarding COVID-19 (N=1263).

Item	Response
Knowledge items	
K1: The earliest outbreak of COVID-19 in China occurred in Hubei Province, n (%)	
Correct	1258 (99.6)
Incorrect/unknown	5 (0.4)
K2: The incubation period of COVID-19 is 1-14 days, n (%)	
Correct	1139 (90.2)
Incorrect/unknown	124 (9.8)
K3: Currently, the main source of infection is patients with COVID-19, n (%)	
Correct	1078 (85.4)
Incorrect/unknown	185 (14.6)
K4: COVID-19 can be transmitted by droplets from a patient, n (%)	
Correct	1239 (98.1)
Incorrect/unknown	24 (1.9)
K5: COVID-19 can be transmitted through touching virus-contaminated surfaces, n (%)	
Correct	960 (76.0)
Incorrect/unknown	303 (24.0)
K6: All age groups can become infected with the new coronavirus, n (%)	
Correct	1165 (92.2)
Incorrect/unknown	98 (7.8)
K7: There is currently no vaccine available that protects against COVID-19, n (%)	
Correct	809 (64.1)
Incorrect/unknown	454 (35.9)
Range of knowledge scores	1-7
Mean knowledge score (SD)	6.06 (0.03)
Perceived belief items, n (%)	
B1: Perceived severity of COVID-19	
Yes	1141 (90.3)
No/I don't know	122 (9.7)
B2: Perceived susceptibility of COVID-19	
High/very high	190(15.0)
Low/very low/I don't know	1073(85.0)
B3: Perceived benefits indicator[a]	
0	6 (0.5)
1	26 (2.1)
2	68 (5.4)
3	1163 (92.1)
B4: Self-efficacy in preventing COVID-19	
Yes	1048 (83.0)
No/I don't know	215 (17.0)
B5: Confidence in the government to control the spread of COVID-19	
Yes	1160 (91.8)
No/I don't know	103 (8.2)

[a] The perceived benefits indicator was established by counting the number of items with “yes” responses for the three basic preventive measures (ie, handwashing, face mask wearing, and staying at home).

Perceived Beliefs

The majority of the older respondents (1141/1263, 90.3%) believed that older people may suffer from more severe symptoms if they are infected with COVID-19 (Table 1). Most respondents (1073/1263, 85.0%) did not perceive that their likelihood of contracting COVID-19 was high or very high. A substantial proportion of participants (1163/1263, 92.1%) perceived the benefits of all three types of preventive measures (ie, handwashing, wearing a face mask, and staying at home). Additionally, 83.0% of the respondents (1048/1263) were confident in their own abilities to prevent the disease, and 91.8% (1160/1263) believed that the government can “win the battle” against COVID-19.

Behaviors

The mean score of preventive behavior toward COVID-19 was 13.73 (SD 1.62, range 7-15). The participants’ preventive behavior changes in response to the COVID-19 pandemic are shown in Table 2. It is reassuring that more than four-fifths of our 1263 participants had increased their frequency of handwashing (n=1025, 81.2%) and wearing a face mask in public venues (n=1035, 81.9%) to ensure their safety; in addition, 86.6% (n=1094) of the older people had reduced their visits to crowded places. However, fewer participants had increased their household ventilation (956/1263, 75.5%) and disinfection (816/1263, 64.6%).

Table 2. Participants’ preventive behavior changes in response to the COVID-19 pandemic in the past week (N=1263), n (%). Questions were answered using the following scale: 1=less, 2=as usual, and 3=more. For the total behavior score, we calculated how many specific behavior changes each participant endorsed. The range of the behavior scores was 7-15, and the mean score was 13.73 (SD 1.62).

Behavior	More	Less	As usual
P1: Face mask wearing in public venues	1035 (81.9)	60 (4.8)	168 (13.3)
P2: Washing of hands	1025 (81.2)	12 (1.0)	226 (17.9)
P3: Household ventilation	956 (75.5)	66 (5.2)	241 (19.1)
P4: Home disinfection	816 (64.6)	38 (3.0)	409 (32.4)
P5: Avoidance of crowds	1094 (86.6)	37 (2.9)	132 (10.5)

Demographic Factors of Preventive Behaviors: Univariate Analysis

As shown in Table 3, region, marital status, education level, residence registration, and monthly household income per capita were significantly associated with preventive behaviors (all *P*<.05). Participants who lived in western regions had significantly lower level of behavior than participants from eastern regions (*P*=.01). Respondents who were married or cohabitating had significantly higher behavior scores (*P*<.001). Rural dwellers and respondents who attended primary school or below had lower behavior scores (both *P*<.001). The behavior scores of participants with an average household income of <¥600 per month (US $91.61) were significantly lower than those of participants with monthly incomes higher than ¥6000 (US $916.07; *P*=.02). Interestingly, a significant association between local community-level control measures and behavior score was observed (*P*<.001); respondents engaged in more preventive behaviors when epidemic control measures were exercised in their areas of residence.

Table 3. Univariate analysis of the demographic variables associated with preventive behaviors (N=1263).

Variable	Participants, n (%)	Behavior score[a]		
		Mean (SD)	*t*/*F* (df)	*P* value

[a] Values based on independent sample *t* tests and one-way analysis of variance (ANOVA) for continuous variables to examine differences between preventive behaviors and demographic variables. For categories of variables with significant ANOVA results (significant at *P*<.05 between the groups), multiple comparisons between each of 2 categories were performed by post hoc analysis (least significant difference).

[b] Significant variables were included in the subsequent multivariable analyses.

[c] Italics indicate statistical significance.

[d,e] Within each column, if two means share same superscript (d or e), they are not statistically different (*P*>.05) from one another.

[f] 1 ¥=US $0.14 on February 20, 2020.

[g] Provincial COVID-19 epidemic level: The number of cumulative confirmed COVID-19 cases on the survey launch day (ie, March 20, 2020) in the province where the respondent was located during the COVID-19 pandemic.

Factors Associated With Behaviors: Multivariable Analyses

The knowledge scores and perceived belief-related variables reported in Table 1, together with significant background variables, were included in the hierarchical linear regression models. In block 1, the demographic factors of region, marital status, education level, registered residence, monthly household income per capita, and local community-level control measures were entered first, accounting for 4.7% of the variance (R^2=0.047, $F_{6,1256}$=5.575, *P*<.001). The score for knowledge about COVID-19 was entered into block 2 and contributed an additional 2.9% of the variance (R^2=0.076, $F_{7,1255}$=8.603, *P*<.001). Finally, factors of perceived beliefs regarding COVID-19, including perceived severity, perceived susceptibility, perceived benefits, self-efficacy in preventing the disease, and confidence in the government, were entered in the third block; these factors were significant in predicting behaviors even after considering the effects of background and knowledge factors, and they contributed an additional 3.2% of the variance (R^2=0.108, $F_{12,1250}$= 8.904, *P*<.001). The linear regression analysis of the preventive behaviors is presented in Table 4 and Table 5.

Education level and registered residence were generally nonsignificant, while some significant marital status and control measure differences were noted. Overall, respondents who were married or cohabitating (vs single, divorced, separated, or widowed, β=0.355, 95% CI 0.150-0.560) and who could not leave the house (vs free entry and exit, β=0.898, 95% CI 0.310-1.486) were more likely to have better preventive behavior scores (*P*<.01). After adjusting for background characteristics, we discovered that older people with higher COVID-19–related knowledge scores had significantly higher behavior scores (β=0.198, *P*<.001). Meanwhile, the results showed that 3 of the 5 components of perceived beliefs, namely, perceived susceptibility (β=0.263, 95% CI 0.022-0.504), perceived benefits (β =0.643, 95% CI 0.305-0.982), and self-efficacy in preventing the disease (β =0.468, 95% CI 0.223-0.713), were positively associated with preventive behaviors (all *P*<.05); however, perceived severity and confidence in the government were not significant predictors of preventive behaviors. Among the influencing factors, local community-level control measures showed the greatest impact on behaviors, followed by perceived benefits.

Table 4. Multivariable analysis of factors associated with preventive behaviors (N=1263).

Discussion

Principal Findings

Older people, who are particularly vulnerable to acute diseases and their complications, are currently greatly threatened by the outbreak of COVID-19. Special effort should therefore be made to encourage older people to practice the behaviors suggested by the government to prevent the disease. An understanding of older people's knowledge, perceived beliefs, and behaviors toward COVID-19, which affect the adoption of related health behaviors, can be a first step to prevent the spread of COVID-19 in this population.

In this study, it was found that Chinese older adults had good knowledge of COVID-19; the respondents had an overall correct rate of 87% on the knowledge questionnaire, which was slightly lower than a rate reported for the Chinese general population (90%) [40] but much higher than that reported for US residents (80%) [41]. The high correct rate was surprising, as previous studies suggested that knowledge scores are negatively related with age [42-44]. However, this finding may be due to the large amounts of publicity related to COVID-19 through various channels that are appropriate to the needs and characteristics of older people, such as vivid prints, marked banners, and broadcasts in dialect. The 2 items with the lowest correct rates are worth mentioning. Knowledge about modes of transmission, which has been proved to be a salient factor influencing the level of adoption of preventive measures [45], should be further improved among older people. Meanwhile, older people should also be informed that an effective vaccine for COVID-19 is not yet available and that taking precautions against the disease is still highly important.

The perceived beliefs of older Chinese residents toward COVID-19 were found to be optimistic overall. Although the majority of respondents (1141/1263, 90.3%) perceived that older adults would suffer from more severe symptoms if they were infected, relatively few respondents (190/1263, 15.0%) thought they were at high risk of acquiring the disease. Moreover, the majority expressed confidence in themselves (1048/1263, 83.0%) and the government (1160/1263, 91.8%) to stop the spread of COVID-19. This optimistic belief could be explained by the unprecedented epidemic control measures taken by the Chinese government after the outbreak of COVID-19 in the country and the concerted efforts of people all over China to prevent the spread of the disease. From January 20, 2020, when person-to-person transmission was confirmed and the Chinese public was notified of this finding, a series of nationwide public health emergency measures, including isolation and quarantine, close management of working and living spaces, and the Examine and Approve Policy on the resumption of work, were implemented by the Chinese government, health institutions, communities, companies, etc [46].

In addition to efforts from all sectors of society, high adherence to the lifestyle modifications suggested by the government and public health organizations greatly delayed the spread of the disease [47]. In our findings, 64.6%-86.6% of respondents reported practicing five major preventive behaviors more frequently in the preceding week. The reason for this finding may be that this study was conducted at a time when these key preventive measures were highly emphasized in China. Similarly high tendencies to adopt these precautionary behaviors during the pandemic have been found in other studies [35,48]. In particular, more than 80% of respondents reported increased handwashing and face mask wearing and decreased time spent in crowds, indicating that basic protective behaviors against COVID-19 had taken root among older people. The majority of participants avoided going out, which can potentially be attributed to the widely disseminated governmental propaganda and social media messages, which continuously instilled and reinforced people's incentives to stay home (eg, personal safety, good citizenship, and contribution to the control of the national epidemic). Moreover, individuals may have felt pressure from the community to adhere to behaviors such as imposed lockdowns or quarantine of entire regions with suspected cases. Handwashing and wearing of face masks have long been regarded as significant preventive habits in the daily life of the public since they were proved to be efficacious in preventing influenza and SARS [49,50]. Lau et al [51] observed that hand-washing and face mask wearing were commonly practiced during the SARS outbreak, and these behaviors were sustained by a large proportion of the public even after the SARS epidemic subsided in Hong Kong. In contrast, the effectiveness of household ventilation and disinfection may have been neglected, with fewer participants reporting that they had practiced these two behaviors more frequently in the past week. Habit has a great impact on routine behavior—including hygiene behavior—and despite their best intentions, people may find it difficult to implement new measures during a pandemic if they were not previously in the habit of performing them [52,53]. Further education on practicing household ventilation and disinfection is needed, as these two measures are indispensable in preventing COVID-19.

In line with previous research [54-56], our study also found that individuals' demographic characteristics had a significant influence on their preventive behaviors. Linear regression analysis of the behavior scores showed that participants who were married or cohabitating were more likely to report that they had complied with advocated protective behaviors more frequently; this finding was consistent with similar studies regarding SARS [57,58]. On the one hand, older adults who are married or cohabiting can receive support from their spouse or partner. Family support has been shown to influence older people's health beliefs and self-care behaviors [59]. The more family support older people receive, the more attention they will pay to their own health, accompanied with increased willingness to acquire health knowledge and more positive preventive beliefs. On the other hand, according to the HBM, advice from family members can be regarded as an external cue to action, which is also a very important factor in increasing various preventive behaviors [60]. Consistent with research by Kong et al [48], age was not a significant factor of preventive behaviors in our study (*P*=.054); meanwhile, other studies have found that compared with younger participants, individuals aged 60 years or older implemented fewer preventive behavior changes [19,61]. Further larger-scale studies are warranted to assess the association between age and behaviors to prevent COVID-19.

Additionally, community-level control measures were found to be significantly associated with the practice of preventive measures. As COVID-19 rapidly spread from a single city to the entire country, the governmental "minimum contact strategy" was implemented nationwide; also, close management and screening of communities and villages to curb COVID-19 were subsequently implemented nationally in China [46]. Although the contribution of community control measures cannot be quantified, our study supports that community-level control measures against COVID-19 are related to significant increases in older adults' practice of recommended preventive behaviors. We further confirmed that respondents who could not leave the house showed higher compliance with suggested preventive measures than those who could move freely as usual. According to the socioecological model, factors of structural, interpersonal, and personal levels determine health-related behaviors [62]. At the personal level, it has been found that older Chinese people feel they have an ethical duty ("filial piety") to protect others, which facilitates their adherence to quarantine. In Wenzel's study [63], "filial piety" suggested the "right and humane" way to act toward one's family and others in the community and guided Chinese older adults in their use of strategies against SARS [63]. As social beings, people's behaviors are subject to the influence of social relationships [64]. Chinese older people not only worry for themselves but also have concern for their significant others regarding COVID-19, which motivates their adoption of precautionary measures. Meanwhile, environmental manipulation and policies are crucial structural-level factors to encourage individuals to practice desired preventive behaviors. According to the WHO, social distancing/self-isolation and lockdown are two important nationwide social measures during a public health crisis [6]. The Chinese government adopted these strategies to mitigate the risk of COVID-19. Therefore, personal perceived ethical duty combined with community actions have facilitated China's response to COVID-19. Particularly, community and home quarantine provided Chinese older adults with ample time to communicate with and influence their significant others. The abovementioned findings highlight the importance of control measures at the community level, which should be considered when planning pandemic control strategies in the future.

In addition to background factors, this study found that knowledge and perceived beliefs toward COVID-19 were significant predictors of preventive behaviors. In accordance with previous findings, this study confirmed that people with adequate knowledge about COVID-19 were more likely to take preventive measures in response to the pandemic than people who lacked such knowledge [56,65]; this suggests that health education aimed at improving people's COVID-19 knowledge plays an important role in promoting preventive behaviors toward COVID-19. With regard to perceived belief–related factors, our study confirmed the positive correlation between self-efficacy in preventing COVID-19 and the adoption of preventive measures found in previous research [32,54]; however, bidirectional effects may exist between these two variables, as it has been suggested that perceived self-efficacy can encourage an individual to adopt certain behaviors to achieve desired outcomes, while success in performing certain behaviors can further augment perceived self-efficacy [66]. Contrary to previous findings [22,30,33], our study found that belief in the efficacy of local health authorities did not significantly predict the target COVID-19 preventive behaviors. The belief in government may not successfully translate into positive behavioral changes at the individual level; additionally, the positive relationship between trust in the government and the practice of preventive behaviors can be mediated by levels of perceived self-efficacy [20]. A relatively strong linear correlation between confidence in the government and self-efficacy (r=0.335, P<.001) was also found in this study.

Some of the items we used to assess the participants' perceived beliefs were derived from the HBM, which includes perceived severity, perceived susceptibility, and perceived benefits. Although most of our respondents perceived that they might progress to serious symptoms if they were infected with COVID-19, perceived severity was not found to be significantly related to COVID-19–related preventive behaviors in this study. Perceived severity has been suggested to have relatively low relevance for preventive health behaviors; however, it may play an important role when individuals have already been diagnosed with certain diseases [25]. Therefore, the fact that the participants had not yet been diagnosed with COVID-19 as well as their low perceived susceptibility could account for the insignificant association between perceived severity and preventive behaviors. Among our participants, perceived susceptibility was found to be a significant correlate of COVID-19 preventive health behaviors. Perceived susceptibility has been consistently found to be a salient determinant of participation in preventive measures during an epidemic among both the general population and older people [23,33,67,68]. Other studies on health screening [69,70] and exercise behavior [71] also found that perceived susceptibility plays an important role in participation in protective behaviors. Despite the significant positive association between perceived susceptibility and engagement in protective behaviors, only 15.0% (190/1263) of the older people in this study perceived that they were highly vulnerable to COVID-19. This finding indicates that older people should be further warned about their higher vulnerability to the disease; moreover, to ensure the effectiveness of warnings, messages issued by public health communicators should be comprehensible, concise, and convincing [22]. Meanwhile, perceived benefits were found to be more prominent in affecting individuals' adoption of preventive behaviors in the aforementioned HBM constructs [26]. When people deem certain preventive health behaviors to be effective in preventing a disease, they are motivated to engage in these behaviors [22,58,72,73]. Indeed, communications that increase individuals' perceptions of the benefits of particular health-related behaviors have been proved to be successful in reducing health threats [74-76]. Health authorities should be reminded to exert effort to provide sufficient health communication messages to enhance older people's perceived susceptibility and benefits in the context of the COVID-19 pandemic, which can greatly motivate these individuals to engage in preventive measures.

Limitations

Our study has some limitations. First, no standardized tool for assessing knowledge, perceived beliefs, or practice of preventive behaviors on COVID-19 has been previously validated. We designed the questionnaire based on the latest official report from the WHO, the Chinese CDC, and the scientific literature; however, the depth of the survey may be limited, as we were obligated to conduct our investigation quickly and recruit as large a sample as possible. Secondly, selection bias may exist. The web-based survey only included people who have access to the internet, and older people who were infected or had close contacts with confirmed or suspected COVID-19 patients may not have wanted to participate in this survey; thus, the generalizability of our findings may be limited. However, web-based surveys may be the most appropriate method of data collection during an epidemic, as this method can prevent transmission; moreover, fielding the survey offline was not feasible, as strict epidemic control measures were being exercised in most parts of the country. Thirdly, this study was cross-sectional, and no casual effect statements concerning the relationship between targeting variables and the performance of preventive behaviors could be made. Fourthly, recall and social desirability bias may exist, as only retrospective self-reports of the participants were collected.

Strengths

Despite the above limitations, this is one of few studies to assess the knowledge, perceived beliefs, and preventive behaviors toward COVID-19 among the older adult population in China. Meanwhile, a large number of respondents from all provinces in mainland China were recruited, enabling us to obtain a wide range of participants with various demographic backgrounds. Additionally, the investigation was conducted in the stable epidemic period (February 19 to March 19, 2020), when community-wide COVID-19 prevention activities were launched by local health authorities; thus, we were able to assess how community-level control measures influenced personal preventive behaviors. Therefore, our results are of practical significance for the design and implementation of health programs for the older population in the prevention of COVID-19 and other emerging epidemics.

Conclusions

Generally, the Chinese older adults in our survey demonstrated good knowledge, optimistic perceived beliefs, and appropriate behaviors toward COVID-19 during the pandemic, which are important factors to limit the spread of the disease. Higher behavior scores were found among older adults who were married and cohabitating and who were restricted by community-level control measures, suggesting that health education programs should pay more attention to people who are single and can move around freely. In addition, our findings suggest that good knowledge and appropriate perceived beliefs are associated with high levels of engagement in behaviors to prevent COVID-19. Therefore, to promote preventive behaviors, continued health intervention programs are advised among older people to improve their knowledge in certain aspects, including transmission modes and vaccines against COVID-19; additionally, older people's perception of their own vulnerability to COVID-19 and the effectiveness of COVID-19–related preventive behaviors should be further emphasized.

Acknowledgments

We are grateful to all the survey participants.

Authors' Contributions

HMW and ZC conceived and designed the study. YC and BYC assisted in the questionnaire design and data collection. HC, YL, and HHZ assisted in the data collection. YC and RZ contributed to the statistical analysis and drafted the manuscript; HMW, YC, and RZ finalized the manuscript. All authors have read and approved the final version of the manuscript.

Abstract

Background: Considerable research has been devoted to examining the mental health conditions of patients with COVID-19 and medical staff attending to these patients during the COVID-19 pandemic. However, there are few insights concerning how the pandemic may take a toll on the mental health of the general population, and especially of nonpatients (ie, individuals who have not contracted COVID-19).

Objective: This study aimed to investigate the association between social media use and mental health conditions in the general population based on a national representative sample during the peak of the COVID-19 outbreak in China.

Methods: We formed a national representative sample (N=2185) comprising participants from 30 provinces across China, who were the first to experience the COVID-19 outbreak in the world. We administered a web-based survey to these participants to analyze social media use, health information support received via social media, and possible psychiatric disorders, including secondary traumatic stress (STS) and vicarious trauma (VT).

Results: Social media use did not cause mental health issues, but it mediated the levels of traumatic emotions among nonpatients. Participants received health information support via social media, but excessive social media use led to elevated levels of stress (β=.175; $P<.001$), anxiety (β=.224; $P<.001$), depression (β=.201; $P<.001$), STS (β=.307; $P<.001$), and VT (β=.688; $P<.001$). Geographic location (or geolocation) and lockdown conditions also contributed to more instances of traumatic disorders. Participants living in big cities were more stressed than those living in rural areas (P=.02). Furthermore, participants from small cities or towns were more anxious (P=.01), stressed ($P<.001$), and depressed (P=.008) than those from rural areas. Obtaining more informational support (β=.165; $P<.001$) and emotional support (β=.144; $P<.001$) via social media increased their VT levels. Peer support received via social media increased both VT (β=.332; $P<.001$) and STS (β=.130; $P<.001$) levels. Moreover, geolocation moderated the relationships between emotional support on social media and VT (F_2=3.549; P=.029) and the association between peer support and STS (F_2=5.059; P=.006). Geolocation also interacted with health information support in predicting STS (F_2=5.093; P=.006).

Conclusions: COVID-19 has taken a severe toll on the mental health of the general population, including individuals who have no history of psychiatric disorders or coronavirus infection. This study contributes to the literature by establishing the association between social media use and psychiatric disorders among the general public during the COVID-19 outbreak. The study findings suggest that the causes of such psychiatric disorders are complex and multifactorial, and social media use is a potential factor.

The findings also highlight the experiences of people in China and can help global citizens and health policymakers to mitigate the effects of psychiatric disorders during this and other public health crises, which should be regarded as a key component of a global pandemic response.

Introduction

Background

After COVID-19 hit the world, health care workers have been rushing to care for infected patients and save lives. In the race to contain the COVID-19 pandemic, it is important for health care providers to not ignore another big risk—the invisible toll on mental health among nonpatients. One of the key lessons we have learned from the COVID-19 pandemic is that living in this public health crisis is extremely stressful for everyone, including those who appear healthy and have not contracted the virus [1]. This was evident in China, where fear, worry, and anxiety about COVID-19 and its health risks were overwhelming as soon as the disease spread across the country [2]. Following the lockdown announced in Wuhan on January 23, 2020, other Chinese cities quickly restricted people from moving around. A mandatory lockdown had forced millions of Chinese to stay at home for weeks, and even months. Living in an isolated environment could make people feel unattached, worried, lonely, and even traumatized [3]. The strong emotions experienced by the Chinese during the initial months of the COVID-19 outbreak were almost unimaginable to the outside world until it spiraled into a global pandemic [2], resulting in millions of cases and hundreds and thousands of deaths worldwide.

As researchers in epidemiology, medicine, and public health worldwide are continuously researching medications, vaccines, and coping strategies for COVID-19, it is important to study how health information on social media and lockdown or quarantine situations may contribute to the toll on people's mental health. Many studies addressing the impact of the pandemic on mental health focus on COVID-19 patients [4], who have shown, for instance, posttraumatic stress symptoms [5] or depression [6]. This study aimed to reveal a holistic picture by evaluating the effects of the COVID-19 pandemic on the mental health of nonpatients based on a national representative sample from China. Using a national representative sample is critical for such a study given the widespread urban-rural differences in China. The COVID-19 pandemic has had different effects across China's cities, towns, and rural areas, as the local responses in these regions depended on a complex interplay of numerous social and economic factors. Hence, the toll on mental health on people in these regions could considerably vary depending on their geographic location (or geolocation) and other internal or external factors.

Social Media Use and COVID-19

Considerable research has been devoted to examining the mental health of patients diagnosed with COVID-19 [5-7] and medical staff who cared for and treated these patients during the pandemic [8,9]. However, not much is known about the mental health conditions of nonpatients, who might experience varying degrees of psychiatric disorders due to COVID-19. Research shows that as people are consistently exposed to negative information about a crisis, their anxiety and depression levels could elevate for an extended period [10]. As COVID-19 spread in China, people began to use WeChat, China's leading social media app, more frequently. By February 8, 2020, over 100 "mini programs" were added to WeChat to provide epidemic status information, and the app's users grew by nearly 60% within 3 weeks [11]. The growing use of social media for crisis management has been well documented in the literature, and social media is considered a powerful tool to share health information related to pandemic risks [12,13].

However, there are controversies concerning the links between social media use and mental health. Studies have found that social media use may decrease satisfaction of life [14] and increase self-harm, suicidal ideation [15,16], psychological distress, depression, and anxiety [14]. Systematic reviews have shown that most of these studies are from Western countries, and a few studies are from Asian countries [14,15]. Insights from Asian countries may not only deepen the understanding of the relationship between social media use and mental health but also provide suggestions for education and policies [14]. People benefit from using social media in terms of promoting behavior change [17], obtaining health information support, and staying connected with others [2]; however, social media could also spread fear or misinformation about COVID-19, thereby causing harm to their mental health and psychological well-being [13]. Thus, more effort is merited to study how using social media to seek and share health information could have an impact on the users' mental health during a health crisis.

Informational, Emotional, and Peer Support

One of the main reasons people have been sharing health information on social media during the COVID-19 outbreak is the social support they gain from other users—a phenomenon that can be best explained by the uses and gratifications theory [18,19]. This theory holds that people use certain media content or platforms to gratify specific informational needs and demands; otherwise, they would no longer come back and use it again. Health information provides significant social support to people with health concerns, resulting in a number of benefits that help symptom control, disease recovery, life safety, and overall well-being [20]. Social support is defined as "the individual feeling valued and cared for by their social network as well as how well the person is embedded into a network of communication and social obligation" [21]. In other words, social support refers to the perception that one is cared for and support is exchanged through interpersonal interactions [22].

Helgeson [23] argues that social support has 3 main forms: informational, emotional, and instrumental support. Informational support refers to the provision of advice, guidance, and other useful information [24]. Emotional support exhibits the expressions of care, concern, empathy, and sympathy [23]. Instrumental support represents the concrete and direct ways in which people assist others [25,26]; this is referred to as "peer support" in this study.

The support users obtain on social media through accessing and sharing pandemic-related information can be viewed as health information support [2]. It functions like a type of social support received from family members, friends, colleagues, or peers during the pandemic. Ample research has identified that health information support provides patients with significant care and emotional support [27]. This type of support can also improve users' capability of making informed medical decisions [28]. Identifying with social media groups has been found to increase one's self-esteem and self-efficacy, and thus reduce uncertainty about the self [29]. Seeking support and social connection is a critical point in the lives of people with chronic conditions [30].

In addition to informational support, social media users gain emotional and peer support from the health information they access [2]. Emotional support is a key component of peer support in health care settings. High emotional support is known to mitigate the stress response and prevent consequent adverse effects on the progression of depression, posttraumatic stress disorder, and prostate cancer [31]. Patients who report more tangible emotional support are more likely to have experienced a positive social interaction with fellow patients and medical professionals [32]. WeChat users can obtain emotional support by chatting with friends, joining social media groups of their interests, and staying connected with others [20].

Peer support is a subcategory of social support, and it is differentiated by the source of support received from peers who are in a similar demographic group or illness community. Social media groups are important platforms to discuss medical conditions, share personal experiences, and seek health information [33,34]. In this study, peer support is defined as a type of support social media users receive from others when they share their knowledge and experiences of COVID-19. However, the quality of health information on the internet may vary depending on the sources, and health misinformation has become a severe threat to public health [35]. For instance, the inaccuracy of online health information deteriorates the physician-patient relationship and erodes trust in doctors [20]. Thus, it would be important to study how the social support about COVID-19 that people receive on social media is associated with their mental health and psychiatric disorders. Overall, peer support complements and enhances mental health by providing the necessary emotional, social, and practical assistance for managing disease and staying healthy.

Mental Health and the Pandemic

Global health crises, especially the COVID-19 pandemic, have diverse and substantial health implications on the human society [1]. The deleterious consequences related to COVID-19 along with the unprecedented mitigation strategies pose major threats to the well-being and mental health of people worldwide [36]. COVID-19 has significantly changed various aspects of our routine life, including economics, travel, interpersonal communication, and health management [37]. When an individual's routine life is suddenly and severely disrupted by a pandemic, the human brain may no longer function normally as usual; this can, consequently, lead to stress or psychiatric disorders [38]. This affects not only the people who have been diagnosed with COVID-19 but also those who seem to be "normal" or "healthy." Thus, a psychiatric disorder may occur in individuals who have not been infected by the virus themselves but have experienced or witnessed the challenges of other individuals during the COVID-19 pandemic [39]. Although findings regarding the relationship between social support and mental health are inconsistent, social support, in general, has been found to provide physical and psychological advantages to combat stressful events and recover from psychological distress [40]. Lack of social support, however, has been linked with the onset and development of depression [41], mood disorders [42], and other medical illnesses such as multiple sclerosis and rheumatoid arthritis [43,44].

Research Questions

Building upon previous findings, this study is among the first to investigate nonpatients' mental health conditions such as stress, anxiety, depression, secondary traumatic stress (STS), and vicarious trauma (VT) during the peak of the COVID-19 epidemic in China. We measured both STS and VT, but not posttraumatic stress symptoms, as COVID-19 was an ongoing crisis when we collected data for analyses. Thereafter, we analyzed the internal (ie, demographics) and external (ie, pandemic and environmental conditions) factors that may contribute to possible psychiatric disorders such as STS and VT. Specifically, we investigated the following research questions (RQs):

- RQ1: Did nonpatients experience any stress, anxiety, depression, STS, or VT at the peak of the COVID-19 outbreak in China?
- RQ2: Did people living in different geolocations experience varying levels of psychiatric disorders?
- RQ3: How did demographics and pandemic situations, such as lockdown, quarantine conditions, and death numbers, contribute to possible psychiatric disorders?
- RQ4: How was social media use associated with psychiatric disorders?
- RQ5: How did health informational, emotional, and peer support mediate the relationship between demographics or pandemic situations and STS or VT?
- RQ6: Would geolocation interact with the health informational, emotional, and peer support people received through social media to predict psychiatric disorders?

Methods

Sampling

A marketing research company helped recruit a national representative sample for this study by using the quota sampling method, with a survey investigating how social media use affected the mental health conditions of people in China. In all, 4500 questionnaires were distributed, and 3820 individuals participated in this survey. After excluding incomplete data, responses from a total of 2185 participants were included for further analyses. These participants were from 30 provinces across China, and lived in big cities (eg, Beijing, Shanghai, Guangzhou, and Wuhan), small cities or towns, and rural areas. To avoid retraumatizing participants with questions about mental health issues or COVID-19, the survey comprised screening questions to exclude patients with COVID-19 or those who currently or previously had depressive or traumatic disorders.

After obtaining approval from the university's institutional review board, we conducted a web-based survey in February 2020, which was the peak of the COVID-19 epidemic in China when most people were forced to live under lockdown conditions due to the spike of confirmed cases. For this survey, participants received a small financial incentive (¥10 or US $1.34 each) and were asked to answer specific questions related to demographics, social media use, changes in mental health conditions, and lockdown conditions. Participants who indicated interest in this study were sent a message that contained the survey URL and login credentials. The survey was password-protected and could not be accessed without these credentials.

Measures

Stress, anxiety, and depression were measured using a 4-point Likert scale, with scores ranging from 0 ("Did not apply to me at all") to 3 ("Applied to me very much, or most of the time"); all other measures were assessed using a 5-point Likert scale, with scores ranging from 1 ("strongly disagree") to 5 ("strongly agree").

Social Media Usage

WeChat is China's dominant social media app, and participants' use of this app was measured using a 6-item instrument that was originally developed for measuring Facebook addiction [45]. The wordings of the questionnaire items were slightly revised to better fit the participants' actual WeChat use during the COVID-19 outbreak. For instance, participants were asked to rate how likely they agreed with 6 statements, including "You feel an urge to use WeChat more as you want to know more about the epidemic" and "You use WeChat for health information on the epidemic so much that it has had a negative impact on your life." The scores on the 6 items were averaged to form the index of social media use (mean 3.123, SD 0.809; Cronbach α=.901). A higher value indicates excessive social media use.

Informational, Emotional, and Peer Support

The scales of informational, emotional, and peer support were adopted and revised based on previous studies [46,47]. Informational support was measured on the basis of 4 items, including "If I have a question or need help related to the coronavirus epidemic, I can usually find the answers on WeChat." The scores on these 4 items were averaged to form the informational support index (mean 3.376, SD 0.900; Cronbach α=.868). Emotional support was measured on the basis of 4 items, including "The health information on WeChat helps me alleviate feelings of loneliness." The emotional support index had a high level of internal consistency (mean 3.292, SD 0.892; Cronbach α=.908). Similarly, peer support was measured on the basis of 6 items, including "WeChat friends give me additional information about the coronavirus epidemic that I am not familiar with." The peer support index also had a high internal consistency (mean 3.245, SD 0.586; Cronbach α=.907).

Stress, Anxiety, and Depression

We used 7 items of the 21-item Depression Anxiety Stress Scale (DASS-21) [48] to measure stress, including "I felt that I was using a lot of nervous energy" and "I found myself getting agitated." These questionnaire items were evaluated on a 4-point Likert scale, with scores ranging from 0 ("Did not apply to me at all") to 3 ("Applied to me very much, or most of the time"). The sum of the scores on these 7 items formed the stress index (mean 4.968, SD 4.455; Cronbach α=.860). DASS-21 was used to measure both anxiety (mean 5.030, SD 4.799; Cronbach α=.860) and depression (mean 5.104, SD 4.975; Cronbach α=.860).

STS and VT

STS is the emotional distress a person experiences when they hear about first-hand trauma experiences of another person [49]. In this study, STS was measured using the 14-item instrument adopted from Bride et al [50], including "I felt emotionally numb" and "My heart started pounding when I thought about the coronavirus epidemic." The scores on these 14 items were averaged to form the STS index (mean 2.466, SD 0.799; Cronbach α=.938). A higher value indicates higher level of STS.

The concept of VT was proposed by Pearlman and Saakvitne [51] in their description of the trauma experiences people have after being exposed to others' trauma stories and having witnessed the pain, fear, and terror that traumatized survivors have endured. In this study, VT was measured using the 8-item instrument developed by Vrklevski and Franklin [52], including "I find myself thinking about distressing material at home" and "Sometimes I feel helpless to assist others in the way I would like." The VT index had a good internal consistency (mean 3.349, SD 0.723; Cronbach α=.861).

Finally, pandemic situations were measured using the following questions: "How long is your residence area locked down to restrict entry of nonresidents?" "Do you have any family members or friends currently under quarantine?" "Do you know any family members or friends confirmed infected by coronavirus?" and "Do you know family members or friends who died due to the coronavirus epidemic?" Data on the participants' age, gender, education, income, and geolocations were also obtained.

Data Analyses

To answer RQ1, we first performed descriptive data analyses with anxiety, depression, stress, STS, and VT. Paired-sample *t* tests were used to compare the levels of different psychiatric disorders. To answer RQ2, we performed one-way analysis of variance with psychiatric disorders as the dependent variables and geolocation as the independent variable. For RQ3 and RQ4, we performed hierarchical regression analyses. STS was entered as the dependent variable in the model, followed by VT, stress, anxiety, and depression. Demographic information was entered in the first step of the model, and pandemic situations were entered in the second step, followed by social media use in the third step. For RQ5, we performed structural equation modeling. Demographics and pandemic situations were used as exogenous variables to predict informational support, emotional support, and peer support, which in turn predicted endogenous variables (ie, STS and VT). For RQ6, we used a generalized linear model to analyze the interaction between geolocation and informational, emotional, and peer support for predicting psychiatric disorders.

Results

Prevalence of Psychiatric Disorders

Compared with the latest census data published by the central government of China [53], the national sample attributes largely matched with the proportion of the Chinese population. The sample demographics were considered as internal factors that may influence the levels of stress, anxiety, or depression (Table 1). Pandemic situations and environmental conditions were considered as external factors that may contribute to STS or VT (Table 2).

The data showed that the pandemic had caused significant harm on people’s mental health. Only 3 weeks after a lockdown was announced in Wuhan, 10% (219/2185) of the participants reported they experienced moderate-to-severe anxiety, and 9.8% (215/2185) of the participants reported they experienced mild anxiety symptoms. Meanwhile, 5.5% (121/2185) of the national sample had moderate-to-severe depression, and 14.5% (316/2185) of the participants reported mild depression. These results are consistent with the findings from other surveys conducted in China during COVID-19 that report approximately 22% of the population experienced anxiety and 20% experienced a combination of depression and anxiety [3], although no study has evaluated traumatic disorders. This study shows that Chinese people displayed a moderate level of STS (mean 2.466, SD 0.799) and a relatively high level of VT (mean 3.934, SD 0.723), with significantly higher VT levels reported than STS levels (t_{2184}=46.747; P<.001).

Table 1. Internal factors contributing to psychiatric disorders (N=2185).

Internal factor	Value
Age (years), mean (SD)	33.43 (31)
Gender, n (%)	2185 (100)
Female	1192 (54.6)
Male	993 (45.6)
Income, n (%)	2185 (100)
Very low income	353 (16.2)
Low income	445 (20.4)
Medium income	1223 (56)
High income	130 (5.9)
Very high income	34 (1.6)
Marital status, n (%)	2185 (100)
Unmarried	715 (32.7)
Married	1470 (67.3)
Education, n (%)	2185 (100)
Middle school or lower	246 (11.3)
High school	492 (22.5)
3-year college	587 (26.9)
4-year college	766 (35.1)
Graduate degree	94 (4.3)

Table 2. External factors contributing to psychiatric disorders (N=2185).

External factor	Value, n (%)
Geolocation	2185 (100)
Rural area	592 (27.1)
Small cities or towns	1189 (54.4)
Big cities	404 (18.5)
Lockdown time	2185 (100)
No lockdown	0 (0)
1-2 weeks	1065 (48.7)
3-4 weeks	795 (36.4)
5-6 weeks	213 (9.7)
7 weeks or more	112 (5.1)
Known quarantine cases	2185 (100)
None	1983 (90.8)
1 person	63 (2.9)
2 people	73 (3.3)
3 people	41 (1.9)
4 or more people	25 (1.1)
Known death cases	2185 (100)
None	2082 (95.3)
1 person	31 (1.4)
2 people	48 (2.2)
3 people	18 (0.8)
4 or more people	6 (0.3)
Known infection cases	2185 (100)
None	2016 (92.3)
1 person	73 (3.3)
2 people	65 (3)
3 people	24 (1.1)
4 or more people	7 (0.3)

Internal and External Factors Contributing to Psychiatric Disorders

Our analyses revealed that a range of internal (ie, demographics) and external (ie, pandemic and environmental conditions) factors are related to psychiatric disorders (Table 3), as well as stress, anxiety, and depression (Table 4). With regard to stress, participants who were younger (β=−.142; *P*<.001), male (β=.054; *P*=.04), married or divorced (β=.078; *P*<.001), and had a higher income (β=.049; *P*=.03) reported higher levels of stress than other participants during the pandemic. These demographics accounted for 2.3% of the variance in stress (ΔR^2=.023; *P*<.001). Higher levels of stress were reported by participants who lived under lockdown for a longer time (β=.028; *P*=.04) and those who knew of more quarantine cases among their friends and family members (β=.105; *P*<.001), as well as more cases of COVID-19–related deaths (β=.117; *P*<.001). These pandemic situations accounted for 4.2% of the variance in stress (ΔR^2=.042; *P*<.001).

With regard to anxiety, participants who were younger (β=−.085; *P*<.001), male (β=.058; *P*=.007), and married or divorced (β=.054; *P*=.03) reported higher levels of anxiety than did the other participants. These demographics accounted for 0.8% of the variance in anxiety (ΔR^2=.008; *P*=.01). Participants who lived longer in a lockdown situation (β=.051; *P*=.02) and those who knew of more quarantine cases among family members and close friends (β=.092; *P*<.001) as well as more cases of deaths among them (β=.085; *P*=.001) reported higher levels of anxiety. These lockdown situations accounted for 3.9% of the variance in anxiety (ΔR^2=.039; *P*<.001).

As for depression, younger participants reported being more depressive than older participants (β=−.094; *P*<.001). Participants who knew of more quarantine cases in family members and close friends (β=.107; *P*<.001) as well as more cases of deaths among them (β=.073; *P*=.02) reported higher levels of depression. These pandemic situations accounted for 3.7% of the variance in depression (ΔR^2=.037; *P*<.001).

With regard to psychiatric disorders such as STS and VT, participants who were younger (β=−.099; *P*<.001), more educated (β=.093; *P*<.001), and married (β=.081; *P*<.001) were more likely to show STS symptoms. These demographics accounted for 1.7% of the variance in STS (ΔR^2=.017; *P*<.001). As these participants knew of more quarantine cases among family members and close friends, they were more likely to develop STS (β=.053; *P*=.048). These pandemic situations accounted for 1.5% of the variance in STS (ΔR^2=.015; *P*<.001). Moreover, female (β=−.059; *P*=.007) and more educated (β=.085; *P*<.001) participants experienced higher levels of VT. These demographics accounted for 1.8% of the variance in VT (ΔR^2=.018; *P*<.001). Knowledge of quarantine cases among family members and close friends also positively predicted VT (β=.057; *P*=.003). These pandemic situations accounted for 0.6% of the variance in VT (ΔR^2=.006; *P*=.01).

Table 3. Factors contributing to secondary traumatic stress and vicarious trauma.

Variables	Secondary traumatic stress				Vicarious trauma			
	β	*t* test (*df*)[a]	*P* value	ΔR^2	β	*t* test (*df*)[a]	*P* value	ΔR^2

Geolocation and Psychiatric Disorders

Participants living in big cities, small cities or towns, and rural areas reported varying levels of stress ($F_{2,2075}$=7.224; *P*<.001). After COVID-19 hit China, participants living in big cities (mean 5.036, SD 4.518) were more stressed than those living in rural areas (mean 4.367, SD 4.351; *P*=.02). Participants living in small cities or towns (mean 5.238, SD 4.460) were also more stressed than those living in rural areas (*P*<.001), but the difference was small between participants living in big cities and those living small cities or towns. A similar pattern was also observed for anxiety, as participants living in these three geolocations reported varying levels of anxiety ($F_{2,2183}$=3.569; *P*=.03). Participants from small cities or towns (mean 5.270, SD 4.747) were more anxious than those from rural areas (mean 4.647, SD 4.820; *P*=.01), but no difference was found between participants from big cities (mean 4.883, SD 4.891) and those from small cities or towns (*P*=.16). Moreover, no significant difference was found between participants from big cities and those from rural areas (*P*=.45).

A similar pattern was observed for depression, concerning the impact of geolocations ($F_{2,2183}$=3.569; *P*=.03). Participants from small cities or towns (mean 5.344, SD 4.877) experienced more depression than those from rural areas (mean 4.682, SD 5.092; *P*=.008). No significant difference was observed between participants living in small and big cities (mean 5.015, SD 5.054; *P*=.25) nor between participants living in big cities and rural areas (*P*=.30).

Social Media Use and Psychiatric Disorders

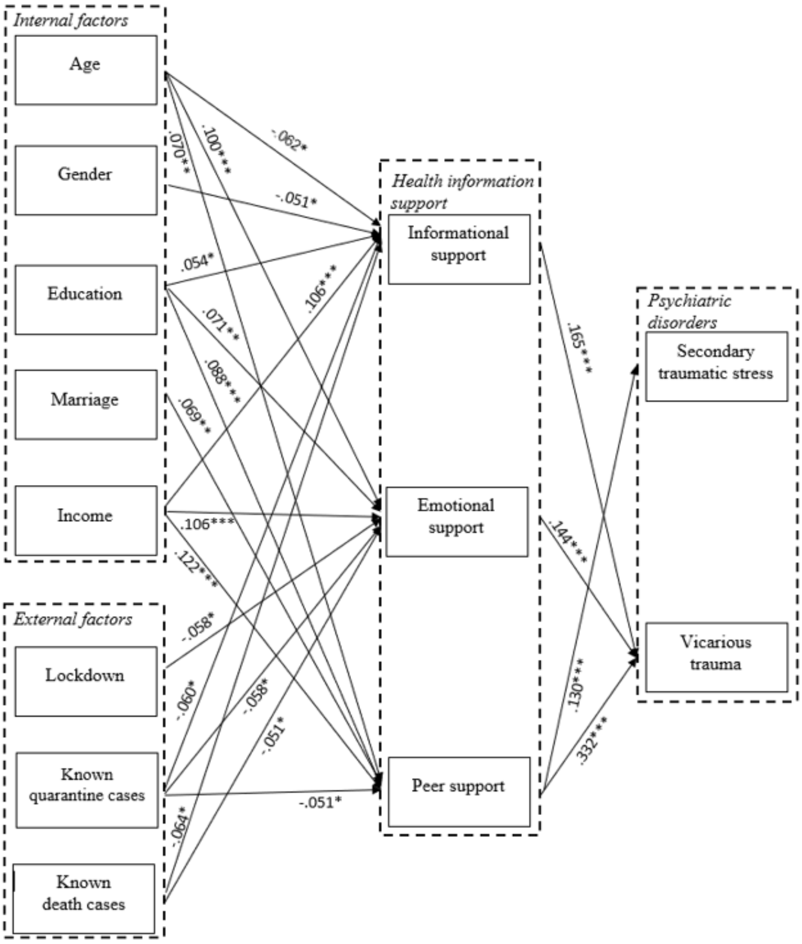
More social media use contributed to STS (β=.307; *P*<.001; ΔR^2=.091; sum of R^2=.124) and VT (β=.688; *P*<.001; ΔR^2=.479; sum of R^2=.481), as shown in Table 3. Participants who used more social media also reported higher levels of stress (β=.175; *P*<.001; ΔR^2=.030; sum of R^2=.095), anxiety (β=.224; *P*<.001; ΔR^2=048; sum of R^2=.095), and depression (β=.201; *P*<.001; ΔR^2=.039; sum of R^2=.083).

Mediating Effects of Informational, Emotional, and Peer Support

Finally, structural equation modeling was performed to evaluate the mediating effects of informational, emotional, and peer support that the participants gained from health information shared on social media. The model had a good fit as demonstrated by the following indices: χ^2_{19}=25.286, minimum discrepancy divided by its *df* (CMIN/*df*)=1.331, *P*=.15, root mean square error of approximation=0.012, comparative fit index=.999, and Bentler-Bonett Normed fit index=0.996. Figure 1 shows that participants who were younger (β=−.062; *P*=.03), female (β=−.051; *P*=.05), and more educated (β=.054; *P*=.05) and those who earned a higher income (β=.106; *P*<.001) received more informational support on social media. On the other hand, participants who were older (β=.100; *P*<.001) and more educated (β=.071; *P*=.007) and those who had a higher income (β=.106; *P*<.001) received more emotional support in using social media. Participants who were older (β=.070; *P*=.005), married (β=.069; *P*=.004), and more educated (β=.088; *P*<.001) and those who had a higher income (β=.122; *P*<.001) received more peer support in using social media.

Knowledge of more quarantine cases among family members and close friends could negatively affect informational support (β=−.060; *P*=.04), emotional support (β=−.058; *P*=.03), or peer support (β=−.051; *P*=.02). Living for longer periods in a lockdown environment resulted in less emotional support via social media use (β=−.058; *P*=.03). More knowledge of deaths due to COVID-19 among family members and friends resulted in less informational support (β=−.064; *P*=.05) and emotional support (β=−.051; *P*=.03) via using social media. Both informational support (β=.165; *P*<.001) and peer support (β=.332; *P*<.001) were found to be associated with higher reported levels of VT. More peer support also increased levels of STS (β=.130; *P*<.001), whereas more emotional support led to an increase in VT levels (β=.144; *P*<.001), but not STS levels (*P*=.36).

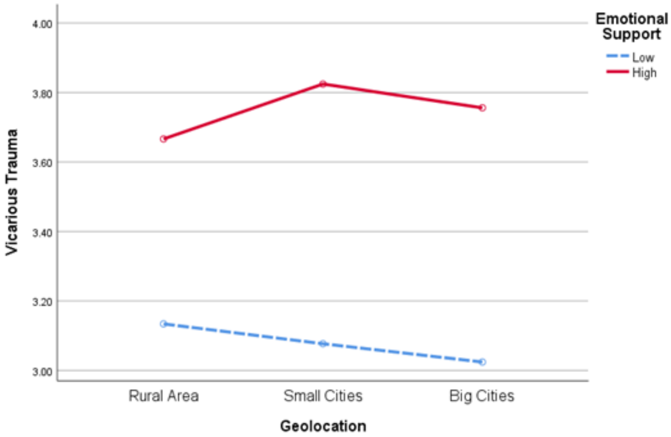
Figure 1. Structural equation modeling to predict secondary traumatic stress and vicarious trauma among participants during the COVID-19 outbreak in China.



Moderating Role of Geolocation

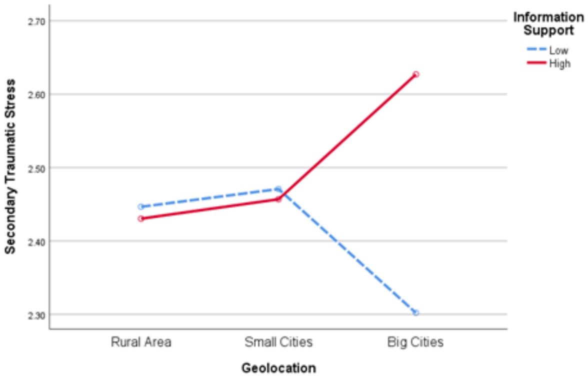
Geolocation had an interaction with emotional support in predicting VT (F_2=3.549; *P*=.029; see Figure 2). Participants from rural areas reported higher levels of VT when they received higher emotional support via social media (mean 3.666, SD 0.796) than when they received lower emotional support (mean 3.134, SD 0.606; t_{462}=7.947; *P*<.001); however, the differences were even larger for participants from small cities or towns (high emotional support: mean 3.825, SD 0.761 vs low emotional support: mean 3.077, SD 0.628; t_{913}=16.012; *P*<.001) and those from big cities (high emotional support: mean 3.756, SD 0.659 vs low emotional support: mean 3.024, SD 0.764; t_{307}=8.713; *P*<.001).

Figure 2. Interaction between geolocation and emotional support for vicarious trauma.



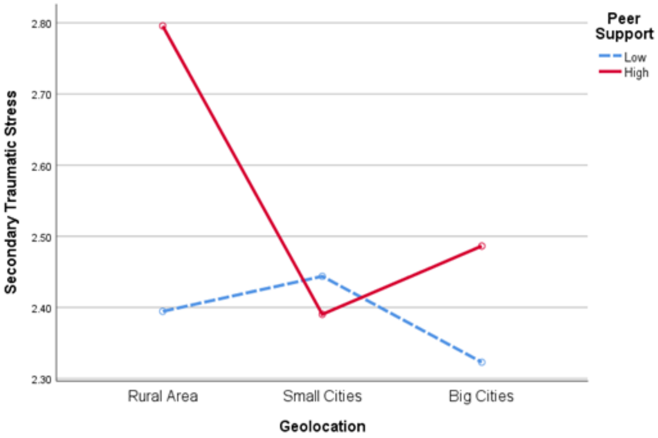
As shown in Figure 3, geolocation interacted with information support in predicting STS (F_2=5.093; P=.006). For participants who lived in rural areas or small cities, no significant difference in STS levels was found between those who received more information support and those who received relatively less information support via social media. However, among the participants who lived in big cities, those who received more information support via social media reported higher levels of STS (mean 2.627, SD 0.953) than those who received relatively less information support on social media (mean 2.302, SD 0.802; t_{299}=3.210; P=.001).

Figure 3. Interaction between geolocation and information support for secondary traumatic stress.



As shown in Figure 4, geolocation also moderated the relationship between peer support and STS (F_2=5.059; P=.006). For participants who lived in rural areas, those receiving more peer support experienced higher levels of STS (mean 2.796, SD 1.029) than those receiving less peer support (mean 2.395, SD 0.732; t_{350}=3.369; P=.001). However, for participants who lived in big and small cities, peer support on social media did not make a difference to the level of STS.

Figure 4. Interaction between geolocation and peer support for secondary traumatic stress.



Discussion

Principal Findings

As the ongoing COVID-19 pandemic affects people worldwide, it is crucial for researchers to conduct investigations that address the mental health consequences of the pandemic in order to mitigate the invisible harms caused to the general population. The findings of this study suggest that the mental health effects of the COVID-19 pandemic could have complex and multifactorial causes, including biological, behavioral, and environmental determinants such as social media usage. The analyses show that COVID-19 had taken a severe toll on the mental health of nonpatients, almost as soon as it started to spread in China. Social media use in addition to the lockdown environment and quarantine conditions have contributed the most to the overall toll on mental health.

Moreover, the analyses suggest that severe psychiatric disorders emerged in the general population of China, with 20% of the participants reporting anxiety, including 1 in 10 participants reporting moderate-to-severe anxiety. Furthermore, approximately 20% of the national sample reported depressive symptoms, of which 5.5% had moderate-to-severe depression. Overall, moderate levels of STS and considerably higher levels of VT were reported by these Chinese participants. The prevalence of psychiatric disorders reported seems particularly detrimental when we consider the facts that none of the participants were diagnosed with COVID-19 at the time of participation or had history of any psychiatric disorders before the COVID-19 outbreak.

Our findings suggest that a number of internal and external factors are related to stress, anxiety, and depression. Among the internal factors, participants who were younger, male, and more educated were more stressful or anxious than other participants at the peak of the COVID-19 outbreak in China. This finding is not consistent with previous studies in a nonpandemic context, which report that female participants tended to be more stressful. A possible explanation may be that younger individuals and men tended to go out more often to help others buy groceries than did older individuals or women, who spend more time at home in a lockdown situation [20]. Another explanation may be that compared to women, men are more susceptible to be stressed because of health reasons [51]. Previous studies have also shown that younger adults had a higher rate of psychological distress than older adults [54]. Future research should also examine different stress types and resilience mechanisms in relation to gender and age to understand how different stressors affect mental health differently.

The finding that social media use contributes to psychiatric disorders could be attributed to the fact that younger people relied more on social media and received more information about the pandemic through social media. It is worth noting that participants with higher income reported being more stressful and anxious than those who were less affluent. Younger, married, and more educated participants also reported having more STS symptoms, with no gender difference observed, suggesting that STS affected both men and women similarly. However, younger and more educated female participants reported higher levels of VT, which requires further research on why VT could affect women more than men.

Among the external factors, geolocation was found to be a critical determinant of mental health in COVID-19 nonpatients. In general, participants living in big cities felt similar levels of anxiety and depression as those living in small cities or towns, whereas participants in rural areas were the least stressful, anxious, and depressive. This may be due to the living conditions of big cities, which are more densely populated, and participants thus saw more infected patients and knew of more COVID-19–related deaths. In China, the medical resources are more readily available in cities than in rural areas; however, availability of more resources did not lead to less anxiety or fear among urban residents. This finding indicates that people in China had accurately assessed the severity of the emerging COVID-19 epidemic in the initial weeks.

Our findings suggest that even the individuals who were not themselves infected with COVID-19 nor were in quarantine could have experienced stress, anxiety, or depression as long as they lived in a lockdown situation or witnessed cases of infection, quarantine, and deaths among their family members or friends. The COVID-19 pandemic did not only endanger those infected with the virus but had also pushed China’s general population into a mental health crisis, and many people even reported that they experienced emotional trauma. All these occurrences were reported within 2 months of the COVID-19 outbreak. Thus, it is evident that living in the pandemic environment can be very debilitating and, in many cases, it has devastating effects on people’s psychological well-being with potentially lifelong consequences.

Another important finding of our study is the relationship between social media use for accessing health information and susceptibility of psychiatric disorders. This finding is consistent with those from a recent study in Wuhan, China—the first epicenter of COVID-19 globally, wherein researchers revealed that excessive social media use may lead to mental health issues [2]. In the present study, participants reported receiving social support from the health information shared on social media; this was especially true for those with more education and higher income. However, some differences were observed in terms of the specific informational, emotional, or peer support they received. Younger, female participants received the most informational support, whereas older participants received more emotional support than others, and participants who were married received more peer support than others. These results suggest that people process health information on social media differently and receive different types of support.

It is important to note that the approach does not suggest that social media use caused psychiatric disorders. We believe that an in-depth knowledge of social media use may contribute to a better understanding of the mechanisms of mental health conditions in a pandemic context.

On the other hand, knowledge of more quarantine cases during the outbreak was found to disrupt all the 3 types of support. Living longer in a lockdown environment had a similar effect of decreasing emotional support from social media use.

Knowledge of more cases of deaths among family members or friends led to them reporting less informational and emotional support. Meanwhile, participants who gained more informational and peer support reported lower levels of STS and VT. When people received more emotional support by using social medial, they tended to report higher levels of VT, but not STS. These findings call for more research on the pathological effects of STS and VT on the nonpatients in a pandemic environment.

It is noteworthy that although participants who knew of more quarantine cases reported receiving less informational, emotional, and peer support via social media, they still reported higher levels of STS and were more affected by mental illness. A possible explanation for this could be that participants who knew of more quarantine cases may have tried to seek information from other sources such as family, colleagues, and friends instead of via social media, and information from these sources may have increased their STS levels. Moreover, our additional data analyses showed that, for participants who knew of fewer than 4 quarantine cases, the information support (r=.069; P=.001), emotional support (r=.061; P=.005), and peer support (r=.113; P<.001) they received on WeChat were positively correlated to their STS levels. However, for participants who knew 4 or more quarantine cases, information support (P=.464), emotional support (P=.805), and peer support (P=.576) were no longer related to STS levels, suggesting that this group of participants generally maintained a high level of STS regardless of social media use. This finding is consistent with previous studies that described the potential anhedonia symptoms people experienced during COVID-19, which is characterized by the failure of experiencing pleasure from activities and is associated with depression, suicide, and other mental health issues [54].

Conclusion

The results of this study suggest that the general public is extremely vulnerable to mental health issues during the COVID-19 pandemic. Living in a pandemic situation can have serious mental health consequences even for those without any history of psychiatric disorders or not being infected with COVID-19 themselves. A range of internal and external factors have been identified that likely contribute to these mental health conditions. For instance, age, gender, marital status, education, and income levels play an important role in individuals' mental health conditions during the pandemic. Geolocation, lockdown duration, and social media use are also found to have an effect on mental health and traumatic disorders. Although people received health information support by using social media, excessive use of social media was found to be linked with elevated stress levels or psychiatric disorders. This finding does not suggest that social media use caused mental health issues but that it can mediate the levels of traumatic emotions experienced by people in the health crisis.

As the world is battling the COVID-19 pandemic, its detrimental effects on mental health will be more evident in the coming months and even after the pandemic is over. Health care providers thus need to carefully monitor psychosocial needs of the public and provide timely psychosocial support whenever needed. We believe that the findings in this research can help global citizens and health policy makers to mitigate psychiatric disorders in this as well as other public health crises, which should henceforth be regarded as a key component of general pandemic response.
