[a]Calculated for the subscale only.

[b]Calculated for the subscale items only.

The Internet Addiction Scale

Internet addiction levels were measured using the Internet Addiction Scale [52]. This 26-item scale includes 5 subscales: "compulsive use," "withdrawal," "tolerance," "time management problems," and "interpersonal and health problems" (for sample items, see Table 1). The scale was adapted into Turkish by Kesici and Sahin [53], where they reported satisfactory reliability and validity properties of the Turkish scale. The Cronbach α coefficient of the total scale was .88, and factor loadings ranged from .44 to .74. Likewise, we calculated a Cronbach α value of .86 for the total scale.

The Cyberbullying Scale

Cyberbullying was measured using 23 items [54]. The authors reported that the Cronbach α coefficient of the single-factor scale was .95. We also found a Cronbach α value of .98 for the scale.

Results

Descriptive Findings

Almost all participants had a smartphone, and approximately two-thirds had a notebook. Further, 543 students (543/665, 81.7%) used technology more than 4 hours a day, and 433 students (433/665, 65.1%) used the internet more than 4 hours a day. Pearson correlation analyses showed a significant correlation between internet use and both vertical individualism (r=.11, *P*=.01) and horizontal individualism (r=.09, *P*=.02). In addition, all subscales of the Internet Addiction Scale were significantly positively correlated with cyberbullying. Table 2 reports the descriptive statistics computed on the study variables.

Validity and Reliability

Prior to the analyses, data were checked for the adequacy of factor analysis [55,56]. Table 2 also shows the suitability of the data for factor analysis. An exploratory factor analysis was employed by using principal component extraction to assess the construct validity of the scales. The percentages of total variance explained ranged from 50.89% to 72.98%, which are higher than the acceptable minimum value of .40 [57,58]. Each measurement item has a factor loading above .40 and a communality value above .40 [59,60]. The corrected item-total correlation coefficients ranged from .67 to .90, indicating moderate to high homogeneity. Cronbach α coefficients ranged from .81 to .98, indicating good to very good internal consistency [61]. Validity and reliability results are presented in Table 1.

Common Method Bias

Harman's one-factor test was used to check common method bias [62]. All dependent and independent variables were subjected to the exploratory factor analysis. The factors together accounted for 64.30% of the total variance, while the first factor explained only 24.96%. These findings suggested that common method bias was not a concern in the data set.

Structural Model

It was theorized that internet addiction would serve as an intervening variable between vertical versus horizontal individualism and cyberbullying. Structural equation modeling was conducted via maximum likelihood to test the model. Results show that the structural model produced acceptable fit indices (Table 3).

The direct effects of vertical individualism on cyberbullying (β=.10, critical ratio [CR]=2.31, P=.02) and internet addiction (β=.28, CR=5.81, R^2=.08, P<.001) were positively significant. The direct effect of horizontal individualism on cyberbullying (β=–.12, CR=–2.96, P=.01) was significant, but it was not significant on internet addiction (β=–.05, CR=–1.08, P=.32). Therefore, the null hypotheses for H1a, H1b, and H2a were rejected, but H2b failed to be rejected. The proposed path coefficient between internet addiction and cyberbullying was also positive and significant (β=.39, CR=3.72, P<.001). The effect size in this relationship was R^2=.18. Therefore, the null hypothesis for H3 was also rejected. Figure 1 shows the results of the structural equation modeling analysis, including standardized path coefficients and significance levels along with the R-squared values and respective error terms.

Table 3. Model fit indices of the structural model.

Indices	Model	Acceptable values
χ^2	1429.18	N/A[a]

[h]TLI: Tucker Lewis index.

[i]CFI: comparative fit index.

[j]IFI: incremental fit index.

Mediation Analysis

A 4-step approach was used to test the mediation effect of internet addiction [71,72]. First, the direct effect of vertical individualism was significant (β=.27, SE=.05, CR=5.79, *P*<.001), whereas the direct effect of horizontal individualism was not (β=–.40, SE=.06, CR=–1.04, *P*=.30). Second, the direct effects of vertical individualism (β=.20, SE=.02, CR=4.57, *P*<.001) and horizontal individualism (β=–.13, SE=.03, CR=–3.16, *P*<.001) on cyberbullying were significant. Third, the direct effect of internet addiction on cyberbullying was significant (β=.41, SE=.02, CR=9.92, *P*<.001). Finally, the Sobel test showed that the indirect effect of vertical individualism on cyberbullying via the mediator (ie, internet addiction) was significant (CR=5.87, SE=.06, *P*<.001). These results support partial mediation and indicate that vertical individualism has a significant effect on cyberbullying through internet addiction.

Gender Differences

One-way multivariate analysis of variance was used to investigate gender differences between women (462/665) and men (203/665) on vertical versus horizontal individualism. Results showed a significant difference between women and men, where men (mean 26.45 points, SD 6.12 points) scored significantly higher than women (mean 25.04 points, SD 5.66 points) in vertical individualism ($F_{2,662}$=6.42, *P*=.002, Wilk's λ=.98, partial η^2=.02). However, the effect size of gender on vertical individualism, while statistically significant, was practically minimal (partial eta-squared=.02). Multivariate analysis of variance results also showed a significant difference in internet addiction between women and men ($F_{5,659}$=7.97, *P*<.001, Wilk's λ=.94, partial η^2=.06), where men scored higher than women. Further, independent samples *t*-test results suggested no gender difference in cyberbullying between men and women (t_{663}=–1.32, *P*=.19). It is important that a previous study [30] suggested significant differences in internet addiction among age groups. However, the sample in this current study was comprised of a restricted age group (17-19 years old); therefore, we were not able to investigate the differences among age groups.

Discussion

In this research, we investigated the relationships among vertical versus horizontal individualism, cyberbullying, and internet addiction via a theoretical model and provided valuable implications for mental health professionals and researchers. Arpaci et al [73] suggested that individualists face higher socialization problems and the risk of failure in communicating with others. Consequently, they prefer alternative environments, such as cyberspace. Therefore, they are expected to be more prone to internet addiction. Accordingly, we expected significant relationships among individualism, cyberbullying, and internet addiction. Our results showed a stronger correlation between internet use and vertical individualism than between internet use and horizontal individualism. This suggests that vertical individualists tend to spend more hours on the internet and thereby, are more vulnerable to internet addiction.

We found a significant intervening effect of internet addiction in the association between vertical individualism and cyberbullying. These results support the important intervening role of internet addiction in the relationship between vertical individualism and cyberbullying. Thus, knowing the individual's cultural orientation and level of internet addiction might be helpful in the prevention or treatment of their cyberbullying behaviors.

Self-reliance and uniqueness are some of the relatively more positive characteristics of horizontal individualists [74], while competition and hedonism are more of the destructive characteristics of vertical individualists [45]. Thus, we expected that vertical individualism would positively predict cyberbullying. Our findings support that vertical and horizontal individualism are significant positive and negative predictors of cyberbullying, respectively. In general, those who score higher for individualism foster a propensity to avoid establishing close relationships with others and gradually withdraw from society and social environments [75]. In addition, these individuals do not take the initiative to solve problems but are more likely to evade responsibility. As a result, research has associated individualism with problematic behaviors [35,46]. However, we investigated the specific effects of vertical versus horizontal individualism, which have not been studied previously. Based on our findings, we conclude that those individuals who seek distinctiveness and are especially concerned with comparing themselves to others (ie, vertical individualists) tend to show more cyberbullying tendencies. On the contrary, individuals who are more self-reliant and seek individuality (ie, horizontal individualists) show lower cyberbullying tendencies. However, the reader should also keep in mind that both predictions have relatively small effect sizes, meaning that although the predictions are statistically significant, their effects are minimal. In short, we conclude that vertical individualists tend to develop cyberbullying behaviors depending on their level of internet addiction. The points raised in this study should be considered when prevention or treatment programs are being developed for cyberbullying. Different treatment approaches to cyberbullying should be employed depending upon whether the individual is vertically or horizontally oriented and his or her level of internet addiction.

These results also indicate that vertical, but not horizontal, individualism is a significant predictor of internet addiction. Previous research indicates an association between individualism and addictive behaviors [33,34]; however, our results provide details of such a relationship. We conclude that individualists who prefer gratification through competition and personal achievement are under greater risk of internet addiction, not those who tend to just value uniqueness with equality.

The findings of our research confirm the findings of Casas et al [18] who concluded that cyberbullying is affected by internet addiction. We found that higher internet addiction levels predict higher cyberbullying behaviors. Therefore, it seems reasonable to assume that addicts will show higher levels of cyberbullying. This conclusion is consistent with previous literature [29,50,76-78].

The findings show that vertical individualism has a significant effect on internet addiction. More interestingly, the findings suggest that vertical individualists are more vulnerable to internet addiction. Further, the findings indicate a significant relationship between internet addiction and cyberbullying. Therefore, prevention programs for cyberbullying should take cultural orientations into account.

Although vertical and horizontal individualism were perceived to be dichotomous rather than orthogonal, the correlation analysis results shown in Table 2 suggest a positive correlation between both types of individualism. It is important that both horizontal and vertical individualists focus on an autonomous self-concept; however, horizontal individualists place a strong emphasis on equality in status, whereas vertical individualists accept inequalities [8].

Although this study is highly original, it has several limitations. First, the sample used in the study was comprised of a restricted age group and thus homogenous; therefore, the theoretical model needs further confirmation across different age groups. Crosscultural studies should be conducted in different cultures to improve the external validity of the findings. Second, cultural orientations are not the only predictors of cyberbullying, nor is internet addiction the only mediator. However, based on the literature, this study used a single exogenous factor, vertical versus horizontal individualism, and a single mediator, internet addiction, in the structural model. Many other dispositional or situational factors and mediators would be equally worthwhile to explore in future studies. Further, there may be several equivalent models that can predict the impact of both cultural orientations or internet addiction on cyberbullying. This suggests that the proposed model is certainly supported, but not proven; therefore, further studies should replicate the research model.

In this study, vertical and horizontal individualism were studied as cultural orientations of the participants, and they were measured using an individual-level measurement within a monocultural sample. In the same vein, others studied and operationalized the same orientations at the individual level. For example, Bourgeois [79] argued that vertical and horizontal collectivism-individualism are testable dimensions of culture at the individual level. He investigated values (ie freedom and equality) of vertical-horizontal individualists and collectivists by collecting data from active party members of the Republican and Democratic parties in New Brunswick, Canada. Similarly, Le [80] investigated the relationships among vertical individualism, narcissism, immature love, and ludus based on data collected from 179 undergraduate students at University of California Davis. The results suggested that vertical individualism has a positive significant effect on narcissism and immature love. The findings suggested that vertical individualists were more prone to ludic love style and saw others as fulfillment of wishes and needs.

Finally, previous literature perceived vertical and horizontal individualism to be orthogonal [11]. However, our results indicate a positive correlation between vertical and horizontal individualism, suggesting a more complex relationship. Confirming this, Triandis [11] argued that, along with the horizontal-vertical dimension, there are many other dimensions defining different varieties of collectivism and individualism.

Abstract

Background: Internet search engines are increasingly being utilized as the first port of call for medical information by the public. The prevalence of allergies in developed countries has risen steadily over time. There exists significant variability in the quality of health-related information available on the web. Inaccurately diagnosed and mismanaged allergic disease has major downstream effects on patients, general practitioners, and regional allergy services.

Objective: This study aimed to verify whether Ireland has a relatively high rate of web-based allergy-related searches, to establish the proportion of medically accurate web pages encountered by the public, and to compare current search results localized to Dublin, Ireland with urban centers elsewhere.

Methods: Google Trends was used to evaluate regional interest of allergy-related search terms over a 10-year period using terms “allergy,” “allergy test,” “food allergy,” and “food intolerance.” These terms were then inputted into Google search, localizing them to cities in Ireland, the United Kingdom, and the United States. Output for each search was reviewed by two independent clinicians and deemed rational or nonevidence based, as per current best practice guidelines. Searches localized to Dublin were initially completed in 2015 and repeated in 2019 to assess for changes in the quality of search results over time.

Results: Ireland has a persistently high demand for web-based information relating to allergy and ranks first worldwide for “allergy test,” second for “food allergy” and “food intolerance,” and seventh for “allergy” over the specified 10-year timeframe. Results for each of the four subsearches in Dublin (2015) showed that over 60% of websites promoted nonevidence-based diagnostics. A marginal improvement in scientifically robust information was seen in 2019, but results for “allergy test” and “food intolerance” continued to promote alternative testing 57% (8/14) of the time. This strongly contrasted with results localized to Southampton and Rochester, where academic and hospital-affiliated web pages predominantly featured. Government-funded Department of Health websites did not feature in the top five results for Dublin searches “allergy testing,” “food allergy,” or “food intolerance” in either 2015 or 2019.

Conclusions: The Irish public demonstrates a keen interest in seeking allergy-related information on the web. The proportion of evidence-based websites encountered by the Irish public is considerably lower than that encountered by patients in other urban centers. Factors contributing to this are the lack of a specialist register for allergy in Ireland, inadequate funding for allergy centers currently in operation, and insufficient promotion by the health service of their web-based health database, which contains useful patient-oriented information on allergy. Increased funding of clinical allergology services will more meaningfully impact the health of patients if there is a parallel investment by the health service in information and communication technology consultancy to amplify their presence on the web.

Introduction

Background

The internet has become a major resource for people seeking information in relation to health. Overall, 57% of Irish adults search for health-related information on the web, and this most often applies to younger people and women [1].

The incidence of allergies has risen steadily in developed countries [2]. Food allergies are thought to affect approximately 1% to 3% of the Irish adult population and are a cause of significant public concern [3,4]. Allergic disease has long been a focus of public attention, with a nationwide questionnaire in 2015 demonstrating that 14% of Irish adults self-report allergic conditions (rhinitis, allergic eye disease, and food allergy, excluding allergic asthma) [5]. The diagnosis of allergic disease is centered upon a detailed clinical history and supported by the judicious use of tests to detect allergic sensitization [6]. Allergic sensitization is determined by skin prick testing or detection of allergen-specific immunoglobulin E (sIgE). When these test results conflict or there is a diagnostic doubt, gold standard investigation is advisable in the form of diagnostic challenges. These time-consuming procedures are only available in specialist centers.

The umbrella term of allergy is one that frequently attracts input from a variety of alternative medicine practitioners, naturopaths, homeopaths, and acupuncturists both in terms of diagnostic testing and claims to treatment. Despite the existence of scientifically robust and evidence-based allergy tests, alternative approaches to diagnosis are widely used by the public, with attempts at regulatory control being previously described as "woefully inadequate" [2]. Alternative tests, including food-specific immunoglobulin G testing, kinesiology, hair analysis, Vega testing, and leukocytotoxic tests, are widely available, lack scientific basis and diagnostic rigor, and have been discredited by a variety of governmental, professional, and expert bodies internationally [6-9]. The use of complementary and alternative medicine (CAM) as a treatment modality for allergy has also been increasingly reported, with 37% of people with allergic disease using CAM during the preceding 12 months in a recent European study [10]. In 2018, 60% of surveyed allergists in the United States had patients who encountered adverse reactions from the use of CAM, with 81% of respondents encountering patients who discontinued conventional therapy while using CAM, irrespective of medical advice [11]. Despite this, alternative approaches continue to be advocated by some health care professionals, including registered medical practitioners. The risks of a misdiagnosis of food allergy include inappropriate dietary restrictions and negative quality-of-life consequences, the misattribution of symptoms to allergic diseases resulting in delayed assessments, the inappropriate fear of life-threatening reactions, and direct and indirect financial costs related to these risks [12].

Objectives

The volume of easily accessible information available on the web offers an excellent opportunity to provide helpful, evidence-based information and services to the information-seeking public. In this study, we sought to examine the web-based information sources accessible to members of the Irish public who were seeking information on allergy testing. We first interrogated allergy testing search requests by Irish internet users. We then examined the prominent sites presented when searching for allergy tests in an Irish setting and determined whether they promoted rational or alternative testing approaches. We initially reviewed these search requests in 2015 and repeated the study using identical search terms in 2019 to identify whether the standard of information available to internet users had changed over time. Finally, we compared the 2019 Irish results with similar UK and US populations using identical search terms.

Methods

Google Trends was used to evaluate interest by region of allergy-related search terms over a 10-year period (January 1, 2009, to December 31, 2018) [13]. The search terms used were "allergy" and related subsearches "allergy test," "food allergy," and "food intolerance." The period of trend analysis was purposely predated to the start of 2019 so that our subsequent searches in July 2019 did not interfere with the trend results. Google Trends data provide a list of countries ranked by the relative popularity of the specified search term, as a proportion of total searches in each country.

Each of the search terms was inputted into Google search and the output reviewed. Output webpages were reviewed independently by two clinicians and classified as *rational*, if the services or information offered were based on clinical history and standard sensitization testing, or *alternative*, if the practitioners offered any non–evidence-based approaches, as outlined in the Irish Food Allergy Network and Irish Association of Allergy and Immunology position statement [7]. Results localized to country level (Ireland) were reviewed initially. Then, a comparison of local results from Dublin, Southampton (United Kingdom), and Rochester (United States) was performed. Sponsored advertisements, forums/discussion groups, duplications, and reports on news or weather were excluded from analysis. Analysis was limited to Google search pages one and two.

Results

Trend Analysis of Allergy-Related Searches Worldwide

Data from Google trends indicate that Ireland has a persistently high demand for information regarding allergy. Trends from 2008 to 2019 demonstrate that Ireland ranks seventh in the world in searches for the term allergy (Table 1). Analysis of data for the subsearch term "allergy test" shows that Ireland is ranked first in the world for this particular search over the timeframe, and second in the world for both other subsearch terms "food allergy" and "food intolerance" [13]. These results demonstrate a high demand for web-based information regarding allergies from the Irish population.

Table 1. Google Trends January 1, 2009, to December 31, 2018, worldwide for the specified search terms.

Search term	Worldwide ranking			Ireland ranking
	First place	Second place	Third place	
"Allergy"	United States	Canada	Philippines	7
"Allergy test"	Ireland	Singapore	United States	1
"Food allergy"	United States	Ireland	Australia	2
"Food intolerance"	Malta	Ireland	Australia	2

Analysis of localized Google search engine results for Ireland (search term "allergy Ireland") in 2015 revealed that alternative diagnostic services and information featured highly (Table 2). At that time, 63% (10/16) of included results were from private companies selling non–evidence-based commercial tests, 19% (3/16) were from private medical services with rational testing procedures, and the remaining 19% (3/16) were from organizations offering evidence-based patient information. Regional localization to Dublin and analysis of the subsearch terms also confirmed the prominence of websites endorsing alternative approaches to allergy diagnostics. Furthermore, 69% (11/16) websites listed under an "allergy test Dublin" Google search promoted alternative non–evidence-based approaches to allergy. Use of the search term "food allergy Dublin" provided similar results, with 67% (10/15) of included results relating to alternative health care websites. The disparity was greater again when "food intolerance Dublin" was used as a search term, with just 13% (2/15) of included webpages promoting a rational assessment approach versus 87% (13/15) promoting alternative approaches.

Table 2. Summary of results of localized internet searches for the specified allergy-related search terms.

Search term, by region	Website results, n (%)		
	Non–evidence-based practices	Medical facility, rational testing	Evidence-based guidelines, journals
"**Allergy**"			
Ireland (2015)	10 (63)	3 (19)	3 (19)
Ireland (2019)	1 (9)	5 (46)	5 (46)
Southampton, United Kingdom (2019)	1 (11)	4 (44)	4 (44)
Rochester, United States (2019)	0 (0)	7 (100)	0 (0)
"**Allergy Test**"			
Dublin (2015)	11 (69)	5 (31)[a]	N/A[b]
Dublin (2019)	8 (57)	5 (36)	1 (7)
Southampton, United Kingdom (2019)	1 (8)	8 (67)	3 (25)
Rochester, United States (2019)	0 (0)	7 (70)	3 (30)
"**Food Allergy**"			
Dublin (2015)	10 (67)	5 (33)[a]	N/A
Dublin (2019)	6 (46)	5 (39)	2 (15)
Southampton, United Kingdom (2019)	1 (9)	4 (36)	6 (55)
Rochester, United States (2019)	0 (0)	5 (50)	5 (50)
"**Food Intolerance**"			
Dublin (2015)	13 (87)	2 (13)[a]	N/A
Dublin (2019)	8 (57)	4 (29)	2 (14)
Southampton, United Kingdom (2019)	3 (27)	6 (55)	2 (18)
Rochester, United States (2019)	1 (11)	3 (33)	5 (56)

[a]The 2015 search results for "Allergy test Dublin," "Food allergy Dublin," and "Food intolerance Dublin" were recorded as either alternative or evidence based only.

[b]N/A: not available.

Subsearch Terms Localized to Ireland (2019)

A greater proportion of evidence-based information was noted upon repeating these Google searches in July 2019. Current searches for "allergy Ireland" result in 9% (1/11) from a private company selling non–evidence-based commercial tests, 45% (5/11) from private health care facilities engaged in rational testing, and a further 45% (5/11) from organizations offering evidence-based patient information. However, searches for "Allergy test Dublin" continued to promote alternative approaches to diagnosing allergy, with 57% (8/14) of the results coming from private companies selling non–evidence-based commercial tests. Results for "Food allergy Dublin" also continued to feature a high proportion of alternative testing approaches (6/13, 46%). This also was seen in searches for "Food intolerance Dublin," which had 57% (8/14) results endorsing non–evidence-based diagnostics.

Regional Differences in the Proportion of Nonevidence-Based Webpages Encountered

Comparison of the 2015 and 2019 results showed a marginal improvement in the availability of rational, scientific information regarding allergy over this timeframe. However, when the Irish search results from 2019 were evaluated against current search results for comparable UK and US populations, significant inadequacies are highlighted. Data were generated with identical search terms localizing to Southampton (United Kingdom) and Rochester (United States). Assessment of these results indicated that the vast majority of websites generated for each search pertained to websites promoting rational evidence-based approaches to assessment. A preponderance of academic and public hospital webpages was noted. Searches for "allergy Rochester New York," "allergy test Rochester New York," and "food allergy Rochester New York" resulted solely in rational testing approaches and scientifically robust information, without any non–evidence-based websites featuring.

Discussion

The Increasing Burden of Allergic Disease

The incidence of allergic conditions in both developed and developing countries has been increasing for over 50 years. One-third of people in the United Kingdom are estimated to suffer symptoms related to allergy at some stage during their lives [2]. The use of the internet has also risen steadily over recent generations, especially involving the investigation of medical conditions on the web. Over 70% of internet users in the United States have stated that they look on the web for health information, with over three-quarters of these queries beginning on a web-based search engine such as Google [14].

The increase in demand for web-based information creates both challenges and opportunities. Appropriate use of the internet enables health services to positively affect the lives of many people living with allergies. People who access health information on the internet have been shown to be more likely affected in their offline approach to health care [15], which in turn impacts on the provision of health care services. Figures on the extent of costs are difficult to obtain in Ireland; however, allergic disease accounts for 6% of general practitioner (GP) consultations in the National Health Service (NHS), 0.6% of hospital admissions, and 10% of GP prescribing budget. The cost (excluding hospital services) to the NHS is approximately £900 million (US $1.2 billion) per year [16]. Inadequately treated allergic disease also leads to a significant reduction in economic productivity with €55 to €151 billion (US $60 to $164 billion) lost per annum in the European Union, according to a 2014 study [17].

Complementary and Alternative Medicine Practitioners

When members of the Irish public search for guidance on the web regarding allergic disease, they are faced with a large volume of alternative testing approaches, often taking precedence over results for rational services. This is rightly a cause for concern. Previous studies in North America show that 91.5% of users will select a website from the first page and that the likelihood of a user clicking a result on the third page is 1.1% [18]. The ease of access to non–evidence-based information has the potential to promote costly practices and to increase the pressure on an already burdened health system through mismanagement of allergic diseases. There are countless medical conditions that attract input from non–evidence-based sources, but allergology has consistently shown itself to be an area of particular interest among CAM practitioners. A study of the websites of over 300 alternative health care providers demonstrated that 85% of naturopaths offer diagnosis, treatment, or efficacy for specifically treating allergic disease or sensitivity [19]. Similarly, a 2018 study investigating the educational quality of 300 food allergy YouTube videos showed that alternative medicine providers were the most common source of such content, with almost half of the videos depicting non–IgE-mediated reactions and frequently recommending controversial diagnostics [20]. In contrast to the word "allergy," which is frequently misappropriated by such websites, a recent study of worldwide internet search results for "anaphylaxis" showed that links to well-established, evidenced-based information were far more often seen [21].

Unmet Clinical Need in Allergic Disease

The internet has created a means of positively impacting the lives of many individuals affected by allergies while simultaneously decreasing the costs placed on the Irish health service. However, these potential benefits rely on the availability of accurate, evidence-based, and accessible resources that are provided by experts in allergology. There is a wide variation in the amount of allergologists working in different European countries, with a mean of 1.81 specialists per 100,000 inhabitants [22]. Figures for Ireland are not directly comparable as the country does not have a recognized training scheme for allergy. With a rate of 0.14 immunologists (pediatric and adult) per 100,000 citizens, who also have commitments to laboratory work, immunodeficiency, and autoimmunity, the relative time dedicated solely to allergy is assumed to be far below the European average [23]. Given that allergy is not currently a recognized medical specialty in Ireland, it should come as no surprise that tertiary allergy referral centers make up a relatively small proportion of localized web-based searches and that services run by GPs are often seen. Much has been previously

published on how best to alleviate the pressure on chronically underresourced tertiary allergy departments [24]. A common theme throughout these (predominantly UK-based) reports is improved support and education of primary care physicians in the field of allergy. Proposed interventions have included development of a network of GPs with special interest in allergy [25,26], a core allergy curriculum for all GPs [27], and better training of nurses, pharmacists, and dieticians to enable them to advise patients in the community [28].

Future Directions in Allergic Disease Management: Investment in Information Technology Resources

Although these proposals are commendable and steps should certainly be taken in their establishment, there can be no doubt that these are long-term investments and change will be slow to occur. There has also been growing interest in the use of information technology (IT)–based interventions, such as telemedicine assessments in adult allergy [29], app-based monitoring of allergic rhinitis [30], and a pilot program of email communication between allergists and nonspecialists for new referrals to allergy clinics [31], with further prospective studies required. Innovative and accessible approaches to delivering allergy services are required in the setting of an inadequately resourced system, where the lack of timely care for patients has undoubtedly contributed to people seeking out alternative practitioners. There is an undeniable need for increased support and funding for dedicated allergy services currently in operation in Ireland. However, to create a meaningful impact on patients' health-seeking behaviors, we need a parallel investment in IT services currently in use by the Irish health service.

In 2019, the information and communication technology capital allocation for the Irish health service was €85 million (US $92 million), making up approximately 0.5% of the total health care budget of over €16 billion (US $17 billion) [32]. The Health Service Executive (HSE) website was given a radical overhaul in 2013, which included development of a web-based database of over 600 health conditions and treatments. This database (entitled *Health A-Z*) contains useful information on the diagnosis and management of allergy and highlights the existence of alternative testing approaches, unambiguously describing them as unproven, unreliable, and best avoided by the public [33]. The content for this sizeable information resource was provided to the HSE completely free of charge from the NHS Choices website in the United Kingdom. Details on the volume of internet traffic to the HSE *Health A-Z* are not readily accessible to the public on the web. In our subsearch results for Dublin in 2019 (for "allergy test," "food allergy," and "food intolerance"), the HSE website never featured within the top 5 results. The question of cost efficacy and suboptimal internet traffic is certainly an issue that has been raised regarding the prototypic NHS Choices website in the past. A report published several years after its launch evaluated the NHS Choices website against the average website of a US company at the time (with a similar volume of monthly visitors) and found that the UK Department of Health was spending nearly four times more on site management, hosting costs, and development than their counterparts [34]. The downstream effect of this was the NHS entering a partnership with a digital marketing agency in 2012, which was specializing in analysis of consumer behaviors. This led to a significant improvement in their volume of web-based traffic [35]. The Irish health system, having saved huge costs in the development of their web-based health database, would undoubtedly benefit from external IT consultancy to improve their reach and strengthen their web-based presence. A public that is well informed and empowered in matters of their own health is a worthy long-term investment, and this applies to all areas of medicine, not solely allergology.

Conclusions

This study provides a snapshot of the information obtained when searching for information relating to allergy on the internet. There is great potential to provide accurate and evidence-based guidance to an increasing population, which would maximize the appropriate use of allergy services in Ireland. Unfortunately, this is not currently the case. Results for costly, non–evidence-based services predominate when searching on the web in Ireland, which differs relative to the United Kingdom and United States. There is a great need to improve the provision of allergy services in Ireland and to educate the Irish public on allergic disease, and investment in local internet resources is central to this endeavor.

Abstract

Background: For the last decade, doctor-patient contradiction in China has remained prominent, and workplace violence toward medical staff still occurs frequently. However, little is known about the types and laws of propagation of violence against medical staff online.

Objective: By using a self-organizing map (SOM), we aimed to explore the microblog propagation law for violent incidents in China that involve medical staff, to classify the types of incidents and provide a basis for rapidly and accurately predicting trends in public opinion and developing corresponding measures to improve the relationship between doctors and patients.

Methods: For this study, we selected 60 cases of violent incidents in China involving medical staff that led to heated discussions on the Sina microblog from 2011 to 2018, searched the web data of the microblog using crawler software, recorded the amount of new tweets every 2 hours, and used the SOM neural network to cluster the number of tweets. Polynomial and exponential functions in MATLAB software were applied to predict and analyze the data.

Results: Trends in the propagation of online public opinion regarding the violent incidents were categorized into 8 types: bluff, waterfall, zigzag, steep, abrupt, wave, steep slope, and long slope. The communications exhibited different characteristics. The prediction effect of 4 types of incidents (ie, bluff, waterfall, zigzag, and steep slope) was good and accorded with actual spreading trends.

Conclusions: Our study found that the more serious the consequences of a violent incident, such as a serious injury or death, the more attention it drew on the microblog, the faster was its propagation speed, and the longer was its duration. In these cases, the propagation types were mostly steep slope, long slope, and zigzag. In addition, the more serious the consequences of a violent incident, the higher popularity it exhibited on the microblog. The popularity within a week was significantly higher for acts resulting from patients' dissatisfaction with treatments than for acts resulting from nontherapeutic incidents.

KEYWORDS

workplace violence; medical staff; social media

Introduction

Background

At the beginning of 2009, China started a new round of medical and health system reformation. Its guiding ideology was to continuously improve the health level of the whole population and promote social harmony, which has improved, to a great extent, the doctor-patient relationship. However, contradictions between doctors and patients are still prominent, and workplace violence toward medical staff occur frequently. The Chinese Hospital Association reported that the proportion of hospitals experiencing workplace violence increased by 90% from 2008 to 2012 [1]. In 2017 itself, there were as many as 54 violent incidents against Chinese medical staff mentioned on the Sina microblog (a leading microblog website and one of the largest social media platforms in China), which attracted public attention and sparked heated debate. For instance, on December 8, 2017, in Tongshan County People's Hospital, a patient's mother hurt a nurse because she was not satisfied with the treatment effect, causing slight bodily injury (signs of abortion) to the medical staff. When the incident was publicized on the Sina microblog, the number of tweets reached 1737 within a week. The frequent outbreak of violent incidents in hospitals and the wide coverage of the incidents by social media have made the doctor-patient relationship even more fraught, which not only reduces the professional security of medical staff [2] but also hinders their professional performance, resulting in a negative impact on patient service and overall health [3-8]. Moreover, violent incidents have a negative impact on the psychological welfare of health care workers who do not want their children to be engaged in health care [9-11].

Workplace violence in the health sector is a worldwide concern, with health care workers being at high risk of being victims [12]. Following the World Health Organization's definition, workplace violence takes 2 main forms: physical and nonphysical violence. Physical violence includes hitting, slapping, kicking, pushing, choking, grabbing, sexual assault, and other forms of physical contact intended to injure or harm. In contrast, nonphysical violence includes threats, sexual harassment, bullying, and verbal abuse and may be perpetrated by various types of people [13]. There are 2 major sources of workplace violence: coworker initiated and public initiated [14]. In the Chinese health sector, workplace violence is mainly caused by patients and their relatives or friends. Scholars have studied the causes of violent incidents from various perspectives. On the basis of the perspective of social roles, Robinson [15] pointed out that due to the differences in the roles of doctors and patients, their viewpoints and interests differ, which leads to cognitive and motivational bias in the attribution process regarding medical information. From the point of view of social psychology, Feng et al [4] analyzed the mechanisms for the inducement of violent incidents related to doctor-patient conflicts, including psychological frustration, anger, social learning, and so on. From the perspective of patient experience, Hu et al [5] proposed that the experience of a poor physical environment, inadequate information communication, large medical expenses, and the perception and experience of treatment outcomes were direct causes of doctor-patient contradiction. From the perspective of crisis management, Li [6] posited that it was caused by conflicts of interest, the inadequate communication of information, negative slants in public opinion, and so on. Duan et al [16] used content analysis to classify violent incidents and associated them with 6 factors: diagnosis and treatment effects, doctor-patient communication, response speed, medical expenses, privacy protection, and patients' or their families' problems.

Objectives

With the development of social media, the microblog has become a key vehicle of public opinion by virtue of its extensive and real-time capabilities for mass communication. Despite the widespread coverage of violent incidents toward medical staff on social media, little empirical research has examined their types and laws of propagation. Although scholars have studied public opinion about violent incidents, they have focused mainly on influencing factors, the dynamic mechanisms of public opinion, and the characteristics of the incidents [17,18]. Some scholars have conducted research on the types and characteristics of microblog communication in light of corporate crisis events [19]. However, due to the particularity of medical services and the diversity of incentives for committing violent acts against medical staff, existing research results cannot effectively guide hospitals and health management departments in managing public opinion about the incidents. In relation to this issue, we took violent incidents against Chinese medical staff as the research object and applied two methods—the self-organizing map (SOM) neural network and function fitting—to conduct a quantitative study. The purpose of this study was to explore the microblog propagation law for violent incidents in China that involve medical staff, to classify the types of incidents, and to provide a basis for rapidly and accurately predicting trends in public opinion and developing corresponding measures to improve the relationship between doctors and patients. We selected 60 cases of violent incidents that led to heated discussions on the Sina microblog from 2011 to 2018 and used crawler software to search the microblog's web data. Starting from the first post about the incidents, every 2 hours, we recorded the number of additional tweets. We used the SOM to demarcate changes in the number of tweets and used the exponential and polynomial functions in MATLAB R2017a (The MathWorks) to predict and analyze the data to achieve better prediction. For hospitals and health management departments, understanding the communication types and the characteristics of the violent incidents being discussed on microblogs such as the Sina microblog can be helpful to institutions for scientifically predicting the propagation rules of incidents, for effectively managing and guiding public opinion relating to doctors and patients, and for improving the doctor-patient relationship.

Methods

Data Collection and Processing

We used "doctor/nurse was hit," "doctor/nurse was slapped," "doctor/nurse was killed," "doctor/nurse was attacked," "doctor/nurse was hurt," and so on as keywords when searching for violent incidents from January 1, 2011, to July 31, 2018,

using the Baidu search engine, and we searched for complete data on the development and outcomes of the target incidents. In total, we collected 403 violent incidents involving Chinese medical staff. According to Duan's classification criteria, we used the content analysis method to analyze the inducements for 60 violent incidents and grouped them into 6 categories: treatment effect, doctor-patient communication, response speed, medical expenses, privacy protection, and patients' or families' own problems [16]. Relying on the crawler software platform of GooSeeker (Shenzhen Tianju Information Technology Ltd), we defined the fetching rules, searched related tweets by keyword, and then collected the website data from the Sina microblog to record the total number of tweets in a week.

As the propagation characteristics of violent incidents against Chinese medical staff on the Sina microblog are not obvious and the degree of influence is relatively low, we considered the total number of tweets of violent incidents on the Sina microblog within a week as the standard and selected 60 typical incidents that drew heated responses and discussion among netizens from 2011 to 2018 as the study samples. The samples covered the 5 direct causes of violent incidents involving medical staff and were representative to some extent. In accordance with the "criteria for human injury evaluation" issued by the Judicial Department in China, the severity of the consequences of violent incidents was classified as "slight bodily injury," "minor injury," "serious injury," "death," or "serious influence on hospital order" (as listed in Multimedia Appendix 1).

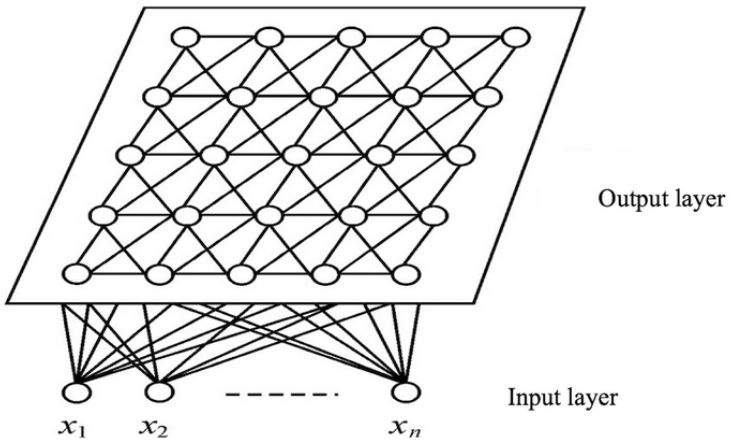
We mainly studied the dynamics of public opinion in the first week after the violent incidents. Therefore, we started to record tweets about the first violent incident reports and then recorded newly added Sina microblog material every 2 hours. We searched 168 hours of data within a week and collected 84 datasets in total. There were differences in the number of tweets for different events, so the data were standardized.

The formula was as follows: adjusted standard value=100×(original value−min)/(max−min). Min and max are the minimum and maximum values for each of the 84 datasets about the incidents.

Network Sample Design

The SOM is an excellent tool in the exploratory phase of data mining [20]. SOM networks learn to cluster groups of similar input patterns from a high-dimensional input space in a nonlinear fashion to a low-dimensional (most commonly two-dimensional) discrete lattice of neurons in an output layer [21], which was widely applied to classification and prediction [22-27]. The neurons in the competition layer can be one-dimensional, two-dimensional, or multidimensional (as shown in Figure 1 [28]). SOMs are reported to be robust and accurate with noisy data [29].

Figure 1. A topology diagram of the self-organizing map network.



The SOM method works as follows [30]. Initially, one has to choose the topology of the map. All the nodes are linked to the input nodes by weighted edges. The weights are first set at random and then iteratively adjusted. Each iteration involves randomly selecting an object x and moving the closest node (and its neighborhood) in the direction of x. The closest node is obtained by measuring the Euclidean distance or the dot product between the object x and the weights of all nodes in the map. The neighborhood to be adjusted is defined by a neighborhood function, which decreases over time.

We used the MATLAB programming language to construct the SOM neural network model and employed functions provided by a neural network toolbox to implement the whole learning process, such as training, emulating functions, and so on. According to the data after standardized processing, the input mode of the network was determined as

where k=1,2,3,…,60 (n=84), that is, there were 60 sets of samples, each of which contained 84 elements.

Results

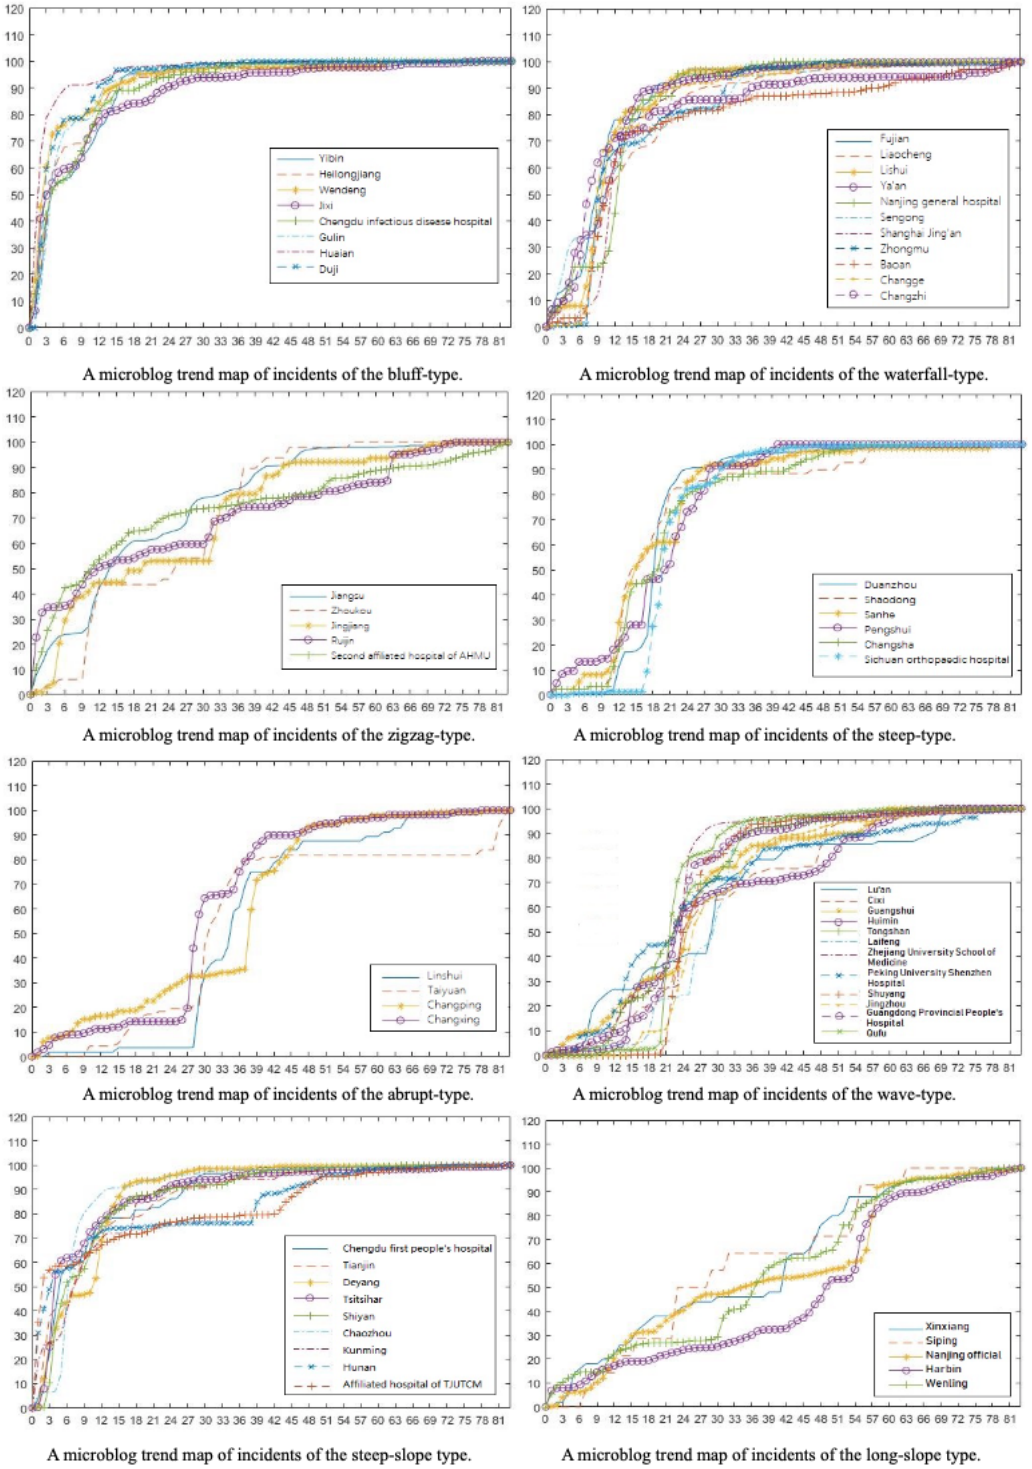
Clustering Results

With the SOM neural network toolkit of MATLAB R2017a, 60 groups of data, containing 84 elements each, were clustered by standardized processing into 8 types. On the basis of the shapes of the trend lines in the graphs, the types of clustering results were named as follows: *bluff*, *waterfall*, *zigzag*, *steep*, *abrupt*, *wave*, *steep slope*, and *long slope* (shown in Figure 2).

By the application of the SOM neural network algorithm, 60 medical incidents against Chinese medical staff were divided

into 8 types, based on the number of dynamic changes in the Sina microblog tweets. In Figure 2, it can be seen that these 8 types of curves generally showed significant differences, albeit similar curves represent similar trends. The types were all named according to the general shapes of the curves. It can be seen from the figures that the microblog transmission curves of each type had distinguishing characteristics (shown in Table 1). The clustering results of the SOM neural network model were good.

Figure 2. A microblog trend map of incidents of the types.



AHMU: Anhui Medical University

TJUTCM: Tianjin University of Traditional Chinese Medicine

Table 1. Clustering results and curve characteristics.

Category	Hot violent incidents with medical staff	Curve characteristics
Bluff type	Yibin Second People's Hospital, December 17, 2017; Heilongjiang Provincial People's Hospital, August 15, 2017; Shandong Wendeng Osteopathic Hospital, March 21, 2017; Jixi People's Hospital, July 11, 2017; Chengdu Infectious Disease Hospital, July 21, 2017; Gulin County People's Hospital, January 14, 2015; Huai'an First People's Hospital, February 10, 2018; Du Ji people's Hospital, March 21, 2016	In the first 12 hours or so, there was a peak period of tweet postings. After which, in the 13th hour, the growth rate suddenly declined and then lasted for 6 hours. After that, in the 19th hour, the number of tweets sped up, and the increase lasted for 6 hours or so. Then, it continued to increase at a slower pace. After the 96th hour, the growth rate was almost zero.
Waterfall type	Fujian Provincial Cancer Hospital, February 7, 2017; Liaocheng People's Hospital, December 4, 2017; Hong Lan Town Health Centre of Lishui District, April 23, 2017; Ya'an People's Hospital, January 5, 2017; Nanjing General Hospital of Nanjing Command, January 17, 2017; Shanxi Sengong Hospital, February 1, 2017; Jing'an District Central Hospital, March 4, 2016; Yanminghu Central Health Center of Zhongmu County, June 11, 2015; Baoan District people's Hospital, September 9, 2013; Changge People's Hospital, November 1, 2015; Heping Hospital affiliated to Changzhi Medical College, November 22, 2016	The early growth rate was slow. At around 12 hours, the growth rate of the microblog increased sharply and then gradually slowed down.
Zigzag type	Jiangsu Provincial People's Hospital, February 16, 2017; Zhoukou Central Hospital, July 12, 2017; Orthopaedic Clinic in Jingjiang City, April 22, 2017; Ruijin Hospital Affiliated to Medical College of Shanghai Jiaotong University, June 27, 2015; Second Affiliated Hospital of Anhui Medical University, November 13, 2012	Growth was rapid in the early stage, and then the growth trend became slow, or even close to 0, followed by a growth phase featuring alternating speeds.
Steep type	Women and Children Health Hospital of Duanzhou District, August 6, 2017; Shaodong County People's Hospital, July 17, 2017; Sanhe People's Hospital, March 21, 2017; Pengshui County People's Hospital, March 24, 2017; Jiangbei Town Center Hospital of Changsha County, May 17, 2016; Sichuan Orthopaedic Hospital, October 10, 2016	In the early stages, the blog was in an incubation period. Then, there was a peak period of tweets posted between the 24th and 48th hours, after which the growth gradually slowed down. After the 114th hour, the growth rate was almost 0.
Abrupt type	Traditional Chinese Medicine Hospital of Linshui County, August 5, 2017; Taiyuan Central Hospital, August 5, 2017; Dongguan Changping Hospital, April 17, 2016; Changxing County People's Hospital, October 4, 2016	The growth rate was slow in the first 30 hours or so, and then, it increased slightly over the next 2 hours or so. Before the 54th hour, the growth rate was almost flat. Then, a peak period of posting occurred between 54 and 72 hours, after which the growth rate gradually slowed down.
Wave type	Lu'an People's Hospital, September 1, 2017; Cixi people's Hospital, June 4, 2017; Guangshui First People's Hospital, April 6, 2017; Huimin People's Hospital, June 15, 2017; Tongshan County People's Hospital, December 8, 2017; Lai Feng County Central Hospital, November 2, 2017; The Second Affiliated Hospital of Zhejiang University School of Medicine, February 20, 2014; Peking University Shenzhen Hospital, February 25, 2014; Shuyang County Nanguan Hospital, April 19, 2014; Jingzhou First People's Hospital, May 5, 2012; Guangdong Provincial People's Hospital, May 5, 2016; Qufu People's Hospital, May 16, 2016	The number of tweets increased gradually over the first 42 hours and then increased suddenly. Then, the growth rate showed a wave-shaped oscillation within 43 to 149 hours. After the 150th hour, the growth rate was almost 0.
Steep slope type	First People's Hospital of Chengdu, March 23, 2017; Tianjin Third Central Hospital, June 29, 2017; Deyang People's Hospital, January 3, 2016; Beigang Hospital, February 17, 2014; Shiyan People's Hospital, February 21, 2015; Chaozhou Central Hospital, March 5, 2014; First Affiliated Hospital of Kunming Medical University, June 7, 2015; Hunan Academy of Traditional Chinese Medicine Affiliated Hospital, September 23, 2013; First Teaching Hospital of Tianjin University of Traditional Chinese Medicine, November 29, 2012	The number of tweets increased sharply over the first 6 hours or so. Then, there was a short pause, followed by a gradual and steady increase from the 84th hour to the 101st hour. After the 102nd hour, the growth rate was almost 0.
Long slope type	Xinxiang Second People's Hospital, November 7, 2017; Siping Central Hospital, October 15, 2017; Nanjing Stomatological Hospital, February 25, 2014; First Affiliated Hospital of Harbin Medical University, March 23, 2012; Wenling First People's Hospital, October 25, 2013	The growth rate of the tweets was stable and lasted for a long time. After 120 hours, it gradually increased.

Correlation Analysis Between the Types of Propagation on the Microblog and the Characteristics of the Medical Incidents

The characteristics of the medical incidents against Chinese staff analyzed in this study were the severity of the consequences and the inducements. To explore the relationships between the types of propagation on the microblog and the severity of the consequences of the medical incidents, we conducted a one-way analysis of variance (ANOVA; single factor) considering the types of propagation on the microblog as the independent variables and severity of the consequence of the medical

incidents as the dependent variable. After administering the Shapiro-Wilk test, the dependent variable was normally distributed. The results show that there were significant differences in the severity of the consequences of incidents associated with the different types of propagation (P=.03). The severity of the consequences of medical incidents of the long slope type (mean 4.00) was significantly higher than those of the bluff type (mean 2.63), waterfall type (mean 2.73), steep type (mean 2.17), abrupt type (mean 2.5), and wave type (mean 2.58). The severity of the consequences of medical incidents of the steep slope type (mean 3.75) was significantly higher than those of the bluff type (mean 2.63), steep type (mean 2.17), and wave type (mean 2.58). The severity of the consequences of medical incidents of the zigzag type (mean 3.80) was significantly higher than those of the steep type (mean 2.17) and wave type (mean 2.58), as shown in Multimedia Appendix 2.

The abovementioned analysis shows that the severity of the consequences of the medical incidents varies with the type of propagation. The severity of incidents of the long slope type, steep slope type, and zigzag type was higher than that of the other types, and most of the incidents in these categories involved a serious injury or death. Therefore, we classified these incidents as a high-severity group and the other incidents as a low-severity group. We used a one-way ANOVA, with these 2 groups, that characterized the consequences of the medical incidents as the independent variable and popularity within a week of the incidents as the dependent variable. Popularity was rated on a 6-point scale according to the number of tweets within a week. We coded 6 for a number of tweets above 5000, 5 for a number from 2000 to 5000, 4 for 1000 to 2000, 3 for 500 to 1000, 2 for 100 to 500, and 1 for 0 to 100. The higher the point score, the higher the popularity. Therefore, the dependent variable is continuous. After administering the Shapiro-Wilk test, the dependent variable was normally distributed. The results show that the popularity of high-severity incidents was significantly higher than that of low-severity incidents (high: mean 3.44; low: mean 2.05; P<.001). We adopted a one-way ANOVA, with the types of inducement for the incidents as independent variables and popularity within a week as the dependent variable. We found that violent acts resulting from patients' dissatisfaction with treatment effects garnered popularity within a week that was significantly higher than the popularity of incidents caused by nontherapeutic effects (treatment effect: mean 3.05; nontherapeutic effect: mean 2.15; P=.02).

We constructed a cross-tabulation of the inducements of the medical incidents and the types of propagation on the microblog. The chi-square test results show that there was no correlation between them.

Forecasting Trends in Network Public Opinion Regarding Violent Incidents

Nowadays, microblogs are becoming important carriers of public opinion on the internet about violent incidents against medical staff, and the traditional methods that medical institutions and health management departments use to control public opinion are severely weakened. The dynamic monitoring of trends and changes in microblog discussions can help hospital and health management departments to take timely countermeasures after violent incidents are publicized. At the same time, relevant departments could make use of the data to predict the propagation of microblog discussions of violent incidents, effectively manage and guide public opinion about doctors and patients, and improve the relationship between doctors and patients. On the basis of the study on stock price prediction by Afolabi and Olude [31], we considered 4 types of propagation, including the bluff, waterfall, zigzag, and steep slope types, for the prediction analysis in this study.

Forecasting Trends in the Spread of Network Public Opinion: Bluff-Type Propagation

The first cluster, consisting of incidents with the bluff-type profile, was selected for the sample. We took the average data of the 8 incidents in the Sina microblog and used the cftool toolkit in MATLAB R2017a to do the exponential function fitting for prediction. We recorded newly added Sina microblog material every 2 hours and searched 168 hours of data within a week, collecting 84 datasets in total. The first 70 of the 84 datasets were selected for fitting. We determined the fitting model and used the last 14 datasets as the prediction results to validate the data. As shown in Figure 3, *fit 1* was the fitting curve, and y vs x was the original data point.

The fitting model for the exponential function was

$$f(x_1) = 93.39 \times \exp(0.001092 \times x_1) - 112.8 \times \exp(-0.204 \times x_1)$$

where x_1 was the data observation point (we took observations every 2 hours) and $f(x_1)$ was the number of related tweets after standardized processing under the observation point.

In the fitting of the model, R^2 (the coefficient of determination) was 0.985, the sum of squares due to error (SSE) was 377.7, adjusted R^2 was 0.9846, and the root-mean-square error (RMSE) was 2.392.

As shown in Table 2, the predicted data values were almost consistent with the actual values, with a maximum relative error of 1.9055% and a minimum relative error of 0.77%. The trend of the data in the forecast section (positions 71 to 84) completely coincided with the actual trend, which shows that the prediction effect of the model for the bluff-type incidents was good.

Figure 3. A data-fitting diagram of the bluff-type incidents.

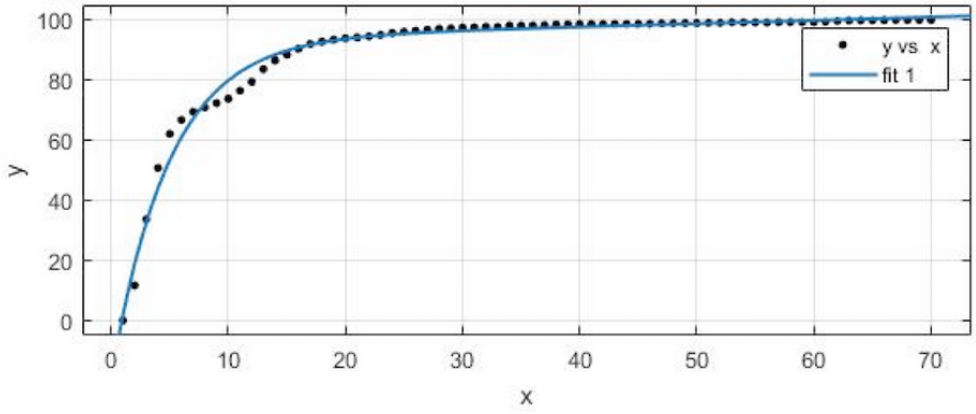


Table 2. A comparison of the fitting value with the actual value of the bluff-type incidents.

Predicted position	Fitting value	Actual value	Relative error (%)
71	100.5967	99.8280	0.7700
72	100.6968	99.8590	0.8390
73	100.7970	99.8918	0.9062
74	100.8973	99.9188	0.9793
75	100.9976	99.9188	1.0796
76	101.0981	99.9729	1.1255
77	101.1987	99.9729	1.2261
78	101.2994	99.9729	1.3268
79	101.4001	100.0000	1.4001
80	101.5010	100.0000	1.5010
81	101.6020	100.0000	1.6020
82	101.7031	100.0000	1.7031
83	101.8042	100.0000	1.8042
84	101.9055	100.0000	1.9055

Forecasting Trends in the Spread of Network Public Opinion: Waterfall-Type Propagation

The second cluster, consisting of waterfall-type incidents, was selected for the sample. We took the average data of the 11 incidents in the Sina microblog for the forecast and made use of the cftool toolkit in MATLAB R2017a to do the polynomial function fitting for prediction. As shown in Figure 4, *fit 2* was the fitting curve.

The fitting model of the polynomial function was

$$f(x_2) = (-1.156e\text{-}05)x_2^4 + 0.002763x_2^3 - 0.2373x_2^2 + 8.783x_2 - 22.33$$

where x_2 was the data observation point (we made an observation every 2 hours) and $f(x_2)$ was the value of the number of related tweets after standardized processing under the observation point.

In the fitting of the model, R^2 was 0.977, the SSE was 1356, adjusted R^2 was 0.9756, and RMSE was 4.568.

As shown in Table 3, the predicted data values were almost consistent with the actual values, with a maximum relative error of 3.06% and a minimum relative error of 1.3401%. The trend of the data in the forecast section (positions 71 to 84) completely coincided with the actual trend, which shows that the prediction effect of the model for the waterfall-type incidents was good.

Figure 4. A data-fitting diagram of the waterfall-type incidents.

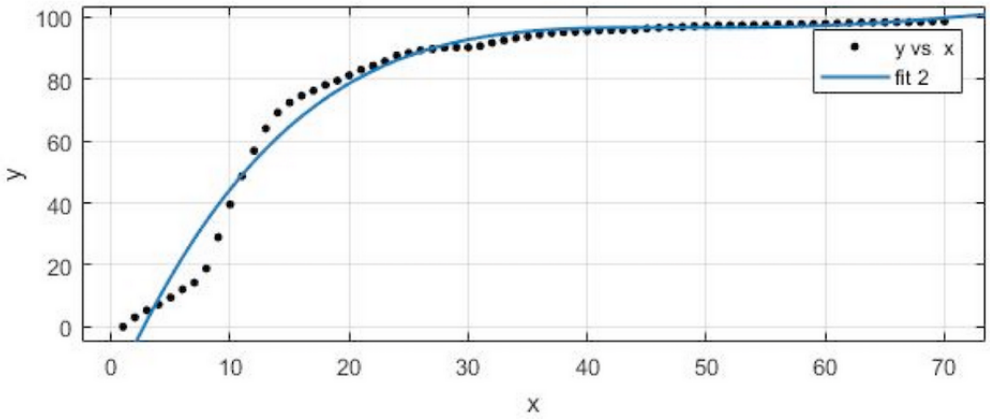

Table 3. A comparison of the fitting value with the actual value of the waterfall-type incidents.

Predicted position	Fitting value	Actual value	Relative error (%)
71	100.1828	98.8402	1.3401
72	100.5052	98.9306	1.5666
73	100.8276	99.0648	1.7483
74	101.1463	99.1315	1.9919
75	101.4575	99.2729	2.1532
76	101.7571	99.2850	2.4294
77	102.0408	99.2850	2.7007
78	102.3039	99.3088	2.9277
79	102.5415	99.4037	3.0600
80	102.7484	99.9145	2.7581
81	102.9191	99.9609	2.8743
82	103.0478	99.9609	2.9956
83	103.1286	100.0000	3.0337
84	103.1551	100.0000	3.0586

Forecasting Trends in the Spread of Network Public Opinion: Zigzag-Type Propagation

The third cluster, consisting of zigzag-type incidents, was also selected for the sample. For the forecast, we took the average data of the 5 incidents discussed in the Sina microblog and made use of the cftool toolkit in MATLAB R2017a to do the polynomial function fitting for prediction. As shown in Figure 5, *fit 3* was the fitting curve.

The fitting model of the polynomial function was

$$f(x_3) = 0.0001973x_3^3 - 0.04018x_3^2 + 3.166x_3 + 5.273$$

where x_3 was the data observation point (we made an observation every 2 hours) and $f(x_3)$ was the value of the number of related tweets after standardized processing under the observation point.

In the fitting of the model, R^2 was 0.9872, the SSE was 584.7, adjusted R^2 was 0.9866, and RMSE was 2.977.

As shown in Table 4, the predicted data values were almost consistent with the actual values, with a maximum relative error of 4.441% and a minimum relative error of 0.8448%. The trend of the data in the forecast section (positions 71 to 84) completely coincided with the actual trend, which shows that the prediction effect of the model for the zigzag-type incidents was good.

Figure 5. A data-fitting diagram of the zigzag-type incidents.

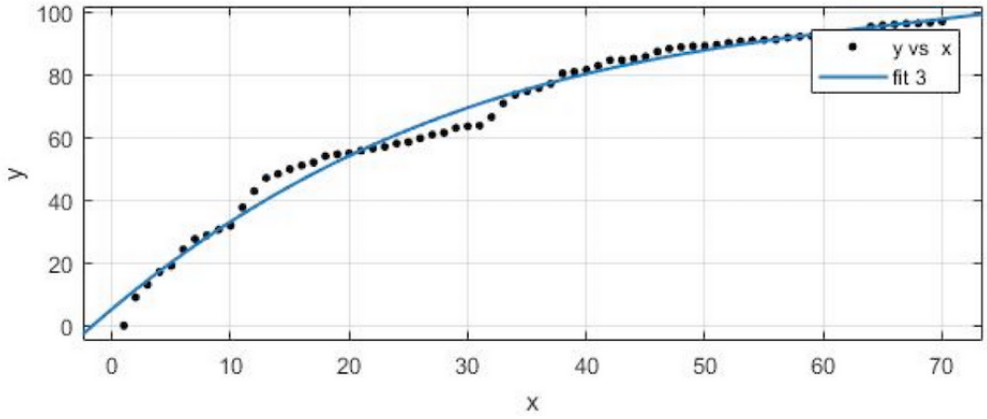

Table 4. Comparison of the fitting value with the actual value of the zigzag-type incidents.

Predicted position	Fitting value	Actual value	Relative error (%)
71	98.1275	97.2985	0.8448
72	98.5737	97.5108	1.0783
73	99.0248	98.0012	1.0336
74	99.4820	98.2928	1.1954
75	99.9464	98.6039	1.3432
76	100.4193	98.8007	1.6118
77	100.9017	99.0006	1.8841
78	101.3950	99.1359	2.2280
79	101.9002	99.2251	2.6252
80	102.4186	99.2435	3.1001
81	102.9513	99.3665	3.4820
82	103.4996	99.6064	3.7616
83	104.0646	99.7724	4.1245
84	104.6474	100.0000	4.4410

Forecasting Trends in the Spread of Network Public Opinion: Steep Slope–Type Propagation

The seventh cluster, consisting of steep slope–type incidents, was selected. For the forecast, we took the average data of the 9 incidents in the Sina microblog and made use of the cftool toolkit in MATLAB R2017a to do the exponential function fitting for prediction. As shown in Figure 6, *fit 4* was the fitting curve.

The fitting model of the exponential function was

$$f(x_4) = 85.79 \times \exp(0.002299 \times x_4) - 100 \times \exp(-0.1424 \times x_4)$$

where x_4 was the data observation point (we made an observation every 2 hours) and $f(x_4)$ was the value of the number of related tweets after standardized processing under the observation point.

In the fitting of the model, R^2 was 0.9987, the SSE was 44.51, adjusted R^2 was 0.9986, and RMSE was 0.8212.

As shown in Table 5, the predicted data values were almost consistent with the actual values, with a maximum relative error of 3.9058% and a minimum relative error of 1.5555%. The trend of the data in the forecast section (positions 71 to 84) completely coincided with the actual trend, which shows that the prediction effect of the model for the steep slope–type incidents was good.

Figure 6. A data-fitting diagram of the steep slope–type incidents.

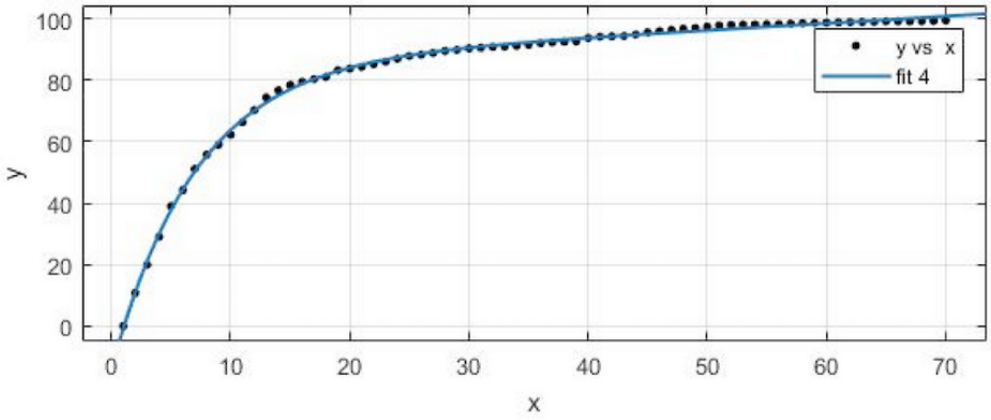

Table 5. A comparison of the fitting value with the actual value for the steep slope–type incidents.

Predicted position	Fitting value	Actual value	Relative error (%)
71	100.9970	99.4260341	1.5555
72	101.2300	99.4703353	1.7383
73	101.4635	99.5033538	1.9319
74	101.6975	99.5719260	2.0901
75	101.9319	99.5832087	2.3042
76	102.1668	99.6310762	2.4819
77	102.4022	99.6367044	2.7006
78	102.6382	99.6995552	2.8631
79	102.8746	99.7121893	3.0740

81	103.3490	99.8030223	3.4311
82	103.5870	99.8845621	3.5742
83	103.8256	99.9749575	3.7088
84	104.0646	100.0000000	3.9058

Discussion

Principal Findings

The theories and methods of public opinion communication are relatively mature, but applications in the field of medical public opinion are relatively few. We believe that this study is the first to apply the theories and methods of public opinion communication to research in medical public opinion and to systematically explore the types of incidents against medical staff and the patterns in which discussions about them propagate on microblogs. Tracking discussions of violent acts against medical staff in China that took place on the internet from 2011 to 2018, we selected 60 cases for our sample that prompted intense discussion on the Sina microblog, used crawler software to collect the data from the web, applied the SOM neural network model to cluster the tweets, mapped changes in the discussion trends over time, and used the polynomial and exponential function methods to analyze and predict communication patterns of public opinion. The results showed that the fit was good.

Our study found that the propagation of web-based public opinion relating to the violent incidents was divided into 8 types: bluff, waterfall, zigzag, steep, abrupt, wave, steep slope, and long slope. Over the first 12 hours or so, the number of tweets in the bluff type of discussion peaked, after which the growth rate declined suddenly in the 13th hour and continued to decline for 6 hours. In the 19th hour, there was an increase in the number of tweets that lasted for 6 hours or so, and then, the growth rate gradually decreased. After the 96th hour, the growth rate was almost 0. For the waterfall-type propagation, the early growth rate was slow. At about the 12th hour, the growth rate increased sharply, then gradually decreased. For the zigzag type of propagation, growth was rapid in the early stage, and then, it decreased and sometimes approached 0, going through a process of alternating slow and rapid growth. For the steep slope–type propagation, there was an early stage incubation period, then a peak period of posting from the 24th hour to the 48th hour, followed by gradually decreasing growth. After the 114th hour,

the growth rate was almost 0. For the abrupt type, the growth rate was slow in the first 30 hours or so, and then, it increased slightly for about 2 hours. Before the 54th hour, the growth rate was almost flat, then it peaked between 54 and 72 hours and after that it gradually decreased. For the wave type, the number of tweets increased throughout the first 42 hours, then the growth rate showed a wave-shaped oscillation within 43 to 149 hours. After the 150th hour, the growth rate was almost 0. For the steep slope type, the number of tweets increased sharply over the first 6 hours or so, followed by a pause, and then by a gradual and steady increase from the 84th hour to 101st hour. After the 102nd hour, the growth rate was almost 0. For the long slope type, the growth rate of the tweets was stable and long lasting, persisting for 120 hours, after which it grew gradually and slowly.

What are the laws of propagation for the different types of violent medical incidents? We attempted to investigate this question with regard to the severity of consequences, the inducements for the incidents, and the popularity of the topic over the course of a week (in terms of the number of tweets). Our study found that the more serious the consequences of a violent incident, such as a serious injury or death, the more attention it drew on the microblog, the faster was its propagation speed, and the longer was its duration. In these cases, the propagation types were mostly of the steep slope, long slope, and zigzag types. In addition, the more serious the consequences of a violent incident, the greater popularity it exhibited on the microblog. Acts resulting from patients' dissatisfaction with treatment effects led to significantly greater popularity within a week than incidents caused by nontherapeutic effects.

Managerial Insights

Our research has important practical implications for both hospitals and governments. Workplace violence toward medical staff happens more often in China than in other countries, which provides multiple opportunities for research on the classification and prediction of incidents and their discussion on microblogs. The findings of this paper provide a new method for hospitals and health management departments in China and other countries to accurately predict communication types and rules of propagation in the discussion of violent incidents and can help relevant departments effectively manage public opinion concerning doctors and patients, ease workplace violence in the health sector, and improve doctor-patient relationships. Specifically, hospitals and health management departments should establish a public opinion monitoring system for doctor-patient relationships. When a violent incident occurs, relevant departments should pay close attention to the relevant tweets and comments and scientifically predict the communication types and rules of propagation based on the causes and severity of the consequences, so as to take effective countermeasures. In the case of incidents that lead to serious consequences, as these incidents would be quickly taken up in public discussion, hospitals and health management departments should promptly investigate the causes and announce the progress and results of the incidents. Some scholars emphasize the necessity to use both traditional media and social media in crisis response for mutual communication [10,32]. In the case of incidents that are caused by patients' dissatisfaction with treatment effects, which the public often attributes to the low technical ability of medical staff and which easily generate heated discussions and lead to negative impacts on hospitals and staff, hospitals and health management departments should investigate the causes; take responsibility; and, through official channels and in a timely manner, clarify the situation, answer questions, and assuage doubts raised by the public.

Limitations and Future Research

Our work has certain limitations that provide directions for future research. In this study, we explored the types and laws of the communication of events on the Sina microblog and analyzed the relationship among the types of communication, the laws of propagation, the causes of events, and the severity of the results. However, this study did not consider factors—such as the hospital type, the response strategies of health management departments and hospitals, and settlement results from judicial authorities—that could have an impact on the propagation of discussions of violent incidents on the microblog. We hope that future scholarly work, while attempting to confirm or refute our key findings, could also complement and expand the abovementioned issues. Future research is thus needed to select more incidents for the prediction analysis and improve the accuracy of the predictions.

Abstract

Background: In remote areas, connected health (CH) is needed, but as local resources are often scarce and the purchasing power of residents is usually poor, it is a challenge to apply CH in these settings. In this study, CH is defended as a technological solution for reshaping the direction of health care to be more proactive, preventive, and precisely targeted—and thus, more effective.

Objective: The objective of this study was to explore the identity of CH stakeholders in remote areas of Taiwan and their interests and power in order to determine ideal strategies for applying CH. We aimed to explore the respective unknowns and discover insights for those facing similar issues.

Methods: Qualitative research was conducted to investigate and interpret the phenomena of the aging population in a remote setting. An exploratory approach was employed involving semistructured interviews with 22 participants from 8 remote allied case studies. The interviews explored perspectives on stakeholder arrangements, including the power and interests of stakeholders and the needs of all the parties in the ecosystem.

Results: Results were obtained from in-depth interviews and focus groups that included identifying the stakeholders of remote health and determining how they influence its practice, as well as how associated agreements bring competitive advantages. Stakeholders included people in government sectors, industrial players, academic researchers, end users, and their associates who described their perspectives on their power and interests in remote health service delivery. Specific facilitators of and barriers to effective delivery were identified. A number of themes, such as government interests and power of decision making, were corroborated across rural and remote services. These themes were broadly grouped into the disclosure of conflicts of interest, asymmetry in decision making, and data development for risk assessment.

Conclusions: This study contributes to current knowledge by exploring the features of CH in remote areas and investigating its implementation from the perspectives of stakeholder management. It offers insights into managing remote health through a CH platform, which can be used for preliminary quantitative research. Consequently, these findings could help to more effectively facilitate diverse stakeholder engagement for health information sharing and social interaction.

connected health care; remote areas; business strategy; Taiwan; population aging; knowledge sharing

Introduction

Background

The global phenomenon of an aging populations has made health care a universal issue, especially in remote areas. Connected health (CH) has been proposed as a promising solution to manage challenges arising in these remote areas. It aims to reduce isolation, enhance safety, increase efficiency, and diminish costs for remote residents [1]. It acts as an alternative solution to make "aging in place" feasible by connecting infrastructure, devices, and health care stakeholders [2]. In remote areas, CH is needed, but as local resources are often scarce and the purchasing power of residents is usually poor, it is a challenge to apply CH in this setting. In this study, remote areas were defined in 3 categories: mountain areas, isolated islands, and remote townships. In these areas, medical and care services are legally allowed to be practiced remotely according to the law and regulation of the state. There are 48 remote townships that account for 44% of the area in Taiwan, while the 0.36 million residents only account for 1.6% of the total population.

There is evidence that CH can increase access to services across a range of medical specialties without detrimental effects and improve opportunities for professional development [3]. However, most of these measures are temporary responses to government policy, and the sustainability of such services is an issue that must be addressed. Consequently, although technological interventions have improved accessibility, efficiency, and cost-effectiveness, the health status of rural residents remains a matter of concern [4]. Thus, the parameters of effective CH implementation in rural and remote contexts need to be explored to suggest strategies to manage issues appropriately.

Research suggests that the maturity of information communication technology, advances in health care, and the integration of health and social care may offer the fundamental infrastructure to boost the CH ecosystem [5]. Taiwan was selected as an ideal research area as it fulfills these requirements. Therefore, the results of this investigation may inspire those who are attempting to manage the issues of aging populations in a remote setting through a knowledge-sharing perspective.

To understand the obstacles faced in the implementation of CH in remote areas, this study explored the developmental barriers of CH in remote areas based on four representative cases in Taiwan. Geographically, CH in Taiwan has been divided into 4 parts: North, middle, South, and East. Each part has a designated hospital to support other hospitals and health centers in their areas. This study aimed to determine ideal strategies and methods by exploring the unknowns to discover insights for those facing similar issues in applying CH.

In this study, CH is defended as a technological solution that reshapes the direction of health care to be more proactive, preventive, and precisely targeted, and thus, more effective. CH provides great value in managing and preventing chronic diseases that result in tremendous burden on health care and social services. Stakeholder analysis was employed to facilitate strategy formation, as it can generate knowledge about how the characteristics of stakeholders influence decision-making processes as well as the relevant actors' behavior, intentions, and interrelations.

Theoretical Basis

The challenges of accessing appropriate health services and of recruiting and retaining staff constrain the quality of health care in remote settings [6]. With respect to a proactive approach to current problems and insights into remote health, gaps remain [7]. Possible strategies for these issues include overcoming geographic isolation and facilitating rural and local health responses. This study explored how stakeholder characteristics influence the decision-making process. The literature suggests that the need to balance conflicts of interest and the influence of organizational factors and professional support may impact the quality of health in remote areas [8,9]. Therefore, this study explored perspectives on stakeholder arrangements, including the power and interests of stakeholders and their respective needs in the ecosystem, as shown in Figure 1.

Figure 1. A simple stakeholder management model (adapted from Freeman and Reed [10]).

Stakeholder analysis is often employed to facilitate the formation of strategies, as it can generate knowledge about how the characteristics of stakeholders influence decision-making processes as well as the relevant actors' behaviors, intentions, and interrelations [8]. Courage, creativity, and a capacity to recognize opportunities for change will be key for public health advocates to create political incentives and manage political risks for leaders. Globalization may be helpful for leaders to gain awareness of the necessity of change and innovative strategies in health care [11]. Better insight into how health systems are structured and how they react over time to better adjust to health programs will also affect stakeholder management [12]. Despite considerable research on risk analysis in health politics, only little insight has been gained.

The value of stakeholder analysis in the health promotion domain is its ability to increase our understanding and capacity to participate in and contribute to health policy development by mapping the relevant actors. Once insights into their position and connection in networks are discovered, strategic planning can then be proposed [13].

General agreement among stakeholders may help the health information system advance in meeting the objectives of improving the governance, efficiency, user and provider satisfaction, and long-term fiscal sustainability of the health care system [14,15]. A stakeholder analysis framework is often used to highlight how key relationships with stakeholders may change with the perceived credibility of the organizational leaders and the legitimacy of their actions, as CH is a disruptive innovation in health care services. It is fascinating to explore how small rural health centers and a well-established, federally qualified community health center contribute to managing the risks of health care [16]. The concept of stakeholder management can help us to understand the tasks and structural changes via the legislation of decision makers [10]. Considerable systematic planning for health promotion that addresses people's lives, work, and leisure can optimize health interventions for specific contextual contingencies and target crucial factors in the organizational context that influence behavior [17].

The rise of the patient-centered concept has increased the complexity of the health care system, which motivates partnerships between the public sector and private actors in stakeholder management [18]. The literature indicates that a situation with a multitude of actors with diverse interests suggests a loosely connected network, for those who attempt to influence policy will need to work with international-level, federal-level, and regional-level actors because they play an important role in bridging and connecting the decentralized regional-level and local-level actors as well as in initiating policy engagement and change [19,20]. Multicriteria decision analysis can add value to the strategic decision-making process in health technology assessment through systematic reviews, as it is more focused on how to engage stakeholders than to explain how to develop the algorithms and methodologies [21]. Analyzing routinely captured health information and giving feedback to clinical staff have been proposed to deliver better outcomes for patients and communities in the CH program [22].

The attempt to identify factors affecting the availability, accessibility, and coordination of services serves to develop and implement culturally sensitive service delivery in remote health care settings. Findings could inform recommendations for the provision of health services to contribute to the broader knowledge of rural and remote health service provision [23]. Access to allied health services is always an issue for people with disabilities living in rural and remote areas. Evidence indicates that CH is a valid option to provide those with disabilities alternative options to receive health care services [24]. Investigation of frail older adults and their stakeholders suggests that an integrated system with a care coordinator to improve connections between services and patients is urgently needed. It is a must to reduce bureaucracy and increase the timeliness of treatment and care. Measures to improve access to health and social care systems for pre-frail and frail patients, as well as their caregivers, must be considered [25]. Also, CH is beneficial for patients with chronic conditions as well as for the frail, by improving access to health care services and allowing them to be monitored at home [26].

Strengthening the rural deployment of stakeholders may attract and motivate graduates to work in rural areas, although the factors influencing recruitment of health professionals are varied [27]. If individual knowledge of successful aging and the associated economic outcomes, such as financial planning for retirement wellbeing, are to be harnessed, stakeholder management can help put pressure on the state to improve the current health insurance system, making it possible to offer a universal social pension that prioritizes people deprived of

income due to a disability, severely debilitating disease, or lost work opportunity during their younger years [28].

Research Questions

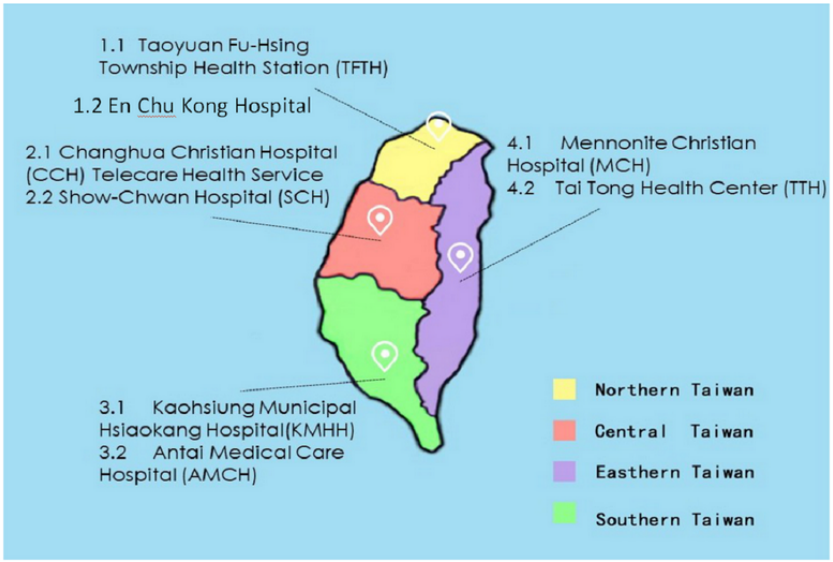
This study aimed to determine how geographical isolation and aging in place can be accommodated through CH stakeholder management based on the knowledge of the stakeholders' identities and their interests and power in remote areas of Taiwan.

Methods

An exploratory approach was conducted involving semistructured interviews with 22 participants from 8 remote allied case studies [29]. The interviews explored perspectives on stakeholder arrangements, including the power and interests of stakeholders and the needs of all the parties in the ecosystem [30,31]. To manage health challenges for the aging population, the Taiwanese government divided Taiwan into 4 parts to conduct a pilot study of CH in 1996 (Figure 2). This provided the foundation for the current infrastructure of CH and smart health in Taiwan. Therefore, this study organized research according to this foundation. An exploratory approach was conducted involving semistructured, in-depth interviews with 22 participants in four remote allied case studies: Northern Taiwan, Central Taiwan, Southern Taiwan, and Eastern Taiwan (Figure 2). Northern Taiwan is represented by 1.1 Taoyuan Fu Hsing Township Health Station and 1.2 En Chu Kong Hospital; Central Taiwan by 2.1 Changhua Christian Hospital Telecare Health Service and 2.2 Show-Chwan Hospital; Southern Taiwan by 3.1 Kaohsiung Municipal Hsiaokang Hospital and 3.2 Antai Medical Care Hospital; and Eastern Taiwan by 4.1 Mennonite Christian Hospital and 4.2 Tai Tong Health Center.

This study investigated how geographical isolation and aging in place can be accommodated through CH stakeholder management with reference to, but not limited by, the interview questions outlined in Textbox 1, based on a qualitative method with focus groups.

Figure 2. Remote health settings in Northern, Central, Southern, and Eastern Taiwan.



Textbox 1. Interview questions used with the focus groups.

1. Who are your stakeholders?
2. How do they influence your business?
3. Do you have cooperative agreements with other organizations?
4. Are these agreements offer you competitive advantages?

Ethics

Ethical approval was obtained from the Ethics Committees of Ulster University (reference no RG3 RMcAdam2). Participants gave verbal consent according to the ethical guidelines.

Participant Selection

The authors selected 8 allied case studies from 4 geographical areas covering all remote areas in Taiwan based on a literature review and the foundation of the governmental pilot schemes referred to in Figure 2. Participants and institutions were chosen accordingly. The participants included those who were responsible for CH projects; patients were excluded due to ethical concerns. Residence in the four administrative areas based on geographic and rural location was the main criterion for selecting participants, and experience with CH was the second selection criterion. These sampling criteria were chosen in order to include the inputs of major and significant participants with various levels of rural experience and management. Consequently, 8 health institutions with 22 participants that represented all remote areas of Taiwan were selected, as shown in Figure 2 and Table 1.

Table 1. Allied health professionals participating in the study.

Geographic area and health care institutions	Role and number of participants	Age (years), range
1. North		
1.1 Taoyuan Fu Hsing Township Health Station	1 GP[a], 1 nurse, 1 civil servant	40-50 (GP and civil servant), 30-40 (nurse)
1.2 En Chu Kong Hospital	1 nurse	30-40
2. Central		
2.1 Changhua Christian Hospital (CCH) Telecare Health Service	4 nurses	30-40
2.2 Show-Chwan Hospital	4 nurses	30-40
3. South		
3.1 Kaohsiung Municipal Hsiaokang Hospital	1 GP, 1 pharmacist	30-40
3.2 Antai Medical Care Hospital	1 nurse, 2 GPs	30-40 (nurse), 40-50 (GPs)
4. East		
4.1 Mennonite Christian Hospital	1 nurse, 1 IT[b] director	40-50
4.2 Tai-Tong Health Centre	1 GP, 2 social workers	25-45

[a]GP: general physician.

[b]IT: information technology.

Data Collection

Following informed consent, researchers conducted face-to-face interviews with 22 participants lasting from 30 minutes to 2 hours. To ensure the significance, validity, and rigor of this qualitative research, several research strategies were conducted regarding the quality of data collection. These protocols include the use of the agile method to allow interviewees' opinions to be validated and exchanged through a semistructured interview manner. Any differences between the interviews were discussed until consensus was reached. Interviews were audiotaped and transcribed verbatim by an independent typist with subsequent validation by the researcher. Meaningful quotations were adduced to represent important themes. To ensure participant confidentiality, data were de-identified before processing.

Data Analysis

In this study, data were categorized using stakeholder and thematic analyses. Stakeholder analysis is conducted according to the degree of the stakeholders' ability to affect health care providers' objectives and health care providers' ability to affect stakeholders' objectives. It follows 4 steps to investigate how health institutions influence stakeholders for their interests: (1) identify stakeholders, (2) assess their interests and influence, (3) develop a communication management plan, and (4) engage and influence stakeholders. In the thematic analysis, codes were derived from the data through several steps including data cleaning, data summarizing, data analysis, and data mining. The categorization of data was continually revisited and reviewed until the themes and categories used to summarize and describe the findings were verified and accurately reflected the data. A qualitative data management system, NVivo 12 (QSR International, Melbourne, Australia), was employed to manage the data throughout the process. First, data were cleaned through an integration process to merge different terms with the same meaning. Thus, CH might be called "remote health," "telehealth," or "telecare" in the interviews, and these terms were merged according to the actual meaning of the interviewees. Second, the data were summarized, clustered, and categorized based on the interviewees' meaning. Third, the data were analyzed and extracted according to the interviewees' meaning at the stage of data mining. For example, some issues were raised by interviewees, but the meanings and root causes of the issues needed to be analyzed.

Results

Participants

A total of 22 participants representing 8 CH groups that covered all the remote areas in Taiwan were involved in this study. The majority of the participants were health professionals such as nurses (12/22, 54%), pharmacists (1/22, 5%), and general physicians (5/22, 22%), accounting for more than three-quarters of the sample. In addition, social workers accounted for approximately 10% (2/22, 9%) of the sample. Information technology professionals and administrators each accounted for 5% of the participants (1/22, 5% each), as shown in Multimedia Appendix 1.

Stakeholder Analysis

Stakeholder analysis was conducted according to the degree of the health care providers' ability to affect their stakeholders' objectives and interests. Four steps of stakeholder management were used: (1) identify stakeholders, (2) assess their interests and influence, (3) develop a communication management plan, and (4) engage and influence stakeholders. Due to the complexity of the data, these steps are described in Multimedia Appendices 1-4. The results revealed the identity of the stakeholders of CH in remote areas, how they influence practices, and how associated agreements bring competitive advantages.

The stakeholders for 8 participating health facilitators were identified (Multimedia Appendix 1). These stakeholders included industrial players (software developers, hardware manufacturers, total solution providers, network providers), users and their associates (end users), government sectors, and academic researchers, which collectively constitute an ecosystem of CH. The industrial players included both software developers and total solution providers (eg, Fora Care Inc, Asus Cloud, Huede Technology, and Far EasTone Telecommunications), while some telecommunications companies fell in both categories of network providers and software developers (eg, Far EasTone Telecommunications and Chunghwa Telecom). This fact may suggest that the CH industry is a multidisciplinary domain. What is noticeable is that not all the health facilitators had a telehealth or telecare center; therefore, some had to rely on industrial players to analyze and manage collected data. Compared with public health facilitators, private health facilitators have different attitudes toward government sectors. Although all the end users were from remote areas, they could originate from mountain areas, remote townships, or isolated islands, which differentiates the nature of their health facilitators.

In Multimedia Appendix 2, the assessment of the interests of each CH stakeholder group and the influence of health facilitators is described. Government sectors are concerned with how to identify significant outcomes to increase and promote political publicity. For academic researchers, innovative topics for research and how to explore unknown and novel concepts to contribute to the body of knowledge seem to be of the utmost importance. End users are looking for user-friendly, efficient, and cost-effective solutions to manage their health care according to health facilitators. However, they may care more about their financial health than their physical health. Although most industrial players are interested in increasing sales through developing and perfecting their products and services, the concepts of software developers and hardware manufacturers will vary due to the nature of their businesses. What is noticeable is that the influence on stakeholders determines the power and strategies of health facilitators.

According to the assessment in Multimedia Appendix 2, potential strategies for health facilitators to develop a communication management plan for stakeholders are shown in Multimedia Appendix 3. First, the communication constraints of health facilitators should be determined, followed by identifying the information to be communicated. Finally, the methodology for communications is determined, to facilitate the communications. The challenges for health facilitators include finding the right people to deliver the communication. The participants indicated that information technology professionals usually do not comprehend their requests and even if they do eventually understand them, they may not be able to make relevant decisions. Moreover, it is difficult to include interdisciplinary people who can accommodate supply and demand from various areas in the CH ecosystem. These considerations constrain communication between health facilitators and their stakeholders. Although the intent to fulfill the stakeholders' interests by exchanging resources is helpful, the degree of the bargaining power of stakeholders differs to that of health facilitators. Regarding the information to be communicated, many health facilitators admit that they still struggle. It should be stressed that strategies for increasing the visibility of institutions can facilitate communication with stakeholders.

From the data presented in Multimedia Appendix 3, the benefits of increasing the profile of health facilitators are clear. Regarding the next phase, Multimedia Appendix 4 provides information about how health facilitators can engage and influence their stakeholders according to the developed communication management plan. Then, the actual plans and strategies put in use are included. Health facilitators might influence stakeholders according to their interests. The participants indicated that industrial players offer free CH samples to receive test feedback from remote areas, especially mountain areas, because the features of geographic isolation and the local authority of general physicians (GPs) could significantly contribute to the development of a considerable number of products that could be brought to the market. After health facilitators achieve a solid reputation in the CH ecosystem, many opportunities for cooperation will spontaneously appear. Although the participants suggested that end users are usually concerned about the affordability of CH products and services, GPs may play an important role in educating patients about the value of CH. Other health facilitators, such as nurses, usually offer alternative solutions for patients to consider. Overall, those who have a typical environment or samples for CH to implement have stronger bargaining power when dealing with industrial players.

As mentioned, stakeholders representing government sectors, industrial players, academic researchers, and end users and their associates. The stakeholder analysis is mapped in Figure 3.

Figure 3. Stakeholder analysis of remote health care (source: adapted from Freeman and Reed [10]).

Initially, industrial players have relatively high importance, as they possess both technologies and economic benefits. Health providers in remote areas should, therefore, manage these closely. Next, government sectors are essential as they are key for funding the remote services as well as implementing rules and regulations. Remote users and their associates are less powerful in the remote health ecosystem than the parties in the first two categories, as they are usually voluntary and have limited economic strength. They are to be kept informed of any updates. Finally, academic researchers are less influential in affecting health care providers' objectives. Thus, they play the role of serving as a reference.

> *Governmental funding is important as we have limited capability to commercialize remote health care in the initial stage…*
>
> *The main purpose of offering remote health care is to address the social equality of health care rather than earning money.*
>
> *Although remote areas lack resources, the geographic features can be ideal locations for industrial players to develop and test their products and services.*
>
> *It is essential to keep connected to the latest health information and progress as well as global trends through academic interactions.*

Full Disclosure of Conflicting Interests

Several themes, such as government interests and power of decision making were corroborated across remote services. These have been broadly grouped into the disclosure of conflicts of interest, asymmetry in decision making, and data development for risk assessment. Health care stakeholders are criticized for finding it hard to reach common ground, as they all have different interests. Industrial players tend to emphasize economic benefits rather than ethics and user privacy, while health care providers value security, ethics, and patient rights above all. Government sectors are concerned with political forces, and academic researchers care most about the social impact.

> *Government is propaganda…they only care about their political achievements.*
>
> *We care about remote residents' lives, feelings, and rights to receive care.*
>
> *The population of remote areas is low; therefore, many businesses tend to ignore residents' interests as their scale is too small to yield economic benefits.*
>
> *A successful experience building up remote health models in Taiwan and expanding them worldwide may contribute significant impacts globally.*

Although stakeholders in the remote health care ecosystem have various interests, they need to rely on each other to survive. Health providers need government's support in establishing infrastructure and initial funding; industry's technologies and services are needed in operating remote offerings alongside academia's publicity and management's inputs to increase their reputation and profile-raising. However, health providers in remote areas usually have little negotiating power in pricing and budget. Therefore, the skill of translating risks into opportunities is desirable to obtain benefits.

> *Big companies offer quality products to our telehealth center for the sake of our hospital; otherwise, they don't care much about small businesses.*
>
> *In remote areas, the infrastructure is poor, as the main telecom companies cannot gain profit from building it. It creates a challenge to practicing remote health even though it is essential for residents.*
>
> *Most of our infrastructure relies on government funding.*
>
> *Government will be happy to support us as long as the practice can show benefits to their political achievements.*
>
> *Many main industrial players have difficulty meeting customers' needs and designing user-friendly products; therefore, they come to us with free products to obtain testing samples in remote settings.*

Asymmetry (Irregularity) in Decision Making

Although remote health care focuses on serving rural residents, their capability of decision making mainly depends on health care professionals, industrial players, and government.

> *Physicians have authority over patients, so their suggestions can strongly influence patients' decisions.*
>
> *If no remote infrastructure and services from industrial players, no connected health can be set up,*

> *but unfortunately, remote residents have no word in decision making.*

As rural residents often are older, of low socioeconomic status, and poor health status and have limited purchasing power, their interests are safeguarded by government and health professionals. Fortunately, as they live in a democratic society, they can wield influence on the government through voting, which provides incentive for the government to invest in remote infrastructure – to earn political capital.

Although remote residents have little power and influence on the CH setting, their voice is often heard through GPs and other health facilitators: "Remote residents pay the same health insurance fees to the government; however, they hardly enjoy any health benefits due to poor infrastructure. It is unfair to them."

It takes effort for GPs in remote areas to fight for residents' rights. In the beginning, outcomes are limited, but little by little, their efforts have produced some fruit.

> *We have tried to contact the main telecom company; however, they show no interest in building infrastructure here as there are no economic benefits.*
>
> *Luckily, we obtained support from the Minister, so that we can have some progress in remote services.*
>
> *Thanks to the attention of the Minister, we got attention through publicity, and industrial people contacted us to discuss cooperation opportunities by offering free products for testing.*

Data Development for Risk Management

To advance the remote health decision-making process, there is a need to think strategically about how data can inform risk, as the challenges of delivering CH in remote areas can travel in two directions. The upside of this challenge may generate better outcomes, but conversely, the downsides of the outcomes can be worse than expected. Geographic isolation and poor health resources may be downsides for CH, yet strategic planning about stakeholder management may maximize opportunities for gain, which may provide entrepreneurial opportunities as companies make money by converting challenges to opportunities. What distinguishes challenges and opportunities is therefore central to business success. Some challenges are having an adverse or positive effect on an organization's profits from overseas activities. Talent that can integrate and facilitate resources to optimize the interests of CH's stakeholders is required.

> *Practicing CH in remote areas does offer many opportunities. There are many examples, including boosting the development of high technologies, offering indications for health care policy making, and shortening the gaps in health implementation.*
>
> *Our experience with CH in remote areas has not only contributed to many publications but also raised the profile of our hospital.*
>
> *The successful experiences of practicing CH may be the best advertisement and marketing strategy for our hospital.*
>
> *Taiwan's geographic features are significant in practicing CH, as it is a representative case study…if CH devices can serve in such a challenging setting as Taiwan's remote areas, there will be no issues in using it all over the world.*

To move forward, a new decision paradigm is needed with the flexibility to consider new insights and scientific information. This approach would not create an environment in which the discussion of risk based on the information is avoided. Currently, although most state and federal regulations are not designed to protect individuals, they protect the public without defining what the public is or how many individuals constitute the public. As part of a new paradigm, researchers and policymakers should carefully consider whether current federal regulations are in fact designed to adequately protect individuals, especially those in vulnerable subpopulations. Any procedural change is an opportunity to engage stakeholders on how these regulations are structured to address these populations and in what contexts. Finally, the paradigm should incorporate evaluation in the decision-making process, as assessing the impact of a decision is vital to the success of future decision making.

Discussion

Principal Findings

This study aimed to identify how geographical isolation and aging in place can be accommodated through CH stakeholder management based on identification of the stakeholders and their interests. We determined the interests of stakeholders and strategies that health facilitators can employ. Industrial players look for participants to test their products and a CH environment to comprehensively develop products for better sales. Governments seek political achievement, and academic researchers pursue interesting topics and data to have an impact society. Offering benefits that can fulfill stakeholders' interests will help to overcome the challenge of resource shortages in remote areas. However, it is not a "one-size-fits-all" solution. Health facilitators should recognize their competitive advantages to differentiate their strengths from those of others. Once their uniqueness can meet their supplier's need, they are able to exchange benefits to address their shortages.

Compared with current and past literature, our findings offer further insights into stakeholder engagement. The knowledge foundation of this study was developed from a current understanding of stakeholders' perspectives from the literature. The importance of the identification of stakeholders in electronic health has been reported [32,33]. Based on this, the concept of the co-creation and co-design of a health facility with stakeholders has been discussed [34,35]. Perspectives on a patient-centric model include an increase in technology adoption [36]. Strategies for successful implementation of technology for aging in place have been studied [37]. Person-centeredness, clinician acceptability, and informatics feasibility have been achieved and ensured through technology applications [35].

Regarding the research context, most previous literature has focused on the health care system in Western or developed countries where remote areas are numerous and internet infrastructures are better developed [4,38-41]. These countries

encounter the challenges of an aging population earlier than developing or underdeveloped countries. In contrast, stakeholder perspectives have not been extensively studied in some regions in Asia that are experiencing a similarly aging population and are interested in developing CH. Taiwan can be seen as a typical case; its rate of aging and degree of advanced technology are as high as those in Western countries [3,42-44]. Additionally, Taiwan has representative remote areas and developed health care performance [3,43]. Therefore, stakeholder engagement in CH should be of interest to improve the challenges with resource shortages in remote areas. Moreover, Taiwan has an integrated health and care system, which can facilitate health information sharing and social interaction more effectively [45].

Possible Bias in Participant Selection

Bias should be prevented to ensure the validity and value of research. However, it is difficult to avoid bias due to its complex factors. Bias can occur from the research environment, participants, and even the researchers themselves. Some researchers may intentionally influence participants to obtain the results expected. Moreover, some bias from researchers occurs unconsciously, which makes it more difficult to prevent. This phenomenon is especially present in qualitative research because qualitative research relies more on the experience and judgment of the researcher. Also, the type of data collected is subjective and unique to the person or situation. Therefore, it is much harder to avoid bias in qualitative research than in quantitative research.

Recognizing that bias exists in all research may be a good start to avoid bias. Then, the researcher should be informed about potential bias so he or she can avoid bias as much as possible. Before the research has been conducted, design bias can occur. Omission bias from selection or sampling may also occur during the research. If the study is not well planned, inclusive bias can occur when researchers look for quick solutions and convenient options.

To avoid bias, the researcher first checked the guidance for qualitative research. Second, the interview plan was discussed with the supervisor at various times to maintain the objectiveness of the interview questions. Indirect and open-ended questions were asked to allow information to flow more freely. Third, all the interviews were recorded and analyzed without personal preference. Finally, independent reviewers were invited to review the research to help maintain objectivity in the research.

Validity

In terms of the validity of the data analysis, this study followed rigorous qualitative research principles to ensure the credibility, transferability, and reliability of the data [29]. The triangulation approach was employed as a testing method to examine the validity of research [30,31]. It helps to capture different dimensions of the same phenomenon. In this study, research data triangulation and investigator triangulation were adopted to test the validity and reliability of research. In the research data triangulation, the interview questionnaires were discussed using the Delphi method with 8 focus groups and analyzed using NVivo software. In the investigator triangulation, multiple investigators, such as health professionals and experts, were invited to evaluate and review the data for selective perception and illumination blind spots in an interpretive manner to understand multiple ways of seeing the data.

Strengths

This study addressed a topic that had previously not been well studied so that it may offer insight for future projects on CH in rural areas. Different from other case studies in which the research focused mainly on developed countries, this study considered a region between developed countries and developing countries in order to discover methods for accommodating the resource shortage in remote areas. This study considered Taiwanese CH as a case study, as it meets all the CH preconditions and essential requirements. Not only are advanced technology and medicine present but the ecosystem for boosting CH is also complete and comprehensive in Taiwan. Recently, Taiwan integrated social care with its health department, to become a health and social welfare department. Chronic conditions are prevalent due to an aging demographic. Geographically, Taiwan has populations in urban areas and in many remote areas and isolated islands. Moreover, it is a mixture of public and private health care systems. These features suggest that if CH practice can be successfully applied in Taiwan, it is likely also to suit other countries around the world.

Limitations

A limitation of this study is that only one case study approach was used, making it difficult to generalize the findings due to a limited sample size. Generic principles and popular interpretations are not easily formed because the purpose of the study was to analyze problems rather than obtain summarized or statistical data. Consequently, certain inductions might be arbitrary and subjective. In addition, technical limitations and researcher bias may be an issue because a standard data analysis method was not used; therefore, the data interpretation and presentation of evidence are influenced by the researcher's choice, which may affect the results of the study. Further generalization is likely to require additional case studies for different potential contexts, which could include diverse case studies that may show cultural differences and influences.

Future Research

The outcomes of this qualitative research can serve as preliminary quantitative research on the degree of the influence of health facilitators on stakeholders' interests. Alternatively, the optimization of two or multiple objectives using a quantitative method can be applied to discover the optimal interests of all stakeholders in future work.

Conclusions

This study contributes to current knowledge by exploring the features of CH in remote areas and investigating its implementation from the perspectives of stakeholder management. Methods to accommodate geographic isolation and aging in place through CH stakeholder management are discussed based on the identification of the stakeholders and their interests and power in remote areas of Taiwan. The results offer insights for managing remote health through a CH platform, which can be used as preliminary quantitative research. Consequently, these findings could help more effectively

facilitate diverse stakeholder engagement for health information sharing and social interaction.

Acknowledgments

This research was supported by the National Natural Science Foundation of China (NSFC, 71672060, 71372081), Ulster University, and SC Limited Company. The APC was funded by the Huaqiao University High-level Talent Research Project and The Straits Postdoctoral Fellowship Funding Program in 2018 (Fujing Financial office #2017 32/605 50X18137). Abstract

Background: Gift giving from patients to physicians, which is prohibited in traditional clinical settings in China, has been found to occur in online health communities. However, there is debate on the validity of online gifts since physicians gain an economic benefit. Moreover, the potential impact of these gifts, particularly with respect to the financial value of the gift, on the online consultation service quality remains unexplored.

Objective: The aim of this study was to explore the impact of gift price on the quality of physicians' online consultation service. Insight into this impact is expected to help resolve existing debate on the appropriateness of the gift-giving practice in online consultations.

Methods: A dataset of 141 physicians and 4249 physician-patient interactions was collected from the Good Physician Online website, which is the largest online consultation platform in China. Based on social exchange theory, we investigated how gift price affects the quality of physicians' online consultation service and how this impact changes according to the physician's service price and number of all gifts received. Manual annotation was used to identify the information support paragraphs and emotional support paragraphs in the answers of physicians. The quality of the information support paragraphs, rather than the complete answer, was used to test the robustness of our model.

Results: Gift price had a positive impact on the quality of physicians' online consultation service (β=4.941, P<.01). This impact was negatively mediated by both the physician's service price (β=–9.245, P<.001) and the total number of gifts they received (β=–5.080, P<.001).

Conclusions: Gift price has a positive impact on physicians' online behavior, although the impact varies among physicians.

KEYWORDS

gift giving; gift price; service price; online consultation service quality; information support; emotional support; online health communities

Introduction

Background

Gift exchange, including giving, receiving, and reciprocating, is generally defined as the circulation of goods to promote ties and bonds between individuals [1]. Generally, gift giving has benefits for emotional expression and relationship building in interpersonal communication [2]. However, gifts exchanged between physicians and patients have been viewed as a form of illegal and unethical payment [3], which can potentially weaken the trust and deteriorate these relationships [4]. Hence, it has been forbidden for physicians to receive gifts from patients in China [4].

However, the practice of online gift giving has emerged with the development of online health communities. Online gifts were initially launched to provide patients with a channel to express gratitude to physicians, and debates about the validity of gifts in online health communities have sparked given the potential for bringing financial benefits to physicians. Some patients consider that online gift giving in online health communities represents a form of extortion with a bribe to a certain degree [5,6], whereas users of some online platforms regard it as a form of respect by acknowledging the knowledge labor of physicians [7]. In addition, physicians express different attitudes with respect to receiving online gifts. Approximately 70% of physicians stated that online gift giving is reasonable, 25% stated that it may make people uncomfortable, and 3% disapproved of this practice overall [7]. The root of these debates is the possible impact of the financial value of the gift on the quality of physicians' online consultation service, which remains unclear.

In addition to these debates, online gifts have also attracted the attention of some scholars. Zhao et al [8] studied physician-patient interactions on the online health community Good Physician Online and confirmed that online gifts from patients could improve physicians' online response rate. However, this study did not delve into the possible effects of the gift price. Gift giving, as a form of social exchange [9], follows the rules of social exchange theory (SET). Therefore, the aim of this study was to use SET to empirically explore how patients' gift-giving behaviors affect physicians' online consultation service quality from the perspective of gift price, which could help to resolve existing debates.

The deprivation-satisfaction proposition [10] in SET, which is based on the marginal diminishing effect [11] in economics, holds that the more people that receive a certain reward, the lower the perceived value of subsequent or similar rewards will be. Therefore, we considered that the total number of gifts a physician receives may have a negative moderating impact on the relationship between gift price and the physicians' online consultation service quality. Finally, comparison level theory, also included in SET, holds that individuals will consider an acceptable outcome at a comparative level according to their previous experiences, which could affect their perception and judgment of subsequent outcomes. Similarly, the physicians' service price might be considered the comparison level, which could affect their perception of the gift price. Thereby, we surmised that a physician's service price might also have a negative moderating effect on the impact of gift price on the quality of their online consultation service. More specifically, this study addressed the following three research questions: (1) how does gift price affect the quality of physicians' online consultation service? (2) how does the impact of gift price on the quality of physicians' online consultation service differ for physicians with different service prices? and (3) how does the impact of gift price on the quality of physicians' online consultation service differ for physicians receiving different numbers of online gifts?

Related Research

SET is one of the most influential conceptual paradigms for understanding workplace behavior [12]. This theory can be traced back to at least the 1920s [13,14], bridging such disciplines as anthropology [15,16], social psychology [10,17,18], and sociology [19]. Although different views of social exchange have emerged, it is widely accepted that social theory involves a series of interactions that generate obligations [20], and these interactions are usually perceived as interdependent and contingent on the actions of another person [19].

Along with rapid development of the internet, online communities have become popular platforms for carrying out routine activities of daily life. Online interaction is an important part of the online community. Such interactions represent social exchanges between participants, which occur in a network context [21]. Therefore, many human behaviors on online communities have been studied in the context of SET. For example, some scholars have focused on purchase intention [22,23], online trust [24,25], and the information contribution intention of consumers in the marketing field [26], along with aspects of self-disclosure [27], reciprocal intention of knowledge [28], and member commitment [29].

Social exchange behaviors in online health communities mainly occur between physicians and patients. Researchers have traditionally explained user behaviors in these communities based on SET, such as the knowledge sharing intention [30], influence factors of providing social support [31], and the motivation of physicians to participate in online health communities [32]. Moreover, gift giving is a form of social exchange, and some researchers have also studied the influencing factors of gift-giving frequency in social network services based on SET [33]. However, less attention has been paid to gift-giving behaviors in online health communities. Therefore, the aim of the present study was to explore gift-giving behaviors in online health communities based on SET.

Hypotheses Development and Research Model

Gift Price and Quality of Physicians' Online Consultation Service

Reciprocity, an important prerequisite for continuous exchange, refers to the fact that one has an obligation to return another's favor [17,34]. Moreover, reciprocity is not only the basis of gift exchange but is also the impetus for the flow of gifts [35]. In addition, the law of equality sets norms for social exchange according to the proportion of pay and return in the process [19]. Generally, interpersonal relationships can only be maintained based on the principles of reciprocity and equality [10].

Individuals are generally motivated to interact with others when they expect positive results [36]. Likewise, patients' gift-giving behaviors in online health communities reflect their expectations for positive results such as higher quality of consultation services and more harmonious physician-patient relationships. However, a physician's participation in an online health community is a social exchange process of professional capital for social and economic returns [32]. Therefore, a social exchange process

could form through patients giving gifts and physicians reciprocating. According to the principles of reciprocity and equality, a physician may provide an online consultation service with relatively higher quality according to the price of the gift that they received. Therefore, we proposed hypothesis 1: gift price has a positive impact on the quality of physicians' online consultation services.

Moderating Role of Gift Number

The marginal diminishing effect principle [37] posits that the value of a commodity depends on the perceived utility value by people. From this theory, the value of the marginal units of a commodity will decrease with an increase in the number of this commodity. Moreover, Homans' [10] deprivation-satisfaction proposition, according to the marginal diminishing effect, holds that the more people that receive a certain reward, the lower the perceived value of subsequent or similar rewards will be.

The reason for this marginal diminishing effect is that from the perspectives of physiology and psychology, both satisfaction and stimulation will decline with each newly added consumption unit [38]. Similarly, early gifts can bring more pleasure and stimulus to physicians. However, as the number of gifts gradually increases, physicians may regard the gift-giving behaviors of patients as a normal part of their interactions. Thus, we hypothesized that physicians' perceived value of gifts would gradually decline as the number of gifts they receive increases. Thus, hypothesis 2 is that the number of gifts that physicians receive negatively moderates the impact of gift price on the quality of physicians' online consultation service.

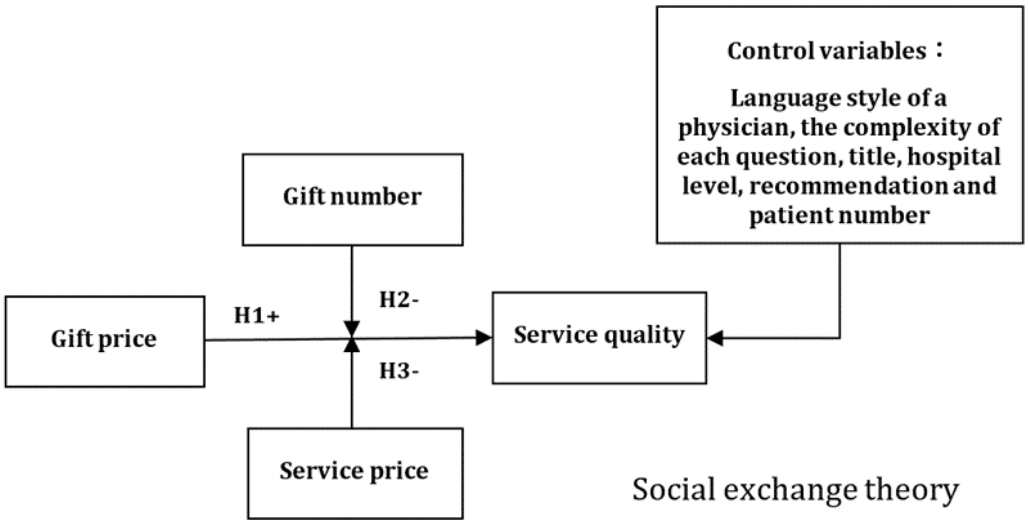
Moderating Role of Physicians' Service Price

Comparison level theory [18] was initially developed to study people's assessments of interpersonal relationships, indicating that people will assess a relationship by comparing it with a known comparison level, which could be determined from one's previous relationships or similar relationships [18]. Specifically, whether a relationship is attractive or satisfactory can be determined by comparing it with the comparison level.

In online consultations, physicians may first receive a consulting fee and thus form a comparison level. When they receive a gift during this process, they may compare the price of the gift with the comparison level. Therefore, a physician's satisfaction with the gift price would be lower when their service price is higher. Furthermore, the positive impact of gift price on the quality of the physician's online consultation service will be weaker when their service price is higher, and vice versa, leading to hypothesis 3: service price negatively moderates the relationship between gift price and the quality of physicians' online consultation services.

Based on the above hypotheses, we constructed the research model that is summarized in Figure 1.

Figure 1. Research model and hypotheses based on social exchange theory. H1: hypothesis 1, gift price has a positive impact on the quality of physicians' online consultation services; H2: hypothesis 2, the number of gifts that physicians receive negatively moderates the impact of gift price on the quality of physicians' online consultation service; H3: hypothesis 3, service price negatively moderates the relationship between gift price and the quality of physicians' online consultation services.



Methods

Research Context

Founded in 2006, Good Physician Online (haodf.com) is the largest online consultation service platform in China. By December 2018, 580,000 physicians from 9379 regular hospitals were participating on the website [39]. Good Physician Online is also the most popular platform for online gift behaviors, and the number of gifts that physicians receive can reach up to several thousand. Hence, we selected this website as the data source for our research.

The main online consultation services provided by physicians in Good Physician Online include written consultation, telephone consultation, and appointment service. In a written consultation, patients need to first pay before they are able to communicate with physicians through text or pictures if necessary. In addition, patients can also purchase online gifts for physicians on the platform to express emotions. Representative examples of the physician-patient interaction and gift-giving behavior are shown in Figure 2.

Figure 2. Examples of physician-patient interactions representing gift-giving behavior.

Data Collection

To eliminate the effects related to seeking consultations for different diseases, we collected data for physicians who only treat diabetes for the following reasons. First, diabetes is one of the most common chronic diseases. According to the 8th edition of the Global Diabetes Map released by the International Diabetes Federation, approximately 425 million adults worldwide were suffering from diabetes in 2017, including 114 million in China, ranking first in the world [40]. Second, diabetes, as a typical chronic noncommunicable disease, has the characteristics of a long onset, complicated etiology, and high difficulty to cure. Therefore, patients with diabetes are more likely to establish long-term and stable online interactions with physicians.

To empirically validate our research model, we developed a crawler targeting physicians who mainly treat patients with diabetes on the Good Physician Online website from October 12 to 13, 2018. The dataset included the personal information of the physicians and the physician-patient text dialogs during consultations. Finally, 141 physicians were included in the dataset, and the number of gifts that were exchanged in the consultations was 4249.

Variables and Empirical Model

Medical service quality has long been a primary focus of scholars in the medical field, including in an online health context. However, a standardized scientific measure of medical service quality in online contexts has not yet been developed. Many studies have focused on the assessment of online health information quality and thus proposed some mature evaluation methods and indicators [41-43]. Based on these methods, some scholars have established the evaluation criteria of online medical consultation services from the perspectives of linguistic characteristics and information quality [44]. However, such evaluation criteria are generally used in assessments of expert consultation because medical information is considered to be professional. Therefore, such evaluation criteria were not considered suitable for the large sample data used in our study.

In the field of electronic commerce, longer reviews often include more product details, which can reduce the uncertainty of product quality [45]. Likewise, a physician's answer is the main determinant of his or her service quality because online consultation services in online health communities are mainly carried out in the form of patients providing a question and physicians providing an answer. Furthermore, the average word count of a physician's answer in a dialog represents each answer's information content in the dialog. Therefore, we used the average word count to measure the quality of physicians'

online consultation services (Phy_Answer) as the dependent variable of our model.

The independent variable was the gift price (Gift_Price): Good Physician Online provides gifts with different prices, in the range of 1 to 200 yuan, for patients to choose from.

In addition, the following two moderating variables were included in the model: (1) service price (Service_Price), as patients need to pay for physicians' online consultation services, and (2) gift number (Gift_Number), which represents the total number of online gifts that physicians received.

Finally, we introduced the following control variables. The first was physicians' language styles (Phy_Style), which was based on the average word count of each physician answer to control for differences caused by physicians' different language styles. The second control variable was the complexity of patient questions (Ques_comp), since the severity of diseases could affect the complexity of questions, which was also controlled based on the average word count of each patient question in a dialog. The title (Title) was also controlled for in the model. Physicians' titles represent their professional ability and offline reputation, and there are three types physicians that participate in Good Physician Online: chief physicians, associate chief physicians, and attending physicians. Since most of the physicians using the website are chief physicians, we combined the other two categories and used one dummy variable to measure physicians' titles (see Table 1). The hospital level (Hospital_Level) was further controlled, which is evaluated by government health departments, and physicians working at hospitals of different levels have access to different medical resources. In Good Physician Online, hospital levels are classified as level A, B or C, with A being the highest quality. However, most of the hospitals that physicians on the website belong to are level A hospitals; therefore, we combined the other two categories and used hospital level as a dummy variable (Table 1). Recommendation was another control variable, which ranges along a scale of 0-5 with 5 being the best, and represents the comprehensive popularity of a physician. Finally, patient number was considered as the number of patients that a physician is caring for, which represents the physician's workload. All of the variables mentioned above are defined in Table 1. In addition, we used multiple linear regression to test the model in SPSS software (SPSS Inc, Chicago, IL, USA), and took the logarithmic value of the patient number, gift price, service price, and gift number to stabilize the variance. Our empirical models are summarized as follows:

(1) $\text{Phy\_Answer}=\alpha_{ij} + \alpha_1 \times Gift\_Price_{ij} + \alpha_2 \times Gift\_Number_{ij} + \alpha_3 \times Service\_Price_{ij} + \alpha_4 \times Control_j + \varepsilon_j$

(2) $\text{Phy\_Answer}=\alpha_{ij} + \alpha_1 \times Gift\_Price_{ij} + \alpha_2 \times Gift\_Number_{ij} + \alpha_3 \times Service\_Price_{ij} + \alpha_4 \times Gift\_Number_{ij} \times Gift\_Price_{ij} + \alpha_5 \times Service\_Price_{ij} \times Gift\_Price_{ij} + \alpha_6 \times Control_j + \varepsilon_j$

where i denotes a dialog and j denotes a physician. α_{ij} are the coefficients to be estimated. $Control_j$ represents the control variables for physician j, and ε_j is the standard error.

Table 1. Descriptions of model variables.

Variables and symbols	Variable types
Control variables	
Phy_Style	Counting variable
Ques_comp	Counting variable
Title	Binary variable (Title is chief physician: 1, otherwise: 0)

Gift_Number	Counting variable
Dependent variable	
Phy_Answer	Counting variable

Results

Descriptive Statistics and Correlations

Descriptive statistics and correlations for the key variables used in the analysis are presented in Multimedia Appendix 1. The results showed a correlation between gift price and the quality of physicians' online consultation service. In addition, correlations between the independent variable and control variables were relatively weak, which helped to yield more stable results.

Empirical Results

The empirical results of the model are summarized in Table 2, demonstrating support for all three of our hypotheses.

Model 1 shows the fitting degree of control variables and the dependent variable (adjusted R^2=0.04, F Change=17.003,

P<.001). In Model 2 (adjusted R^2=0.051, *F* Change=14.907, *P*<.001), gift price had a significant positive impact on the quality of physicians' online consultation services, which supports hypothesis 1. In model 3 (R^2=0.059, *F* change=15.079, *P*<.001), we added the interaction term of gift number and gift price based on model 2, showing that gift number plays a negative role in regulating the relationship between gift price and the quality of physicians' online consultation service, which supports hypothesis 2. Similarly, the results of model 4 (adjusted R^2=0.063, *F* change=16.613, *P*<.001) showed that service price negatively moderates the relationship between gift price and the quality of physicians' online consultation service, supporting hypothesis 3.

[a]N/A: not applicable; the variable was not included in the model.

Robustness Check

The quality of the information support paragraphs, instead of the complete answer, was used to test the robustness of our model. Specifically, we used the average word count of a physician's answer to measure the quality of the physician's online consultation service, but ignored the content included in the answer. However, online consultation services provided by physicians generally include two parts: information support and emotional support [46], which are the main functions in online health communities [47]. Therefore, we divided every answer of physicians into these two parts by manual annotation and explored the impacts of gift-giving behaviors on these components separately.

First, an expert was invited to define information support and emotional support according to related knowledge and real data. Information support was defined as the provision and exchange of information related to medical technology and medical process, such as diseases (diagnosis, prescription, treatment, and notes during treatment), hospitalization, registration, and others. In other words, information support refers to physicians answering professional questions and providing information. Emotional support was defined as expressions that are clearly not related to medical technology from physicians, such as gratitude, sympathy, comfort, support, encouragement, respect, courtesy, and responsibility. Care, supervision, active greetings, and offering active solutions to problems from physicians are all examples of emotional support; other cases should be judged flexibly according to the context. We then selected two graduate students with professional backgrounds to annotate 18,392 physician answers manually based on these definitions. The consistency check showed that the kappa value of information support was 0.85, whereas that of emotional support was 0.78. Finally, inconsistent data were annotated again by the expert. Descriptive statistics and correlations for all variables are shown in Multimedia Appendix 2. These results reflect that physicians typically pay more attention to patients' information needs (mean 38.870) than to their emotional needs (mean 3.595). Therefore, we decided to use the information support of physicians to check the robustness of our model, and empirical results are presented in Table 3.

We found a significant positive impact between gift price and the information support of physicians (Model 1: R^2=0.025, *F* Change=11.086, *P*<.001; Model 2: R^2=0.033, *F* Change=9.767, *P*<.001; Model 3: R^2=0.035, *F* change=9.457, *P*<.001; Model 4: R^2=0.038, *F* change=10.297, *P*<.001). Moreover, both gift number and service price negatively moderated the impact of gift price on physicians' information support. Hence, these three results are consistent with the main model, indicating that our model is robust. We also found that gift price positively affected the emotional support of physicians, but there was no moderating effect of gift number and service price (Model 5: R^2=0.071, *F* change=20.913, *P*<.001; Model 6: R^2=0.071, *F* change=18.298, *P*<.001).

[a]Information support.

[b]Emotional support.

[c]N/A: not applicable; the variable was not included in the model.

Discussion

Principal Findings

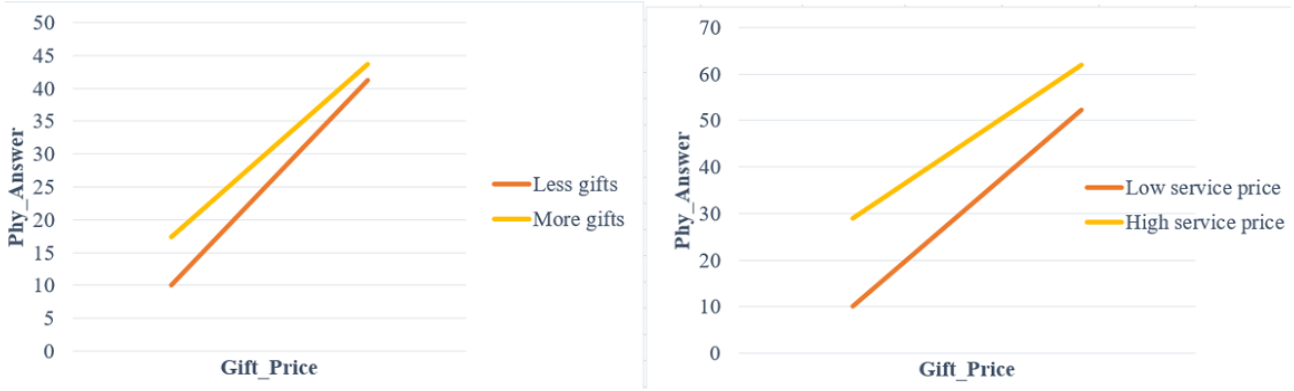
Our empirical results supported all three of our hypotheses. First, in online medical consultations, gift price positively affects the quality of physicians' online consultation service. This suggests that in response to patients' mental and economic efforts, physicians will reciprocate with better online service, which contributes to establishing more stable physician-patient relationships. This result confirms the existence of the principles of reciprocity and equality in online physician-patient interactions. Furthermore, these principles are also widespread in other online communities. For example, researchers have verified that an increase in the number of reciprocity messages the actor broadcasts in online social networks increases the reciprocity reactions from his or her audience [21]. Similarly, some scholars have found that there is a consistent reciprocal mode between the information users publish and the answer they receive in an online gaming community [48].

Second, the number of online gifts physicians receive plays a negative role in regulating the impact of gift price on the quality of physicians' online consultation service, proving that a marginal diminishing effect exists not only in the field of economics but also in people's productivity, life, and social management. Some researchers have studied the relationship between individual income and happiness based on this theory, proving that higher income increases happiness in developing countries, whereas this effect is minimal in developed countries [11].

Third, service price negatively moderates the relationship between gift price and the quality of physicians' online consultation service. The gift price in Good Physician Online ranges from 1 to 200 yuan, accounting for about one quarter of the service price on average. In addition, the service price could be used as the comparison level for physicians when they judge the value of gifts because patients always pay for the consultation before sending gifts. Comparison level theory was originally developed to study people's assessment of interpersonal relationships, such as the perception of marital relationships [49]. Subsequently, scholars have applied this theory in many different contexts. For example, researchers confirmed that workers' reported satisfaction levels were inversely related to their comparison wage rates [50] and idealized advertising images reduced women's satisfaction with their attractiveness [51]. Collectively, these studies demonstrated that comparison level theory is a psychological phenomenon

that widely exists in several aspects of human society. For further explanation of these interaction effects, see Figure 3.

Figure 3. Interaction effects of gift number and service price.



Finally, both information support and emotional support could be enhanced by physicians when they receive gifts with higher prices. However, compared with patients' emotional needs, physicians in online health communities tend to pay more attention to their information needs.

Theoretical Implications

Our study contributes new knowledge in several key ways. First, despite previous research about the impact of online gifts in social networks and live broadcast platforms [33,52-55], few scholars have paid attention to the gifts provided in online health communities. Furthermore, research related to gift-giving behaviors in an online health community verified that online gifts from patients could improve the speed of physicians' answers during the consultation [8], but ignored the potential effect of gift price. Our study is among the first to use real data to empirically examine the effect of gift price in an online health community, which is a universally beneficial sector.

Second, SET was proposed in the 1960s and has since been widely applied in various fields. In recent years, SET has often been used to explain user behaviors in online contexts [22,56-58]. Our study further adds to this literature by verifying that the physician-patient interaction is also a form of social exchange.

Third, scholars have long highlighted the importance of emotional support [59], but few studies have empirically investigated this assumption. Our study revealed the actual situation of information and emotional support in the online medical field using a manual annotation approach. In addition, the text of physician-patient interactions contains an abundance of valuable information, which has inspired us to adopt a text mining analysis in future research.

Practical Implications

The original intention of online gifts in online health communities is to provide patients with a channel to express gratitude to physicians. However, this channel has been questioned since its launch from an ethics perspective because physicians can receive economic benefits from this practice. Although patients purchase gifts voluntarily, they may still feel embarrassed and uncomfortable [5]. Moreover, some physicians have recommended refusing gifts from patients under the pressure of public opinion and professional ethics [60,61]. All of these questions motivated our reflections about the validity of online gifts in online health communities.

The results of our study indicate that gift price has a significant positive impact on the quality of physicians' online consultation service, and the impact is stronger for physicians that receive fewer gifts or a lower service price. These conclusions could provide practical guidance for patients, but such speculation is beyond the scope of this study. Furthermore, we do not encourage sending gifts with higher prices to physicians as this may lead to unhealthy gift-giving trends in online health communities and undermine online physician-patient relationships. Thereby, we propose some suggestions from the perspective of platform management. First, compared with service price, the gift price in some online health communities is sufficiently high to affect the interactions between physicians and patients; thus, we recommended lowering the gift price or narrowing the price range to mitigate this impact. Second, we suggest that more value should be placed on the function of emotional expression. Specifically, patients could be granted more permissions such as sending images or voice messages when they write their greetings associated with gifts. Third, in addition to online gifts, other free channels for emotional expression could be provided to relieve the discomfort of patients.

Finally, the results of our robustness check revealed that physicians pay more attention to patients' information needs rather to their emotional needs when they provide online consultation services. However, emotional support is more effective than information support in alleviating patients' poor conditions in online health communities [62]. Therefore, we recommend that physicians could attach more importance to patients' emotional needs during online consultations, which could contribute to achieving a better treatment effect and improved patient satisfaction.

Limitations and Future Research

Several limitations and prospects of this study must be considered. First, we focused on only one context, which helps us improve the internal validity but may also reduce the generalizability of our findings. Therefore, future research should be performed to validate our results in other contexts. Second, there is no available mature criterion to measure online medical service quality. In this study, we used both the word

count and content of physicians' answers to measure service quality. However, it is still difficult to fully represent the actual quality of physicians' services. In the future, we will continue to explore new ways to measure the quality of physicians' online medical services. Third, the possible cumulative effect of gifts was ignored in our study, which could also be explored in future research. Fourth, multiple methods should be used to understand the true significance of these key findings, such as a quality study.

Conclusions

Despite the original intention of online gifts as offering a new channel for patients to thank physicians, people remain suspicious of the validity of online gifts. Our study offers a better understanding of the impact of online gifts and contributes to settling existing disputes in this field. We found that the quality of physicians' online consultation service could be affected by the price of gifts received from patients, which implies that online gifts are more than a simple channel for patients to express their emotions. However, we hold that it is important to consider online gifts from an objective and rational perspective since online gifts in online health communities are still new. We believe that this paper can help provoke new ideas and perspectives about the validity of online gifts in online health communities.

Abstract

Background: Research on the use of video-mediated technology for medical consultations is increasing rapidly. Most research in this area is based on questionnaires and focuses on long-term conditions. The few studies that have focused on physical examinations in video consultations indicated that it poses challenges for the participants. The specific activity of wound assessment through video in postsurgery consultations has not yet been studied. Furthermore, a comparative analysis of face-to-face and video settings on the moment-to-moment organization of such an activity is original.

Objective: The aim of this study was to examine the impact of video technology on the procedure of postsurgery wound assessment and its limits.

Methods: We recorded 22 postoperative video consultations and 17 postoperative face-to-face consultations. The primary purpose of the consultation was to inform the patient about the final pathology results of the resected specimen, and the secondary purpose was to check on the patient's recovery, including an assessment of the closed wound. The recordings were transcribed in detail and analyzed using methods of conversation analysis.

Results: The way that an assessment of the wound is established in video consultations differs from the procedure in face-to-face consultations. In the consultation room, wound assessments overwhelmingly (n=15/17) involve wound showings in the context of surgeons reporting their observations formatted with evidentials ("looks neat") and subsequently assessing what these observations imply or what could be concluded from them. In contrast, wound assessments in video consultations do not tend to involve showing the wound (n=3/22) and, given the technological restrictions, do not involve palpation. Rather, the surgeon invites the patient to assess the wound, which opens up a sequence of patient and physician assessments where diagnostic criteria such as redness or swollenness are made explicit. In contrast to observations in regular consultations, these assessments are characterized by epistemic markers of uncertainty ("I think," "sounds...good") and evidentials are absent. Even in cases of a potential wound problem, the surgeon may rely on questioning the patient rather than requesting a showing.

Conclusions: The impact of video technology on postoperative consultations is that a conclusive wound assessment is arrived at in a different way when compared to face-to-face consultations. In video consultations, physicians enquire and patients provide their own observations, which serve as the basis for the assessment. This means that, in video consultations, patients have a fundamentally different role. These talking-based assessments are effective unless, in cases of a potential problem, patient answers seem insufficient and a showing might be beneficial.

video consultation; remote consultation; physical examination; assessment; patient-physician relationship; conversation analysis

Introduction

Video consultations are generally found promising for use in the medical domain, especially due to advantages such as remoteness, convenience for patients and informal caregivers, and reduced anxiety [1-4]. However, the implementation of video consultations into real-world settings is complex. Most research in this area focuses on long-term conditions and is based on questionnaires to elicit patient and clinician experiences, reporting both positive and negative experiences with video consultations. The experiences often seem to depend on the context (eg, a long-term condition in which the clinician and patient have a pre-existing relationship, and on whether both parties are confident in dealing with technical issues [5,6]). Adaptation to the context can be accomplished by involving the patient in the choice of consultation modality. In a comparative study on video versus face-to-face consultations in follow-up care after colorectal cancer surgery, video consultations based on patient preference were shown to be equivalent to face-to-face consultations in terms of patient satisfaction and perceived quality of care [7]. The type of patients that might be most suitable for video consultations is unclear, but it is recognized that patients' reasons and ability to use video consultation may change over time and with experience [8]. One of the advantages of the video format is that it affords visual access, which at least in theory enables physicians to visually assess what patients show. Nevertheless, physical examination has been regarded as problematic in the video setting [9]. Patients' self-examinations in front of the camera, such as measuring weight, blood pressure, heart rate and rhythm, and oxygen saturation, appeared to be challenging in various respects [10]. One of the challenges was that patients had to do a physical examination while simultaneously making it visible to the clinician. Hence, visual access may not be just an advantage; it can also create new problems.

Conversation analytical studies of medical video consultations are beginning to uncover microlevel dimensions and challenges of video-mediated consultations [10-12], sometimes explicitly in comparison with copresent consultations [13]. Pappas and Seale [11,12] analyzed medical video consultations with a primary care physician or nurse and a patient at one end of the connection and a consultant (a medical specialist) at the other. The professional who was with the patient and, therefore, had direct perceptual access to the patient's body, assessed the patient's foot and used the visual channel to demonstrate the assessment to the physician on the other end [12]. Seuren et al [10] identified various challenges of video consultations in secondary care related to instructions for patients to self-measure oxygen levels and manipulate the camera and the body to capture what should be viewed by the physician.

A key domain of interest to medical video consultations is the physical examination, which requires the physician's visual access to the patient's body. Visual access is an affordance [14] of video-mediated interactions, despite the "fractured ecologies" [15] of the patient and the physician inherent to the interaction. It has been found that, by doing physical examinations, the remote physician transposes observational authority to the patient's site [12]. Relatedly, examination conducted by patients themselves may enhance their autonomy with regard to their own health [10]. Hence, physical examination in video consultations may have the potential to instigate a shift in the physician-patient relationship or, more broadly, in the way that medicine is practiced.

When physicians examine patients, they may communicate the findings of their observations to the patient [16-18]. Simultaneously with the act of examination, physicians may produce talk that is subordinated to the examination, which is called online commentary. There is usually no mutual gaze and no response from the patient due to a lack of shared access to the object of evaluation (eg, a physician inspecting a patient's ear). Alternatively, patients may be invited to provide an initial self-assessment as long as they have access to the object of examination.

There are two primary formats for communication along with physical examination, namely, reports of observations and assessments of what is observed [16,19]. In cases of an *observation report* (eg, "I don't see"), the conclusions such as "looks good" should be drawn by the patient. With *assessments* of what is observed (eg, "that looks good"), it is the physician who presents a conclusion. Essentially, the power of both formats lies in the physician's epistemic "ecological advantage" [16] to be able to perceptually (seeing, hearing, feeling) assess the state of the patient's body. The criteria or "codes" for the evaluation that are discursively constructed in the interaction serve as an apparatus of the physician's professional vision [20]. The ecological advantage, thus, encompasses rights with regard to both the examination and constructing observation in certain assessment categories.

Assessments are evaluations of objects and events in talk-in-interaction [21]. Assessments can be elicited both by verbal actions (eg, questions, prior assessments) and by embodied conduct or experience (cf [21,22]). Goodwin and Goodwin [23] discern assessments on distinct levels of organization, with assessment activities as one such level. Assessment as an activity refers to multiple participants jointly producing an assessment in multiple turns, using intonation, overlap, intensifiers, nods, and other resources. Relevant to such assessment activities is that the participants have differential access to the assessable, which is reflected in their talk. For instance, saying "that sounds good" attends to the fact that the assessable was available through a coparticipant's description [23]. Displaying agreement on or producing concurring assessments is important in assessment activities. The same speaker can repeat an assessment; although, subsequent assessments may display diminished participation and, thus, bring the activity to a close. Overall, an activity of assessment is a structure that participants collaboratively bring to a climax and then withdraw from.

A specific occasion for the occurrence of assessments are "informative showings" [24], which involves showing something "new" such as the current state of the wound and a recipient who is informed by the showing. In the medical context, a showing enables the physician's professional vision [20] as a basis for assessment rather than that joint visual perception that is achieved by the showing (cf [25-27]).

The question this paper addresses is how assessments of a surgical closed wound are collaboratively produced in video consultations where the physician lacks direct perceptual access to the assessable, which is available in the face-to-face setting. This question provides insights to the ways that video technology as a mode of communication affects clinical practice.

Methods

The data consist of 39 video recordings of follow-up consultations after abdominal cancer surgery, including 17 copresent consultations (average length 13 minutes and 40 seconds) and 22 video consultations (average length 12 minutes and 20 seconds). The data were collected in the context of a study comparing the conversational organization of video-mediated consultations with regular consultations at the outpatient clinic during the first postoperative consultation after discharge [13]. The first postoperative consultation was chosen because of the potentially considerable burden of a visit to the outpatient clinic, and thus, video consultations had a potential advantage in this phase. The inclusion criteria were patients ≥18 years of age who had received abdominal cancer surgery. The exclusion criteria were an inability to give informed consent and a lack of proficiency in Dutch. A total of 39 patients participated (21 female and 18 male) often accompanied by one or more family members and 3 male surgeons who were experienced in video consulting before the start of the study. The type and complexity of the surgery was comparable for all patients; although, some were laparoscopic operations, which involved three or four small incisional wounds for the trocars, rather than one large wound. At discharge, the patients were informed about the follow-up consultation scheduled approximately 2 weeks after the operation. The goal of the follow-up consultation was explained as discussing the final pathology results and checking on recovery. The results sometimes involved bad news but were mostly brought on as a confirmation of what was expected. The question about recovery, including the wound assessments, usually came as a second order of business for the consultation [13]. The patients were offered follow-up consultations through video or as a regular consultation at the hospital. After they chose either of these options, they were informed about the study and asked to participate. They all gave their consent; although, 1 patient requested at a later time for us to not use the recording or transcript in any scientific publication or presentation of the study.

A waiver for medical ethical approval was obtained from Radboud Medical Center Ethical Committee in June 2017. The data were collected in June-July 2017 and March-June 2018. Each consultation was recorded using two cameras, one directed mainly at the surgeon and one at the patient and those that accompanied them, either in the consultation room or on the surgeon's desktop computer. The recordings, thus, reflect the real-life circumstances of the surgeon, who does not have access to whatever the patient sees or hears such as delays, perturbations, or sequential mismatches (cf [28]). The particulars of the ecological setup at patients' homes may have influenced some practical choices, for instance readjusting their body to the screen to make them visible rather than turning the camera toward the spot, which is another way to show things in video communication [29]. For the hospital recordings, the surgeons sometimes turned away the camera or even turned it off during the physical examination for ethical reasons; these recordings were not excluded from the data set, although they were inevitably inapt for detailed analysis of the examination. The consultations were transcribed based on conversation analysis conventions [30,31] (see Multimedia Appendix 1), and all names were replaced by pseudonyms.

To juxtapose assessments in copresent and video-mediated consultations, we first identified all wound assessment activities in the data and whether it involved a showing or not. The next step was to examine each case microanalytically using multimodal conversation analysis [32,33]. These analyses were inherently comparative, resulting in an understanding of the methods used for doing wound assessments contingent on the medium. In the next section, we discuss five illustrative cases of wound assessments, two in the copresent setting and three in the video setting, that are representative of our findings.

Results

Wound Assessment

We found that in the copresent setting, wounds were generally assessed on the basis of a showing of the wound. On the contrary, in the video-mediated setting, showings were rare. Table 1 provides an overview of the occurrence of wound assessment, wound assessment including showing, and no wound assessment.

Table 1. Frequency of showing-based and talk-based wound assessment in copresent and video-mediated consultations.

Group	Showing-based wound assessment, n (%)	Talk-based wound assessment, n (%)	No wound assessment, n (%)
Copresent (n=17)	15 (88)	1 (6)	1 (6)
Video-mediated (n=22)	3 (17)	12 (51)	7 (32)
Total (N=39)	18 (46)	13 (33)	8 (21)

In the following section, we first analyzed the face-to-face default method and then the default video-mediated communication (VMC) method. We found no communicative differences between laparoscopic wounds and other wounds. The two assessment procedures were mostly initiated by the physician who enquires about how the wound is healing. We also discuss one video consultation where the wound assessment is initiated by a patient who reports a potential problem. This allows for an in-depth understanding of the intricacies of wound assessment through video.

The Face-to-Face Default Method: Showing-Based Wound Assessments

Showing-based wound assessments are characterized by a relatively stable structure. It is initiated by the physician asking whether the wound(s) are healing well. The patient's answer is a tentatively positive evaluation of the wound, upon which the physician expands the sequence with a request to show the wound or an invitation to undress behind the curtain for a physical examination. During the showing or examination, the physician produces observation reports using evidentials and evaluations ("looks neat," "looks uneventful"). The evaluations tend to be rather brief with general descriptors like "neat," "good," and "uneventful." The excerpt in Figure 1 is an example of a copresent showing-based wound assessment. The physician is enquiring about the patient's recovery, having asked about fever and illness (data not shown) and then about the wounds (line 1).

```

The showing-based wound assessment activity begins with the physician's yes/no-question (line 1), asking whether the small wounds healed well. The patient confirms with an epistemic downgrade ("according to me" line 2), thus, making an independent assessment by the surgeon a relevant next action. The request to show the wound "can you- briefly pull up the shirt" (line 3) displays a relatively high entitlement [34], thus, building on the structure of wound assessment as projected by the patient's previous turn. The patient complies immediately (see line 3 and Figure 2), aligning with the activity. As soon as the wound is visible, the physician reports that it "looks neat" and confirms the patient's initial evaluation ("yeah" line 5). Note that the physician uses an evidential ("looks") to present a conclusion rather than an observation report, later rephrased as "looks uneventful" (line 9), which is produced softly and, thus, displays diminished participation and an orientation to activity closing [23].

Figure 2. Screenshot for excerpt 1 (video time: 5:59).

Giving visual access in the showing-based assessment activity does not need to be requested explicitly, as it was in Figure 1. The activity structure in the copresent setting allows for more subtle collaborative orientation to the relevance of showing as can be seen in Figure 3.

Figure 3. Excerpt 2. Regular consultation number 36 (video time: 7:37).

```

When asking how the wound is healing (line 2), the physician points at the patient's belly, indirectly orienting to the show-ability of the wound. After a single-item positive assessment by the patient's partner (line 3) and one from the patient (line 4), the patient rises to initiate a showing (Figure 4). Hence, he expands the initial positive assessments allowing the physician to independently self-assess the wound and arrive at a concurring assessment. That is, the patient's claim about the showable wound makes the showing relevant as a way of facilitating independent access (cf [24]). As the showing is emerging nonverbally, the physician produces a checking question ("yeah?" line 5), which elicits an epistemically downgraded assessment from the patient's partner ("we do think so" line 6) and an upgraded one from the patient's daughter who sits off-camera ("really pretty" line 7). The physician then receives the now perceptually available wound as newsworthy ("oh" [35]; line 8), touches the belly just over the scar with two fingers (Figure 5), and assesses the wound using the same lexical form as the patient ("looks neat"). Hence, the structure of a wound-assessment activity in the consultation room is opened with a physician question and expanded with a showing, which leads to a concurring assessment by the physician. The physician assessment is formatted with an evidential ("looks"), displaying direct access to the assessable.

Figure 4. Screenshot 1 for excerpt 2 (video time: 7:38).

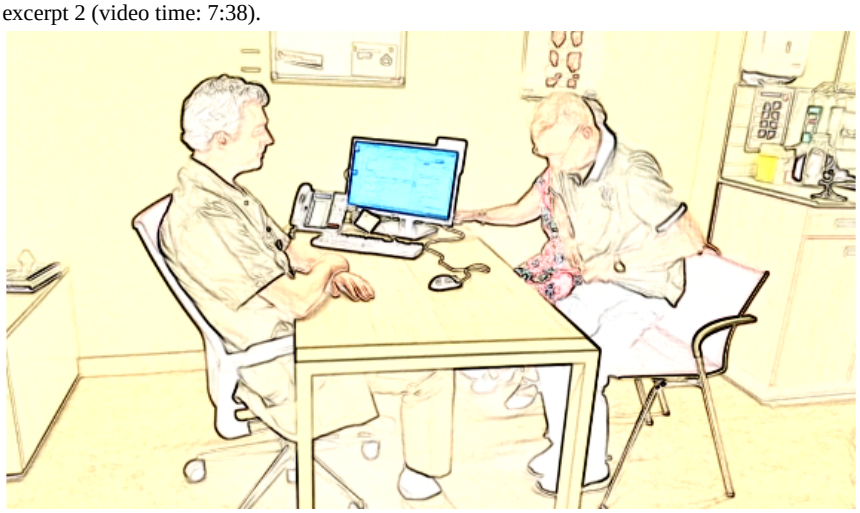

Figure 5. Screenshot 2 for excerpt 2 (video time: 7:41).

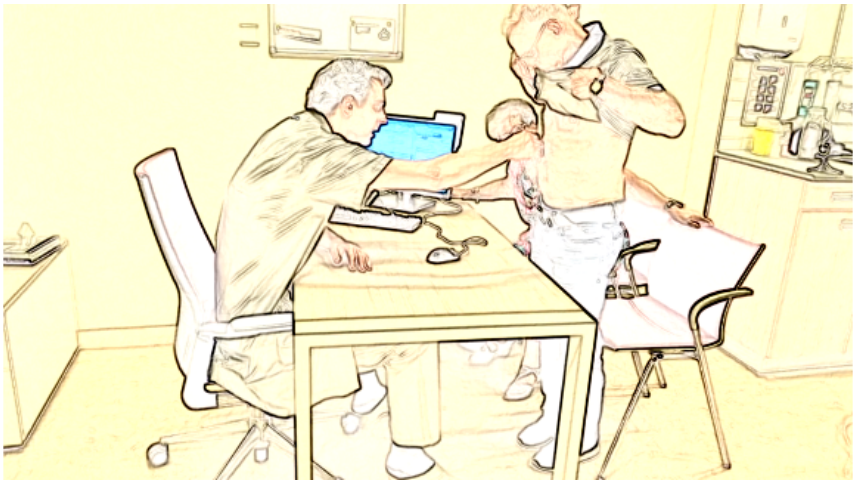

The VMC Default Method: Talk-Based Wound Assessments

The VMC default method is a talk-based assessment, which is characterized by a different structure and different epistemic marking compared to showing-based assessments. These sequences also typically begin with the physician asking whether the wound is healing well. Figure 6 is an example of a talk-based wound assessment typical for the video setting.

Figure 6. Excerpt 3. Video consultation number 16 (video time: 3:53).

1	DOC:	en U:UHM zijn- is de WOND goed genez↑en (.) de wondjes,
		and U:UHM have- has the WOUND healed well (.) the small wounds, (0.9)
2	PAT:	JA (.) honderd procent;
		YEAH (.) a hundred percent;
3		(0.8)
4	DOC:	geen uh ROODheid of ZWELling,
		no uh REDness or SWELLing,
5		(1.2)
6	PAT:	nee nee nee nee nee (.) ik kan niks opnoemen;
		no no no no no (.) I can't name anything;
7		(.)
8	DOC:	N↓EE (.) okE (.) perfect;
		NO (.) okAY (.) perfect;
9		(1.1)
10		.hh u::hm (.) NOU dat klinkt allemaal heel erg GOED;
		.hh u::hm (.) WELL that sounds all really very WELL;

The assessment activity opening question received a positive assessment from the patient, in this case with the epistemic upgrade "a hundred percent" (line 2), which formulates the confirmation as an extreme case and, thus, legitimizes it [36]. The physician does not continue with a showing request nor does the patient initiate a showing. Rather, the physician poses a subsequent question to verify the patient's answer. This question explicates two diagnostic criteria for wound assessments, namely, "redness" and "swollenness," and makes relevant a confirmation of the absence of these symptoms from the patient. The patient then responds with multiple "no's," responding to not only the immediately preceding question but to the physician's course of action, checking recovery [37]. This is elaborated with a more explicit assessment by the patient ("can't name anything"), which again legitimizes the multiple sayings of "no" (cf [36]). The physician accepts and evaluates this answer ("perfect"), and then explicitly closes the "recovery" sequence with a qualified assessment: ".hh u::hm (.) WELL that sounds all really very WELL." Note that this qualification displays the differential access [23] by the patient and physician to the wound ("sounds"), and acknowledges the patient's evaluation(s) as the epistemic basis for this closing assessment. Hence, a talk-based wound assessment in VMC is an assessment activity similar to a showing-based assessment, but it involves questioning rather than showing. Furthermore, its climax assessment reflects differential access and is, thus, epistemically weaker than in a showing-based assessment.

Even when patients produce slightly less overtly rhetoric wound assessments than "hundred percent," showings are not oriented to relevant next actions. This can be seen in Figure 7, in which the patient reports a potential minor problem with the wound ("only near my navel").

Figure 7. Excerpt 4. Video consultation number 12 (video time: 3:10).

13		(1.2)
14	DOC:	nou dat is allemaal FIJN om te HOren (.) [u:hm] **well that is all NICE to HEAr (.) [u:hm]**
15	PAT:	[ja] **[yeah]**
16	DOC:	dus uh ja dan is het toch allemaal GOED verLOpen; **so uh yeah then it did all go WELL;**

In response to the activity-opening question (line 1), the patient first confirms, produces a general description of what can be seen on the body ("bruises are gone (.) almost"), and then gives an explicit verbal confirmation that the wounds are healing well. This is elaborated with a formulation of the visual observation of the wounds as the epistemic basis of this claim ("you almost don't see them anymore some you can't see anymore" line 6). Note that the patient uses the impersonal "you," designing this claim as objective rather than as epistemically marked as her own observation.

The patient then expands the positive assessment with a minor problem ("only near my navel" line 9, "that one is still a bit" line 12) although this is contrasted with an overall positive assessment ("but the rest is gone" line 12), which proposes a closing of the assessment. The physician responds with the qualified assessment "well that is all NICE to Hear," not orienting to the minor problem report but treating the patient's wound assessment as relatively unspecific ("all") and as news that he had no direct independent access to. The presented conclusion that follows ("so uh yeah then it did all go WELL") is built on this general, positive news receipt and covers the whole surgery process, thus, moving out of the activity of wound assessment.

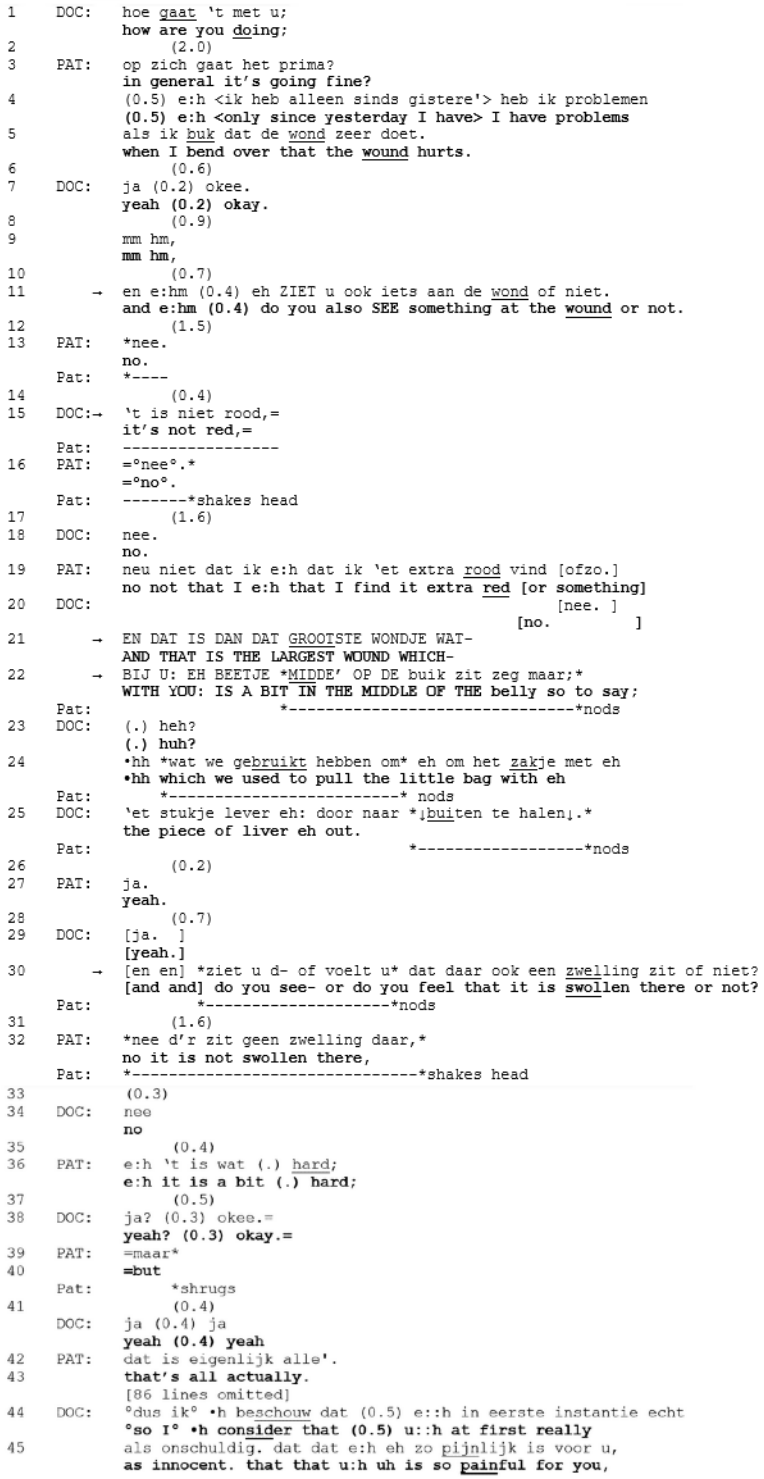
In summary, talk-based wound assessment sequences include the specification of diagnostic criteria ("redness," "swollenness"), perceptual basis ("some you don't see anymore"), or reference to a location on the body ("near my navel"). These may be elicited by the physician or volunteered by the patient. Generally, in such VMC talk-based assessments, physicians arrive at qualified wound assessments, marking them as epistemically grounded in the patient's evaluation rather than in their own observation or examination.

Patient-Initiated Wound Assessments in VMC

In the examples so far, the assessment sequences were initiated by the physician enquiring about the wound. However, wound assessments may also be initiated by patients rather than physicians with a report or question addressing some sort of trouble with regard to the wound. Although wound (or location) showings do occur (n=3/22 of video consultations), even patient-initiated sequences, which make a wound assessment relevant, may unfold as *talk-based* assessments in video consultations. In such cases, the interaction tends to be stretched over several sequences. The possibility of showing the wound is disregarded, despite the fact that visual access is available through the video connection. Figure 8 shows an example of a lengthy talk-based wound assessment in a video setting. In response to the question about how the patient is doing (line 1), she reports pain related to the wound as a first concern (cf [13]), which opens up the wound assessment activity.

To begin with, the patient refers to the viewable wound in her presentation of the problem (lines 4-5), which creates an opportunity for the physician to request a showing (a so-called "touched-off" showing [38]). However, rather than requesting that the patient show the wound, he accepts this initial problem account ("yeah (0.2) okay" line 7), which arguably projects history taking as a next activity [39]. Nevertheless, the physician does *not* take a turn, remains silent for 0.9 seconds, and then produces a continuer ("mhmm" line 9), creating a context for the patient to elaborate on the complaint. In the silence that follows (0.7 seconds), the patient does not continue, and the physician initiates the talk-based assessment activity. Hence, the initial problem report by the patient seems to create an interactional limbo in the structure of the assessment activity in which an opportunity to request a showing has passed.

Figure 8. Excerpt 5. Video consultation 1 (video time: 1:54).



The physician, asking whether the patient also sees something at the wound, orients to the viewability and, thus, potential show-ability of the wound. The patient denies something can be seen, and the physician expands by making explicit what could be seen, namely, redness (line 15). This further question also receives a "no," but is then elaborated on with an account that implicitly proposes a scale of redness indicating the wound is not "extra red" (line 19). "Not extra red or so" implies the wound is (a bit) red, which may be a flag for trouble to the physician. Saliently, the patient produces this assessment without direct visual access (ie, she is not simultaneously inspecting the wound). Moreover, it is marked with an epistemic downgrade ("I find" line 19), thus, designing this observation as not only rooted in her earlier observation but also as subjective (or "subject-side" [40]). A showing could have resolved these issues, but this is not what happens. Rather, the physician checks whether the complaint is about the largest wound (line 21) and indicates roughly where this is located on the patient's belly (line 22). In this way, again, a viewable (location on the belly) is talked about without being shown. After the participants have reached an agreement about which wound is being discussed (line 27 and 29), the physician launches another diagnostic

question: "[and and] do you see- or do you feel that it is swollen there or not?" The seeing as a source of observation is redirected to feeling regarding the diagnostic criterion of "swollenness" (line 30). Hence, the patient is not invited to look "through the doctor's eyes," but to touch "on behalf of the physician." This implies showing is now less relevant, as a showing might be perceptually inadequate to assess swollenness.

From this point onward, the patient reports tactile observations including that it is "not swollen there" (line 32), followed by a further potentially troublesome description "it's a bit (.) hard" (line 36), which introduces yet another category. Nevertheless, the sequence is collaboratively closed with an orientation to the problem as minimal ("that's all actually" line 43) and, thus, not in need of further discussion. The physician then starts a new but related sequence on the patient's activities during the past weeks (data not shown), which eventually leads to his wound and pain assessment as "innocent" (line 45) with multiple disfluencies and hedges ("uh's," "at first really"), and an epistemic downgrade ("I consider that"). Hence, a talk-based assessment in cases of potential trouble may reside in talk to avoid a showing request. It includes the explication of multiple diagnostic criteria and may involve reference to various sensorial observations by the patient, and it eventually leads to a qualified wound assessment.

Discussion

Principal Results

Our primary finding is that video consultations differ from copresent consultations with regard to wound assessment. Talk-based wound assessment is the dominant trajectory in video consultations, while showing-based wound assessment is the dominant method in copresent consultations. Both trajectories are generally initiated with an informing question by the physician, but the subsequent steps differ. The activity continues with either a showing or examination of the wound, or with one or more questions enquiring the absence of specific diagnostic criteria (eg, redness, swollenness). Showing-based assessments work toward evidentially grounded general assessments ("neat," "good," "uneventful"), while talk-based assessments arrive at qualified assessments, which display a lack of direct access to the assessable ("sounds," "I consider that"). Hence, wound assessments in video consultations are grounded in patient assessments, which implies a shift in clinical practice from primacy of the doctor's gaze to the patient's evaluation of how the wound(s) are healing. Even in cases of potential wound trouble in video consultations, physicians may rely on talk and avoid requesting a showing of the wound despite its apparent relevance. Such talk-based assessment sequences can be stretched substantially, with physicians bringing up multiple questions to enquire about symptoms and observations from the patient, both visual and tactile. Hence, despite the possibility of visual access and the interactional relevance, the participants displayed an orientation to avoid a showing in video consultations.

Comparison With Prior Work

We may speculate about the reasons for the avoidance of showing closed surgical wounds in video consultations. A general reason could be that asking a patient to undress or show part of the nude belly or torso while being in the private sphere (usually the living room) with others potentially present and showing part of the nude body on camera are delicate things to do. In contrast, the hospital's consultation room is marked with a clinical setup and assets (eg, physician wearing white coat, curtain, examination table, medical instruments), creating a context where showing the body and physical examinations may become relevant or may be expected by patients or physicians. Possibly, as participants' experience with video interactions evolve, showing practices may occur more naturally. The avoidance of showings and, thus, direct visual access by the physician in video consultations implies that the "ecological advantage" [16] of physical examination may not or does not naturally apply to the video setting.

This means that physicians have less authority in diagnosing the wound and that patients are instead more agentive and epistemically amplified compared to face-to-face consultations. Similarly, Seuren et al [10] suggested that physical examination in video consultations may enhance patient autonomy, as patients become more active participants in the examination, having to handle instruments (eg, to measure oxygen in blood) or modify the camera. Nevertheless, physicians' qualified assessments indicate a degree of uncertainty as a result of the restrictions of the medical armentarium inherent to the medium (eg, the impossibility of palpation) and reliance on patient reports and observations (cf [12]). This might explain why prior studies on physicians' perspectives on applicability of video consultations revealed an anticipated need for physical examination as the main reason for not opting for video consultations [1,6]. The question is, however, under which conditions is it necessary to conduct a physical examination. In the majority of cases, talk-based assessment was sufficient to assess wound-healing, which implies the early postoperative phase is a context in which video consultations appear effective.

Limitations

A limitation of our study is that we cannot exclude that the patients who chose a hospital consultation were more insecure about their recovery, including the wound(s), than those who opted for a video consultation. In that case, our findings could not only be explained by the medium of communication. However, in examining the data, we found multiple cases of patients in the hospital setting who did not present any insecurity with regard to their recovery, and we also found cases of potential insecurity (ie, patient reporting pain) in the video data. Another limitation is that the observed phenomenon may be related to the specific goal of the consultation. In our data, the reason for the consultation was the news delivery of the pathology results, and an examination of the wound was not explicitly announced. However, in the face-to-face consultations, showings and the physicians' invitations to "have a look" were utterly unproblematic. Nevertheless, it is possible that in video consultations where the goal of the interaction is more closely linked to examination, medically relevant showings are more common and are also volunteered by patients (cf [10,12]). Patients may even close the curtains or do the video consultation from their bedroom. Hence, medical assessment practices are

likely to further evolve with participants' growing familiarity with video-mediated interactions.

Conclusions

Overall, it has become clear that video-mediated and copresent medical interactions differ with regard to assessments of medical assessables such as wounds. It was particularly the comparative perspective that yielded new insights, providing evidence of normative orientations with regard to showing that intersect the medical dimension of the talk and the medium of communication. This underscores the relevance of the communication channel for the organization of institutional talk-in-interaction [41] and shows that juxtaposing equivalent interactions through different media is worthwhile, particularly when the choice for the one or the other medium is an "emic" choice for both the patient and—in a different way—the physician. New communicative affordances such as patients sharing images of their body parts with their phones are likely to further affect medical interactions.

A practical implication of our study is that physicians may have to do "extra work" in video consultations to facilitate showing-based assessments. Furthermore, they should consider under which circumstances (eg, closed wound inspection) a hospital visit is more suitable than a video consultation. Another practical implication is that talk-based assessment seems to reduce the physician's medical authority, as it ascribes more authority to the patient. This reliance on patient observation and judgement is in line with increased self-management as a form of patient empowerment in video consultations [10,42], which is generally regarded as beneficial. It nevertheless seems important that practitioners are aware of potentially shifting authority.

Acknowledgments

We would like to thank Christian Licoppe for a data session at Télécom Paristech and the participants of data sessions at Copenhagen University and at King's College London for their valuable input to the analysis of our data. We are also grateful to Willem van de Heuvel and the computer and information sciences MA students for their initial transcriptions of the videos, Anita Pomerantz for her feedback on an earlier version of the manuscript, and to two anonymous reviewers for their valuable comments.

Conflicts of Interest

None declared.

Abstract

Background: Video-mediated clinical consultations offer potential benefits over conventional face-to-face in terms of access, convenience, and sometimes cost. The improved technical quality and dependability of video-mediated consultations has opened up the possibility for more widespread use. However, questions remain regarding clinical quality and safety. Video-mediated consultations are sometimes criticized for being not as good as face-to-face, but there has been little previous in-depth research on their interactional dynamics, and no agreement on what a good video consultation looks like.

Objective: Using conversation analysis, this study aimed to identify and analyze the communication strategies through which video-mediated consultations are accomplished and to produce recommendations for patients and clinicians to improve the communicative quality of such consultations.

Methods: We conducted an in-depth analysis of the clinician-patient interaction in a sample of video-mediated consultations and a comparison sample of face-to-face consultations drawn from 4 clinical settings across 2 trusts (1 community and 1 acute care) in the UK National Health Service. The video dataset consisted of 37 recordings of video-mediated consultations (with diabetes, antenatal diabetes, cancer, and heart failure patients), 28 matched audio recordings of face-to-face consultations, and fieldnotes from before and after each consultation. We also conducted 37 interviews with staff and 26 interviews with patients. Using linguistic ethnography (combining analysis of communication with an appreciation of the context in which it takes place), we examined in detail how video interaction was mediated by 2 software platforms (Skype and FaceTime).

Results: Patients had been selected by their clinician as *appropriate* for video-mediated consultation. Most consultations in our sample were technically and clinically unproblematic. However, we identified 3 interactional challenges: (1) opening the video consultation, (2) dealing with disruption to conversational flow (eg, technical issues with audio and/or video), and (3) conducting an examination. Operational and technological issues were the exception rather than the norm. In all but 1 case, both clinicians and patients (deliberately or intuitively) used established communication strategies to successfully negotiate these challenges. Remote physical examinations required the patient (and, in some cases, a relative) to simultaneously follow instructions and manipulate technology (eg, camera) to make it possible for the clinician to see and hear adequately.

Conclusions: A remote video link alters how patients and clinicians interact and may adversely affect the flow of conversation. However, our data suggest that when such problems occur, clinicians and patients can work collaboratively to find ways to overcome them. There is potential for a limited physical examination to be undertaken remotely with some patients and in some

conditions, but this appears to need complex interactional work by the patient and/or their relatives. We offer preliminary guidance for patients and clinicians on what is and is not feasible when consulting via a video link.

Introduction

Background

There is a significant push from decision makers across the world to make better use of digital technologies, including video consultations [1-3]. Virtual media such as Skype (Microsoft Corporation), FaceTime (Apple Inc), and Attend Anywhere (Attend Anywhere) are increasingly being used for web-based communication between patients and clinicians. In outpatient departments, drivers include addressing high nonattendance rates and rising costs. Patients are often keen to use video consultations given the potential for reduced time and travel, especially for tertiary care [4-6]. The coronavirus disease 2019 (COVID-19) pandemic has provided significant additional pressure to deliver video-mediated services, rapidly and at scale, to reduce face-to-face social contact and help to reduce the spread of the disease.

Published research on video outpatient consultations has been summarized in several recent reviews [7-10]. These show great potential for video consultations in terms of acceptability, safety, and effectiveness in patients considered clinically eligible across a range of conditions, such as diabetes [11-15], ophthalmology [16], cancer [17,18], chronic kidney disease [19], spinal cord injury [6,20,21], chronic obstructive pulmonary disease [22,23], mental health conditions [24,25], Down syndrome [26], cerebral palsy [27], chronic pain [18,28,29], therapies (eg, speech and language therapy [30-32]), support after premature birth [33], support of patients in care homes [34], and plastic surgery [35].

Much of this literature uses either experimental methods, classifying service models primarily by the technology used and secondarily by the task or clinical work supported by that technology, or questionnaires and semistructured interviews, typically with small samples, to assess feasibility and acceptability. There is limited evidence on costs [36]. Patients have expressed some concerns about privacy and security and ease of use of the technology [37,38]. Some studies have reported less enthusiasm for video consultations among older people [39,40]. Qualitative studies have reported concerns over technical issues such as pixilation or audio quality and quality of care, for instance, because of the lack of physical examination [9,38,41,42].

There has been limited research focused specifically on the dynamics of video-mediated interaction in health care consultations and the ways in which communication might be altered by the use of video. To date, only 8 studies have examined such interaction in video consultations, with only one analyzing video recordings at both *ends* of the consultation. Ekberg et al [30,43] looked at the use of virtual media to support cognitive behavioral therapy and speech and language therapy, finding that in both cases, practitioners were able to adapt consultations and communication accordingly. In a series of studies on video-mediated vascular and cardiology consultations, Pappas et al [44-46] explored video consultations in which the patient, supported by a general practitioner (GP) or nurse, consulted remotely with a specialist from their GP practice. They found that clinical assessment and decision making worked well and that the video medium supported collaborative discussion and shared care. However, professionals needed to adapt their interaction to accommodate the video medium (eg, switching between consultative and interprofessional talk, while manipulating camera angle) so as to ensure ongoing patient involvement [44-46]. A previous study by our team compared video consultations of diabetic and postoperative cancer patients with matched face-to-face consultations and provided an overview of what is gained and what is lost when clinicians and patients interact remotely for instance, finding that the overall length of a video consultation is shorter and there are more breaks in the conversation compared with an equivalent face-to-face encounter [9,47]. Stommel et al [48] studied openings of postsurgical video consultations, revealing small but significant interactional differences, with more prosocial talk at the start of video consultations, and the role of companions in a video consultation, revealing that they are mostly off-screen, invisible to the clinician, and rarely involved in the interaction [49].

There is a growing body of evidence outside of health care that highlights the ways in which video calling might alter interaction [50]. Early studies on video-mediated interaction highlighted how technology could be detrimental to conversational flow [51-53]. In face-to-face interaction, people can see and hear actions as they are produced, but in video-mediated interaction, they see and hear them milliseconds later, a phenomenon known as latency. Such delays seem small but are meaningful in conversation as they interfere with the system of rules that participants use to determine who gets to talk at which point in the conversation (turn-taking [54]) and address problems such as misunderstandings (repair [55]). By preventing participants from adequately applying these rules, video technology can affect the quality of interaction and user experience. Other studies raise questions about if technical failures, such as hearing no sound or new types of interruption, for instance, a family member entering the room, impact the interaction [56-58]. Such evidence has yet to be considered in relation to video consultations in health care.

In summary, although the evidence on video consultations indicates that they are feasible, safe, and effective in health care, the evidence on interaction in such consultations is limited. Only a handful of studies have considered the impact of the video medium on the microdynamics of interaction in medical consultations [36]. The result is that little is currently known about how different communication strategies, types of communication (speech, bodily conduct, gaze, and posture), the material properties of technology, and/or the quality of web-based connection shape interaction in video consultations in health care.

We studied interaction in video consultations in four clinics in two National Health Service (NHS) trusts (one acute and one community). The Qualitative Analysis of Remote Consultations (QuARC) study built on several years' work by our team looking at the national-level context for video consultations, the organizational context supporting adoption and implementation, and microlevel interactions between patients and clinicians [9,47,59]. The QuARC study combined data from 2 previous studies—the Virtual Online Consultations-Advantages and Limitations (VOCAL) study, a National Institute for Health Research (NIHR)–funded study of diabetes and cancer clinics in East London using Skype, and the Oxford Telehealth Qualitative Study (OTQS), a Wellcome Trust-funded study of specialist community heart failure teams in Oxford using Skype or FaceTime—and conducted detailed interactional microanalysis across video consultation data.

Aims, Objectives, and Research Questions

As set out in the QuARC study protocol [10], the aims of the study were to identify and analyze the communication strategies through which remote consultations are accomplished and to produce guidance for patients and clinicians to improve the communicative quality of video consultations. Specifically, our objectives were (1) to conduct a secondary analysis of a multimodal dataset of 37 remote consultations with diabetes, antenatal diabetes, cancer, and heart failure patients and their clinicians using a combination of ethnographic and microanalytic approaches to investigate how interaction is affected by mediation via Skype or similar apps and (2) develop guidance for patients and clinicians in conducting remote consultations.

Our research questions were as follows:

1. What are the (often implicit or unspoken) communication strategies through which technology-mediated consultations for diabetes, cancer, and heart disease are successfully accomplished?
2. How do patients and clinicians negotiate misunderstandings in technology-mediated consultations, and what strategies are more effective?
3. What can we learn from a detailed linguistic analysis of real-life remote consultations to guide other clinicians and patients interested in or actively using Skype and other video platforms for medical consultations?

Methods

We have previously published a detailed study protocol [10]. This section provides a summary along with an update on the analytic approach.

Study Design and Approach

A mixed methods design was used to study video consultations in 4 contrasting clinical settings (diabetes, antenatal diabetes, cancer, and heart failure patients) across 2 NHS trusts (Oxford and London). The study was informed by linguistic ethnography, which uses both linguistic and ethnographic approaches to understand how social and communicative processes operate in a range of settings and contexts, combining video and audio recordings of consultations, interviews, and observations from 2 previous studies (VOCAL and OTQS, detailed above) to examine in detail how patient-clinician interaction is shaped by use of Skype and FaceTime.

Project Management and Governance

This study was delivered by a core working group (SS, LS, DC, JW, and TG) and supported by an independent steering group with a lay chairperson and cross-sector stakeholder representation, including patients, NHS stakeholders, and national-level decision makers.

Both studies from which data were drawn received ethical approval for a detailed analysis of video recordings of video consultations. VOCAL was approved by the National Research Ethics Service Committee London–City Road and Hampstead in December 2014 (14/LO/1883) and OQTS by the South Central–Berkshire Research Ethics Committee in September 2015 (15/SC/0553). All participating staff and patients in both studies gave their informed consent to be audio and video recorded during consultations and for the data to be used for research purposes.

Setting

The study took place at 2 NHS trusts in London and Oxford, each of which explored the use of video consultation services. Table 1 provides an overview of the clinical settings in which recordings of consultations took place. The diabetes service in London had an established video consultation service, whereas the other 3 were piloting or setting up video consultations at the time of the respective studies. Video consultation services in heart failure and antenatal diabetes ceased at the end of the respective studies. Further details on each of the settings can be found in publications from VOCAL [9,47] and OTQS (C Papoutsi et al, unpublished data, 2020).

Table 1. Summary of the four clinical settings in which video consultations took place.

Clinical setting	Population	Clinical provision	Staff	Video consultation service
Diabetes services (London)	Adult/young; adult patients (18-80+ years), with high prevalence of type 2 diabetes in ages 16 to 25 years, plus significant risk factors (eg, poverty, diet, or ethnicity)	Integrated community diabetes service, with consultants providing 6-monthly reviews and ongoing support from diabetes nurse specialists	Lead diabetologist, 5 consultant diabetologists, and 6 specialist nurses	Established in 2010 because of typically low engagement with traditional service models, poor health outcomes, increasing use of unplanned care via A&E[a]; delivered largely by lead diabetologist (who offered virtual consultations to all adult/young adult patients as an alternative to follow-ups), with other staff slowly coming on board; using Skype (consumer version) on desktop at the time of the study
Antenatal diabetes services (London)	Expectant mothers (around 350 per year) with gestational diabetes	Outpatient consultations (including preappointment tests and checks) combined with optional weekly telephone clinic (for those needing close monitoring); key medical information (eg, blood sugar readings) stored in patient-held maternity folder	3 diabetes consultants, 3 obstetricians, 2 nurses, and 1 midwife	Piloted as part of the VOCAL[b] study, with video consultations led by 1 consultant and using Skype (consumer version) on a clinic desktop
Hepatobiliary and pancreatic cancer surgery services (London)	Patients with pancreatic/liver cancer who had major surgery and a prolonged postoperative phase; diverse demographic, living up to 200 miles from clinic	Tertiary service, with clinic run once per week, 2 to 3 patients were typically seen for postoperative cancer follow-up	1 consultant surgeon, 2 specialist registrars, 1 clinical nurse specialist, and nurse assistants	At the start of the VOCAL study, the clinic had begun to introduce virtual consultations to spare selected patients unnecessary travel, run in a shared hospital space alongside other clinical services, and using Skype (consumer version) on a clinic desktop
Heart failure service (Oxford)	Heart failure patients (typically 65+ years) with reduced ejection fraction, many unable to get to clinic (owing to frailty or severe symptoms)	Community outreach service delivered by heart failure specialist nurses working with the hospital-based heart failure service, local general practitioners, other community services, social services, and ambulatory assessment units	5 specialist heart failure nurses	Piloted at the time of the OTQS[c] study to evaluate if video consultations could help deploy limited resources safely, efficiently, and effectively without loss of patient or staff satisfaction. Heart failure specialist nurses were equipped by their employing trust with iPads with SIM cards to enable real-time access to patients' records, enabling the use of Skype or FaceTime

Sampling and Data Collection

We collected data over 30 months (VOCAL, 2015-2017; OTQS 2016-2017). The data sources are summarized in Table 2, with further details below.

Our dataset consisted of 37 video recordings of consultations (Table 2) from the VOCAL and OTQS studies. The goal of sampling in both studies was to capture the breadth of experience of video consultations, seeking maximum variety in clinical, social, ethnic, and personal circumstances (Table 3) and in health and information technology literacy. It was a precondition of ethical approval that clinicians could exercise judgment about which patients to invite to the study.

Exclusion criteria were no 3G internet access at home, lack of familiarity with the technology, clinical inappropriateness (eg, in London, the need for direct physical examination), inability to give informed consent, and comorbidity preventing participation (eg, severe visual impairment). In the diabetes clinic, which included a high proportion of limited English speakers, bilingual health advocates trained in the use of remote consulting were available, so limited English was not an exclusion criterion there. In the antenatal diabetes and cancer surgery clinics, those who were comfortable with a family member interpreter were included, but a remote interpreting service was not available. In the heart failure service, all participating patients were native English speakers.

To enable comparison, we collected 28 audio recordings of matched face-to-face consultations (Table 2). Participants were selected on the basis that the type of consultation was similar to those conducted remotely (eg, routine follow-up cancer appointments) and that the consultant would consider such cases suitable for a video consultation.

Table 2. Overview of data and analysis of the Qualitative Analysis of Remote Consultations study.

Type of data	Data description	First order interpretation	Higher order interpretation
Consultation data	• Video recordings and screen capture (at patient end and clinician end) of 37 virtual consultations (12 diabetes, 6 antenatal diabetes, 12 cancer, and 7 heart failure); audio recording of 28 face-to-face consultations (7 diabetes, 6 antenatal diabetes, 6 cancer, and 9 heart failure)	• What is said and done in consultations (video and face-to-face); unfolding interaction and strategies for communication; how technology is used in consultations (video and face-to-face); and how participants felt	• How people interact and communicate, how people create and maintain order and coherence in consultations together, and how video technology shapes, enables and constrains this; the relevance of different channels (verbal, visual, gesture, or gaze); and how these all shape the actions of users
Contextual data	• Accounts of 26 patients before/after the appointment (19 from VOCAL[a] and 7 from OTQS[b]) and 35 staff involved in delivering video consultations (28 from VOCAL and 7 from OTQS) combined with field notes from before/after face-to-face and video consultations at patient and clinician end • Documents (16 from VOCAL; 7 from OTQS) (eg, operating procedures and meeting minutes) • Researcher field notes about people and technologies delivering video consultations; including diagrams of how people, technologies, and clinical work interact • Demographic data	• Key interactions and interdependencies; key organizational routines and how these are changing over time; and accounts of clinical work and how this is shaped or reshaped through use of video consultations • Basic patient information, including age, gender, and ethnicity	• Social structures (eg, professional standards and definitions of excellence; what actors *know* and how they interpret the strategic terrain) and assumptions built into the technology about, for example, capability of users, how people interact, privacy and consent, the nature of clinical work, and how all these interact • Background and context to detailed micro-analysis

Table 3. Overview of consultations in the Qualitative Analysis of Remote Consultations dataset.

Clinic	Total recorded	Male or female	Age (years), median (range)	Ethnicity
Diabetes (video)	12	5 male, 7 female	23 (21-50)	White British (5); white other (2); black Caribbean (1); Asian Bangladeshi (1); Asian Indian (3)
Diabetes (face-to-face)	6	3 male, 3 female	26 (21-58)	White British (2); black Caribbean (1); Asian Bangladeshi (2); Asian other (1)
Antenatal diabetes (video)	6	6 female	34 (30-37)	White British (1); black Caribbean (1); Asian Bangladeshi (1); Asian other (3)
Antenatal diabetes (face-to-face)	6	6 female	33 (26-36)	White British (0); black Caribbean (1); Asian Bangladeshi (3); Asian Indian (1); Asian other (1)
Cancer (video)	12	4 male, 8 female	74 (55-85)	White British (9); white other (1); black Caribbean (1); Asian Indian (1)
Cancer (face-to-face)	5	3 male, 2 female	69 (45-75)	White British (2); black Caribbean (2); Asian other (1)
Heart failure (video)	7	3 male, 4 female	67 (33-87)	White British (7)
Heart failure (face-to-face)	9	1 female, 8 male	60 (56-78)	White British (9)

Video consultations for the VOCAL study were recorded by a researcher (JW) using a small digital camcorder with a wide-angle lens. For the OTQS study, they were recorded by a researcher (CA/TG) using a small digital camcorder and a handheld iPad (Apple Inc). Face-to-face consultations were audio recorded using a digital Dictaphone. We captured clinician and patient interaction with the videoconferencing software using a commercially available screen-capture software tool (ACA Systems) to record screen images showing on each party's computer screen as a video file. This was run directly from a USB memory stick.

Each end of the consultation resulted in 2 digital files: 1 screen capture and 1 video. We synchronized these into 1 file using video editing software, meaning that the video of the computer screen could be played exactly in parallel with a video of the patient looking at the screen, and then aligned the patient and clinician *ends* (an example screenshot is shown in Multimedia Appendix 1). In several cases (Table 4), the consultation was recorded only at one end. This was either because the patient did not wish to be filmed in their home but was happy to be filmed from the clinic or because it was not practically possible to arrange for recording to take place at both ends.

We transcribed all face-to-face and video consultations using a specialized program, Transana [60], which allows researchers to capture the complexity of data, such as body language, while simultaneously following video, audio, and transcription (Multimedia Appendix 1).

In both studies, we made contemporaneous field notes at each patient's home and at the clinic, for instance, relating to the patient's material circumstances or the physical circumstances in which the clinician makes the remote call. We interviewed key staff at each site involved in setting up and conducting video consultations and patients as soon as possible after their video consultation.

Table 4. Summary of video consultation recordings.

Video recording	Cancer	Diabetes	Antenatal diabetes	Heart failure	Total
Dual clinic, dual home	4	0	1	2	7
Dual clinic, single home	1	0	1	3	5
Single clinic, dual home	1	2	1	1	5
Single clinic, single home	3	1	3	1	8
Dual clinic, no home	2	7	0	0	9
Single clinic, no home	1	2	0	0	3
Total	12	12	6	7	37

Theoretical Approach

We used 2 complementary theoretical approaches that see communication as a dynamic interaction that emerges moment by moment, which allowed us to examine the role of technology in shaping interaction. First, we used the *ethnography of communication* [61] to produce systematic and richly contextualized descriptions of the communicative genres, events, and practices that are observed in a particular culture to identify the key features of video consultations and attend systematically to contextual factors (eg, lack of spatial proximity and restricted visual field) that may produce differences with face-to-face consultations. Second, we used conversation analysis (CA) [62] to guide the fine-grained examination of the patterning of interaction, (ie, how consultations are managed by participants moment by moment). We focused on the linguistic, bodily, and contextual resources used by participants to create and maintain order and coherence and how different modes and channels of communication, such as the verbal and visual, shape actions (eg, physical examination).

Analysis

As is usual in linguistic ethnography, the analysis combined *zooming in* on interaction to understand how video consultations are successfully conducted, with *zooming out* to the clinic and wider organization to understand the context in which they take place. This process began with repeated viewings of video recordings among the team, which included representation from linguistics, sociology, psychology, and medicine with the aim of identifying "recurrent and stable details of talk-in-interaction" [62]. From this, we identified 4 questions for an in-depth study:

1. How do patients and clinicians open and close video consultations?
2. How are physical examinations accomplished in video consultations?
3. How do patients and clinicians address problems with the technology?
4. How is turn-taking affected by the video-mediated setting?

For the first 2 questions, we built collections of all openings, closings, and physical examinations, respectively. For the third question, we built a collection of cases in which the technology failed (eg, there was no audio) or where a failure in the technology was addressed (eg, a patient says his image is frozen). For the fourth question, we built a collection of cases where the patient and clinician struggled with smooth turn-taking, and so had repeated overlapping talk and/or stopped talking. Silences and overlapping talk are common in all conversations [54]; hence, not all cases of overlap and silence in our data were necessarily a result of the video medium. We therefore (1) only included consultations recorded at both patient and clinic ends, allowing us to determine that latency (ie, the transmission delay between one participant saying something and the other hearing it) was an issue, and (2) focused on points in the conversation where speaker transition should take place, but the latency caused problems.

In line with CA [63,64], we transcribed data using Jeffersonian and Mondada systems (Multimedia Appendix 2), employing a range of symbols and conventions to capture *what* participants say, *how* they say it (eg, pauses and volume), and accompanying *nonverbal* communication (eg, gaze and head movement). Guided by the principles of sequence organization and turn design [65,66], we then examined each case (eg, individual opening) to determine the actions that participants performed, how these actions were organized in the consultation [67,68], and the communication practices that participants used to make

these actions recognizable. We then searched for patterns and commonalities across each collection to distinguish between communication strategies that were relevant for single instances and those used more systematically, for instance, the ways in which clinicians use different opening questions. In other words, we identified the norms and conventions that participants appeared to rely on in video consultations.

Finally, once we had a solid appreciation of the patterns of communication across collections, we identified areas where there was *trouble*, such as potential misunderstandings, and grouped these into key challenges. At this point, we *zoomed out* to our contextual data with the aim of better understanding how and why such challenges occur (eg, the way in which Skype technology is set up on computers and what this requires of clinicians when they open video consultation) and how they are negotiated.

Patient and Public Involvement

Patients and their caregivers were key to the research. We set up a dedicated patient advisory group (PAG) in 2015 to enable patients to review documents and give feedback on their experiences and to incorporate patient feedback within the respective studies. We have since set up a standing group, Patients Active In Research on Digital health, who, along with the PAG, have reviewed emerging findings (including anonymized video clips) from the QuARC study and provided feedback on developing guidance on video consultations. Finally, we worked with a design company to co-design guidance and an accompanying animation that involved 2 workshops with a total of 50 members of the public, followed by a review of materials via email. This process was critical in developing both content and design of these outputs (eg, guiding us not only to focus on how to do a video consultation but also to include technical setup).

Results

Overview of Findings

We found that for this highly selective group of patients and clinicians, the use of video technology typically (but not always) enabled effective consultations that followed the conventional organization of a consultation [68]. Patients and clinicians adapted quickly and easily to the video-mediated context, transferring communication strategies from face-to-face communication to successfully complete web-based consultations. For example, in video consultations, the webcam is positioned above the screen, making mutual gaze impossible, but participants had no problem positioning their head and shoulders in front of the camera and looking at the screen to show that they were engaged and directing their attention to their coparticipant.

Clinicians managed to start consultations in the same way as a face-to-face consultation by asking, for instance, “How are you today?” and inviting patients to provide updates on their condition since the last consultation [69]. Patients responded in the conventional way, either reporting no problems or highlighting recent changes (eg, high blood sugars). When clinicians were engaged in other activities, such as updating the patient’s record, they made this clear by saying, for instance, “If I go silent, I’m writing. Okay?” Closing of consultations was straightforward, and followed the same pattern as face-to-face consultations, with the clinician checking if the patient had any further questions and then closing down the discussion, arranging a follow-up as needed, and saying goodbye.

The use of video calling (30 Skype, 7 FaceTime) was a novel form of communication for many users (particularly for older participants, Table 3). Younger patients appeared particularly comfortable with the technology, but even those with less technological affinity had few problems using the technology once they had some assistance, for instance, from a carer. When clinicians and users initially made contact, we observed that in many cases, consultations were characterized by surprise, amusement, and a sense of informality. This often continued into the consultation, with participants sometimes joking, generally, and about the use of video. It was striking that those clinicians who were new to the video medium felt quite distracted by having their own image appear on the screen for the first time—working out how to minimize or ignore it was an important step in re-establishing a formal, professional focus.

It was when we began to look at these issues in detail that we became interested in how it is that people interact effectively via video. Across the 37 video consultations in our dataset (12 hours and 21 min of total consultation time), we identified 3 key challenges that (some but not all) participants faced when doing video consultations: (1) establishing a connection and starting a video consultation, (2) dealing with disruption to conversational flow caused by technical issues with audio or video, and (3) conducting a physical examination via video. We describe each of these below, along with the communication strategies used to negotiate them. We present data extracts illustrating the analysis in the figures below (full transcriptions following CA conventions are included in Multimedia Appendix 3).

Challenge 1: Establishing a Connection and Starting a Video Consultation.

The start of a video consultation is a crucial time when the patient and clinician seek to establish a technical connection and determine if this is good enough for the consultation to go ahead. This process was not always straightforward. The combination of consultation and contextual data in our study enabled us to distinguish between *preopenings* involving steps to establish a connection and *openings* involving greetings like *hello*, followed by *how are you?* type questions [69] that signal the start of the clinical consultation.

Before a video consultation can get started, steps must be taken at both *ends* to enable the patient and clinician to establish a connection. For some participants, this opening sequence could be stressful, as they sought to ensure that the relevant equipment was in place and the technical connection was working to enable the clinical element of the consultation to begin. Depending on the technology, participants needed to first identify each other via their web-based user name (ie, exchanging remote addresses) and exchange phone numbers and/or email addresses (also, at the clinic end, ensure that internal procedures, standards,

software functionality, and administrative systems are in place to support the consultation; refer to Greenhalgh et al [70] for further details). The clinician would then usually *dial* the patient, who, by answering, would show that they were ready for the consultation. On the whole, preopenings ran smoothly. In some cases, participants experienced trouble, including outdated software that required *on the spot* updates (n=2), lost passwords (n=2), or misunderstandings about which platform to use (n=1). The problem was typically resolved by one participant (usually the clinician) calling the other by telephone, finding a solution, and then restarting the video connection.

Once a connection was established, opening greetings at the start of a video consultation were critical, not only in prompting conversation but also in indicating that participants could see and hear one another. It was at this point when technological issues, such as limited audio, were acknowledged and addressed. When clinicians and patients were familiar with the technology and potential problems, openings ran smoothly, and problems were quickly resolved. However, when one or more participants were not familiar with the technology, this could quickly lead to confusion and delay (often related to issues of breakdowns and latency, discussed below).

Take the example in Figure 1, which was taken from the start of a postoperative cancer consultation in which the patient's relative did not turn on the camera when she answered the doctor's video call; in the middle of line 1, when the daughter says *answer*, the doctor appears on their screen (screenshot, Figure 1).

Figure 1. Example of a clinician and patient establishing a connection at the start of a Skype consultation. Da: daughter; Dr: doctor; Ns: nurse.

```
01  Da:  oh. did I just answer wrong?
02  Dr:  (no)
03       (3.0)
04  Ns:  [(                )
05  Da:  [there's the doctor mum.
06  Dr:  (          )
07       (3.9)
08  Dr:  hello?
09       (.)
10  Da:  hi,
11       (0.4)
12  Ns:  hi. [(we) can't see you¿
13  Dr:      [hi.
14       (0.4)
15  Dr:  [we can hear you but we]
16  Da:  [ you  can't  see  us:?]
17  Dr:  can't see you; can you see
18       us?
19       (0.2)
20  Da:  I can see you:?
21       hold o:n,
22       (1.4)
23  Dr:  you need to (.) turn your
24       camera on?
25  Ns:  (oh)
```

In this example, the patient and clinician have already done the work of preopening, the patient has been invited to a video consultation, with Skype addresses and video appointment times confirmed to enable that to happen, and phone numbers confirmed ensuring an alternative means of communicating. Once a connection is established, the patient and clinician do not greet each other but instead query the connection and confirm at the patient's end that they can see the doctor. Then, 2 periods of silence follow (3.0 and 3.9 seconds, respectively). During this time, the doctor is unsure what is happening: by *not* greeting, the patient and her daughter do not provide the doctor with evidence that they have a working video connection meaning that, for the doctor and nurse at the other end, it is not clear if there is a problem with the connection or video. The doctor's *hello* with its strong rising pitch (line 8) is not a greeting, but a means of testing if the patient and/or daughter can hear him—a practice that we found repeatedly when there was a problem with the connection and participants wanted to see if they could still hear each other. When the daughter is heard to have responded with *hi* (line 10), this provides evidence that they can hear, that the connection works, and that the problem is purely visual (as the nurse points out in line 12). The daughter moves to turn the camera on, the doctor confirms that they can now see, and the consultation begins. Unlike in a face-to-face consultation, it is only at this point that the doctor asks *how are you*, signaling the start of the clinical consultation and enabling the social rituals of *being a doctor* and *being a patient* to begin.

Challenge 2: Dealing With Disruption to Conversational Flow

The technology used in video consultations is intended to facilitate interaction. In our dataset, there were only 10 (of 37) consultations in which participants experienced no problems

with the audio or video. In the other 27 consultations, we identified 49 instances in which a breakdown in audio and/or video disrupted the conversational flow. In 25 of these consultations, we had recordings at both *ends* (ie, clinician and patient; Table 3), allowing us to identify 151 cases in which latency disrupted interaction.

Such disruptions are significant as they not only disrupt conversational flow but also potentially impact the quality and outcome of consultations (Table 5). We provide a detailed analysis of the breakdowns and latency below.

Table 5. Frequency and duration of breakdowns and latency issues in video consultations.

Type of problem	Frequency[a]	Duration (range)
Audio or video breakdown at the start of a consultation		
No sound at the start		
Unsolved: clinician calls the patient on the phone using Skype for video	3	6.5 to 9.5 min
Solved: after disconnecting and reconnecting, the sound works	2	53 to 127 seconds
No video at the start		
Unsolved: camera does not work and participants make do with audio only	1	5 min and 5 seconds
Solved: either participant had forgotten to turn on the camera	8	6.8 to 22.3 seconds
Audio or video breakdown during a video consultation		
Garbled sound: the quality of the sound suddenly degrades, causing a problem with audibility, the consultation is halted, participants check when the audio works, and then resume the consultation	24	3.7 to 56.8 seconds
Bad audio throughout: the quality of the audio is poor because of technical problems, causing frequent noise or low volume	3	Continuous[b]
Video cutout: the video briefly cuts out on one side, before automatically resuming; may happen because of an incoming call	2	1.4 to 8.4 seconds
Bad video throughout: the quality of the video is poor because of a bad internet connection, causing the image to blur, freeze, or even cut out completely	1	Continuous[b]
Breakdown in connection during a video consultation		
Automatically solved: the connection cuts out briefly, but resumes automatically; participants briefly discuss and check if the connection works before resuming	2	6.1 to 15.4 seconds
Requiring reconnection: the connection is dropped completely and participants have to redial to get the connection back	3	43.5 to 71.9 seconds
Latency		
Brief overlap: participants talk at the same time, but either drops out after 1 or 2 syllables of overlapping talk	122	Up to 0.5 seconds
Competition for turn: participants talk in overlap for a while, using multiple explicit strategies to figure out whose turn it is	29	0.5 to 10.5 seconds

[a]Reporting the number of problems we identified in the dataset relating to latency and breakdowns.

[b]It is not possible to report exact duration as there were problems, either with audio or video, throughout. This results in continuous issues.

Breakdowns

Breakdowns in audio and/or video quality occurred at different times in video consultations and with variable duration and impact (Table 5). At the start of consultations, we identified 5 cases with no audio and 9 cases with no video. In the 5 cases with no audio, 3 were in the cancer service (because of technical problems caused by interference with other devices) and involved the clinician taking up to 9.5 min to try to solve the problem before calling the patient by phone and using video calling merely for the visual connection (once the other devices were identified, such interference was resolved), 1 involved the clinician disconnecting and reconnecting twice and using the inbuilt testing service (taking 2 min and 7 seconds), and 1 involved the patient disconnecting and then reconnecting (53 seconds). Audio breakdowns were only observed in Skype consultations.

Problems with the video connection at the start of consultations were typically the result of the patient or clinician not turning on their camera (8 cases). In 1 case, the clinician could not get the camera to work and, after just over 5 min, decided with the patient that they would proceed with an audio-only consultation.

Problems during consultations were often (but not always) disruptive. We found 24 cases where there was a minor problem with the audio resulting in, for instance, soft or garbled talk (Table 5). These lasted up to 57 seconds but were typically resolved in less than 10 seconds, with participants waiting for audio to be restored. The patient or clinician then pointed out that they had not heard something, and the other participant

then repeated their last sentence before continuing with the consultation.

In 4 consultations, the quality of the hardware or a slow internet connection caused persistent problems with audio (n=3) or video (n=1). In 2 cases, one with a low volume on the patient's end, the other with a repeated *frozen image* of the patient, participants attempted to solve the problem initially and then agreed to *make do*. In the other 2 cases, the audio frequently suffered from noise or distortions. For 1 consultation, this led to repeated minor problems (n=13), with each party repeatedly unable to hear, and halting the consultation to seek clarification. In the other, a postoperative cancer consultation, there was distortion making it hard to hear, resulting in a misunderstanding about the medication dose. In the extract in Figure 2, the doctor recommends that the patient shift to a higher dose formulation of Creon (pancreatic enzyme replacement)—25,000 instead of 10,000 units; however, the patient mishears and the level of disruption to the audio then limits opportunities for the patient to indicate that they have not understood, what conversation analysts refer to as limited *repair space* [55,71].

Figure 2. Example of significant disruption to a Skype consultation due to audio problems. Pt: patient.

```
01  Dr:  one suggestion,
02       (0.9)
03  Dr:  you're taking the ten thousand
04       capsules, [isn't it.
05  Pt:            [yes.
06       (.)
07  Dr:  they are also available at twenty-five
08       thousand.

10       so (0.4) so you could take (0.2) just
11       one capsule with light (.) meals,
12       and then two [or three for big meals.
13  Pt:               [ah.
14       I see.
15       (0.4)──────────────────────────────────── Start of audio
16       uhm at the (       )¿ they do not uhm     distortion
17       make (0.2) five (thousand) ones.
18       [uh (you) can only get ten thousand
19  Dr:  [hm
20  Pt:  ones. (   ) have to- yes.
21       I (could)- (.) I could (lower) the dose.
22       (.)
23       [yeah
24  Dr:  [you c- you could──────────────────────── End of distortion
25       ask your GP the next time you
26       [get the (creon),
27  Pt:  [mm hm,
```

In this example, the clinician's recommendation to change to a 25,000-unit strength capsule is indistinctly audible at the patient's end, but the patient appears to mishear and to understand that the consultant wants her to start taking 5000-unit strength capsules (line 17). She indicates that she understands with "ah I see" (lines 13-14), but then points out that Creon is not available in 5000-unit strength (lines 16-17), revealing her misunderstanding. The clinician then has the opportunity to rectify the problem [72], but audio distortion, caused at least in part by the microphone at the patient's end, means that the doctor appears to have trouble making out what the patient is saying and to assume that she heard correctly, recommending that the patient ask her GP for a change in unit strength (lines 24-26). The technical breakdown means that he does not notice that the patient misheard and so continues with the misunderstanding unnoticed and unresolved.

We found 2 cases in which the video was temporarily disrupted on one end of the consultation. In each case, the problem was quickly and automatically resolved (Table 5).

In 5 cases, the connection cut out completely: in 2, the connection was quickly and automatically restored, and in 3, participants had to reconnect themselves.

Latency

Spoken conversation is characterized by a turn-taking system, a set of rules participants use to determine whose turn it is to talk. This system serves to minimize both silence and overlapping talk in a conversation, the principle being 1 speaker at a time [54]. Research has shown that participants in a conversation favor direct responses (each person taking over immediately when the other has finished speaking) [73]. Delays in turn-taking and significant overlap usually indicate that there is a communication problem [74]. In our dataset, we found that short periods of latency (up to approximately 200 milliseconds) were tolerated or ignored, but that more significant latency

(approximately 500 milliseconds and above) interfered with this system, resulting in silence and overlapping talk or interruption.

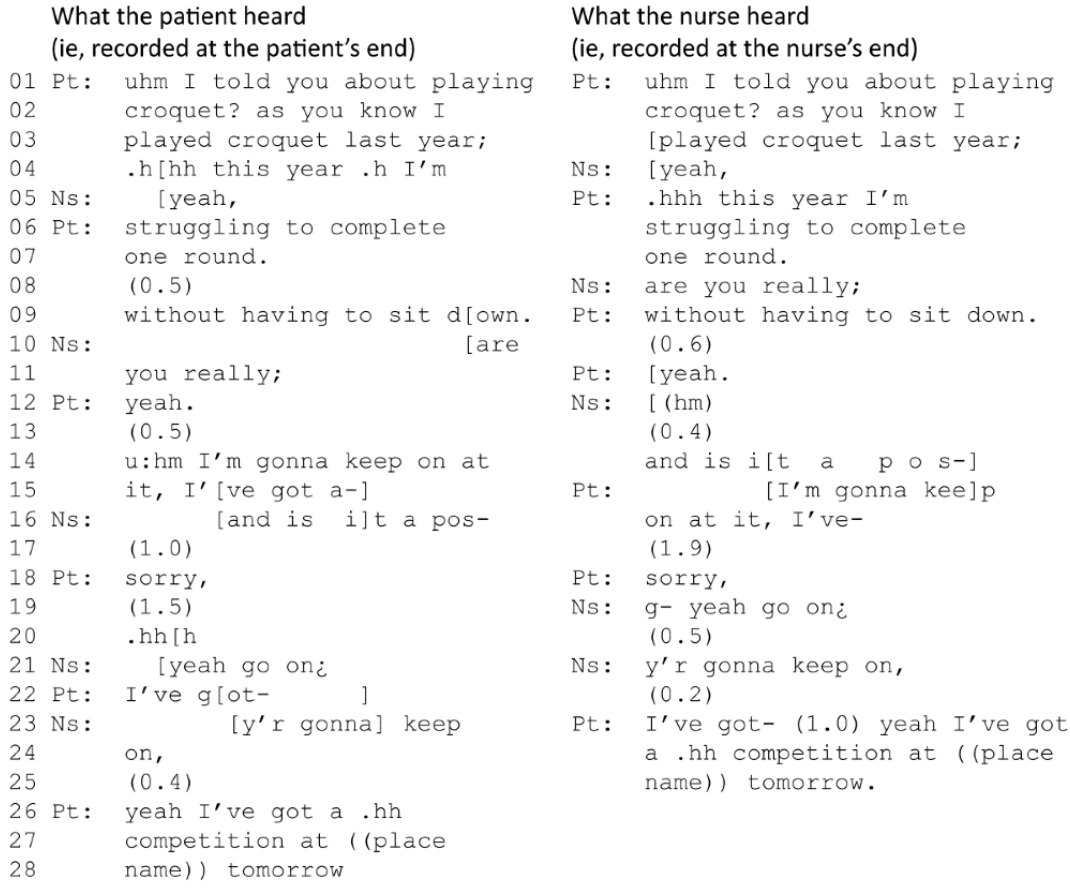
The 151 cases of significant latency that we found were unevenly distributed across our dataset, with 67 instances in 21 consultations in which problems were resolved in less than 10 seconds and another 84 instances in only 4 consultations in which problems were not only more frequent but typically took longer to resolve. In 1 of the 4 consultations, there were 47 instances of latency.

Of the 151 cases of latency, 122 were quickly resolved with 1 participant dropping out (ie, stopping talking) after 1 or 2 syllables of overlapping talk (Table 5), and the conversation quickly resumed with minimal impact on flow. In the remaining 29 cases (23 of which were from the 4 consultations with repeated instances of latency), problems were more disruptive and took longer to fix. Here, participants actively competed for the right to talk, resulting in complete sentences overlapping. Latency resulted in longer exchanges in which participants had to work out whose turn it was to talk, which regularly took between 0.5. 10.5 seconds. Conversations were resumed by participants saying something like *sorry* or *go on* and/or repeating the last thing the other person said.

Consider the example in Figure 3, from a heart failure consultation in which the patient is talking to a specialist heart failure nurse about their back problems. Latency in the connection makes the discussion challenging. As the patient tells the nurse about his back problem and the restrictions it places on his day-to-day life (column 1, line 15), the nurse seemingly interrupts to offer a solution (line 16) before the patient has resumed his story. This supposed *interruption* is a result of latency. As can be seen from the nurse's end (column 2), from her point of view, she does not begin to talk in the middle of the patient's turn (line 16), but actually starts her turn before the patient (line 15). Due to the latency in the call, she cannot know that the patient has already begun talking again; similarly, the patient cannot realize that the nurse has begun to offer a solution to his presented problem. The result is overlapping talk. Both also deal with different problems: from the patient's perspective, the nurse interrupts him; from the nurse's perspective, it is the other way around. However, the latency means that neither of them can know this. Eventually, both then stop talking, and it takes a series of silences and *repair sequences* (eg, the patient's *sorry*, and the nurse's *yeah go on*) before the patient can resume his narrative (line 22).

In the 29 cases where latency caused disruptions to conversational flow, participants relied on the same communication strategies they use in face-to-face conversation to try to negotiate the problem. However, latency also caused problems when using these strategies. For example, in Figure 3, the nurse tells the patient to *go on* (line 21), and the patient then resumes his talk as is usual when face-to-face but, because of latency in the connection, the nurse does not realize that the patient has resumed his talk. The nurse then repeats part of his talk (line 23) as an additional strategy to give him the turn, causing the patient to again stop talking (line 22) and confirm before definitively resuming his talk (line 26).

Figure 3. Example of latency disrupting conversational flow in a video consultation for heart failure. Ns: nurse; Pt: patient.



Challenge 3: Conducting Physical Examinations Via Video

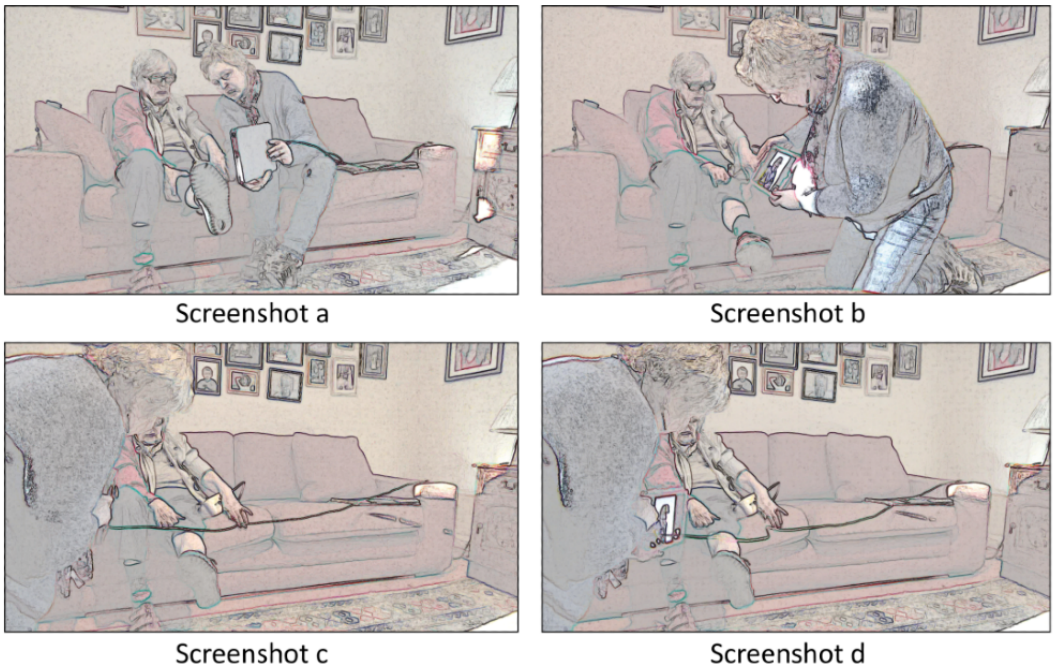
Clinicians and patients are concerned about the appropriateness and safety of conducting physical examinations in a video consultation [75,76]. Data from the heart failure service (including 7 video and 9 face-to-face consultations combined with contextual data about the setting; Table 2) provided a unique opportunity to examine what is possible in terms of physical examination in routine heart failure reviews between specialist heart failure nurses working from a community hospital and patients in their homes. Typically, in a face-to-face consultation, heart failure nurses measure weight, blood pressure, oxygen saturation, and heart rate and rhythm; they also assess edema (fluid build-up in the soft tissues), usually by examining the lower legs, and listening to the patient's chest with a stethoscope for signs of fluid overload or infection. With the exception of listening to the chest, the same examination can be attempted remotely, using a blood pressure monitor put on by the patient or relative (perhaps incorporating an irregular heartbeat indicator to estimate whether atrial fibrillation is present) and getting the patient or a relative to gently press on the lower leg (*digital pressure*) to produce an indentation (*pitting*) that is indicative of edema.

These examinations appeared to be very straightforward when the clinician and patient were colocated. However, in the remote setting, the same physical examinations presented specific challenges: (1) adequate design of instructions to guide video examinations (nurses had to explain tasks using lay language and check that instructions were being followed), (2) accommodation of the patient's desire for autonomy (on the part of nurses and relatives) in the light of opportunities for involvement in their own physical assessment, and (3) conducting a physical examination while simultaneously making it visible to the nurse (patients and relatives needed adequate technological knowledge to operate a device and make the examination visible to the nurse as well as basic biomedical knowledge to follow nurses' instructions). We have presented a detailed analysis of these challenges and the strategies used to attempt to overcome them in a separate paper [77].

Heart failure patients tend to be elderly, and many have poor exercise tolerance, mobility problems, or comorbidities, making attendance at the clinic potentially difficult. For the 9 patients in our sample attending the consultation in person, physical examinations were all successfully conducted by the clinician with minimal assistance from attending carers. For the 7 consulting by video, all participants (clinicians, patients, and, sometimes, relatives) had to employ novel communication strategies to collaboratively negotiate the challenges of achieving a satisfactory physical examination in the remote setting. Participants relied on a range of unspoken assumptions about the technology and their respective knowledge and understanding of medical procedures and the meaning of measurements. Clinicians and patients ran into unforeseen problems, either with the procedure (eg, the patient put a blood pressure meter incorrectly) and/or the technical process (eg, video quality prevented full visual assessment). Although complex, in 5 consultations, these problems were resolved with patients and/or their relatives asking the clinician for feedback or instructions and working with them to successfully complete the examination.

There were 2 consultations in which it was not possible to complete an attempted physical examination. In both instances, this was because the patient or relative was not able to hold the phone or tablet and test for edema at the same time. Take the example in Figure 4, of a heart failure patient and her daughter, in which they have been instructed by the clinician to examine the patient's right leg for edema; the daughter attempts to aim the camera at the patient's leg while at the same time trying to monitor the screen, as can be seen in the top 2 screenshots. This does not work adequately, and the nurse is not able to get a view of the patient. When she finally—after minutes of moving around—manages to aim the camera at the patient's leg (screenshot c, Figure 4), she is instructed by the nurse to press into the patient's leg. She lets go of the tablet with one hand and loses control (screenshot d, Figure 4), the result being that the camera is no longer aimed at the patient's leg. The nurse thus cannot assess if the patient has edema, and following this failed attempt, they agree to stop the examination. It is also worth noting that the patient end of the examination takes place in a living room that was not designed for clinical examinations. The sofa is much lower than a seat in a clinic, there is no examination couch, and the lighting in the home and on the tablet is not designed to provide the level of illumination considered standard for a clinical examination.

Figure 4. Heart failure patient and relative attempting examination for edema.



The 86-year-old patient shown in Figure 4 knows the nurse well and has seen her before in the clinic and at home. Having recently lost her husband, she had not been well and was admitted to the hospital with pneumonia. She deteriorated, resulting in close management by her GP and the specialist heart failure nurse. This story of acute deterioration in an older patient with multimorbidity is typical of the 16 patients with heart failure in our sample. Similar to the patient in Figure 4, those consulting via video were also doing so from a space (typically a living room) that was not designed for clinical examinations in which chairs were often too low, there was no examination couch, lighting was limited to standard bulbs, and there were often personal objects (eg, lamps or ornaments) that might impede movement or be knocked over. Hence, although 5 of the 7 remote examinations were completed, many found the process physically, practically, and technically challenging. Most were familiar with the technology from a clinic visit but had not necessarily practiced either in this kind of assessment or in using multiple devices to aid the process, especially in an environment that had not been designed with clinical assessment in mind. Unlike in face-to-face consultations, success was often dependent on the type of technology (smartphone, tablet, or laptop), the presence of a third party who could assist the patient, the patient's mobility, and the technological competence of the participants. Participants often reflected that it might be easier to perform a remote physical examination the second time as they were now aware of the problems they might encounter.

Discussion

Principal Findings

Our study has shown that, at least for this group of patients and clinicians, interaction in the majority of video consultations is effective. Observation and recording of video consultations, combined with theoretical sensitivity to the ways in which technology mediates communication in clinical consultations, has enabled us to do the following. First, we have shown that when participants experience technical or operational issues in video consultations (eg, when experiencing a problem connecting due to latency), they generally find a way to negotiate these, falling back on tried and tested rules of communication transferred from face-to-face situations. Familiarity with technology helps. Second, in a small proportion of consultations, technical interruptions before or during consultations may require workarounds such as using a standard telephone line to overcome lack of audio, and, in a few cases, it may threaten the quality of communication and clinical safety. Third, we have shown that in the minority of cases where significant latency occurs, clinicians and patients do not always hear the same thing at the same time. Finally, we have revealed that video consultations necessitate patients (and potentially carers too) to take an active role in understanding and manipulating the technology (eg, to change what the other party can see) and their surroundings (eg, adjusting lighting). For those consultations involving a remote physical examination, this involves a complex process of giving and receiving instructions and ensuring visual presence.

Strengths and Limitations

Careful analysis of verbal and nonverbal interaction, combined with a focus on social context, has enabled a robust understanding of the role played by language and social interaction in video consultations. Such detailed analysis takes time. Although we were fortunate to have data from 2 separate and fairly large qualitative studies, these comprised a relatively limited range of consultations in only 4 clinical conditions. Only 1 of these, heart failure, involved remote physical examinations.

CA is an established methodological technique for studying social interaction that allowed us to systematically identify challenges and to then generate and analyze relevant collections across our dataset. This is a key strength of our study. When the original studies were designed, we did not set out to examine

1 of these challenges—latency. This meant that the dataset we analyzed did not allow us to determine the precise timings of all instances of latency. When selecting data to analyze the impact of latency on conversational flow we therefore focused on cases where both participants talked in overlap following a point where turn transition could have taken place (eg, after a question) [54]. Future studies of latency in video consultations should ensure a comparison of recordings from both *ends* at every point.

Our dataset included video and audio recordings of consultations using Skype and FaceTime because these were the platforms being used at the time. Neither of these platforms was specifically designed for clinical consultations, and it may be that next-generation video consultation software (eg, Attend Anywhere) or more advanced peripheral technologies, such as noise-canceling microphones, may produce less in the way of breakdowns in conversations. We recommend that any future published studies of video interactions include details of the specific technologies used.

Comparison With Other Studies

To our knowledge, our study is one of the first to apply linguistic ethnographic approaches to the study of video-mediated consultations in health care. As such, it represents a significant addition to the existing literature, which has been dominated by trials and focused on issues of feasibility and acceptability and has also included some conventional CA without linguistic ethnography [44,46]. It extends our previous research on this dataset of video-mediated consultations, which include a multilevel analysis of the policy, organizational, and interactional aspects (using the Roter interaction analysis system) [9,47], and an in-depth analysis of physical examinations via video [77].

Our research confirms findings from our own and other studies that there are interactional differences between video and face-to-face consultations and potential for collaborative decision making via video [30,43,44,48,49,78]. Our study also corroborates that people tolerate some silence in conversation but work to minimize it [57] and that delays of 0.5 to 1 second can cause significant problems [52,53]. We have added to this, providing a detailed account of the frequency and duration of breakdown and latency issues specific to video consultations, showing that, in line with studies of how overlapping talk is negotiated in face-to-face conversations [79,80], participants have strategies for dealing with these problems.

Previous work has shown that speakers typically rely on what phenomenologists refer to as *reciprocity of perspectives* [81], meaning that both parties assume that the other hears and sees what they hear and see. Any differences, as far as speakers can be aware, are assumed to be irrelevant until proven otherwise [82]. Our study is the first to explore the relevance of this in video consultations in clinical settings, with 29 cases identified in which participants acted as if there were no delays and were not aware that there was a delay. This meant not only that it took them longer to solve the problem of overlapping talk but also that when they used conventional strategies for solving overlapping talk, this could lead to new problems (Figure 3). This has potentially significant implications for quality and safety, for instance, when communicating medication dosage.

Meaning of the Study

Our findings suggest that care is needed on the part of health care providers, commissioners, and policy makers in rolling out this new service model. Our own study and that of others has shown that video consultations appear to be largely safe and effective (albeit in a small sample of clinics and clinicians, and with patients identified by clinicians as *suitable* for a video consultation) [8,9,83], follow the conventional format of a face-to-face consultation, and any interactional challenges tend to be overcome. However, there is also a potential for significant problems, for instance, around miscommunication of dose or diagnosis, or misunderstandings because of technological breakdown.

Until recently, video consultations have tended to be an optional extra for many working in health services. The specter of COVID-19 has rapidly changed the landscape [84]. Clinicians and patients face a high risk of infection if they consult face-to-face, meaning that video consultations have significant advantages, both in cases where patients or clinicians are self-isolating because of symptoms of COVID-19 and where patients with other conditions are being seen remotely in an effort to reduce infection risks. In short, with a rapidly spreading disease, the pressure is on to reduce the number of people consulting face-to-face. Rolling out such a service at speed is, in some ways, similar to what we have studied in that many consultations are likely to involve dealing with routine, nonacute issues in a range of conditions with already known patients.

Before the COVID-19 pandemic, resources to support video consulting tended to be ad hoc and limited. In most cases, clinicians and patients were conducting video consultations without guidance for what works for which patients, clinical condition, or stage of diagnosis. That remains the case at the time of publication with, if anything, increased uncertainty about how video consultations can best be used as workflows are rapidly reorganized during the COVID-19 crisis. This lack of guidance means that clinicians and patients can run into unforeseen problems and communicative challenges that they may not know how to negotiate or easily resolve. Some problems potentially go unnoticed (eg, inadequate lighting misrepresents the patient's condition in a remote physical examination), which poses potential risks to the patient.

Guided by the findings from this and previous studies and in collaboration with patients (see above), we have developed a suite of freely available resources for patients and clinicians (available online [85] and summarized in Multimedia Appendix 4). This includes guidance on setting up and running video consultations for patients and clinicians, sets of frequently asked questions, downloadable leaflets and posters, and an animation. Our original intention, before the COVID-19 epidemic, was to provide a generic resource that could support patients or clinicians in setting up and running a video consultation. This remains the case. However, guided by emerging evidence, we have adapted guidance to ensure accessibility and relevance for those using video calling during and beyond the COVID-19 pandemic.

Unanswered Questions and Future Research

Communication in video consultations is under-researched. Further qualitative work is needed to examine interactional issues across a broader range of settings, conditions, and populations to inform the development of video consultations and to support patients and clinicians who choose to use them. This includes other kinds of remote physical examination for other conditions and with other types of patients (including those like older people or those with frailty who typically need more health care consultations but have limited experience of video technology).

Questions remain about the extent of latency, its often subtle effects [80], and the implications of how overlapping talk is understood differently by each participant. Further work is needed to consider a wider range of overlapping talk and to gain detailed understanding of how latency affects conversational flow and may cause misunderstandings in video consultations.

There have been significant advancements in technology in recent years, enabling both standalone platforms (eg, Skype) and those dedicated to video consultations (eg, Attend Anywhere). Future studies should examine what, if any, technical and interactional benefits the latter bring, including improved peripherals (eg, better screens or webcams) and use of companion devices (ie, multiple devices in combination).

Conclusions

Video consultations are interactionally different from face-to-face consultations. The use of video technology has the potential to change the way in which patients and clinicians interact, particularly when problems with audio or video interrupt the usual flow of interaction or where a physical examination is required. The use of evidence-based guidance, combined with training and support, can help clinicians and patients to more quickly identify and work through technical problems and avoid the potential for significant misunderstanding. Such resources are likely to be essential if video consultations are to be delivered at scale.

Acknowledgments

The authors thank the staff and patients who participated in the VOCAL and OTQS studies and members of the study steering groups, especially Mrs Jenni Bowley, who chaired these. The authors also thank Chrysanthi Papoutsi, who collected some of the data at the clinician end of consultations in the OTQS study. This study was funded by the NIHR Research for Patient Benefit program (grant reference number PB-PG-1216-20012). The views expressed are those of the author(s) and not necessarily those of the NIHR or the Department of Health and Social Care. Development of guidance on doing a video consultation and the accompanying animation for patients was additionally supported by a Wellcome Trust Senior Investigator Award to TG (grant reference WT104830MA) and a Health Foundation grant (to support the extension of video consultations in England, scale-up improvement award to TG, SS, JW, and NHS partners). SS and TG are partly funded by the NIHR Biomedical Research Centre (BRC), Oxford, United Kingdom (grant reference number NIHR-BRC-1215-20008).

Authors' Contributions

SV had the original idea of introducing virtual consultations at Barts Health and established the service as a pilot in 2010. CA introduced video consultations at Oxford University Hospitals Trust, piloting the service in 2016. CA is a clinical academic and cardiovascular lead for the Oxfordshire Clinical Commissioning Group. SB and SV are consultants, and JM is a senior project manager at Barts Health. All were involved in refining study design, facilitating access to the study sites, data collection, and patient engagement in the respective OTQS (Oxford) and VOCAL (Barts Health) studies. TG was the chief investigator of the OTQS and VOCAL studies. SS had the initial idea for combining data from VOCAL and OTQS and was the chief investigator for this study and (as such) its guarantor. She was involved in all aspects of study design, data collection and analysis, and writing; she drafted the first version of the paper. JW is a senior academic involved in all aspects of the research. He led ethical applications for VOCAL and OTQS, on the meso- and microelements of the VOCAL study and on data collection for OTQS. DC is a senior academic with expertise in sociolinguistics, and LMS is a postdoctoral researcher specializing in CA. Both contributed methodological perspectives on the analysis of language and communication. LS led microanalysis of video consultation data. All authors have reviewed and approved the final manuscript.

Abstract

Background: Chronic musculoskeletal pain has a vast global prevalence and economic burden. Conservative therapies are universally recommended but require patient engagement and self-management to be effective.

Objective: This study aimed to evaluate the efficacy of a 12-week digital care program (DCP) in a large population of patients with chronic knee and back pain.

Methods: A longitudinal observational study was conducted using a remote DCP available through a mobile app. Subjects participated in a 12-week multimodal DCP incorporating education, sensor-guided exercise therapy (ET), and behavioral health support with 1-on-1 remote health coaching. The primary outcome was pain measured by the visual analog scale (VAS). Secondary measures included engagement levels, program completion, program satisfaction, condition-specific pain measures, depression, anxiety, and work productivity.

Results: A total of 10,264 adults with either knee (n=3796) or low back (n=6468) pain for at least three months were included in the study. Participants experienced a 68.45% average improvement in VAS pain between baseline intake and 12 weeks. In all, 73.04% (7497/10,264) participants completed the DCP into the final month. In total, 78.60% (5893/7497) of program completers (7144/10,264, 69.60% of all participants) achieved minimally important change in pain. Furthermore, the number of ET sessions and coaching interactions were both positively associated with improvement in pain, suggesting that the amount of engagement influenced outcomes. Secondary outcomes included a 57.9% and 58.3% decrease in depression and anxiety scores, respectively, and 61.5% improvement in work productivity. Finally, 3 distinct clusters of pain response trajectories were identified, which could be predicted with a mean 76% accuracy using baseline measures.

Conclusions: These results support the efficacy and scalability of a DCP for chronic low back and knee pain in a large, diverse, real-world population. Participants demonstrated high completion and engagement rates and a significant positive relationship between engagement and pain reduction was identified, a finding that has not been previously demonstrated in a DCP. Furthermore, the large sample size allowed for the identification of distinct pain response subgroups, which may prove beneficial in predicting recovery and tailoring future interventions. This is the first longitudinal digital health study to analyze pain outcomes in a sample of this magnitude, and it supports the prospect for DCPs to serve the overwhelming number of musculoskeletal pain sufferers worldwide.

Introduction

Background

Chronic musculoskeletal pain has vast global prevalence [1] and annual costs in the hundreds of billions of dollars in the United States [2,3]. Musculoskeletal disorders are debilitating and may contribute to the opioid epidemic, as they are the most common noncancer indication for an opioid prescription in the United States [4-6]. Nonsurgical care, including exercise, education, and behavioral health, is universally recommended as the first-line treatment for the majority of chronic musculoskeletal conditions [7] given that it can achieve similar outcomes to surgery with reduced cost and lower risk [8,9]. However, conservative care has significant barriers to effective implementation and requires higher patient engagement to be successful [10,11]. Notably, conservative care administered in a clinical setting is also costly, and ongoing monitoring is often infeasible. Given the growing burden of chronic musculoskeletal pain, a scalable and effective mode of conservative care delivery is needed.

Digital health interventions have the potential to improve conservative care outcomes for chronic musculoskeletal pain by increasing patient engagement through electronic delivery of interventions. This approach can better enable patients to take a proactive role in their treatment and learn to self-manage their chronic pain symptoms. With the ubiquity of smartphones, low-cost sensor technology, and advanced analytical approaches to assess complex health care data, the prospect of digital technology for improved patient care is apparent and is reflected in the growing number of clinical trial protocols and review papers on the topic [12]. Digital therapies are shown to be effective for improving outcomes associated with conditions requiring self-management and behavioral change, such as type 2 diabetes [13], hypertension [14], and insomnia [15]. In addition, patient willingness to seek surgical treatment is shown to decrease following participation in a digital care program (DCP) [16]. Chronic pain, although often difficult to diagnose and treat clinically, is also shown to improve with the aid of digital therapy [10]. For chronic musculoskeletal pain specifically, the DCP in this study was previously evaluated in two randomized control trials and demonstrated effectiveness for improving pain and disability associated with knee pain [17] and low back pain [18]. Although these previous musculoskeletal pain studies show potential for a digital therapeutic approach to improve outcomes, they are limited in sample size (<200 subjects) and real-world effectiveness has yet to be shown. In this study, we assessed engagement and subject-reported outcomes over a 12-week period following enrollment in the DCP in a sample of over 10,000 users with chronic knee or back pain.

Objectives

This study had two objectives. First, we sought to determine whether the DCP is scalable and effective in a large sample of real-world patients. Given the magnitude of the chronic musculoskeletal pain population, scalability is one of the greatest potential benefits of a DCP, so the efficacy of a DCP in a large sample of real-world patients is important to assess. Key questions include if high levels of engagement can be sustained and if efficacy demonstrated in smaller randomized control trials is maintained in the larger real-world population. On the basis of results from the smaller randomized control trials, we hypothesized that the DCP would improve subject-reported pain over a 12-week period and that engagement with the DCP would be a necessary factor for improvement. A scalable digital intervention for engaging patients with safe conservative therapies for lasting self-management would have the potential to reduce the economic burden and improve the quality of life for a large population of patients.

Second, we sought to analyze the large dataset generated from the DCP to generate novel insights into patient recovery trajectories, which would create an opportunity to develop personalized interventions for individual patients. Little is known about the patient-specific response and rate of improvement for chronic musculoskeletal pain between clinical visits. Patients are typically assessed by clinicians during initial evaluations and, then, at follow-up appointments that may be weeks or months apart. A DCP enables regular (eg, weekly) collection of subject-reported outcomes throughout the recovery process. Statistical modeling methods can then be applied to these large longitudinal datasets to assess the rate of change in outcomes and if baseline data can predict recovery response. In this study, we used statistical modeling on a large longitudinal sample to evaluate nonlinear changes in pain over time and predict subject-specific pain response groups (rapid vs gradual) from baseline demographic data. Understanding how pain improves over time would inform our knowledge of pain recovery, identify variables associated with recovery, and allow for better care of patients unlikely to have rapid pain responses.

Methods

Study Design

This was a retrospective cohort study of consecutively recruited participants. Employees and their dependents at 30 participating employers across the United States were invited to complete a web-based application to participate in the Hinge Health DCP. Employees were diverse and included both office and service-based roles such as data analysts, manual laborers, truck drivers, catering staff, and outdoor instructors. Participants with low back or knee pain were recruited through email, direct mail, and posters. The trial was approved by the Western Institutional Review Board and complied with all ethical regulations. Participants provided informed consent and completed the intervention remotely. Each participant participated in 1 of 2 digital care pathways: 1 for chronic knee pain and the other for chronic low back pain. The only differences between the 2 pathways were the specific exercise regimens and some condition-specific education materials (eg, anatomy and surgical options). To mitigate the risks of selection bias, we included all

participants who had registered in the Hinge Health program by the cutoff date (May 6, 2019). We were able to verify that the study sample provided adequate power (after correcting for intrauser clustering effects, a sample size of 10,000 gave us a power of 0.97 to detect a 5-point change in our primary outcome with a type 1 error rate of 0.01). A summary of the key attributes of the cohort is provided in Table 1.

Inclusion criteria to qualify for participation in the DCP included being ≥18 years and not >80 years at the time of enrollment, having at least 12 weeks of back or knee pain, and having a baseline visual analog scale (VAS) score for pain greater than 0. Additional inclusion criteria for this study included starting the DCP, defined as completing at least one exercise session or reading 1 educational paper in the first 2 weeks following registration. Participants were excluded during registration by completing a screening questionnaire, which rejected patients with *red flag* symptoms, including signs of fracture, joint instability, infection, cancer, and cauda equina syndrome. Thus, this study included all consecutively qualified participants who enrolled in the DCP between February 6, 2017, and May 6, 2019, meeting the above inclusion and exclusion criteria

Table 1. Demographics and outcome measures (N=10,264).

Variables	Baseline			Final		
	Overall	Back pain (n=6468)	Knee pain (n=3796)	Overall	Back pain (n=6468)	Knee pain (n=3796)
Age (years), mean (SD)	43.57 (11.14)	42.58 (10.91)	45.26 (11.33)	N/A[a]	N/A	N/A

Digital Care Program

Following registration, participants received a tablet computer via mail with the Hinge Health app installed, along with 2 Bluetooth wearable motion sensors with straps and instructions to be placed above and below the painful region during the in-app exercise therapy (ET). In the lower back program, a sensor was placed on the posterior lower back and anterior chest, and for the knee program, a sensor was placed over the anterior tibia and thigh. Sensors utilized standard accelerometer and gyrometer technology (InvenSense MPU-6050, TDK Electronics, Tokyo, Japan) and were used to objectively monitor compliance and performance of exercises. ET sessions comprised light-intensity stretching and strengthening exercises commonly used in clinical practice. The ET sessions were administered using animations and instructional videos to demonstrate how to perform each exercise. While performing the exercise, the app then displayed real-time graphics showing the position of the user's relevant body parts based on the wearable sensors and indicated if the exercise was within the

desired range of movement (see Multimedia Appendices 1 and 2.

Participants were assigned a personal coach and communication was performed via text message, email, or in-app messaging throughout the DCP. Health coaches completed certification through a coaching school approved by the National Board for Health & Wellness Coaching. Coaches attempted to interact with participants via their preferred communication method at least weekly. Phone calls with the coach were also offered to participants up to 3 times during the DCP. Each participant was also placed on a peer support team of 20-30 participants that utilized a discussion forum within the app, as previous qualitative research showed this to be an important feature [19]. All app participation was completed remotely, at times and places chosen by the participant. Each week, participants were instructed to complete at least three sessions of sensor-guided ET, read 2 education papers, and log their symptoms at least twice. Participants were able to complete more ET sessions or read more education papers if desired. Behavior change topics were addressed through education papers and brief interactive modules, and focused on common cognitive behavioral therapy topics, including catastrophizing, active coping methods, and fear avoidance. Additional behavior change mechanisms used in the program included goal setting and tracking. Finally, participants were encouraged to engage in 3 aerobic exercise activities per week and perform up to 4 brief modules based on cognitive behavioral therapy between weeks 3 and 9. Each participant also maintained access to treatment as usual. The app was developed, owned, and sponsored by Hinge Health, Inc.

Outcomes

The primary outcome was VAS pain for the question "Over the past 24 hours, how bad was your [back/knee] pain?" from 0 (*none*) to 100 (*worst imaginable*). This was asked weekly during the 12-week period immediately after an ET session, and participants also had the option to report VAS unprompted, for a total of up to 2 pain scores per week. Our definition of a minimally important change in VAS pain was a 30% or 20-point decrease from baseline. Secondary outcomes included the patient health questionnaire 9-item scale (PHQ-9, 0-27) for depression, the generalized anxiety disorder 7-item scale (GAD-7, 0-21) for anxiety, the work productivity and activity impairment (WPAI) scale, the knee injury and osteoarthritis outcome score—pain subscale (KOOS—pain, 100-0) for knee pathway participants, the Modified von Korff scale (MvK, 0-100) for back pathway participants [20,21], and surgery likelihood ("What do you think are the chances you'll have [back/knee] surgery in the next year, in %?", 0-100%). These secondary outcomes were collected at baseline, 6-weeks, and 12-weeks. Other baseline measurements obtained at week 0 consisted of participants' age, gender, and BMI. Participants' engagement with the DCP was measured by recording the number of ET sessions completed, the number of coaching interactions, and the number of education papers read. Each coaching interaction was further categorized as participant-to-coach or coach-to-participant; phone calls with a coach were not recorded as an interaction. Program satisfaction was asked at week 12 ("On a scale of 0-10, how likely is it that you would recommend the Hinge Health program to a friend or colleague?", 0-10).

Statistical Analysis

The distribution of gender and BMI in the knee and back pathways were compared using 2-sided Fisher's exact test and Mann-Whitney test, respectively. The association of baseline variables with program completion status was modeled using a logistic regression model and Wald's confidence intervals for the odds ratios (ORs) estimated. Exploratory analyses visualized the relationship between overall pain reduction over the course of the DCP and the total number of ET sessions (grouped in equisized bins assuming an average of 35 ET sessions for program completers). VAS pain trends were modeled using piecewise linear regression splines. Intersubject variability in the rate of change was modeled through random effects and used a first-order autoregression correlation structure to model within-subject correlation in residuals. Optimal knot locations for the spline were determined by a cross-validation procedure that evaluated model fit on a grid of knot locations. The fixed effects were estimated using a linear mixed-effects model (Multimedia Appendix 3). Significance (*P* value) evaluation was based on Wald *t* values with a Satterthwaite correction. For pain-response subgroup analysis, a Gaussian mixture model was fitted to the estimated spline coefficients to discover clusters corresponding to subgroups within the cohort, each with a distinct pain reduction trend. Adjusted ORs were computed to understand the association between participants' characteristics and the representative pain reduction trends for each subgroup. Finally, classification algorithms were trained to distinguish the 3 response groups based on the participants' demographic and baseline measurements alone, and performance was evaluated using 5-fold cross-validation. All analyses were performed using R statistical computing software.

Results

Participant Demographics and Digital Care Program Completion

Of the 10,264 DCP participants, 6468 self-reported back pain and were enrolled in the back-pain pathway and 3796 self-reported knee pain and were enrolled in the knee-pain pathway. The average age was 43.6 years, and the average BMI was 30.25. The proportion of female participants in the DCP was 50.00% (5132/10,264). Compared with the back-pain pathway, BMI was 1.3 kg/m^2 higher (P<.001) and the proportion of female participants was 3.9% higher (P<.001) in the knee-pain pathway. The difference in mean age between pathways was not significant (Table 1).

In all, 73.04% (7497/10,264) of the participants completed the DCP (referred to as *completers*), defined as completing at least one exercise session or reading 1 educational paper in weeks 9-12. Older users were more likely to complete the DCP (OR 1.037, 95% CI 1.03-1.04), whereas those with a higher BMI were less likely to complete the DCP (OR 0.973, 95% CI 0.97-0.98). No other baseline measures were significantly associated with completion (Multimedia Appendix 3). On average, completers engaged in 10.45 weeks with 35.02 ET

sessions and 19.39 education sessions. Table 2 summarizes the engagement by pathway for all participants and completers. No injuries or other adverse effects of DCP engagement other than temporary discomfort were reported.

Table 2. Mean engagement and SD for the full cohort and for completers by pathway (N=10,264).

Variables	All			Completers		
	Overall	Back pain	Knee pain	Overall	Back pain	Knee pain
Number of participants, n (%)	10,264 (100.00)	6468 (63.02)	3796 (36.98)	7497 (73.04)	4676 (72.29)	2821 (74.32)

[a]ET: exercise therapy.

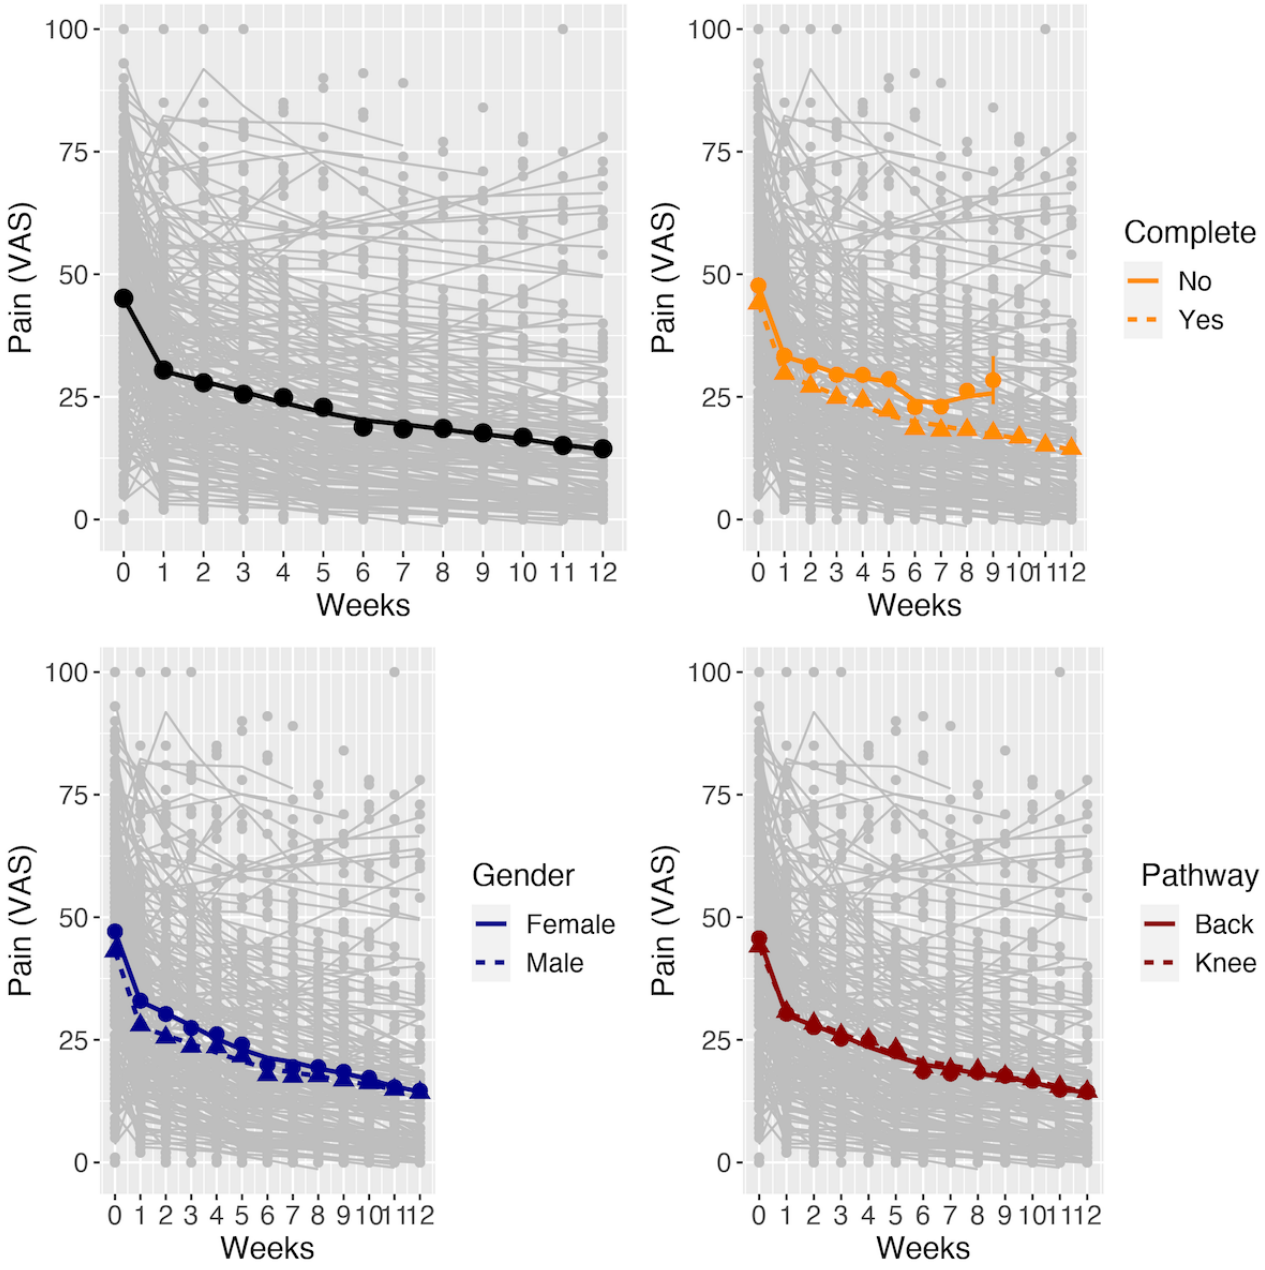
Longitudinal Changes in Pain

On the basis of a linear mixed effects model, the estimated mean reduction in pain by week 12 was 68.45% (30.89 points). Participants' pain scores changed nonlinearly over time (Figure 1). The mean change in pain scores per week (adjusted for sex, pathway, baseline age, BMI, anxiety, and depression scores) was 15.96 points for week 1 (P<.001) and 1.11 points per week for weeks 6-12 (P<.001) but was not significant for weeks 2-5. The conditional and marginal R-squared statistics [22] for our model were 0.94 and 0.54, respectively.

Minimally important change from baseline pain (defined as either a VAS pain reduction of 20 points or 30% with respect to baseline) was achieved by 78.60% (5893/7497) of completers and 69.60% (7144/10,264) of all participants.

Completers demonstrated greater pain reduction than noncompleters (Figure 1, top right) with an increased mean reduction rate of 0.48 points per week (SE 0.14) in weeks 2-5. Final pain reduction was nearly identical for both male and female genders (Figure 1, bottom left). However, there was a significantly higher mean reduction rate for male participants in the first week (mean difference=0.89 points per week, SE 0.46), and lower mean reduction rates in weeks 2-5 (difference=0.47 points per week, SE 0.09) and weeks 6-12 (difference=0.22 points per week, SE 0.05). Compared with the knee pathway, the back pathway was associated with a higher mean pain reduction rate (difference=3.1 points per week, SE 0.48) in the first week, but the pathway was not a significant variable in later weeks (Figure 1, bottom right).

Figure 1. Longitudinal changes in pain. The panels show the average pain scores computed for the entire study cohort (circles) and the fitted means (lines) computed for weeks 0-12 of the study. Top left shows the overall fitted mean. The plots on the top right, bottom left and bottom right show the means for subjects grouped by completion status, gender, and pathway, respectively. Weekly recorded pain and fitted curves for a random sample of subjects are plotted in gray on each panel. Error bars indicate 1 SE of the mean. F: female; M: male; VAS: visual analog scale for pain.

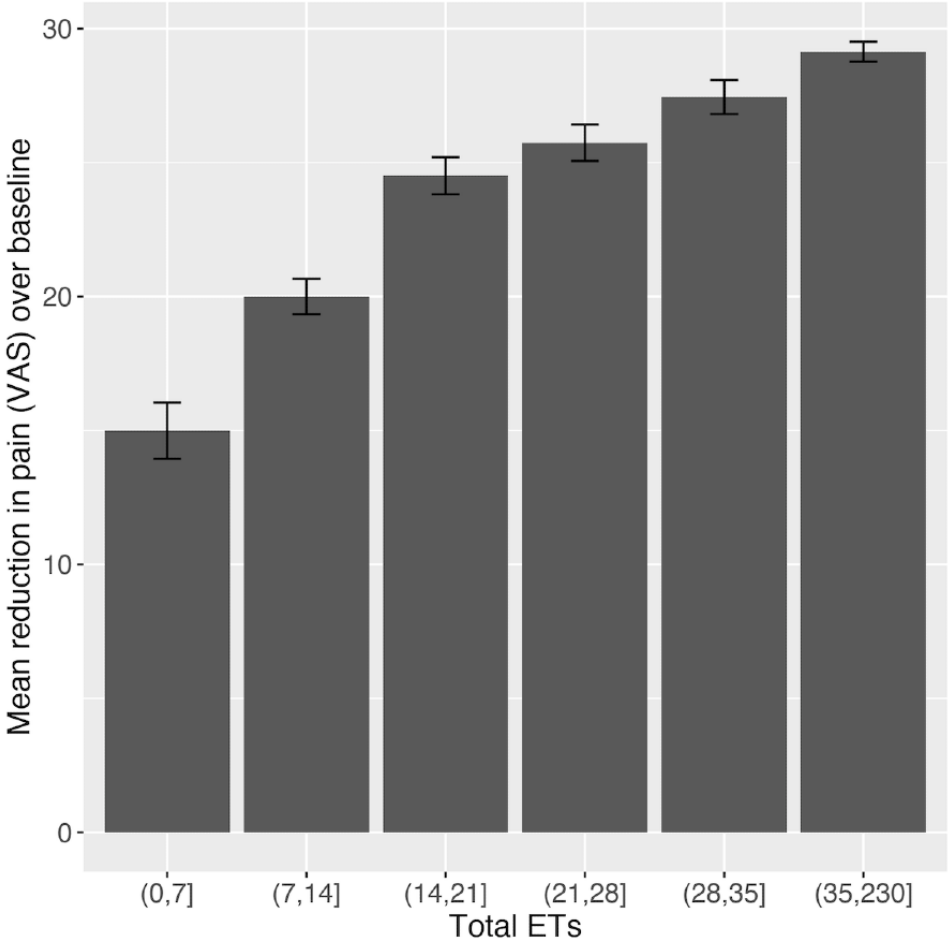


Effect From Engagement

Increasing levels of ET engagement in the DCP were associated with greater reductions in VAS pain score (P<.001; Figure 2). Notably, the relationship between the change in pain score and the number of ET sessions was nonlinear, with initial ET sessions contributing a higher proportion of the mean reduction achieved. The rate of reduction (adjusted for gender, pathway, baseline age, BMI, anxiety, and depression scores) for the initial 10 ET sessions was 1.9 VAS points per session (SE 0.2; P<.001).

The number of weekly coach interactions was also associated with a reduction in pain with a mean reduction of 0.18 VAS points per interaction (SE 0.06; P=.003) for the first 30 interactions. The number of participant-to-coach interactions, specifically, was associated with a mean rate of reduction in pain of 0.30 VAS points per interaction (SE 0.1; P=.003) for the first 20 interactions. The number of coach-to-participant interactions was not significantly associated with pain reduction.

Figure 2. Association between pain reduction and ET sessions. Bar plots show the mean reduction in pain achieved over the DCP grouped by the total number of ET sessions. Error bars indicate 1 SE of the mean. DCP: digital care pathway; ET: exercise therapy; VAS: visual analog scale for pain.



Mental Health and Other Secondary Outcome Measures

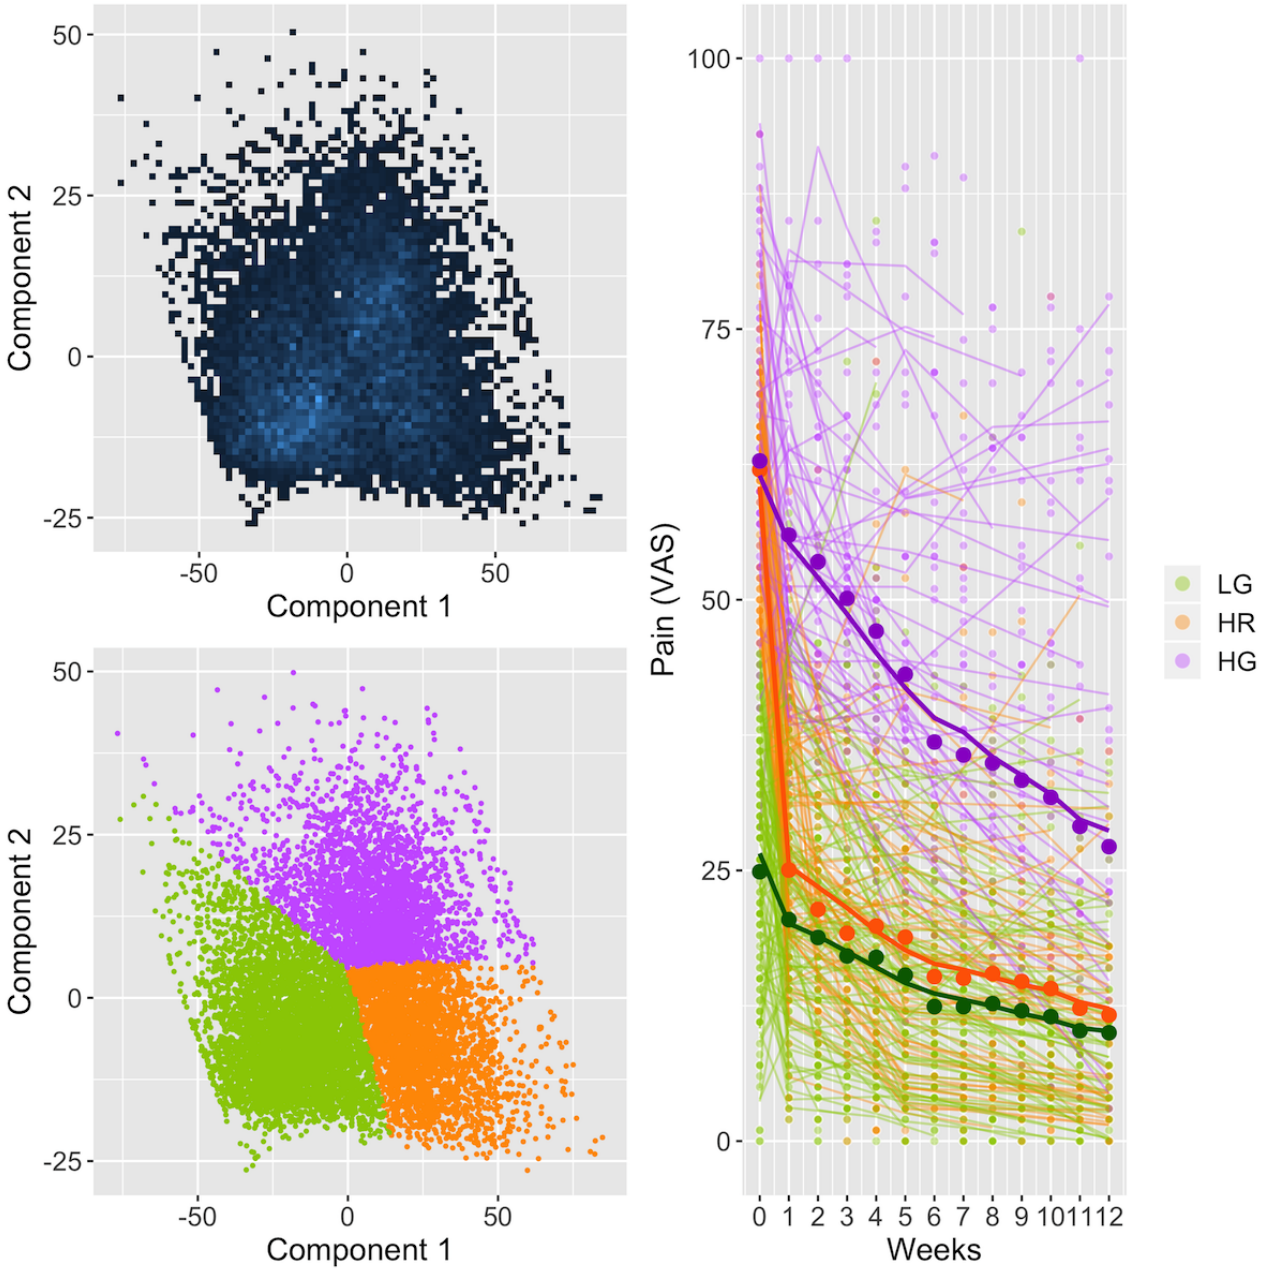
For participants categorized as having depressive symptoms (PHQ-9≥5) at baseline, the mean baseline PHQ-9 score was 12.01 and decreased by 57.9% to 5.05 at week 11 (P<.001). Differences between the pathways were not significant. The percentage of patients with depressive symptoms at baseline and at the end of the study was 21.1% and 11.4%, respectively. For participants categorized as having anxiety symptoms (GAD-7≥5) at baseline, the mean baseline GAD-7 score was 11.49 and decreased by 58.3% to 4.78 at week 11 (P<.001). The back pathway participants had a 0.46 point (P<.001) greater mean GAD-7 reduction than those in the knee pathway. The percentage of patients with anxiety symptoms at baseline and the end of the study was 28.3% and 14.2%, respectively (PHQ-9 and GAD-7 values at week 6 were carried forward to impute missing values at week 12).

With respect to baseline, the mean surgery likelihood score decreased by 67.4% (8.15 points, P<.001) overall, and by 66.8% and 68.2% for knee and back pathway participants, respectively. The mean KOOS—pain decreased by 33.9% (5.19 points, P<.001) in knee pathway participants and the mean MvK decreased by 51.4% (8.20 points, P<.001) in the back pathway participants. The within-participant correlation coefficients for KOOS—pain and MvK scores (with VAS pain) were 0.59 (95% CI 0.58-0.61) and 0.80 (95% CI 0.79, 0.81), respectively, indicating strong correlations between the primary and secondary pain variables. The mean WPAI score decreased by 63.94% from baseline (20.29 points, P<.001). The DCP final satisfaction score was 8.97/10 with a net promoter score of +64/100.

Distinct Pain Response Groups

Intersubject variation in pain reduction trends motivated a subgroup analysis of pain response, and 3 distinct response groups emerged (Figure 3). Participants with high pain at baseline and gradual improvement were designated as *high gradual* (HG). Participants with high baseline pain but a rapid decline were labeled *high rapid* (HR), and those with low baseline pain and gradual response were labeled *low gradual* (LG). All LG participants had baseline pain below 50. HR participants had the highest mean pain reduction over the duration of the DCP (48.8 points, 80.0%), followed by the HG (33.3 points, 54.1%) and LG group (15.3 points, 64.0%).

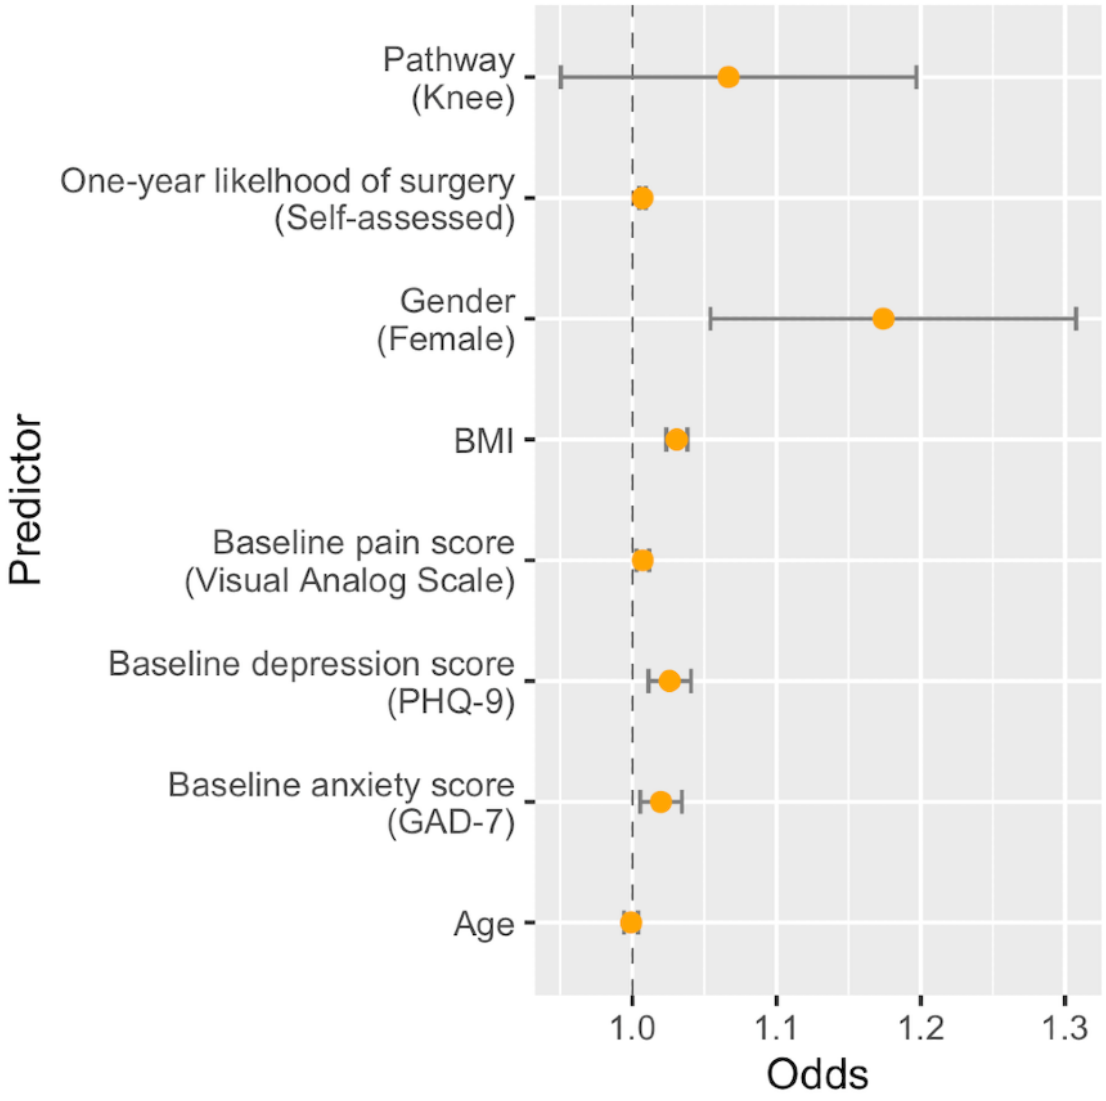
Figure 3. Pain response subgroups. Pain reduction trend clusters obtained by fitting a 3-component GMM identified 3 subgroups (HG, HR, and LG response). (Top left) 2D density plot of the first 2 principal components of the fitted splines shows each of the 3 subgroups. (Bottom left) Curves denoted by their respective principal components 1 and 2 are assigned to a cluster based on maximum posterior likelihood. (Right) Random sample of pain reduction trends colored by subgroup and the respective mean trends. 2D, 2 dimensional; GMM, Gaussian Mixture Model; HG, high-gradual; HR, high-rapid; LG: low-gradual.



Relative to the HR response, female participants had 17.3% (*P*=.002) higher odds of an HG response (Figure 4). The odds of an HG response also increased by 3.1% (*P*<.001) per unit increase in BMI and increased by 2.2% (*P*=.001) and 2.1% (*P*=.002) per unit increase in PHQ-9 and GAD-7, respectively.

Classification of response groups based on baseline attributes achieved a mean accuracy of 76% (SE 0.3%) using a random forest algorithm, evaluated using 5-fold cross-validation. The classifier had a mean area under the precision-recall curve of 68.92% (SE 2.04%). Nearly equal numbers of participants belonged to the HR and HG response groups. Subgroup analysis details are provided in Multimedia Appendix 3.

Figure 4. Association of baseline variables with a high-gradual or high-rapid pain reduction trend. For each baseline variable, the plotted values indicate the odds ratios for a gradual response (with reference to a high-rapid response) for a unit increase in the corresponding predictor. The error bars denote the 95% profile-likelihood CIs.



Discussion

Principal Findings

This study demonstrated the positive effect of a 12-week DCP on chronic musculoskeletal pain outcomes in a large sample of real-world patients. Specifically, participants experienced a 68.5% average improvement in VAS pain between baseline and 12 weeks, and 78.60% (5893/7497) of program completers (7144/10,264, 69.60% of all participants) achieved clinically meaningful improvement. Completion was high, with 73.04% (7497/10,264) of participants reaching the final month, and completers engaged in a mean of 35.0 ET sessions, 19.4 education sessions, and 91.5 coach interactions during the DCP. It is well known that unless a digital health intervention fits into users' daily lives, only a small proportion of all participants who sign up actually complete the program [23,24]. The exceptional completion rate of our study may be due to the multipronged strategy of our DCP that uses both a digital and a human interface to engage with participants. Furthermore, both the number of ET sessions and participant-to-coach interactions were positively associated with improvement in pain, supporting that the level of participant engagement influenced outcomes. These results support the effectiveness of a DCP for musculoskeletal pain in the real-world setting, and the large sample size supports the prospect for scalability to serve a large number of chronic low back and knee pain sufferers worldwide.

Comparison With Literature

The observed 68.5% average improvement in VAS pain in this DCP outperforms the pain reduction effect sizes observed in a variety of conservative care interventions with similar timeframes. For pain associated with knee osteoarthritis, comparable conservative care interventional studies demonstrate an average improvement in VAS pain of 19%-48% [25-28]. For low back pain, comparable studies demonstrate average improvements in VAS pain of 29%-53% [29-34]. Similarly, a systematic review of randomized clinical trials for low back pain showed a within-group standardized mean difference of 1.07 (95% CI 0.87-1.27) for pain reduction at 13 weeks [35], whereas a standardized mean difference of 1.37 (95% CI

1.33-1.40) for pain reduction at 12 weeks was observed in this study. Not only does this study demonstrate greater improvement in pain for both knee and low back pathways but it also has a much larger sample size than previous studies, which typically did not exceed 100 subjects. Furthermore, this study found a strong correlation between changes in VAS pain and secondary pain measures (KOOS—pain for knee and MvK for back), further supporting the validity of the VAS pain measurements. Finally, compared with other studies utilizing therapeutic exercise for chronic pain, this study demonstrated a similar lack of adverse events. This is likely attributable to the benefits and safety of light intensity stretching and strengthening exercises, and in this study may also be due to the exercise guidance provided by the wearable sensors.

Patient Engagement

Notably, most previous studies have occurred in traditional clinical settings, where multiple barriers prevent both patients and clinicians from engaging in conservative care [36]. For example, adherence of chronic low back pain patients to home exercises prescribed from traditional physical therapy ranges from 30% to 50% and remains a significant challenge for administering effective care [37,38]. A primary benefit of a digital care approach for chronic musculoskeletal pain is the ability to engage patients with their treatment and self-management. Smartphone apps can cost-effectively deliver education and encourage healthy behaviors, whereas sensors can provide exercise guidance and track engagement [39]. The DCP in this study engaged 73.04% (7497/10,264) of users to completion, with completers engaging in 10.5 of the 12 weeks, including 3.3 ET sessions, 2.4 education papers, and 7.2 coach interactions per week (mean ET sessions 2.9, mean education sessions 2.2, and 7.0 coach interactions per week among all participants). Notably, this study demonstrated an association between pain improvement and both the number of ET sessions and the number of coach interactions, suggesting that the level of participant engagement impacted the results. Specifically, the first 10 ET sessions and the first 30 coach interactions were the most influential in pain improvement. Of note, a recent study evaluating a DCP in a similar population showed lower engagement and no relationship between exercise and pain reduction, suggesting that specific program implementation details (ie, sensor-guided exercises and health coaching) may have a large effect on outcomes [40].

Mental Health Outcomes

Depression and anxiety are known to often occur in patients with chronic musculoskeletal pain [41], so the effects of this DCP on symptoms of depression and anxiety were also assessed. Behavioral health coaching and education on cognitive behavioral therapy concepts were key elements of the DCP's multimodal digital care approach. A large body of research confirms the effect of psychological factors, such as depression and anxiety, on chronic pain [42,43]. In particular, an association between chronic low back pain and psychological factors has been shown, and related therapeutic approaches, including cognitive behavioral therapy and mindfulness-based stress reduction, have demonstrated effectiveness for back pain reduction [44]. This study showed that outcomes for participants with symptoms of depression and anxiety decreased on average by 57.9% and 58.3%, respectively, over the course of the DCP. This suggests a strong relationship between mental health and pain improvement; however, a causal relationship between these entities cannot be determined. Notably, mental health improvements were very similar across knee and back pathways, whereas a small difference (0.46 points) in GAD-7 outcomes was noted. This is unlikely to be clinically meaningful. Future work will further explore the effect of coaching and other behavioral health support on pain and functional outcomes.

Predicting Pain Response

In addition to clinical effectiveness, another potential benefit of a DCP is the insight gained from longitudinal tracking of outcome data in large populations. The large sample size in this study, combined with data collection at regular and relatively frequent time intervals, enabled the discovery of distinct clusters of pain response trajectories over time. Participants were classified as gradual versus rapid pain responders, and patient-specific features that influenced the likelihood of pain response category were identified. By clustering distinct trends in pain response over time for each subject, we specifically uncovered 3 distinct pain response subgroups. Two groups had high baseline pain but differed in the rate of recovery (rapid vs gradual), whereas the third group had low baseline pain with gradual recovery. Notably, we were able to forecast with 76% accuracy which of these pain response groups a user would fall into based on their baseline information. Looking specifically at the 2 groups with high baseline pain, the rapid response was more likely to occur in male participants, those with lower BMI, or those with lower depression or anxiety scores. These pain response groups enable a better understanding of temporal changes in pain during the rehabilitation process and may ultimately help to identify pain recovery mechanisms. Furthermore, continued research into response patterns may ultimately allow for a more personalized approach to care, including more accurate prognosis and additional treatment options for patients likely to have a more gradual recovery.

Strengths and Limitations

This study has several limitations, including the lack of a control group and the lack of physical function outcomes. Notably, previous randomized trials of this DCP on smaller populations (N<200) demonstrated positive effects on pain and functional outcomes (Oswestry disability index, KOOS—physical function short form) compared with control groups [17,18]. This study assessed outcomes in a sample of more than 10,000 users and demonstrated similar effectiveness. Another limitation of this study is the lack of long-term outcomes, and future studies should assess if participants are able to sustain healthy behaviors and self-management promoted in the DCP. Some potentially important demographic variables (ie, education, ethnicity, income, and smoking status) and medical history variables (ie, diabetes, hypertension, and mental health) were not obtained. Finally, this study was conducted through employers, which limits the applicability to clinical settings with higher proportions of uninsured, elderly, or work-disabled patients. However, this study was conducted with employees from 30 different companies across the United States and included a

wide diversity of job types (eg, truck drivers, manual laborers, office workers), suggesting that the findings are applicable to a broad population. In addition, older patients were more likely to complete the program than younger ones, emphasizing that digital health tools are not only useful to the younger population.

The strengths of this study include the large sample size in the real-world setting, which demonstrated scalability and enabled the discovery of unique features, such as distinct pain response clusters in longitudinal real-world data. In addition, this study had similar age and sex distributions for knee and back pain participants, enabling direct comparison of the separate knee and back pathways. The average pain response for these separate pathways was quite similar (Figure 1), which is notable given the assumed underlying pathological differences between knee and back pain, but supports recent work urging practitioners to move beyond separating body regions when managing chronic musculoskeletal pain [45]. Finally, this study demonstrates significant improvements in self-reported workplace productivity (WPAI, 61.5% improvement) and surgery likelihood (67.4% reduction), suggesting that a DCP may have considerable economic benefits.

Future Directions

DCPs may ultimately be used to complement clinical musculoskeletal practice, and further research is warranted on their use by patients and providers. This study supports the efficacy and scalability of a DCP for facilitating safe conservative care and promoting healthy behavior change. However, critical reviews have identified a lack of external and long-term validation of digital health tools [46]. Many previous studies on digital interventions for chronic low back pain have presented unconvincing results [47]. Given that digital health tools are typically developed in the private sector, and good clinical research can be time-consuming and challenging, we see a need for collaborative efforts between industry and academic medicine to optimize digital health technologies for effective conservative care implementation, adoption, and access in the broad, real-world population with musculoskeletal pain.

Conclusions

This study supports the efficacy and scalability of a DCP for chronic low back and knee pain in a large, real-world population. Participants demonstrated very high completion and engagement rates, and a significant positive relationship between engagement and pain reduction was identified. This is the first longitudinal digital health study to analyze musculoskeletal health outcomes in a sample of this magnitude, and it supports the prospect for DCP scalability to serve the overwhelming number of chronic back and knee pain sufferers worldwide. Furthermore, the large sample size enabled the prediction of rapid versus gradual pain response from baseline information, which may prove beneficial for prognosis and tailoring future interventions.

Acknowledgments

The sponsors of the study, Hinge Health, Inc, facilitated data collection. The sponsor and all authors participated in the decision to submit the paper for publication.

Authors' Contributions

JB, VA, and JK contributed to the study design, analysis plan, interpretation, and manuscript drafting. JB and VA contributed equally with JB leading analysis strategy and interpretation for clinical impact, VA conducting statistical analysis, and each drafting half of the manuscript. MS, PZ, DK, and MF contributed to manuscript drafting and editing. All the authors had access to all the raw data. JB and VA led all data analysis, data interpretation, and writing of the report.

Conflicts of Interest

JB and VA were academic collaborators in this study and were paid as consultants for their expertise in conducting this study. JB and VA had unrestricted access to the data and led the analysis and interpretation of the results. Subsequent to paper completion, author VA became employed at Hinge Health, Inc, and received salary and equity compensation. Author JK is employed at Hinge Health, Inc, and receives salary and equity compensation. MF and DK are clinical advisors to Hinge Health, Inc, and receive equity compensation. Abstract

Background: Research has shown that text-based communication via telemedicine will continue to be a mode of communication that patients and physicians use in the future. However, very few studies have examined patients' perspectives regarding the increased use of text-based communication versus face-to-face (FtF) communication.

Objective: This study aimed to understand and compare the potential differences in patients' perceptions of communication effectiveness with their physicians through different modes of communication.

Methods: We conducted a web-based survey of 345 patients to explore the impact of different channels on effective communication and perceived health behavior and outcomes. We tested the impact of patients' perceived communication and media effectiveness on their self-efficacy, communication satisfaction, and perceived health outcomes, separately for text-based information technology (IT)–mediated communication and FtF communication. Furthermore, we conducted a group comparison to identify significant differences across these 2 groups.

Results: We found no significant differences between patients' perceptions of effective communication using either IT-mediated communication or FtF communication with their physicians. However, we found significant differences in patients' perception of media effectiveness: patients perceived FtF communication to be a more favorable medium (P=.02). Interestingly, we found no significant difference in terms of benefits (P=.09) and success (P=.08) of IT-mediated communication versus FtF communication.

Conclusions: The results of this study imply that patients can achieve the same level of communication effectiveness with their physicians using IT-mediated communication as they would in comparable FtF interactions, but patients view FtF communication to be a more favorable medium than IT-mediated communication.

Introduction

Effective Communication Between Patients and Physicians

Effective communication with physicians is especially important for all patients and specifically for patients with chronic diseases, as these conditions require long-term continuous care [1]. Studies have shown that effective communication facilitates improvements in patients' physical health outcomes, self-care efficacy, and self-care management [2]. According to the Centers for Disease Control and Prevention, 60% of adults in the United States suffer from at least one chronic disease and 40% suffer from two or more. These patients account for 90%

of the US $3.3 trillion annual health care costs. Managing the symptoms of chronic disease can help to reduce these costs significantly.

In recent years, patients' and providers' use of technology has been gaining more prevalence as patients communicate more regularly with their physicians using technology [3] and an emphasis has been placed on telemedicine. According to a report by the American College of Surgeons [4], physicians no longer make house calls, and for a growing number of patients, text messaging and telemedicine have become alternatives to phone calls and traditional office visits. Several studies have shown patients' use of email, patient portals, and secure messaging to communicate with their physicians [5]. Research has also examined how information technology (IT)–mediated communication among patients with chronic disease can improve their health outcomes [6,7] and how media differ in effectiveness according to the communication process for which they are used (eg, scheduling an appointment and discussing acute symptoms). However, few studies have examined if patients' perceptions of communication effectiveness differ between IT-mediated communication and face-to-face (FtF) communication. Existing research mainly examined differences between FtF communication and video and voice communication [8-10]. Research about patients' perceptions of text-based IT-mediated communication is limited. Therefore, it is unclear if patients perceive the quality of care that is delivered FtF differently from text-based communication. As text-based IT-mediated communication is gaining more popularity [11], it is imperative to investigate how it impacts effective patient-physician communication. This gap in the literature creates an opportunity for health IT scholars to understand patients' perspectives regarding the effectiveness of text-based IT-mediated communication. Thus, we examine if patients' perceptions of communication effectiveness differ for FtF communication versus text-based IT-mediated communication.

Effective patient-physician communication is also an important factor in patient satisfaction, self-care efficacy, and perceived health management outcomes. Patients who experience effective communication with providers report greater satisfaction [12], self-care efficacy [13], and perceived health management outcomes [14]. These outcomes of effective communication are important, as patients who manage their health can improve their quality of life and reduce health care costs. Therefore, we also examine how perceptions of communication effectiveness facilitate patient satisfaction, self-care efficacy, and health management outcomes.

To date, researchers have studied the design, adoption, and use of information systems in health care extensively from the organizational and health provider perspective. However, there is paucity in understanding how the use of these emerging technologies can be compared with the use of traditional FtF models of care among patients. As effective communication can improve the quality of care for patients by empowering their self-care efficacy and health management, it is critical to understand patients' perceptions of effective communication using different channels and how it impacts their satisfaction, self-care efficacy, and health management outcomes. This study begins by reviewing relevant communication theory and health communication literature to understand the role that media play in patients' perceptions of effective communication. Next, it presents 2 competing models of effective communication, followed by the details and results of a national cross-sectional survey that tested them.

Background

IT-mediated communication has the potential to improve cost-effectiveness, quality, and accessibility of health care services [15-18]. Several studies have reported on telemedicine and telehealth in terms of its acceptance [19,20], adoption [21-23], compliance [24], quality [25], and trust [26]. Yet, it is unclear how the quality of patient-physician interactions differs between traditional FtF interactions and text-based interactions. Most research that has examined differences in FtF interactions and IT-mediated interactions has compared video and phone consultations with FtF consultations among healthy patients. For instance, research has shown that simulated patients who either had video or FtF consultations with medical interns did not experience differences in satisfaction, perceived information exchange, interpersonal relationship building, or perceived shared decision making [9]. Similarly, patients who received an FtF, a phone, or a video consultation reported no differences in distress levels after the consultation [27]. Moreover, small samples of patients who were screened for neurocognitive problems (N=8) or took part in cognitive interventions for the elderly (N=11) using video consultations or FtF consultations experienced no differences in cognitive or diagnostic outcomes [28,29], respectively, although communication effectiveness was not assessed. The literature is promising and suggests that there are no significant differences in the quality of care that is delivered using FtF, video, or phone consultations. At the same time, it is unclear if the same results would hold when comparing text-based channels and FtF communication among patients with chronic diseases who require regular communication with their providers and use text-based communication with their providers [3].

Cues-Filtered-In and Cues-Filtered-Out Perspectives

Frameworks that are useful for understanding the differences in communication effectiveness between FtF communication and IT-mediated communication are the cues-filtered-out and the cues-filtered-in perspectives. The cues-filtered-out perspective [30] assumes that IT-mediated communication hinders effective communication because of its reduced nonverbal cues (gestures, smiles, pats on the back, nods to show attentiveness, and eye contact), in comparison with channels that offer the transmission of more nonverbal cues such as the phone, videoconferencing, and FtF communication. A systematic review has shown the importance of nonverbal cues in patient-provider interaction in that when doctors make appropriate eye contact, do not interrupt patients, or pay attention to patients' nonverbal signals, patients' objective (eg, blood pressure) and subjective (eg, pain scores) health care outcomes improve [2]. The cues-filtered-out perspective echoes concerns about the use of telemedicine, such as the depersonalization of care, lack of physical presence, inhibition

of patient participation, and physician dominance of the medical encounter [31].

One theory that falls in the cues-filtered-out perspective is the social presence theory [32]. This theory posits that media differ in their capacity to transmit nonverbal and verbal information; therefore, the less cues a medium can transmit, the less warmth and involvement patients and providers experience with one another. Indeed, a systematic review about patients' experiences with remote monitoring for chronic conditions showed that patients view remote monitoring as jeopardizing interpersonal connections with their providers and do not want remote monitoring to replace FtF interactions [33]. Similarly, patients have reported missing FtF interaction with their providers when they receive telemedicine [34]. The abovementioned research suggests that patients experience less connection with their providers via telemedicine and do not want telemedicine to replace FtF communication. These results are in line with the cues-filtered-out perspective. Research has yet to show these same findings among text-based IT-mediated communication.

The cues-filtered-out perspective is in contrast to the cues-filtered-in perspective. In light of inconsistent findings for the cues-filtered-out perspective, a competing theory of social information processing was developed [35], thus creating the cues-filtered-in perspective. The cues-filtered-in perspective assumes that people adapt to the medium to achieve effective communication, regardless of the number of cues a medium transmits. This theory posits that patients and providers using IT-mediated communication can achieve the same outcomes as FtF communication, if interaction time is not restricted. Per the social information processing theory, patients and providers will use more verbal cues to achieve quality interactions and to exchange the same amount of information as they would if they were communicating FtF. In line with the social information processing theory, research has shown that simulated patients who used video, phone, or FtF communication with medical students in medical consultations reported no differences in patient satisfaction, information exchange, interpersonal relationship building, or shared decision making [9]. Similarly, patients who used either FtF communication or a video consultation with their physicians reported no differences in their physician's ability to develop rapport, use shared decision making, and/or promote patient-centered communication [31]. The abovementioned research suggests that patients do not perceive significant differences in communication using the phone, video, or FtF medical consultations, which is in line with the cues-filtered-in perspective. At the same time, research has yet to show this empirically among text-based IT-mediated communication.

Communication Effectiveness, Satisfaction, Self-Care Efficacy, and Health Management Outcomes

In addition to examining differences in patients' perceptions of communication effectiveness, this study also examines differences in patient satisfaction, self-care efficacy, and health management. Effective patient-physician communication is an important factor in patient satisfaction. A large-scale intervention has shown that communication skills training for 1537 physicians improved patients' satisfaction with provider communication [12]. At the same time, a systematic review of studies about patient satisfaction with interactive video consultations revealed mixed feelings about video consultations: Patients appreciate the accessibility of expert care, less travel, and reduced waiting times, but patients do not like communicating with their provider using video consultations [36]. Notably, this result is the opposite of the aforementioned studies that found that patients reported no differences in patient satisfaction when they used video, phone, or FtF communication in medical consultations with providers [9,31]. This research aimed to address these mixed results and advance the understanding regarding patients' perceptions of satisfaction.

Communication effectiveness is also important for self-care efficacy and health management. Patients who experience effective communication with providers (eg, feel listened to, respected, and that their provider explains things clearly) are more motivated to take care of themselves. Similarly, patients who have quality relationships with their providers (eg, "My provider listens carefully to me" and "It is easy to communicate with my provider") report greater levels of self-care efficacy and health care management [2,13]. Indeed, patients who have diabetes and effective provider communication report greater insulin adherence [37] and glycemic control [14]. We investigated the impact of communication effectiveness on patient satisfaction, self-care efficacy, and health management.

Methods

Research Model and Construct Development

To examine the differences in patients' perceptions of FtF communication and IT-mediated communication, we apply 2 competing perspectives to advance the understanding regarding the impact of patients' perceptions of effective communication and its impact on patient satisfaction, self-care efficacy, and health management outcomes. Per the cues-filtered-in perspective, patients should experience no differences in effective communication using IT-mediated communication (vs FtF communication) with their physicians, and, in turn, patients should report no differences in positive relationships between effective communication and self-care efficacy (H1A=H1B), effective communication and patient satisfaction (H2A=H2B), and effective communication and health management outcomes (H3A=H3B) using IT-mediated communication (vs FtF communication) with their physicians. Conversely, per the cues-filtered-out perspective, patients should experience more effective communication using FtF communication (vs IT-mediated communication) with their physicians, and, in turn, patients should report stronger positive relationships between effective communication and self-care efficacy (H1A<H1B), effective communication and patient satisfaction (H2A<H2B), and effective communication and health management outcomes (H3A<H3B) using FtF communication (vs IT-mediated communication) with their physicians.

Another important aspect of effective communication with providers is patients' perception of media effectiveness. Media effectiveness refers to the degree to which patients perceive that a specific medium helps them accomplish their communication

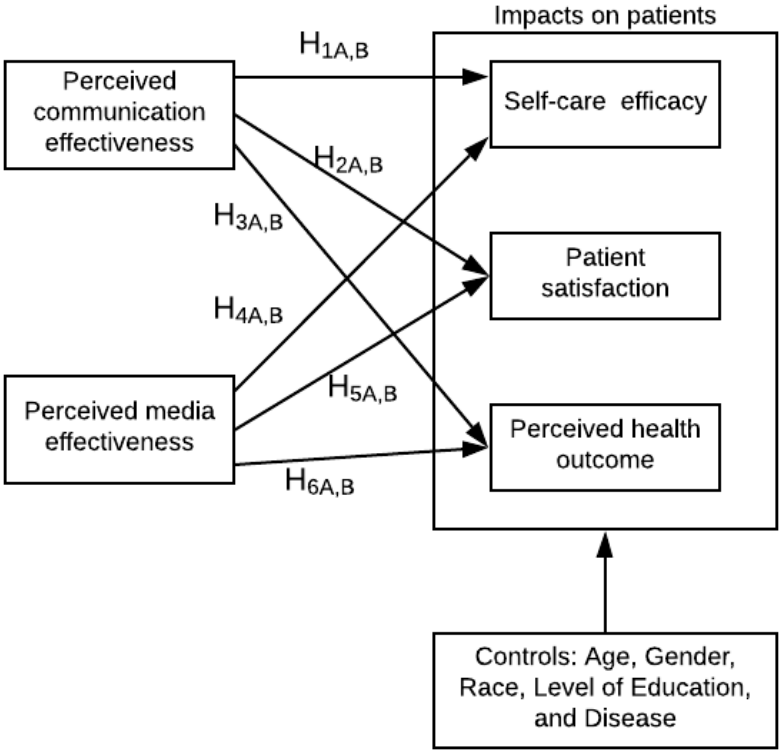
goal. Media effectiveness is operationalized using the same scale as communication effectiveness (eg, unsuccessful to successful, inefficient to efficient, and inappropriate to appropriate). However, we rephrased the questions to ask how effective the mode of communication is (media effectiveness), rather than how effective the interaction with one's provider is (communication effectiveness). As such, we are using this construct to separate *communication effectiveness with providers* from *communication effectiveness with a communication mode* to aid understanding about patients' perceptions of communication effectiveness with their providers using different media. Patients might describe interactions with their physicians as effective because they accomplish their communication goals, but they might not describe the mode of communication they used with their physician as effective because they might have preferred to use another mode of communication. Thus, we are attempting to differentiate between the different aspects of patients' perceived communication effectiveness (PCE) by parsing media effectiveness from communication effectiveness.

A similar concept to media effectiveness is media richness or a medium's capacity to facilitate shared understanding, as a rich medium facilitates insight and rapid understanding [38]. The media richness theory [39] operationalizes media richness based on objective characteristics of the medium, such as the speed of feedback, personal focus, the number of cues, and the ability to use natural language. As defined, media richness does not account for patients' perceptions of media effectiveness because it refers to intrinsic characteristics of a medium. As such, we are using the media effectiveness construct to understand any differences between patients' perceptions of communication effectiveness with providers, rather than the media richness construct.

The cues-filtered-out and cues-filtered-in perspectives offer 2 competing predictions for differences in perceived media effectiveness in physician interactions. Per the cues-filtered-in framework, patients should experience no differences in media effectiveness using IT-mediated communication (vs FtF communication) with their physicians, and, in turn, patients should report no differences in positive relationships between media effectiveness and self-care efficacy (H4A=H4B), media effectiveness and patient satisfaction (H5A=H5B), and media effectiveness and health management outcomes (H6A=H6B) using IT-mediated communication (vs FtF communication) with their physicians. Conversely, per the cues-filtered-out framework, patients should experience greater media effectiveness using FtF communication (vs IT-mediated communication) with their physicians, and, in turn, patients should report stronger positive relationships between media effectiveness and self-care efficacy (H4A<H4B), media effectiveness and patient satisfaction (H5A<H5B), and media effectiveness and health management outcomes (H6A<H6B) using FtF communication (vs IT-mediated communication) with their physicians.

To investigate these competing predictions, we first test the proposed model (Figure 1) separately for text-based IT-mediated communication (group A) and FtF communication (group B). Then, we compare the coefficients of PCE and perceived media effectiveness between the 2 groups in the Results section.

Figure 1. Effective communication comparison (face-to-face communication vs text-based information technology–mediated communication).



Data Collection

We designed and used a web-based questionnaire to survey a national sample of patients. To collect the data, we hired Qualtrics Panels. Qualtrics Panels is a market research company in the United States that partners with more than 20 sample providers to supply a network of diverse, quality respondents across the country. We used quota-based sampling to recruit approximately equal sample sizes of participants who communicated with their physician using text-based IT communication and FtF communication. Eligibility criteria included being aged at least 18 years, being located in the United States, and having engaged in communication with their physician in the previous month. Eligible participants in Qualtrics' panel were sent an incentivized invitation with the study link in various ways, such as email, a panel portal, and text messages. Participants were first presented with an informed consent document. After agreeing to participate, they began the survey questions. Qualtrics determines the monetary incentives for taking the survey, such as cash, gift cards, and vouchers. To avoid self-selection bias, survey invitations do not include specific details about the content of the survey and are kept very general. We ensured to use neutral wordings to develop the survey and used the semantic scale to avoid any common method bias. We found that none of the correlation values among the constructs exceed 0.90 [40]. Correlation matrix is provided in Multimedia Appendix 1.

Results

Characteristics of Participants

In total, 349 participants completed the survey, from which we used 345 complete usable responses. Participants' ages ranged from 35 to 85 years (mean 63, SD 9), and 45.2% (156/345) participants were male. A screening requirement of the survey was that all participants have been regularly communicating with their primary care physician over the past month. Of the 345 participants, 86 (24.9%) reported having diabetes, 69 (20.0%) reported arthritis, 52 (15.0%) reported heart disease, 34 (9.8%) reported pulmonary diseases, 28 (8.1%) reported psychiatric disorder, 17 (4.9%) reported hypertension, 17 (4.9%) reported chronic inflammatory disease, 16 (4.6%) reported thyroid, 12 (3.5%) reported immune system disorder, 7 (2.0%) reported hypertension, and 7 (2.0%) reported renal disease. For the most frequent mode of communication with physicians, of the 345, participants 134 (38.8%) reported FtF communication, whereas 211 (61.1%) participants reported the use of technology, including 152 (44.0%) patient portals, 121 (35.0%) email, and 72 (20.8%) text messaging. Of the 345 respondents, 45 (13.0%) participants completed a 2-year degree, 69 (20.0%) participants completed a 4-year degree, 72 (20.8%) participants earned a professional degree, and 145 (42.0%) participants attended some college.

Measurement Model

We used R software (R Project for Statistical Computing) and the Lavaan package to analyze the data. To test the proposed model (Figure 1), we measured PCE using 11 bipolar semantic differential scales [41]. Example items include insufficient/sufficient, adverse/beneficial, inadequate/adequate, unsuccessful/successful, useless/useful, disadvantageous/advantageous, and inefficient/efficient. We used the same scales to measure perceived media effectiveness. For the outcome variables including patient satisfaction, self-care efficacy, and perceived health management outcomes, we adapted survey questions from previous studies and used a semantic scale ranging from 1 (strongly disagree) to 5 (strongly agree) to measure each construct. The measurement properties of each construct are reported in Table 1.

Table 1. Psychometric properties of measurement model.

Constructs	Description	Number of items	Cronbach alpha	Average variance extracted	Source
Perceived media effectiveness	Patients' perception of medium's capacity to facilitate shared understanding	10	.94	0.83	Spitzberg [41]
Perceived communication effectiveness	The degree to which patients accomplished their communication goal	10	.95	0.84	Spitzberg [41]
Patient satisfaction	The degree to which patients experienced interest, accomplishment, and overall satisfaction in conversation with their provider	5	.93	0.82	Hecht [42]
Self-care efficacy	The degree to which the patients feel confident in managing their own care	7	.87	0.70	Plotnikoff et al [43]
Perceived health outcome	Patients' expectations of positive physical and self-evaluative outcomes	4	.91	0.72	Anderson et al [44]

We compared the proposed model for 2 groups based on the respondent's most frequent mode of communication with their physicians: group A (IT-mediated communication) versus group B (FtF communication). Following the common criteria

suggested in the literature [45,46], we examined the composite reliabilities of each construct and average variance extracted to ensure that the instrument had adequate reliability and convergent validity. Table 1 presents these statistics.

Hypothesis Testing

To evaluate the model's fit, we developed a structural equation model and tested for multigroup comparison while controlling for age, gender, race, the level of education, and the type of disease of the respondents. The results are presented in Table 2. To compare the 2 groups, we calculated a separate model for each group. If we assume that the residual values from the 2 models are normally distributed, we can test the hypothesis that the coefficient of PCE in group A is equal to the same coefficient in group B (ie, $beta_{PCE(A)}=beta_{PCE(B)}$) versus the alternative that they are unequal. The test statistic follows the Student t distribution [44] with v degrees of freedom where $v=n_1+n_2-4$ (n_1: sample size of group A and n_2: sample size of group B). The results of the group comparison analysis are presented in Table 3.

Table 2. Results for information technology–mediated communication and face-to-face communication groups.

Dependent and independent variables	Group A: information technology–mediated communication			Group B: face-to-face communication

H6A versus H6B	2.093 (333)	.04

[a]A: information technology–mediated group.

[b]B: face-to-face group.

The results showed that among both groups, PCE and perceived media effectiveness had a significant positive impact on patients' self-efficacy (H1A, H1B, H4A and H4B), patient satisfaction (H2A, H2B, H5A and H5B), and perceived health management outcomes (H3A, H3B, H6A and H6B). The data also revealed that there is no significant difference in PCE between FtF communication and IT-mediated communication, yet there is a significant difference between the 2 groups in terms of perceived media effectiveness. Patients perceive FtF

communication to be more effective in improving their self-efficacy than IT-mediated communication.

Additional results found that both PCE and media effectiveness have a significant impact on improving patients' satisfaction. There is also a significant difference in the impact of PCE and media effectiveness on patient satisfaction. The impact of communication effectiveness and media effectiveness on patient satisfaction is significantly higher for FtF communication in comparison with IT-mediated communication.

Furthermore, the results revealed that PCE and media effectiveness significantly improved patients' perceived health outcomes. Interestingly, there is no significant difference in the impact of PCE on perceived health outcomes across groups. However, there is a significant difference in the impact of perceived media effectiveness on perceived health outcomes. Patients who communicate FtF revealed a significantly higher association between media effectiveness and perceived health outcomes.

To further understand the differences in PCE and perceived media effectiveness, we compared the IT-mediated group A's and the FtF communication group B's responses for each scale item using *t* tests. We found no significant difference between FtF communication and IT-mediated communication groups in items that form PCE. We did, however, find significant differences between FtF communication and IT-mediated communication groups in items that formed perceived media effectiveness. There were significant differences in perceptions of media effectiveness in terms of sufficiency, adequacy, advantage, favorableness, and suitability. Patients who primarily used FtF communication (vs IT-mediated communication) assigned significantly higher scores to the abovementioned items but assigned no significant difference between the 2 groups in terms of media appropriateness, benefit, success, usefulness, and efficiency. The test results are presented in Table 4.

Table 4. Group comparison for perceived communication effectiveness and perceived media effectiveness.

Semantic scale	Perceived communication effectiveness		Perceived media effectiveness	
	t value (*df*)	*P* value	*t* value (*df*)	*P* value
Inappropriate: appropriate	−0.53 (333)	.598	−1.24 (333)	.21
Insufficient: sufficient	−0.25 (333)	.80	−2.62 (333)	.01
Adverse: beneficial	−0.97 (333)	.33	−1.70 (333)	.09
Inadequate: adequate	−1.11 (333)	.27	−3.23 (333)	.001
Unsuccessful: successful	−0.63 (333)	.53	−1.74 (333)	.08
Useless: useful	−1.07 (333)	.29	−1.76 (333)	.08
Disadvantageous: advantageous	−0.03 (333)	.98	−2.47 (333)	.01
Unfavorable: favorable	−1.18 (333)	.24	−2.43 (333)	.01
Inefficient: efficient	−0.50 (333)	.62	−1.47 (333)	.14
Unsuitable: suitable	−0.91 (333)	.37	−2.58 (333)	.01

Discussion

Theoretical Implications

In this study, we applied competing approaches to advance the understanding regarding patients' perceptions of effective communication with their primary care physicians. In a national sample of patients with chronic diseases, we compared patients' perceptions of effective communication with their provider using either text-based IT-mediated communication (email, patient portal, and messaging) or FtF communication. The primary results revealed no significant differences between patients' perceptions of effective communication using either IT-mediated communication or FtF communication, which is in line with the cues-filtered-in perspective. Interestingly, at a more granular level, patients perceived FtF communication to be a more favorable medium than IT-mediated communication, which is in line with the cues-filtered-out perspective. As a result, differences in perceived media effectiveness impacted differences in patients' self-care efficacy, satisfaction, and perceived health management outcomes between patients who used either FtF communication or IT-mediated communication with their physicians. The results imply that patients can achieve the same level of communication effectiveness with their physicians using IT-mediated communication as they would in comparable FtF interactions, but patients view FtF communication to be a more favorable medium than IT-mediated communication.

The results are promising as they show that as patients increasingly use different forms of IT-mediated communication, such as patient portals, email, and text messaging, to communicate with their physicians, patients will continue to adapt to the medium and achieve the same level of effectiveness, satisfaction, self-care efficacy, and health care outcomes as they would in comparable FtF interactions with their physicians. At the same time, the data show that although patients report no differences in effective communication with their physicians using IT-mediated communication or FtF communication, patients report FtF communication as a more effective mode of communication relative to IT-mediated communication. In turn, the positive relationships between media effectiveness and self-care efficacy, patient satisfaction, and perceived health

management were stronger for patients who used FtF communication.

Practical Implications

The results of this study are consistent with previous research that has shown that patients generally describe their experience with telehealth positively, yet they still value their FtF contact with health care professionals [32,33]. Patients with chronic diseases have reported many benefits of IT-mediated communication, such as improved self-management, shared decision making, better access to health care, and peace of mind. However, these potential benefits are often balanced against concerns about losing interpersonal contact. Patients often view IT-mediated communication as jeopardizing interpersonal connections with their providers and an unsuitable replacement for FtF interactions. These concerns are evident in the data, as further exploration of the underlying items that led to differences in perceived media effectiveness between FtF communication and IT-mediated communication showed that patients perceived FtF communication as a significantly more sufficient, adequate, advantageous, and favorable medium than IT-mediated communication. Notably, there were no other significant differences between FtF communication and IT-mediated communication in semantic scales that patients used to describe media effectiveness such as usefulness, success, appropriateness, and beneficial. These results suggest that patients perceive IT-mediated communication to be an effective medium for accomplishing communication goals with physicians (eg, share blood pressure data and make an appointment), but they prefer FtF communication and view it as a more suitable and favorable medium.

These mixed findings often lead researchers to infer that the sustained use of IT-mediated communication will be ensured with occasional FtF visits to physicians [47]. Nonetheless, these findings suggest a fundamental difference in how researchers and practitioners should approach patients' adoption and use of telemedicine. More research needs to be done to shift the focus from examining the usefulness of the technology to examining how best to educate users to use the technology to improve relationships with physicians. Telemedicine holds great potential for reducing the variability of diagnoses as well as improving clinical management and delivery of health care services by enhancing access, quality, efficiency, and cost-effectiveness [48,49]. Furthermore, evidence points to important socioeconomic benefits to patients, families, health practitioners, and the health system, including enhanced patient-physician communication opportunities [50]. IT-mediated communication has yet to be consistently employed in the health care system to deliver routine services. Creating effective relationships between patients with chronic diseases and physicians is important. When patients and physicians work together to determine optimal treatment plans in a value-centered manner, this significantly improves patients' confidence in self-care, satisfaction, and self-care management. These improvements can happen through text-based IT-mediated communication [24]. However, there is a need to educate patients about the effectiveness of IT-mediated communication. Managerial multidisciplinary efforts that draw expertise from communication sciences, health informatics and IT, public health, and health management and policy are required to ensure that telemedicine and electronic health systems are designed with a patient-centered focus and with attention to educating patients about how to use text-based technology to communicate with their physicians. Patient-physician communication will continue to evolve with time, both as a byproduct of technological advances as well as shifting societal values. In urban or developed areas, hospital beds are mainly occupied by patients with chronic diseases, decreasing bed availability for other patients in need. Recently, Centers for Medicare and Medicaid Services published a proposal for the management of patients with chronic illness that would allow physicians to be paid for non-FtF encounters. The realization of these innovative initiatives calls for changing the provider culture and workflow systems to allow the full incorporation of telemedicine into traditional care. Furthermore, patients need to be educated about how to interact with and use these technologies to communicate effectively with their providers and to manage their own care.

Conclusions

In this study, we investigated differences in patients' perceptions of IT-mediated communication and FtF communication. The results support that there is no significant difference in effective communication for using technology versus FtF communication. However, patients perceive FtF communication as a significantly more favorable, suitable, and sufficient medium in comparison with IT-mediated communication. More research about how to educate patients to use technology and how to use technology to improve relationships with physicians is needed.

Abstract

Background: Initiation of insulin therapy for the management of type 2 diabetes can be an unwelcome and distressful development for patients. Current evidence suggests that telemonitoring can help improve glycemic control in type 2 diabetes and can support empowerment to self-manage diabetes. This telemonitoring intervention was underpinned by an empowerment approach.

Objective: This study aimed to evaluate the clinical effectiveness and feasibility and the patients' and health care providers' experiences of a 12-week telemonitoring intervention with telephone support for patients commencing insulin therapy. This paper focuses on the impact on patient empowerment.

Methods: An observational, pre-post, multimethod, and triangulation design was employed to study a 12-week automated electronic telemonitoring intervention with telephone support from a diabetes clinical nurse specialist (CNS). Forty patients were recruited from the clinic as they were about to commence insulin therapy. In the quantitative arm, biometric data (hemoglobin A_{1c} [HbA_{1c}] and weight) and psychosocial data (diabetes empowerment scale [DES] scores and diabetes distress scale [DDS] scores) were gathered by the research team at baseline (T1), the end of the intervention (T2), and 3 months postintervention (T3). Data on hospital admission and general practitioner (GP) visits were collected for the duration of the study. In the qualitative arm, separate focus group interviews were conducted with the CNS team supporting the intervention (n=2) and patients (n=16).

Results: Of 39 patients who completed the intervention, 23 (59%) were male. The mean age of the sample was 62.4 years (range 37-80 years). The mean HbA_{1c} (mmol/mol) decreased significantly between T1 and T2 (mean difference [MD] −17.13; *P*<.001) and T1 and T3 (MD −18.16; *P*<.001), with no significant impact on weight. In the focus groups, patients reported an increased awareness to self-manage diabetes and feelings of safety and comfort. There were 13% (5/39) of patients who had hypoglycemia on two or more occasions. A significant increase in the mean DES score occurred between T1 and T2 (MD 0.62; *P*=.001) and T1 and T3 (MD 0.72; *P*<.001). The mean DDS score decreased between T1 and T2 (MD −0.64; *P*=.002) and T1 and T3 (MD −0.6; *P*=.002). The mean patient satisfaction with the intervention was above 4 out of possible 5 on all items on the Telemedicine Satisfaction and Usefulness Questionnaire. We observed a reduction in diabetes clinic attendances and GP visits. A significant increase in workload was reported by the CNS team.

Conclusions: This intervention had an empowering effect for patients in the self-management of type 2 diabetes and has the potential to meet the need for safer and more effective care in insulin initiation in the community setting. We observed a significant

increase in workload for health care staff. Telemonitoring needs to be streamlined with health care delivery and accompanied by adequate support services.

Introduction

Background

The goal of diabetes treatment is optimal glycemic control and prevention of complications. International guidelines recommend the initiation of insulin when people with type 2 diabetes have signs and symptoms of acute decompensation that are no longer controlled by oral hypoglycemic drugs and lifestyle [1]. Insulin initiation is often delayed, and once started, achieving optimal doses requires a frequent scheduled review of blood glucose levels and individualized dose titration [2]. The failure to commence and intensify treatment is termed *clinical inertia* and is a considerable problem in primary care practice [3]. There are multiple barriers to optimal insulin treatment in primary care at the patient and practitioner levels, and there is a need for interventions to improve self-management support and integrated insulin support systems [4].

Once insulin is commenced, many patients are not followed up until the next clinic appointment, resulting in delays in achieving the optimal insulin dosage [5]. The barriers to initiating insulin include misconceptions about insulin, perceived difficulty in management for both physicians and patients, and risk of hypoglycemia and weight gain [6]. Lack of time is a common health care system–related barrier to insulin initiation [5]. Starting insulin is stressful for patients, and providing adequate support and monitoring during this process can present challenges for health care providers, particularly in between health care visits [7]. The safe and effective transition to insulin therapy requires health care providers to examine alternative ways of empowering the patient in self-management.

Empowerment can be viewed as both a process and an outcome [8]. It can be viewed as a process when an intervention aims to equip patients and their families with the self-awareness, autonomy, knowledge, and skills to become *comanagers* of their condition in partnership with health professionals. The desired outcome is enhanced confidence and skills to manage the physical, emotional, and social impacts of diabetes in their daily lives. Patients who feel empowered by their health care practitioner develop a greater sense of self-control, which may lead to better glycemic control [9]. Positive effects of telemonitoring include patient empowerment to self-manage [10] healthy coping and problem solving [11], and improved practitioner-patient relationships and patient engagement have also been reported [10-13].

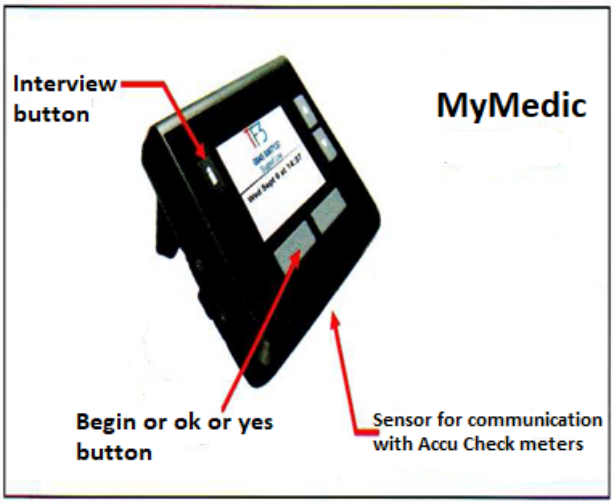
A review by Risling et al [14] found that the consistent lack of conceptual clarity on what constitutes empowerment in the electronic health (eHealth) context means that evaluating patient empowerment associated with eHealth technology is challenging. More recently, Risling et al [15] found that patients in a digital study identified the relational and informational elements of empowerment and recommended that these key areas should shape the focus of the evolution of patient empowerment in digital research. Telemonitoring has been found to be effective as a confidence, decision-making, and self-care enhancer in older persons with chronic heart failure [16,17]. Telemonitoring surveillance systems have left patients with feelings of greater self-control, heightened motivation for lifestyle changes, and improved quality of life [18].

Aims

This study sought to implement and evaluate telemonitoring with telephone support in a real-world setting using an observational, pre-post, mixed methods design in a cohort of patients who were about to commence insulin therapy. A MyMedic hub (Figure 1) was placed in the patients' home for 12 weeks. The patients recorded their blood glucose readings as normal, and at the times agreed, they sent their blood glucose readings to a monitoring center using the hub. The schedule for upload was agreed between the diabetes team and the patients, and the hub unit prompted the individual to upload their readings as agreed. The team reviewed the blood glucose results and contacted the participant, if necessary, to seek additional information on their symptoms and well-being. Insulin was adjusted according to need via telephone discussions using an insulin adjustment plan.

This paper aimed to describe the impact on hemoglobin A_{1c} (HbA_{1c}), hypoglycemic events, patient empowerment, diabetes distress, and satisfaction with telemonitoring from the patients' perspective. In addition, the experience of using telemonitoring to facilitate the transition to insulin therapy was explored from the perspective of the diabetes team and health care organization.

Figure 1. MyMedic hub.



Methods

Study Design

An observational, pre-post, multimethod, triangulation design was used to evaluate the feasibility, clinical effectiveness, and resource implications of telemonitoring support for patients commencing insulin therapy in the real-world setting. The design was underpinned by an empowerment philosophy. The mixed methods approach allowed for a holistic overview of using telemonitoring in diabetes care, generating physiological data and exploring receptiveness of technology and the core aspects of empowerment.

Population

To be eligible for inclusion in the study, patients had to be aged older than 18 years with type 2 diabetes and commencing with insulin therapy. Patients with a score below 4 on the clock drawing test were excluded, as this indicates the cognitive inability to self-manage insulin [19]. The patients were recruited by the clinical nurse specialist (CNS) team from hospitals and community-based diabetes clinics in the Northwest of Ireland. The sample size was determined by cost, available time of the CNS to support, telemonitoring equipment, and timeline for the feasibility study resources to provide the intervention. The project team determined that 40 patients would be enough to yield useful data and be achievable within the available resources to fund the project.

Sample

Convenience sampling was used. When the decision to commence a patient on insulin was made, the CNS invited them to participate in the study. One participant chose to discontinue from the study after 1 week because of the problems experienced with connectivity. The recruitment took place from April 2016 to June 2017.

Intervention

Following recruitment and consent, the patients were commenced on insulin therapy and provided with the telemonitoring system in addition to standard care. Standard care of this cohort includes telephone calls with the CNS with visits to the diabetes clinic as needed to collate blood glucose readings and to adjust insulin levels once a week.

A MyMedic hub (Figure 1) was placed in the patients' home for 12 weeks by a telecare support officer from Fold TeleCare who was contracted to provide the monitoring on behalf of the Health Service Executive (HSE), Ireland. The telecare support officer who installed the hub in the home taught the patients how to send their readings and gave instructions about what to do if anything did not work.

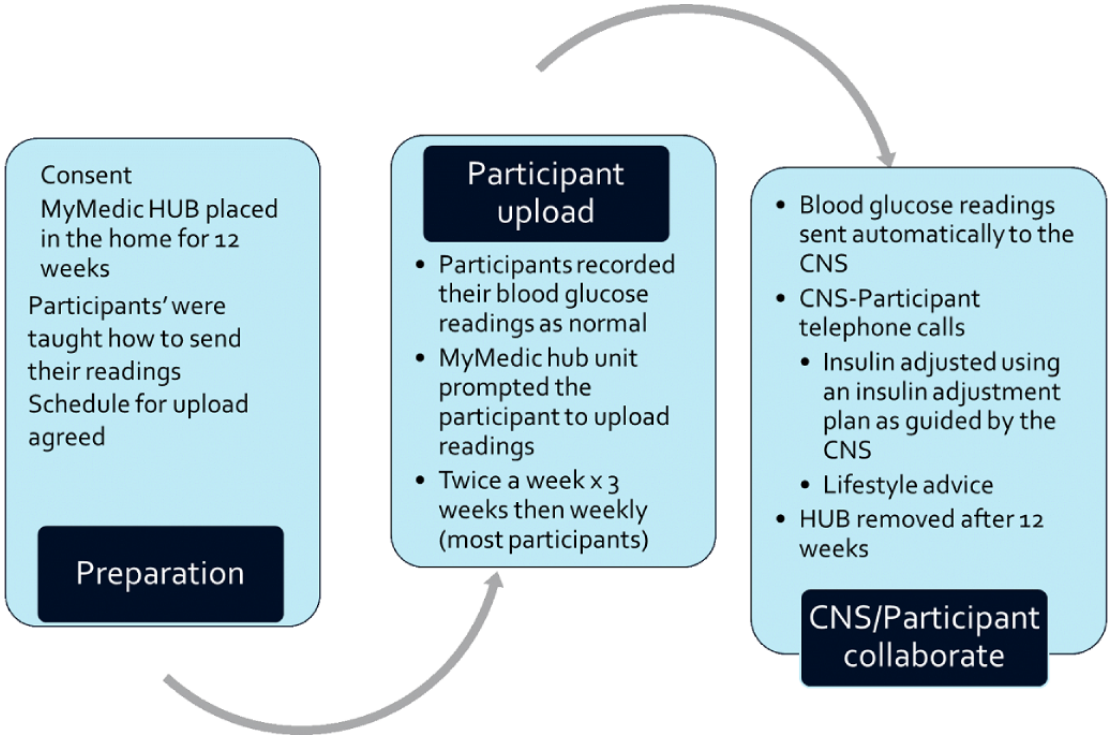
The patients recorded their blood glucose readings as instructed by the CNS. The usual practice is that patients on basal insulin self-test their blood glucose levels four times daily or more to establish the pattern of glucose through the day and to comply with the HSE guidelines [20]. At the times agreed, they sent their blood glucose readings to a monitoring center using the hub. The hub unit prompted patients to upload their readings as agreed with the CNS. Most patients uploaded twice a week for the first 3 weeks and then weekly for the remaining 9 weeks, as they needed more intensive support at the beginning. This was based on a similar study by Turner et al [21]. We contacted the authors to find out about their titration guide and frequency of dose adjustment, which was every 3 days initially and then weekly once stable. The American Diabetes Association and the European Association for the Study of Diabetes joint guidelines [22] recommend increasing basal insulin dose by 2 IU every 3 days until fasting glucose reaches the desired range individualized for each patient. As the target is neared, dosage adjustments should be more modest and occur less frequently.

None of the patients required more than weekly uploads after week 3. If the participants did not upload their blood glucose levels at the scheduled time, the telecare support officer contacted them by telephone to remind them.

The readings were sent automatically to the web-based platform. The CNS accessed the data for the individual on a prearranged date and contacted the participant, if necessary, to seek additional information on their symptoms and well-being. The record was displayed in a diary format, showing the patient's

readings at each time of the day. This allowed the review of glucose data throughout the day. Charts, graphs, and tables could be created from these data to allow analysis. Insulin doses were entered onto the system with any changes to the care plan to allow sharing of data between health professionals. Blood glucose data were saved onto the patients' health service electronic file in pdf. Patients could contact their CNS or general practitioner (GP) if they were worried about their blood glucose readings, as per usual care. Insulin was adjusted according to need using an insulin adjustment plan, as guided by the CNS. After the 12-week period, the hub was removed from the patients' home (Figure 2).

Figure 2. Intervention. CNS: clinical nurse specialist.



Usual Care

A retrospective audit of 12 patients from 2015 showed that clinic visits ranged from 1 to 3 (mean 1.75) in the 12-month period following the commencement of insulin therapy. Phone calls from the CNS ranged from 0 to 4 per patient (mean 1.7). In this cohort, the mean HbA_{1c} remained relatively stable over 3 collection points—at baseline (T1; 8.5%), 6-month follow-up (8.6%), and 12-month follow-up (8.4%). No clinically or statistically significant changes occurred across the time points.

Data Collection

Data on biomedical variables were collected at a face-to-face meeting with the CNS. HbA_{1c} and BMI data were collected at T1, 12 weeks (at the end of the intervention; T2), and 6 months postbaseline (3 months postintervention; T3). The CNS kept an ongoing telephone call log of insulin dose, patient-reported hypoglycemia symptoms, call frequency and length, and main topics discussed in the calls. In addition, self-efficacy was measured using the Diabetes Empowerment Scale-Short Form [23], and the Diabetes Distress Scale was used to assess diabetes-related emotional distress [24], at the same time points. Satisfaction with the telemonitoring intervention was measured using the Telemedicine Satisfaction and Usefulness Questionnaire at T2 [25]. All T2 and T3 questionnaires were completed remotely via telephone by a researcher not involved in the intervention. All data were entered into the SPSS statistics version 24 (IBM Corp) and checked for accuracy.

All telemonitoring patients were invited to a focus group interview at T2. Two focus group interviews were conducted with 4 and 12 patients in the first and second groups, respectively, at a community health care venue. The aim of each interview was to explore the expectations, achievements, and opinions of the patients of the telemonitoring intervention, and the interviews were facilitated by an experienced interviewer not involved in the intervention, using a topic guide. Once all patients had completed the intervention, the 2 diabetes nurse specialists who coordinated the intervention were interviewed.

Data Analysis

Quantitative Data

Tests of distribution were carried out on all variables before statistical analysis. Variables with a normal distribution were analyzed using the repeated measures analyses of variance test to compare the pre- and postintervention HbA_{1c}, weight, BMI, diabetes empowerment scale (DES) score, and diabetes distress scale (DDS) score at T1, T2, and T3. A *P* value of less than .05 was considered significant. Variables not normally distributed were analyzed using the Friedman test, and if significant, the Wilcoxon test was used to determine which time points are significantly different from T1.

Qualitative Data

Initially, all interviews were openly coded. The descriptive content analysis was carried out using a framework [26].

Emerging codes were examined and compared for any overlap in meaning, and similar codes were collapsed to form higher-order codes. This constant comparative process continued throughout the data analysis process until the major categories that account for the data were developed. The relationships between categories were explored and made explicit. During the analytic process, detailed memos were recorded, which tracked the emerging understandings and the relationship between the categories identified. The findings are reported textually, supported by relevant quotations from the participants. The computer software package NVivo 10 (QSR International) was used to assist in the organization, management, and retrieval of the qualitative data.

Ethics

Ethical approval was received from the regional hospital Research Ethics Committee before commencement of the study. Mechanisms were put in place to ensure that the rights of the participants and their well-being were given precedence over data collection. All proposed participants were given both written and verbal information about the study. Patients were informed about the study face to face and invited to participate. Willing patients were met by the CNS to obtain written consent to participate. All data were anonymized and password protected and stored in accordance with the Data Protection Act, Ireland [27].

Results

Demographics

A convenience sample of 40 patients commenced the intervention, with 1 participant withdrawing early because of connectivity issues. All remaining 39 patients completed the 12-week telemonitoring and completed data collection for all time points postintervention. Table 1 provides the participants' demographic information.

Table 1. Participant demographics (N=39).

Demographics	Values
Age (years)	
Mean	62.4
Range	37-80
Gender, n (%)	
Male	23 (59)
Female	17 (43)

Biomedical Variables, Hemoglobin A_{1c}, Weight, and Insulin Dose

HbA_{1c} (mmol/mol) decreased significantly between T1 and T2 (mean difference [MD] −17.13; P<.001) and T1 and T3 (MD −18.16; P<.001). This represents a 21.2% drop in HbA_{1c} at T3 (Figures 3 and 4). No significant change occurred in weight or BMI over the 6-month period (Table 2). The mean insulin dose at T1 was 17.25 IU (SD 11.1) and ranged from 6 to 60 IU. We audited HbA_{1c} at follow-up in clinic visits in 2019 and found that the changes in HbA_{1c} (mean 60.4 mmol; P<.001) from T1 were maintained.

Figure 3. Changes in mean hemoglobin A_{1c} (mmol/L).

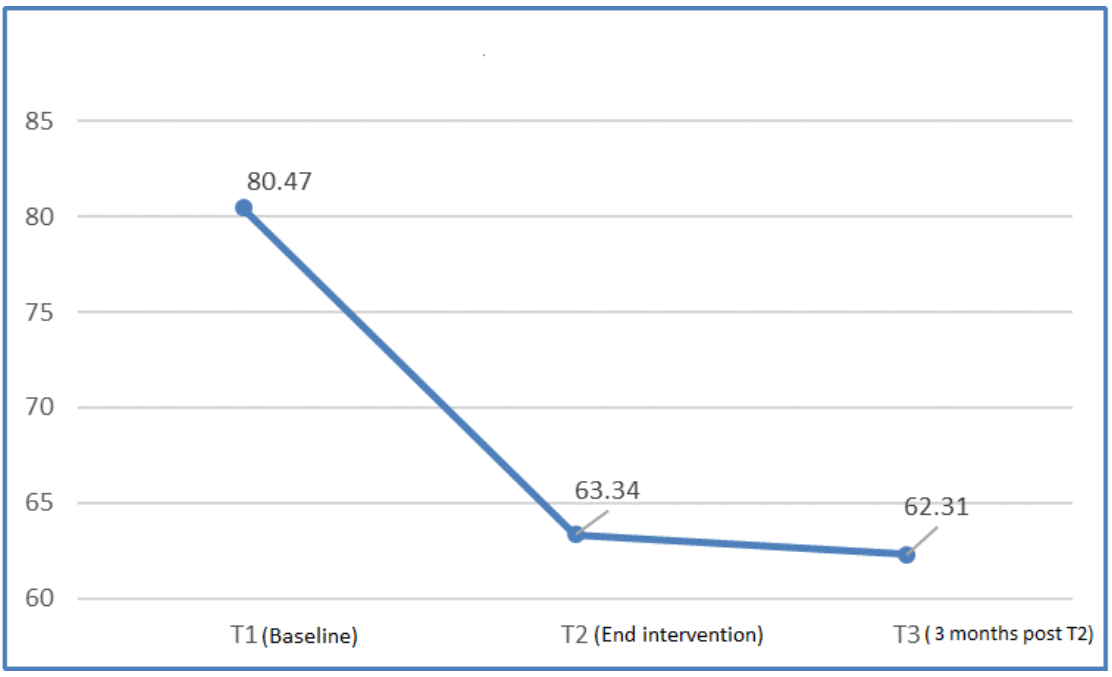


Figure 4. Changes in mean hemoglobin A_{1c} (%).

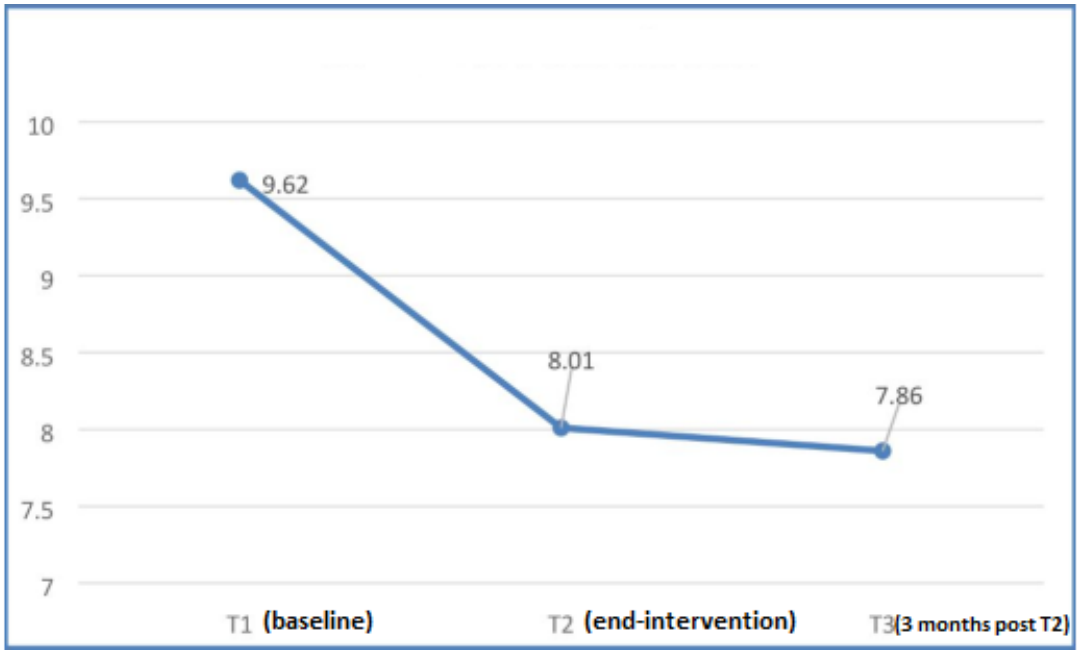

Table 2. Change in weight and BMI among participants (N=39).

Timepoint	Weight (kg), mean (SD)	BMI (kg/m^2), mean (SD)
T1 (baseline)	85.21 (22.75)	30.16 (7.32)
T2 (end of the intervention)	85.18 (20.93)	30.15 (6.82)
T3 (3 months postintervention)	85.63 (21.55)	30.36 (6.97)

Diabetes Empowerment Scale Scores and Diabetes Distress Scale Scores

From T1 to T2, an increase in mean DES score (MD 0.62; $P<.001$) and a decrease in mean DDS score (MD −0.64; $P=.002$) occurred. These differences from T1 were maintained at follow-up at T3 (DES score: MD 0.72; $P<.001$ and DDS score: MD −0.6; $P=.002$; Figures 5 and 6).

Figure 5. Changes in mean total diabetes empowerment scale (DES) scores.

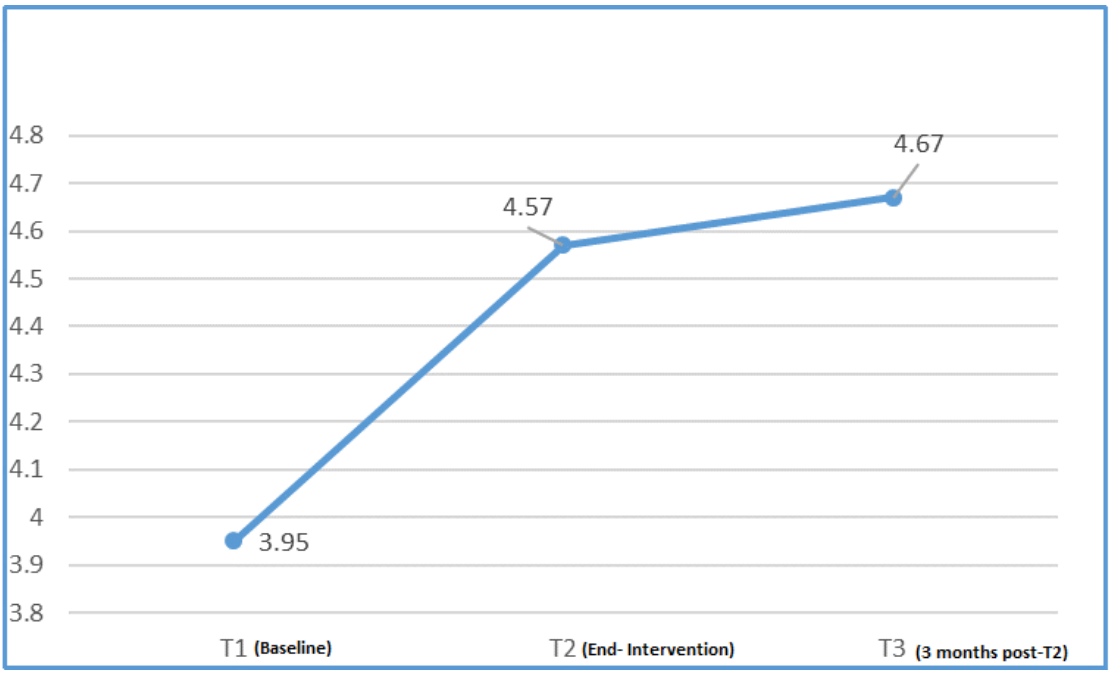

Figure 6. Changes in mean total diabetes distress scale (DDS) scores.

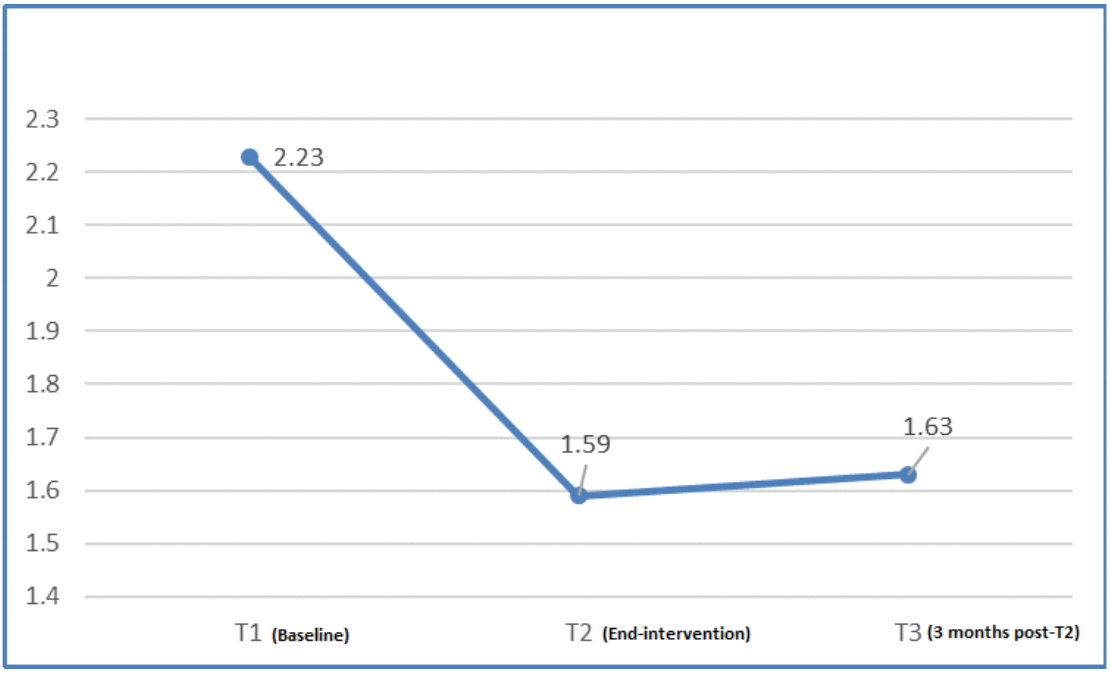

Hypoglycemia

A total of 13% (5/39) of patients had low blood glucose levels during the intervention. Specifically, 3 patients had 2 to 3 episodes, which stopped with advice or dose adjustment. The other 2 patients had multiple episodes, resulting in one patient discontinuing insulin and the other having insulin doses adjusted several times during the study and after. However, during the telephone calls with the CNS, 38% (15/39) of patients reported symptoms of hypoglycemia, demonstrating the need for support for people commencing insulin therapy.

Patient Satisfaction

The mean satisfaction score was above 4 out of a possible 5 on all items on the Telemedicine Satisfaction and Usefulness Questionnaire, indicating a high level of participant satisfaction with the telemonitoring intervention.

Timing and Frequency of Telephone Support

The number and duration of calls were tailored to patients' need. The mean number of calls logged during and after the intervention per participant was 11.5 (SD 4.16). The mean length of the call per participant ranged from 4 min to 15 min. The majority (369/450, 82.0%) of calls were initiated by the CNS, 11.6% (52/450) of calls were initiated by the patients, and 6.2% (28/450) initiation was not documented. The calls reduced dramatically on completion of the intervention, accounting for 8.0% (36/450) after 12 weeks.

The most frequent issue discussed in the telephone calls was poor glucose control (n=176) experienced by the majority of participants (36/39, 92%), followed by injection technique (n=76) reported by 92% (36/39) of participants, patient-reported symptoms of hypoglycemia reported by 38% (15/39) of participants, and self-monitoring of blood glucose technique (n=43) reported by 74% (29/39) of participants. Insulin dosage adjustment (n=147) was the most frequent intervention given to participants (n=37) on one or more occasions by the CNS, followed by healthy eating advice (n=109) and physical activity advice (n=62).

Hospital, General Practitioner, and Diabetes Clinic Visits

Of the total participants, 25% (10/39) attended the diabetic clinic and/or visited the GP and/or experienced an unplanned hospital visit. Of those, 18% (7/39) of participants attended the diabetes clinic, with 2 participants attending twice, and 10% (4/39) of participants visited the GP regarding their diabetes, with 1 participant visiting twice. Unplanned hospital admission was experienced by a minority (3/39, 7%) of the overall number of participants. In the retrospective audit of 12 patients who commenced insulin in 2015, there were 21 clinic visits—we do not have data for this groups' GP visits or hospital admissions.

Qualitative Findings

The thematic analysis of the patient focus group interviews led to 4 main themes: psychological impact of diabetes, increased diabetes empowerment, nurse in the corner, and using the technology. These and their associated subthemes are summarized in Multimedia Appendix 1. The CNS focus group resulted in 5 themes and subthemes, which are summarized in Multimedia Appendix 2: usual transition to insulin, safe transition to insulin therapy using telemonitoring, increased patient empowerment, administrative supports and requirements, and technology. For the focus of this paper, we have selected the themes that relate to patient empowerment for discussion and triangulated the findings from the patient and CNS focus groups and the questionnaire data.

Psychological Impact of Diabetes

In the focus groups, patients talked about the impact of diabetes on their psychological well-being and the need for more support for dealing with the emotions and stress experienced because of the diagnosis and the effects of the illness. They discussed the negative emotions experienced by them because of diabetes,

including anger and agitation with the diagnosis and frustration with the complexity of managing diabetes:

> *There's a lot of agitation and stress around it. For me, in the beginning...when I was diagnosed with diabetes I was very angry because I neither drank nor smoked and I always kept active and working.*

Diabetes Empowerment

In the focus groups, the patients discussed increased self-awareness around the need to self-manage the chronic disease along with developing the knowledge, skills, and confidence to do so. Taking part in the telemonitoring project changed patients' thinking around taking responsibility to manage their diabetes. Having the machine in their home and being responsible for monitoring the blood glucose shifted their thinking:

> *It changes your life forever. It's up to yourself then—do you want it or not. You grab it with both hands.*

Being accountable to someone was a motivating factor in increasing awareness and led them to consider and think about the results they were seeing:

> *It's made me more aware anyway because I'm thinking all the time maybe these bloods are too high, and the nurse is going to say this or maybe they're too low.*

Patients' distress decreased and confidence increased with the comfort of knowing that someone was keeping an eye on the blood glucose all the time:

> *It's giving you control back. You're getting some control over your diabetes when that thing is in the house. Like you say, you can go and download. If you don't feel right about anything in the week that you have done it or in the couple of days, you can go and download it and the nurse will phone you back and reassure you whether it's right or wrong or what you want to do. That's what I like about it.*

Another major source of self-efficacy was mastery experience through taking steps to control diabetes and seeing positive results. In this study, achieving blood glucose control increased their perseverance with managing diabetes:

> *You stick at it. If you're getting good results all the time, you stick at it.*

The patient focus group findings were corroborated by the data from the DES score questionnaires. A significant increase in mean DES score occurred between T1 and T2 (MD 0.62; P=.001) and T1 and T3 (MD 0.72; P<.001; Figure 4).

The CNS team focus group findings also support improved patient self-management with increased patient knowledge and confidence:

> *They're now very confident in managing their insulin so it doesn't stress them if the doctor says we'll just increase that by 2 units. They usually know, and they'll come out and they say to me, I knew we needed to increase that. So, they have gained great confidence in insulin which doesn't happen to everybody.*

The CNS reported problems in the past with the timely uptitration of insulin. Many barriers exist in the usual care of patients to achieving an optimal insulin dose because of not having access to complete and accurate patient data, large caseloads, and insufficient time for the practitioners to frequently contact the patients to adjust their insulin doses. Moreover, 14 patients effectively used an insulin self-adjustment tool, which resulted in earlier titration of insulin to gain timely and improved blood glucose control:

> *I just saw one of them yesterday and she said to me, I did put the insulin dose down a little bit a couple of months ago but actually I had to put it back up again, I didn't ring you because I knew that would be fine...this is a 78-year-old lady. When I say she didn't want to go on insulin, she was absolutely definitely against insulin. To just hear her talking so confidently about her insulin dose and adjusting it and the rationale for the changes she made was great actually.*

Not everyone in the study was taught to self-manage insulin, as it was different from traditional practice and would require further exploration and development for implementation to the wider diabetes population. However, those patients who did use the tool demonstrated increased knowledge and a desire to titrate their own insulin in response to higher blood glucose levels:

> *If it went back up again it would be a case of going to the diabetic nurse and readjusting your insulin. I wouldn't mind if I had to adjust the insulin from now on because you know how it works now.*

Nurse in the Corner

Patients described the telemonitoring as "It's like a nurse in the corner." Having access to the diabetes nurses and knowing that they were reviewing their blood glucose levels gave the patients comfort and a sense of safeness. It also meant that there was quicker intervention when their blood glucose levels were not right, and in their opinion, it reduced their need to visit the hospital and GP.

The added comfort or security relates to the vulnerability the patients felt while commencing insulin. This was an unknown territory, and having close monitoring with professional oversight meant that they felt safe. This links to the development of confidence to manage their diabetes, as an improved emotional state underpins the development of self-efficacy or confidence to manage diabetes:

> *Having it there, I know it's there and I know if I have a problem, I'm going to get the call and the nurse is going to talk me through it. It's hard to explain the comfort that you have in that.*

An Empowering Nurse-Patient Relationship

In the focus group, the CNS participants identified the need for a more equal relationship and enhanced partnership between the nurse and the patient and recognized the role of the

intervention in empowering patients toward self-management. This eased the nurse into the watchful observer role:

> *I suppose that we are always talking about self-management and for the self-management to work it has to be teamwork. It can't be a them and us. You're always trying to build up relationships.*

The CNS perceived that the change in the nurse-patient relationship was toward one of enhanced partnership—a mutual goal that allowed the patient and the nurse to have an equal footing in its achievement:

> *even after the telemonitoring period, we still get phone calls from the patients but it's interesting that there's more an equal relationship with us. It isn't the kind of traditional nurse and patient relationship.*

Increased Workload

CNS participants did highlight that although the telemonitoring system potentially led to much greater efficiencies in terms of patient monitoring and treatment, they strongly voiced the need to have adequate resources to support such a system. One of the key areas of concern was related to adequate nursing resources. As this new telemonitoring system generated large dataset for each patient and these data were being uploaded daily, there was an expectation that nurses would be seeing and reviewing these data regularly. However, because of workload pressures and staff resources, CNS participants reported that often patient data may not be reviewed for several days after upload, and they identified this as a source of concern for patient safety. They would recommend using the track, trend, and triage service, which was not used in this study:

> *the 'buts' are that it definitely added to our work time and I suppose that just the pressure of knowing that you had a responsibility to those patients to look at those readings no matter what else was going on in the service was an additional pressure, I think you would have to restrict the numbers, especially with just the 2 of us; you would have to decide on a certain number at each time. You couldn't just do it all.*

Discussion

Principal Findings

In summary, we observed a significant reduction in HbA_{1c} levels without a significant increase in weight. Patient empowerment scores increased and DDS scores reduced, and these findings were corroborated by the participants' experiences explored in the focus group interviews. These effects were maintained at follow-up 3 months after the intervention ended. Other effects reported by the participants included increased knowledge and competence to self-manage their condition. Some participants engaged in self-titration of insulin using a tool developed by the CNS. A total of 5 patients had episodes of hypoglycemia. A significant increase in workload was reported by the CNS team, which led to several recommendations for streamlining the delivery of telemonitoring with the current service and for additional supports to the health care team.

Patient Empowerment

Patient empowerment in diabetes is fundamental to achieving behavior change, and it is important that the motivation to change is driven internally rather than externally [8]. Self-determination theory proposes that addressing the 3 psychological needs—autonomy, competence, and relatedness—fosters a motivation to engage in healthy behaviors. The extent to which these 3 needs are met or unmet in the social context predicts well-being and thriving [28]. The findings of this study suggest that these 3 psychological needs were met. The CNS observed a positive impact on the nurse-patient relationship, with a balancing out of power and a sense of letting go from the CNS perspective. The perception of increased partnership was empowering to both parties. Patients' autonomy increased with an improved awareness and a heightened level of responsibility for the self-management of diabetes. In a large prospective observational study involving 4341 multinational patients, the quality of the patient-provider relationship was significantly correlated with insulin adherence and HbA_{1c} levels [29].

The patients' knowledge and competence increased in both the effect of their lifestyle behaviors on blood glucose control and how to change them. They attributed this change to the increase in the monitoring of their blood glucose level and the support from the CNS. In a review of qualitative data from seven trials and observational studies of telemonitoring for long-term conditions in primary care, Hanley et al [30] concluded that generating and recording the telemonitoring data had an empowering effect on patients to self-manage. Being active participants in their care increased confidence and enabled them to negotiate prompt access to care.

Insulin Self-Management

Although the central aim of this study was to explore the experience of using telemonitoring to facilitate the transition to insulin therapy, some patients expressed confidence in their knowledge and skill to self-manage their insulin dosage. The CNS participants also indicated an increase in their confidence to let patients self-manage. Empowerment occurs when the goal of the health care practitioner is to enable the patient to critically think and make informed decisions about their care [8]. Self-titration of insulin is well established in type 1 diabetes, but for most patients with type 2 diabetes, dose titration is still carried out by physicians and diabetes nurse specialists. The evidence suggests that this is not the best process to achieve the optimal glycemic control, and self-titration of insulin in type 2 diabetes may be more effective [2]. Computer-assisted self-titration has been found to improve patient awareness of blood glucose management and increase self-efficacy to manage insulin [31]. Our findings suggest that the use of telemonitoring combined with self-titration of insulin empowers people to self-manage and warrants further investigation.

Less Distress, Increased Empowerment Scores, and Fewer Attendances

High levels of diabetes distress negatively affect insulin adherence and glycemic control [29]. The DES scores and DDS scores demonstrated that patient confidence in the ability to

manage diabetes increased and diabetes distress decreased significantly by the end of the 12-week intervention. These findings were supported by the results of the focus group interviews where patients and the CNS team spoke at length about reduced distress and increased patient confidence in their ability to self-manage diabetes. They also reported fewer attendances to the GP and hospital clinics, and we observed a reduction in the number of clinic visits for the intervention group compared with a retrospective cohort. However, the intervention group received a much higher number of calls from the CNS than the retrospective cohort. Telemonitoring and support for people with diabetes have previously demonstrated improvements in self-management and reductions in psychological distress [32].

Glycemic Control

There was a clinically and statistically significant change in HbA_{1c} at 3 months after the end of the telemonitoring intervention to support the introduction of insulin in glucose management, however, with no significant impact on weight. HbA_{1c} reduced by 1.61% at T2 and 1.76% at 6 months from T1. It could be argued that this reduction would usually be observed with the introduction of insulin, and without a control group, it is difficult to posit that the effects are because of the telemonitoring intervention. In a longitudinal study that evaluated the change in HbA_{1c} values after the usual approach to start insulin therapy in 779 patients in primary care practices in Germany and 646 patients in the United Kingdom, with a mean HbA_{1c} of 8.1% (SD 1.3%) and 9.3% (SD 1.5%), respectively [33], the average-adjusted HbA_{1c} improvements in the first 12 months were 0.5% (95% CI 0.4%-0.6%) in Germany and 1.0% (95% CI 0.7%-1.3%) in the United Kingdom. Between 12 and 36 months, these improvements in glycemic control were maintained in both patient groups, without additional improvement in glycemic control. This would suggest that using telemonitoring to initiate insulin is more effective, and in our group, the reduction in mean HbA_{1c} was maintained when we audited the group data in 2019. A randomized controlled trial (RCT) of telemedicine with lifestyle adjustment and titration of metformin plus other oral hypoglycemics or insulin in a Danish type 2 diabetes population demonstrated a 14.6% drop in HbA_{1c} (−15 mmol) with telemedicine and 10.6% (−10 mmol) reduction in their control group [34]. In our retrospective audit of 12 patients commencing insulin in 2015, we saw no clinically significant change in HbA_{1c}, which may be because of the multiple barriers to optimal insulin treatment in primary care at the patient and practitioner levels, and this demonstrates the need for structured self-management support and integrated support systems [4].

Adverse Effects

Some patients did experience hypoglycemia both during and after the intervention, indicating the need for monitoring and support for this population. In an RCT aimed at reducing cardiovascular events in patients with type 2 diabetes using intensive therapy vs standards therapy to reduce HbA_{1c}, the rate of hypoglycemic episodes requiring medical assistance was 3.1% in the intensive therapy group and 1.0% in the standard therapy group, and the mean weight gain at 3 years was 3.5 kg and 0.4 kg in the 2 groups, respectively [35]. In our study, no significant change occurred in weight over the 6-month period. Hypoglycemia and weight gain are among the many recognized worries experienced by both patients and health care practitioners when considering insulin treatment [36]. Although 13% (5/39) of patients had episodes of hypoglycemia, both the patients and the CNS participants felt that telemonitoring increased efficacy and patient safety in the transition to insulin therapy. The intervention allowed more timely adjustment of insulin levels, which leads to faster control of blood sugar levels. Patients reported a reduced need to visit the GP and hospital clinics probably because of the increased level of contact with the CNS during the intervention.

Acceptability

In our study, the use of telemonitoring while transitioning to insulin therapy was highly acceptable to patients, and the use of the technology caused them few problems. There were minor issues with uploading results at the start of the intervention, which could be overcome with an additional visit or better scheduling of the visit from the technology support person.

This intervention has the potential to allow the CNS team to provide more efficient and safe care to the patients, a finding corroborated by Jalil et al [37], but it comes at a cost. The telemonitoring system generated a large dataset for each patient, which had to be reviewed. On reflection, the team felt that they should have availed of the full track, trend, and triage service that is offered as part of the telemonitoring system. This has been found in other studies with one exasperated GP referring to the management of the *tsunami* of patient monitoring data generated by the Whole System Demonstrator project of telemonitoring in long-term conditions in the United Kingdom [38].

The increase in the workload of the team could have been alleviated by administrative support. This would enhance the service by freeing the CNS team to focus on their health care role. There were some teething issues with the introduction of the technology, which caused frustration in both patients and the CNS team. The learning that occurred during the project would allow for a more streamlined approach to the introduction of telemonitoring, with several recommendations for a change to integrating the system with the current service. Although our CNS sample size was small, the findings mirror those of larger studies that have suggested that if the telemonitoring system is not streamlined with the current models of practice, this will impede their uptake by health care professionals [30,38].

Conclusions

The use of telemonitoring while transitioning to insulin therapy was highly acceptable to patients with high satisfaction and increases in confidence and knowledge. The intervention transformed the nurse-patient relationship and resulted in the empowerment of patients to self-manage. Patients reported an increased awareness and level of responsibility and confidence for self-management of diabetes. There was a significant decrease in the DDS score, and both patients and the CNS team reported reduced patient distress. Some patients also expressed

confidence in their knowledge and skill to self-manage their insulin dosage. The CNS team also indicated an increase in their confidence to facilitate patients to self-manage. There was a positive impact on the nurse-patient relationship, with a balancing out of power and a sense of letting go from the CNS team. The increased sense of partnership was empowering to both parties.

There was a clinically and statistically significant drop in HbA_{1c}, as expected with the introduction of insulin in glucose management, with no significant impact on weight and improved sense of patient safety from the patient and practitioner perspective.

Overall, the use of the technology caused a few minor problems for patients. The intervention allowed the CNS team to provide more efficient and safe care to the patients, but it came at a cost. There was a significant increase in the administrative workload of the team, which could have been alleviated by administrative support. There were some teething issues with the introduction of the technology, which caused some frustration in both patients and the CNS team, which may be alleviated with a more streamlined approach and integrating the system with the current service.

Limitations and Further Research

Some limitations of this study need to be considered, and where appropriate, recommendations for further research are proposed. Data in this study were generated through convenience sampling of patients attending one health care region in Ireland, and the number of patients recruited was restricted to 40 by limited nursing and technological resources. In addition, as this was a volunteer sample, these participants may be more motivated toward successful self-management of their diabetes and transition to insulin. Considering this, the findings of this study cannot be generalized to other settings.

The small sample size of both the patient and the CNS groups results in very low study power, which reduces reliability and generalizability. This study design did not allow comparison of this intervention with a control group, which limits the ability to fully determine the effectiveness of the intervention. We audited a retrospective cohort of patients to explore the impact of the intervention; however, we recognize the methodological limitations of this approach. A larger RCT would be useful to allow causal comparisons to be made between telemonitoring-supported care of type 2 diabetes during transition to insulin and conventional care. Measurement of other performance metrics such as frequency of GP visits, levels of technical support needed, and time spent by CNSs in telephone support would also determine the feasibility of such an approach. However, the mixed methods approach used in this study, drawing on both quantitative and qualitative data to support findings, does demonstrate congruence toward patient empowerment experiences when using telemonitoring with telephone support to self-manage diabetes.

Future research design in this area might also consider examining whether improvements in patient outcomes are associated with the effects of using the monitor alone or in combination with increased telephone support and/or the use of an insulin titration scale. Moreover, although this study did look at T1 data and examined the effect at the end of the 12-week intervention and at 3-month follow-up and found positive effects in relation to decreased DDS scores and increased DES scores, further research that would examine if these positive effects were sustained over a longer period would lend strength to the value of such interventions.

Abstract

Background: Today, telehealth is experiencing exponential growth in utilization. Paralleling this trend is the growth in the telehealth industry, with sharp increases in the number of platforms, functionalities, and levels of integrations within both the electronic health record and other technical systems supporting health care. When a telehealth network is intended to be used across independent health care systems, an additional layer of complexity emerges. In the context of regionalized telehealth networks that are not within the same health care system, not only are technical interoperability challenges a practical barrier, but administrative, clinical, and competitive elements also quickly emerge, resulting in fragmented, siloed technologies.

Objective: The study aimed to describe a statewide approach to deploying an interoperable open access telehealth network across multiple health systems.

Methods: One promising solution to the abovementioned concerns is an open access telehealth network. In the field of telehealth, an open access network (OAN) can be defined as a network infrastructure that can be used by health care providers without a closed or proprietary platform, specific obligatory network, or service-specific telehealth technologies. This framework for the development of an OAN is grounded in practical examples of clinical programs that function in each stage of network maturity based on the experience of the South Carolina Telehealth Alliance (SCTA). The SCTA's experience details successes and challenges in an ongoing effort to achieve an OAN. The model describes an OAN in stages of collaborative maturity and provides insights into the technological, clinical, and administrative implications of making the collaboration possible.

Results: The four stages of an OAN are defined according to operational maturity, ranging from feasibility to demonstration of implementation. Each stage is associated with infrastructure and resource requirements and technical and clinical activities. In stage 1, technical standards are agreed upon, and the clinical programs are designed to utilize compliant technologies. In stage 2, collaboration is demonstrated through technical teams working together to address barriers, whereas clinical and administrative teams share best practices. In stage 3, a functional interoperable network is demonstrated with different institutions providing service through common telehealth end points at different patient care sites. In stage 4, clinical workflows are streamlined and standardized across institutions, and economies of scale are achieved through technical and administrative innovations.

Conclusions: The approach to OAN development described provides a roadmap for achieving a functional telehealth network across independent health systems. The South Carolina experience reveals both successes and challenges in achieving this goal. The next steps toward the development of OANs include advocacy and ongoing engagement with the developers of telehealth technologies regarding their commitment to interoperability.

telehealth; health information technology

Introduction

Background

Today, telehealth is experiencing exponential growth in utilization [1,2]. Paralleling this trend is the growth in the telehealth industry, with sharp increases in the number of platforms, functionalities, and levels of integrations within both the electronic health record (EHR) and other technical systems supporting health care. When a telehealth network is intended to be used across independent health care systems, an additional layer of complexity emerges. In the context of regionalized telehealth networks that are not within the same health care system, not only are technical interoperability challenges a practical barrier, but administrative, clinical, and competitive elements also quickly emerge, resulting in fragmented, siloed technologies. These observations echo those of the rapid deployment of EHRs that led to fragmentation and barriers to interoperability across systems that have become a practical issue and barrier to optimal care for patients, providers, and health systems [3]. As rapid deployment of telehealth technology follows a similar trajectory, it becomes increasingly important to learn from the EHR example and develop roadmaps for telehealth collaborative solutions before siloed technology becomes standard practice.

Open Access Network

One promising solution to these concerns is an open access telehealth network. In the field of telehealth, an open access network (OAN) can be defined as a network infrastructure that can be used by health care providers without a closed or proprietary platform, specific obligatory network, or service-specific telehealth technologies. An OAN functioning at the highest level of maturity would also include clinical and administrative workflow standardization. Many manufacturers offer turnkey solutions for starting telehealth programs by selling closed systems and/or proprietary technologies. Although these solutions address immediate needs, they also create closed or siloed networks that cannot be easily accessed or expanded and lack interoperability with other telehealth solutions.

An OAN benefits a health care system as a whole by mitigating the need for proprietary equipment and the specialized staff and contracts that support such equipment. In addition, individual institutions and broader regional health care systems benefit from an OAN as they are able to connect to a more extensive array of subspecialty providers using the same technology, thus saving space, cost, and time in the deployment of equipment. Finally, both providers and patients benefit from familiarity with standardized equipment, increasing adoption for these pivotal end user groups. Open platforms ensure that additional consideration is given to maintaining reasonable costs for broad participation among regional health systems.

Similar to the experience of EHR development, the need for telehealth interoperability was acknowledged nearly a decade ago [4], though the reality of interoperability and effectiveness are not well described [5]. Although the development of an interoperable telehealth network is less complex than a full health information exchange, there are many parallels to consider. The National Quality Forum introduced measures for health information exchange interoperability (Table 1), and the majority of measures go beyond whether the systems are technically interoperable and instead focus on whether the system is used as intended and if that use is effective [5]. In much the same way, a telehealth network may be built to be interoperable, but health systems may choose to selectively deploy this function. For instance, these systems are likely to make variable investments in their own telehealth efforts that are reflective of their variable business cases for making technical decisions. It should be no surprise then that during the growth of telehealth there may also be the need to focus on metrics that relate to interoperability. In this paper, a statewide approach to deploying an interoperable OAN across multiple health systems is described.

Table 1. National Quality Forum domains and subdomains of interoperability.

Domain	Subdomains
Exchange of EHI[a]	• Availability of EHI • Quality of data • Method of exchange
Usability of exchanged EHI	• Relevance • Accessibility • Comprehensibility
Application of exchanged EHI	• Human use • Computable
Impact of interoperability	• Patient safety • Cost savings • Productivity • Care coordination • Improved health care processes and health outcomes • Patient/caregiver engagement • Patient/caregiver experience

[a]EHI: electronic health information.

Methods

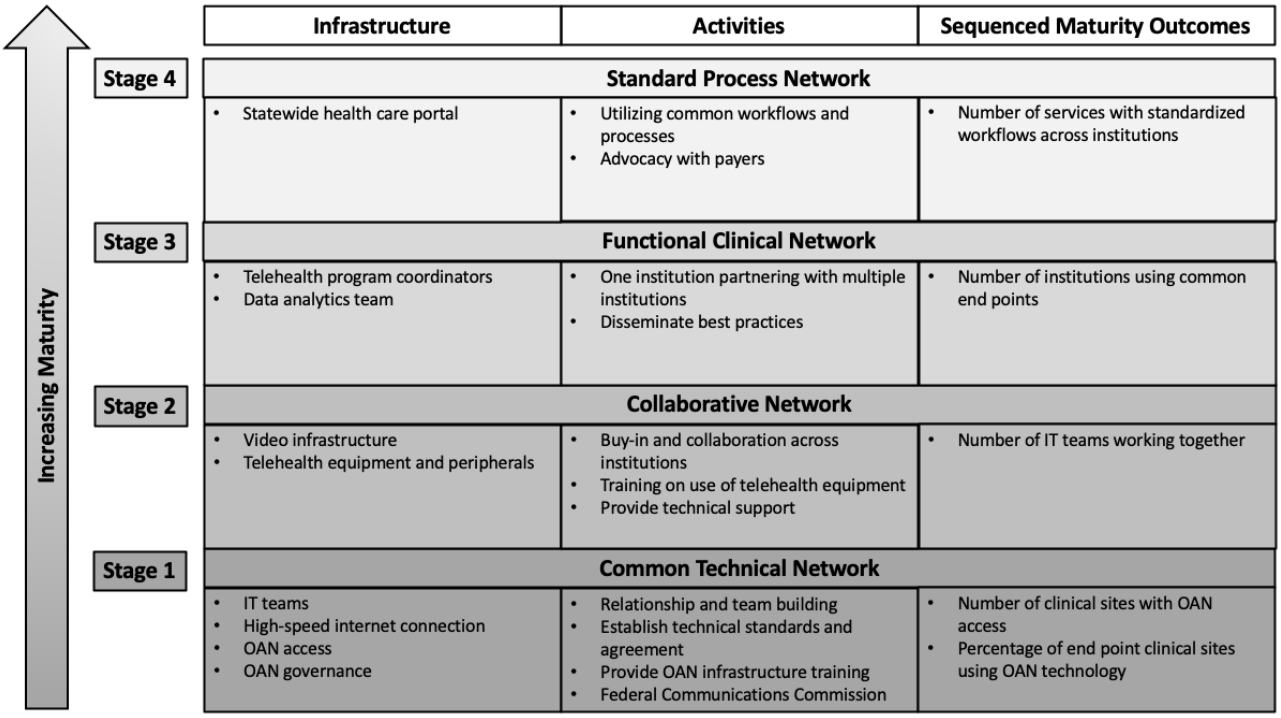
The framework for the development of an OAN is grounded in practical examples of clinical programs that function in each stage of network maturity. Although the model is intended to be generalizable, the experience of the South Carolina Telehealth Alliance (SCTA) is used as a representative use case. The SCTA was established in 2013 as the product of legislatively appropriated state support for telehealth in South Carolina. The multistakeholder alliance includes representatives from local health care systems and payers and has a mission to support the delivery of high-value telehealth across the state. Across South Carolina's 46 counties, there are currently over 400 sites equipped for telehealth services. The SCTA's experience details successes and challenges in an ongoing effort to achieve an OAN. The model presented here describes an OAN in stages of collaborative maturity and provides insights into the technological, clinical, and administrative implications of making the collaboration possible.

Results

Developmental Stages of the Open Access Network

In South Carolina, a vision for technologic interoperability was and remains a key strategy of the state-sponsored telehealth network [6]. The aspirational goal is to allow access to all providers wishing to leverage any deployed telehealth technology in the state. Although achieving this goal is an ongoing challenge, South Carolina has made substantial progress and learned important lessons. A four-stage process is being used to develop and mature a statewide OAN (Figure 1). These four stages are defined according to operational maturity, ranging from feasibility to demonstration of implementation. Each stage is associated with infrastructure and resource requirements, technical, and clinical activities. In stage 1, technical standards are agreed upon, and the clinical programs are designed to utilize compliant technologies. In stage 2, collaboration is demonstrated through technical teams working together to address barriers, whereas clinical and administrative teams share best practices. In stage 3, a functional interoperable network is demonstrated with different institutions providing service through common telehealth end points at different patient care sites. In the fourth and final stage, clinical workflows are streamlined and standardized across institutions, and economies of scale are achieved through technical and administrative innovations (eg, common scheduling portals and standard contract language; Figure 1).

Figure 1. Proposed model for maturing a telehealth open access network. FCC: Federal Communications Commission; IT: information technology; OAN: open access network.



Stage 1: Establish a Common Technical Network

Establish a Collaborative Forum

As in all collaborative efforts that involve multiple stakeholders, establishing a forum for communication, discussion, and gaining trust among the parties is essential. These stakeholders are likely to be asked to accommodate some adjustments internally for the good of the network; thus, it is important to involve them at early stages of strategic planning and the setting of short- and long-term goals. In South Carolina, the SCTA engages stakeholders with an advisory council and a system of workgroups that operate under the alignment of a formal strategic plan [6]. These workgroups, made up of personnel from the various involved institutions, are responsible for operationalizing the plan within their respective organizations and reporting back to the advisory council. The SCTA information technology (IT) workgroup has become a common ground for members to build relationships and make collaborative decisions with the common goal of interoperability, scalability, and support of the network.

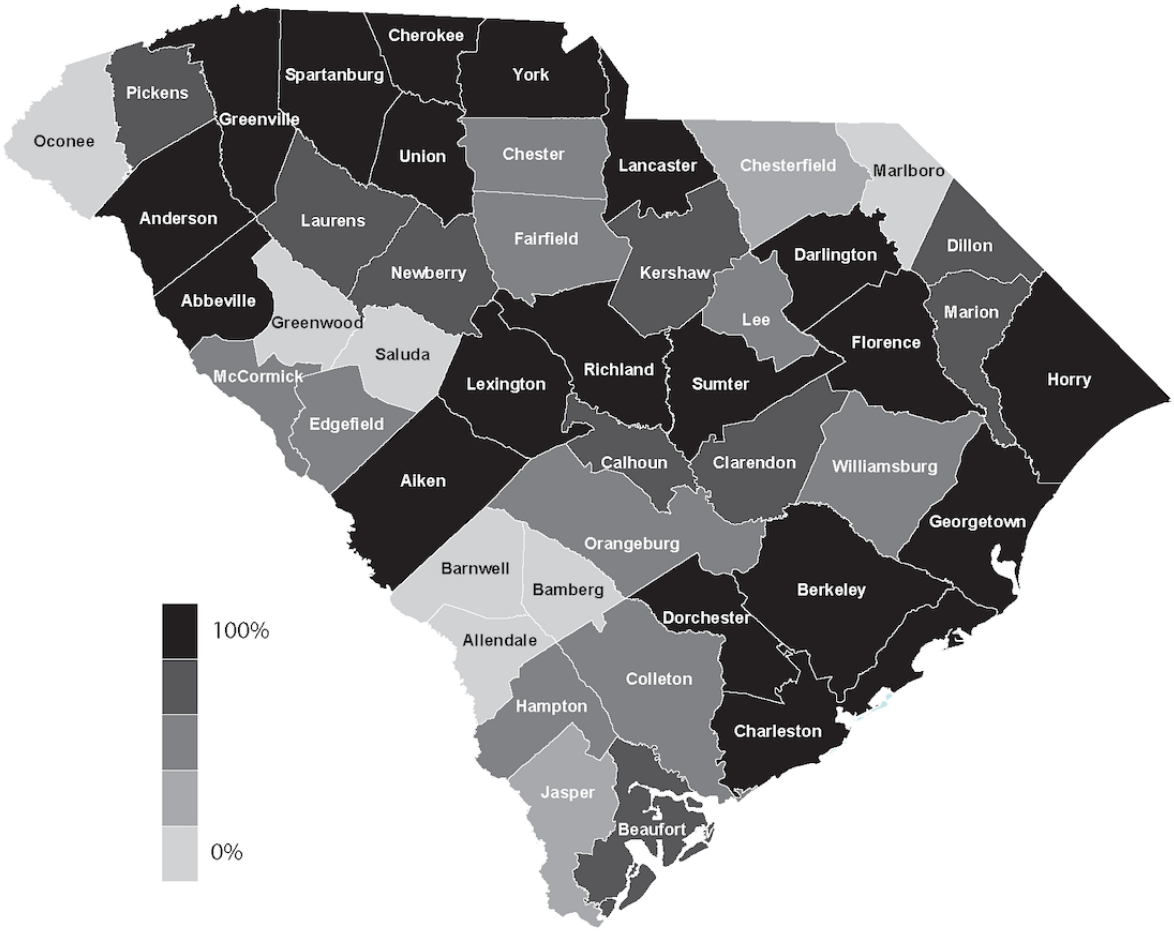
Establish Technical Standards and Agreement

As discussed, the inception of a regional telehealth network requires careful planning and coordination of efforts. Defining network requirements and functionality helps drive important decisions on technical protocols and the types of equipment used. The backbone of the OAN in South Carolina is a video network whose interoperability is made possible by using standardized specifications. These specifications are based upon open standards as defined by the International Telecommunications Union (ITU) and via a collaborative approach defined by the IT workgroup within the SCTA [7]. ITU open standards address specific requirements for functionality, interoperability, and compatibility. Through the utilization of existing infrastructure, the network leveraged investment protection while allowing sites and health care providers choices in the platforms they would use if they met the ITU open systems standards.

Assess and Address Broadband Availability

In South Carolina, rural health care providers often lack technical support, person power, and adequate broadband access. This limited connectivity compounds existing health care access issues, particularly in a region that is mostly rural (Figure 2). Although broadband access is beyond the scope of this paper, it is an important element to address when considering an OAN. When South Carolina designed and implemented a statewide telehealth network, one of the primary requirements was the ability to be used across rural providers and independent health care systems. Many of these health care systems had existing infrastructure and isolated networks that could be reconfigured to work together as one large statewide telehealth network. To build the network, South Carolina utilized the Federal Communications Commission's (FCC) rural health care program that subsidized infrastructure and broadband connectivity, effectively creating a dedicated statewide health care network. The network is known as the Palmetto State Providers Network (PSPN) [8]. Today, PSPN has over 300 participating health care sites providing affordable low-latency dedicated bandwidth with access to secure encrypted video infrastructure for the delivery of telehealth applications and services.

Figure 2. Federal Communications Commission broadband availability in South Carolina.



Open Access Network User End Points

Telehealth end points are hardware platforms that users control to establish connections between referring and consulting telehealth participants. An end point is where physical and logical connections to video and audio systems such as cameras, speakers, and microphones are made. End points are the *end of the line* for the video conferencing connection and are different from other components of a video conferencing network such as gateways or multipoint conference units (bridges), which are video infrastructure components.

End points used in telehealth settings must be dependable and easy to use and meet the needs of the patient and health care provider. Under the OAN system, the patient and provider are not limited to consultations within a specific platform. There are many platforms/end point choices that promote technological efficiencies and streamlined patient care. End points come in a number of platforms and include software and PC-based, tablets, wall-mounted hardware-based units, dedicated desktop units, and the popular clinical cart units widely used in hospital settings. In health care facilities where space and resources are at a premium, the ability to utilize end points across multiple telehealth services and platforms is essential to the growth of the telehealth provision and utilization. The South Carolina approach to end point decisions is to educate providers on what is available, listen to the provider's needs, and then recommend the best solution. Ultimately, it is the health care provider's decision on what is the best end point for the delivery of health care services.

Open Access Network Technical Support

With the deployment of health care networks that provide services for critical and acute care patients, technical reliability is mandatory. Choosing industry-proven commercial-grade network equipment is an essential component for reliability. Having service-level agreements with the manufacturers and providers of network equipment is also a critical element to building and operating a strong network. Knowing that all equipment fails over time, managing equipment life cycles, and providing routine scheduled maintenance and upgrades are essential in maintaining a robust telehealth network. Networks

built with designed redundancy or high availability offer both hardware protection and the ability to perform maintenance and upgrades anytime, day or night. Utilizing site and service agreements, the SCTA offered a collaborative approach to technical support where the regional health care systems provide technical and site support to rural providers and smaller clinics in their region.

Open Access Network and Telehealth Software

One primary question faced when telehealth software is applied within an OAN is whether the software restricts the type of end point that can be utilized. A key component of this question is whether the telehealth end points not manufactured by the vendor can be used when the vendor's software initiates the video call. In addition, there are multiple questions that should be collaboratively discussed and considered before selecting telehealth software (Table 2). Conversely, it is important to consider whether the end points that are manufactured by the vendor can be utilized without the vendor's software. Many national telehealth vendors are moving toward interoperability with computers and tablet-based devices, and many video conferencing products can be configured to call video solutions across a range of video clients. When applying telehealth software, which leverages or augments video conferencing, there are typically two broad uses: encounter management and video network management. Encounter management involves assistance with the workflows of the clinical process; this may include gathering of data to assist clinical decision making, such as radiological imaging to assist in the assessment of a stroke. Encounter assistance may also include administrative functions of care, such as scheduling, facilitating collaborative documentation between care teams, or providing information for billing purposes. However, the functionality of the end points or the software remains constricted by certain specifications determined by telehealth software and equipment manufacturers. For instance, many telehealth encounters are facilitated with the use of far-end camera control in which the distant provider can simulate the in-person experience by controlling the camera on the patient's side. The ability to leverage this functionality may depend on the functionality of telehealth support software or on the specific camera included in the end point. Restrictions in functionality may also be experienced for the use of examination peripherals, which exclude some services from being offered as the appropriate standard of care.

Table 2. Questions to consider when evaluating technologies for users of the open access network.

Category	Questions
Infrastructure	• What problem are we solving? • What are the current video client- or cloud-based services in use? • Does the technology require changes to existing OAN[a] infrastructure? • Does the technology require additional infrastructure?

OAN standards/compatibility	• Will functionality be lost when crossing between software and certain standards-based endpoints in the network? Specifically:
	  • Far-end camera control
	  • Peripheral examinations devices including examination cameras and stethoscopes
	• Are there any end points that software apps provided by a vendor cannot connect to via video?
	• Are the new technologies compatible with the OAN?

Technical support/outcomes	• What are the technical support requirements? • Is there the ability to monitor the end points to ensure they are online when clinically needed? • Is the technology able to provide feedback to monitor key process metrics and data to support relevant quality and outcome measures?
Legal/compliance	• What are the state and federal regulatory requirements (including Health Insurance Portability and Accountability Act, Family Educational Rights and Privacy Act, and Commission on Accreditation for Law Enforcement Agencies)? • What are the information security requirements addressing the use of video technologies in health care settings? • What end point encryption is required?

[a]OAN: open access network.

The process of selecting technology for use within the OAN requires careful planning to ensure interoperability and appropriateness for each use case. Table 2 outlines several categories of questions that may be helpful to consider in this process.

Stage 1 Example: Connecting Medication-Assisted Therapy Providers to Drug and Alcohol Treatment Centers

An illustrative example of the South Carolina program that is in stage 1 of OAN maturity is that of the telehealth-enabled medication-assisted therapy program that connects eligible prescribers to local drug and alcohol treatment centers to treat patients with opioid use disorder. As the need for this clinical service was identified, the key stakeholders met to establish a collaborative forum to discuss the questions listed in Table 2 and apply the OAN standards that had been established by the SCTA technology workgroup. Broadband capability was assessed at each of the drug and alcohol treatment centers that were provided with federally subsidized broadband, when necessary. The program utilizes standards-based video conferencing equipment and software to connect the patient with contracted providers, and technical support is provided by

a common SCTA support partner. As the program matures, workgroups are forming to progress toward clinical and administrative consensus.

Stage 2: Collaborative Network

Although agreeing upon technical standards is an essential first step, the challenging process of collaboration must be a continuous area of focus to achieve the purposes of the OAN.

Ongoing Technical Collaboration

The implementation of a regional telehealth network requires a high degree of collaboration among the participating sites and service providers who may be unaccustomed to external collaborations. The coordination of efforts on a shared vision for a telehealth network is crucial for successful implementation and deployment. Regulatory requirements and threats to IT security create an environment where IT staff are very protective of their organization's networks. These factors create challenges to establishing trust and working together for the common goal of a statewide health care network. In South Carolina, a three-step process was used to develop and mature statewide IT relationships. In step 1 through the SCTA, we formed an inclusive statewide IT workgroup with representation from members of participating sites. Representation included participation from rural health care providers, community hospitals, regional hospitals, and the state's largest medical centers. In step 2, the workgroup agreed upon a common vision for the network and developed standards used to implement the network with a focus on protecting existing infrastructure and end point investments. In step 3, key stakeholders worked together to enhance the network by addressing needs for accessing technical support, online directory services for end points, and a shared on-call pool for emergent support needs. Working collaboratively and building trust are the cornerstones for developing and implementing a statewide OAN.

Collaborative Design in the Context of Performance and Security

Network Security

With federal and state mandates for the protection of health care information, South Carolina designed the OAN to utilize encryption technologies for all video calls. End points across multiple institutions and clinical sites are configured to standards that include required encryption configurations. Laptops utilized in the delivery of telehealth have encryption technologies installed to protect the laptop and its data from unauthorized access. User accounts are needed for access to all PC-based video clients.

Network Management

Successful design, implementation, and support of a telehealth network is not complete without a comprehensive network management policy and process. Network management should address procedures for the following:

1. Service level agreements on uptime, trouble resolution, and customer expectations.
2. Asset and inventory management
3. Proactive real-time monitoring of all critical systems
4. Equipment life cycle management
5. Problem escalation procedures
6. Equipment manufacture support agreements
7. Ticketing system for reporting, resolving, and managing trouble calls
8. Knowledgebase for information sharing

Clinical Collaboration

Establishing a venue for clinical collaboration is another important, perhaps essential, element of a successful OAN. Even for competing organizations, there is room to collaborate on quality and value alignment care processes. Indeed, the experience in South Carolina has demonstrated that for some services, telehealth can actually help forge partnerships across potentially competing health systems.

This stage was first demonstrated in a partnership between the Medical University of South Carolina (MUSC) and the South Carolina Department of Mental Health. Both entities serve many of the same community hospitals by providing emergency room consultations via telehealth. Although the services and even video end points differed, the two institutions worked together to leverage technology resources and agreed-upon approaches to solving technology problems for the sites they commonly serve. Technical collaboration has matured between the provider groups with common practices both in technology choice and security and network support. Clinical collaboration has been established with one provider group providing care on the inpatient side and another in the emergency department and outpatient setting requiring clinician communication for smooth handoffs.

Administrative Collaboration

An important element for the long-term success of a collaborative OAN effort across health systems is leadership buy-in and administrative inclusion. Establishing a mechanism for discussing the administrative elements of contracting, credentialing, scheduling, and business planning while the clinical and technical work is underway can greatly streamline any difficulties faced and lead to synergies in how each participating health system operates in the telehealth space. If possible, having the telehealth network included within the core strategic initiatives and alignment with the health systems mission is ideal for ensuring long-term success of the OAN.

Stage 2 Example: Telemental Health Services in South Carolina

Stage 2 of the OAN was first demonstrated in a partnership between the MUSC and the South Carolina Department of Mental Health. Both entities serve many of the same community hospitals by providing emergency room consultations via telehealth. Although the services and even video end points differed, the two institutions worked together to leverage technology resources and agreed-upon approaches to solving technology problems for the sites they commonly serve. Technical collaboration has matured between the provider groups, with common practices both in technology choice and security and network support. Clinical collaboration has been established with one provider group providing care on the inpatient side and another in the emergency department and outpatient setting requiring clinician communication for smooth

handoffs. Administrative collaboration has also been ongoing such that leadership finds the relationship so important that this same division of telemental health services that began in community hospitals is now replicated in MUSC's own children's hospital as well.

Stage 3: Functional Clinical Network

The first two stages of OAN maturity deal with technical and collaborative infrastructure. In stage 3, there is a focus on the demonstration of a functional interoperable network, with different institutions providing services through common telehealth end points at a patient site. To make this transition, there is a focus on distributing the established guidelines to focus on training and smooth *launching* or *go live* of services. Finally, quality metrics are tracked to ensure fidelity and encourage ongoing quality improvement. Attention to this ongoing process acknowledges that the technical, clinical, and administrative and achievements of stages 1 and 2 may not be fully matured and require ongoing attention and modifications. Embracing interoperability will likely lead to scaling of functionality to cost while using common end points. It is in stage 3 where these realities are confronted to move toward stage 4 while not sacrificing clinical integrity.

Distribution of Best Practices

For providers at multiple institutions to put the OAN technology to use, there must be a shared understanding of the best practices established by the workgroups during stages 1 and 2. Although all intricacies of the technology choices are not necessarily of utmost importance to this group, a basic understanding of telehealth and how to use and troubleshoot the technology is vital. In addition, when a consensus has been reached to the questions listed in Table 2, a forum for distributing these guidelines to a larger group helps to overcome knowledge barriers. The SCTA has worked through the distribution of instructional information in a variety of ways. Both content advisory and education workgroups exist to help increase general awareness and make more detailed training documents available. These range from a large library of promotional videos to a repertoire of online training modules developed in collaboration with the state's public television and broadcasting agencies and the South Carolina Area Health Education Consortium. Although these materials are in continued development, their use in conjunction with state and regional group training sets the stage for more in-depth on-site training. These program-specific training for providers and support staff provide employees from multiple institutions with a shared understanding before any go live.

Program Go Live

Collaborative use of open access technology by multiple institutions requires substantial coordination and support throughout the process of program development and transition to patient care. This is often best facilitated through dedicated telehealth coordinators or designated contact personnel at each institution. These designees are able to provide a source of continuity between IT, clinical, and administrative teams and host forums for discussion among the institutions. As the training is completed, they are able to host a series of *mock* connections before the rollout of services involving actual patient care and then monitor the first several patient encounters. During this transition period, the coordinators are able to help troubleshoot or find solutions to issues that might otherwise provide a less-than-optimal experience for either the patient or provider.

Quality Metric Tracking and Improvement

As in any process improvement effort, establishing metrics of success that can be tracked over time is essential. Ultimately, monitoring successful uses of common end points into the OAN by multiple institutions is a useful metric, but there are likely others needed to obtain this goal. In that stage, the practical realities that inhibit full deployment of the OAN are addressed or at least acknowledged as areas of optimization. These differences in functionality do not exclude the possibility of interoperability, but the clinical and cost needs may understandably be prioritized over interoperability in stage 3. In this stage, these practical realities are acknowledged, and a course is toward interoperability through process improvement and adjustments to technologies.

Stage 3 Example: Federally Qualified and Rural Health Centers

As the established infrastructure for providing health care for underserved citizens, many of the federally qualified health centers and rural health centers in South Carolina provide examples of stage 3 OAN maturity. These centers are able to use standards-based equipment to allow for connections to services between their own sites and community-based sites such as schools and drug and alcohol rehab facilities and to receive care from distant sites. They have contributed to several of the workgroups tasked with establishing standards and technology, administrative and clinical infrastructure, and the development of specific clinical programs. Their staff members and providers have taken advantage of common training materials and sessions to learn and help establish best practices. On-site training at these sites and those providing care is facilitated by coordinators, ensuring that all involved are ready for an organized go live. Patient care at these sites may utilize different workflows; however, the use of standards-based equipment and common practices, enable efficient use of technology. Finally, quality metrics are beginning to be established at these clinics to track and facilitate the continuous improvement of patient care.

Stage 4: Standard Process Network

Once a use case of two institutions using a common end point has been demonstrated, the transition to stage 4 maturity is underway. In this stage, optimization of the network focuses on the elements that will truly make the OAN add value to the regional care system. In this stage, clinical workflows can be standardized across institutions, and economies of scale can be achieved through administrative and technical innovations.

Establishment of Common Workflows

With the standardization of clinical workflows, there is a common experience of the clinical providers and staff, allowing for an elevation of skill level and generalization of knowledge and competencies. Administrative innovations may include common scheduling portals, standardization of contract

language, and streamlining of credentialing needs. From a technical perspective, optimization may include the use of software-assisted functionality that complies with interoperability standards. Technical response teams are now highly coordinated with open lines of communication.

Shared Administrative and Clinical Resources

A common Web portal for the OAN could be instrumental in bringing many of the aforementioned elements together. However, to remain open access, the costs of the network should remain reasonable for broad participation and not require the use of scaled functionality for all services. Willing partners should not be excluded from the network within the bounds of the agreed-upon standards and compliance with established workflows and procedures. Uniquely, at this level of collaboration, partnerships on service are enabled, in which otherwise competing institutions may find themselves collaborating with shared resources, such as common physician call pools when providers are in short supply.

Payer Advocacy

At the most mature stage of maturity, programs are able to reach a scale in which utilization and quality metrics are well established. After some time, at-scale health outcomes and cost efficiencies are also able to be measured. Multiple provider groups are then able to leverage these data to advocate for improved reimbursement either through legislation or direct negotiation with individual payers. Although some programs may ultimately rely on multiple funding mechanisms to ensure sustainability, a collaborative approach to demonstrating the value of telehealth programs and ultimately improving the reimbursement landscape is beneficial to all involved.

Stage 4 Example: School-Based Telehealth

The South Carolina school-based telehealth program is an illustrative example of a statewide telehealth program that has moved through each OAN stage of maturity. Early in this program's development, a commitment was made to adhere to open access standards when selecting technology, and broadband capability in rural schools was established with the help of the FCC-funded PSPN. As multiple health systems and provider groups became involved, the school-based telehealth workgroup within the SCTA was established to provide a framework for team building and sharing of ideas related to both clinical and technological standards. A collaborative IT support network was essential to the growth of this program as relationship building between school and provider IT teams was fundamental to both establishing and maintaining connectivity. Eventually, it became evident that a tiered call pool approach in which a school nurse's request for a visit could be sent first to a local provider, then to a provider group at the most local regional health care system, and then to a group at the largest state medical system was the best strategy to keep care local while still providing a quick response. For this to become a reality, a common clinical and administrative support network was established. This model has most recently been implemented using a common software platform that can be accessed by multiple end points that meet the open access standards. Although this platform has not become a fully statewide portal, its use has encouraged common workflows and processes, and with increased collaboration, the program has increased efficiency and utilization. Most recently, data have shown that the program may be associated with more cost-effective health care utilization patterns, and the provider groups are working together to advocate for improved reimbursement policies from a variety of payers.

Exception to the Rule: Intentional Fragmentation of an Open Access Network

Interoperability in telehealth solutions is often a goal rather than a full reality for most health systems. Although this is true for many health care IT solutions, it is compounded with telehealth because of the realities of different functionalities needed for different clinical situations. Health systems and telehealth vendors are often in diligent pursuit of an *enterprise solution*, though modifications and exceptions to the standardizations in place remain common for certain clinical services. Embracing the idea that alternative technologies may be needed to achieve clinical goals can be helpful if it allows for a focus on prioritizing what exceptions and options are tolerable, and to work on the integrations needed. This prioritization can be seen as being intentional with your telehealth systems' fragmentation. Areas of prioritization to consider when faced with conflicting telehealth technology needs include the following:

1. Clinical functionality
2. Delays in service delivery pending prolonged integrations
3. Functionalities that add efficiencies not present in a health system's legacy workflows
4. Cost
5. End user experience, including the patient

Once a set of priorities are established, and some fragmentation of the telehealth technology ecosystem is allowed, it should also be the goal of eventual full standardization. Working toward a system with smooth user experience, maximized functionality, and optimal cost may require long-term goal setting and shared decision making across varying levels of health systems governance.

Examples of Intentional Fragmentation From the South Carolina Open Access Network

Example 1 of Deviation From the Open Access Network: Telestroke

Telestroke, which is a highly successful use of telehealth across the country, is an example of successful clinical collaboration on common technology that is not tied to the South Carolina OAN. The operational needs of this type of program include on-demand call access to providers and rapid integration of radiological imaging, which often leads to the use of niche, proprietary software apps, as it did here in South Carolina. This telestroke network has led the way in terms of clinical collaboration, with multiple health systems contributing to a common pool of providers for the good of the region and sustainability of the service. However, integrating the OAN with this high-volume, high-stakes service remains a challenge, and thus intentional fragmentation of the OAN permitted.

Example 2 of Deviation From the Open Access Network: Tele-Intensive Care Unit

One example of a telehealth program that is unlikely to meet even the most basic OAN standards are the most widely used technologies for tele-intensive care units (tele-ICUs). Tele-ICU, as conventionally defined, offers continuous remote patient monitoring from a multidisciplinary clinical ICU team led by an intensivist in a fixed space operations center. Each ICU patient room being monitored is wired with two-way audiovisual communication technology, and an emergency alert button is installed that can be activated during patient crisis. The most common technology for this clinical application includes proprietary software that enables a centralized patient census along with easy access to the audiovisual communication system. The two-way communication system is controlled by the remote clinicians and is supported by a separate vendor from the tele-ICU system. Some clinical information derived from the EHR is included in the centralized system, although this varies across programs and is often limited to basic electronic data provided from discreet data fields in the EHR (eg, patient vital signs and laboratory testing). A tele-ICU clinician workstation in the operations center includes 8 to 12 separate monitors and has numerous technologic interfaces established between the operations center and the remote ICU, including EHR interfaces, physician order entry interfaces, bedside monitor waveform interfaces, radiology viewing interfaces, and internal communication systems for operations center personnel.

Discussion

Telehealth is a rapidly growing component of the US health care system. Yet, to achieve large-scale adoption, policy makers and health care stakeholders should consider options that cross the traditional boundaries of proprietary health care marketplaces. The OAN is one approach that facilitated the statewide telehealth network in South Carolina.

The approach to OAN development described here provides a roadmap for achieving a functional telehealth network across independent health systems. The South Carolina experience reveals both successes and challenges in achieving this goal. The next steps toward the development of OANs would include advocacy and ongoing engagement with the developers of telehealth technologies regarding their commitment to interoperability. In addition, focus on health system partnerships, and collaborative processes round out the essential elements of the OAN.

Abstract

Background: Patient follow-up is an essential part of hospital ward management. With the development of deep learning algorithms, individual follow-up assignments might be completed by artificial intelligence (AI). We developed an AI-assisted follow-up conversational agent that can simulate the human voice and select an appropriate follow-up time for quantitative, automatic, and personalized patient follow-up. Patient feedback and voice information could be collected and converted into text data automatically.

Objective: The primary objective of this study was to compare the cost-effectiveness of AI-assisted follow-up to manual follow-up of patients after surgery. The secondary objective was to compare the feedback from AI-assisted follow-up to feedback from manual follow-up.

Methods: The AI-assisted follow-up system was adopted in the Orthopedic Department of Peking Union Medical College Hospital in April 2019. A total of 270 patients were followed up through this system. Prior to that, 2656 patients were followed up by phone calls manually. Patient characteristics, telephone connection rate, follow-up rate, feedback collection rate, time spent, and feedback composition were compared between the two groups of patients.

Results: There was no statistically significant difference in age, gender, or disease between the two groups. There was no significant difference in telephone connection rate (manual: 2478/2656, 93.3%; AI-assisted: 249/270, 92.2%; P=.50) or successful follow-up rate (manual: 2301/2478, 92.9%; AI-assisted: 231/249, 92.8%; P=.96) between the two groups. The time spent on 100 patients in the manual follow-up group was about 9.3 hours. In contrast, the time spent on the AI-assisted follow-up was close to 0 hours. The feedback rate in the AI-assisted follow-up group was higher than that in the manual follow-up group (manual: 68/2656, 2.5%; AI-assisted: 28/270, 10.3%; P<.001). The composition of feedback was different in the two groups. Feedback from the AI-assisted follow-up group mainly included nursing, health education, and hospital environment content, while feedback from the manual follow-up group mostly included medical consultation content.

Conclusions: The effectiveness of AI-assisted follow-up was not inferior to that of manual follow-up. Human resource costs are saved by AI. AI can help obtain comprehensive feedback from patients, although its depth and pertinence of communication need to be improved.

(J Med Internet Res 2020;22(5):e16896) doi:10.2196/16896

KEYWORDS

artificial intelligence; conversational agent; follow-up; cost-effectiveness

Introduction

Artificial intelligence (AI) is a system that can correctly interpret external data, learn from such data, and flexibly apply the acquired knowledge to achieve specific tasks and goals. With the dramatic improvement of computer power to process big data, AI is already ubiquitous in our daily life in the past 50 years. In the past several years, the application prospect of AI in surgery, radiology, dermatology, and oncology is up-and-coming [1-3].

Telemedicine is a medical method used to provide clinical and educational services for remote areas. Information and communication technology are used to transmit medical information [4,5]. Telemedicine attempts to overcome challenges in health services delivery due to distance, time, and rough terrain by improving cost-effectiveness and accessibility of health services in both developing and developed regions [6]. It is an "open and evolving science that incorporates advancements in new technologies and adapts to the changing health demands and social environments." [7] With the growth of AI and big data analytics, the scope and capability of telemedicine have expanded in recent years. Current telemedicine applications can be divided into four categories: patient monitoring, medical information technology, AI-assisted diagnosis, and information analysis collaboration [7]. With the assistance of AI, telemedicine might be an effective method for disease assessment, diagnosis, management, and monitoring [6], especially in chronic disease [8-12], skin diseases [13], and postoperative follow-up care [14].

Postoperative follow-up is an essential part of orthopedic surgery. Medical institutions can provide service for discharged postoperative patients through follow-up. Traditional methods include phone calls, emails, visiting, and reexamination at clinic; all of these methods need a lot of medical resources. With the development of AI and telemedicine, computers or mobile phones could be used to complete more and more of the follow-up work.

In this paper, we describe an AI-assisted system for the follow-up of patients after surgery. The study's aim was to compare the cost-effectiveness and feedback composition of the AI-assisted system with a traditional method for postoperative follow-up.

Methods

Ethics Approval and Consent to Participate

This study was approved by the Research and Ethics Institutional Committee of Peking Union Medical College Hospital (PUMCH).

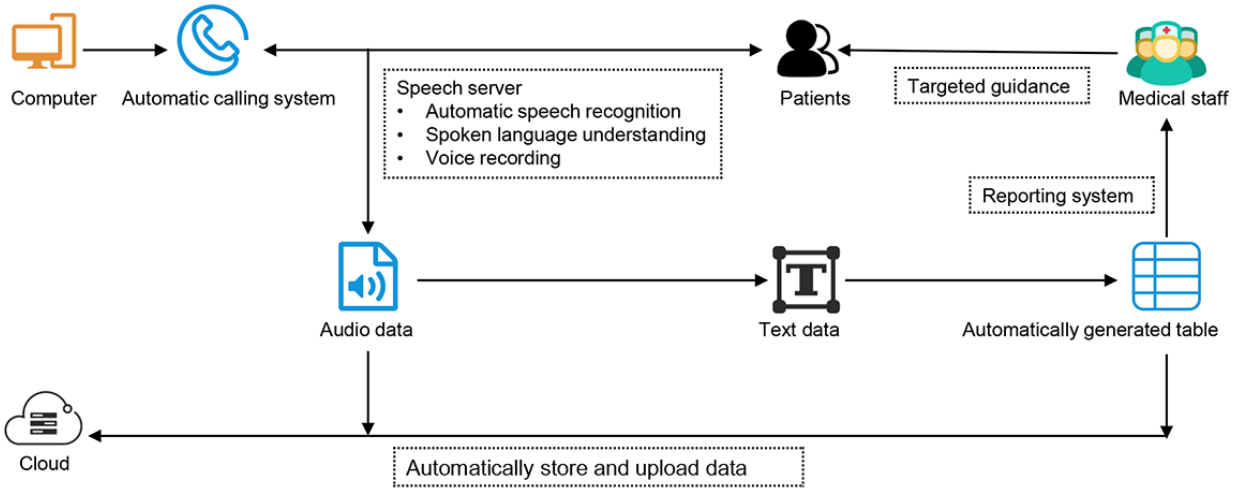
Patient Enrollment and Data Collection

The AI-assisted follow-up system was launched in the Orthopedic Department of PUMCH in 2019. We enrolled 270 patients who had undergone orthopedic surgery at PUMCH from April 2019 to May 2019. This group of patients was defined as the AI-assisted follow-up group since all of the postoperative follow-up was completed by an AI-assisted follow-up system. 2,656 patients who had undergone orthopedic surgery at PUMCH from April 2018 to March 2019 were enrolled as the manual follow-up group. The postoperative follow-up of this group was completed by manual phone calls. Patient characteristics for both groups were collected from the hospital information management system including gender, age, and disease type.

AI-Assisted Follow-Up System

Figure 1 presents a block diagram of the AI-assisted follow-up system. The AI-assisted follow-up system obtained baseline information for each discharged patient including the ID number, gender, age, discharge date, diagnosis, telephone number, and caller location. The system called patients via automated speech telephony delivery in batches from 8:30 AM to 8:30 PM every day allowing hundreds of calls to be made daily. Interactions between the system and patients were based on machine learning, speech recognition, spoken language understanding, and human voice simulation technology. Communication contents included patient satisfaction in the hospital environment, nursing, and health education; wound recovery; functional training; postoperative complications; and other surgery-related medical consulting. The system was able to identify dialects in different parts of China via speech recognition technology and voice information was converted into text in real time. An example of transcribed dialogue that was automatically converted into text is shown in Textbox 1. A report, shown in Table 1, was generated and automatically uploaded to the cloud afterward. Surgeons and nurses could review the report and respond to patient feedback, if necessary.

Figure 1. Block diagram of the AI-assisted follow-up system.



Textbox 1. Transcription of a sample dialogue.

System: Hello, this is Peking union medical college hospital. Could you please take a few minutes to complete a follow-up survey? Thank you!

Patient: ok.

System: our follow-up questions mainly include three aspects: ward environment, propaganda, and nursing. All of the following questions are ranked from 0 to 5, with 5 being the most satisfactory and 1 being the worst. We will record your questions at the end of the follow-up, and would you please help us complete the complete survey?

Patient: yes, no problem.

System: what is your score for the quiet and tidy environment of the ward? The full score is 5 points.

Patient: well, give it a five.

System: ok, may I ask how satisfied you are with the ward environment introduction, health guidance, and the matters needing attention after discharge, etc., given by the nurses during your stay in the hospital? Would you please rate

Patient: well, give it a five.

System: ok, please rate the nurses' responsibility, fit degree, injection technique, regular patrol, response speed, and other nursing work.

Patient: well, five points.

System: ok, what are your complaints about this hospitalization?

Patient: perhaps the most unsatisfactory part is that the doctor is too busy and has too few opportunities to communicate with patients.

System: do you have any other questions for feedback or consultation?

Patient: no.

System: thank you very much for your cooperation. We have recorded your problems and will reply to you as soon as possible. Please keep your mobile phone free and remember to review it on time.

Table 1. Automatically generated table for the dialogue in Textbox 1.

Parameter	Information
Basic information	Patient name, ID number, gender, age, discharge date, diagnosis, and caller location[a]
Dialogue result	System hang up after dialogue
Number of dials	1
Call duration (s)	97
Question 1 score	5
Question 2 score	5
Question 3 score	5
Total score	15
Feedback question	Doctors are too busy to communicate with patients
Follow-up date	2019/6/24

[a]Basic information is automatically extracted from the hospital information management system.

Manual Follow-Up

Follow-up with the control group was performed by phone. Calls were made one by one depending on the availability of human resources. The communication contents were consistent with the AI-assisted follow-up group. Reports were recorded and uploaded manually. Feedback from patients were recorded by the operator and reported to surgeons and nurses.

Evaluation Indicators

Evaluation indicators of follow-up included telephone connection rate, follow-up rate, feedback collection rate, and session duration. Telephone connection rate = (number of effective follow-ups + number of invalid follow-ups) / number of patients called × 100%. Follow-up rate = number of effective follow-ups / (number of effective follow-ups + number of invalid follow-ups) × 100%. Feedback collection rate = number of patients with effective feedback / number of effective follow-ups × 100%. Effective follow-up was defined as the complete collection of data in Table 1 (excluding the feedback question parameter), while invalid follow-up was defined as the absence or incomplete collection of data in Table 1. Effective feedback included patient feedback about nursing, health education, hospital environment, and medical consulting. Moreover, feedback content should be specific and constructive such as dissatisfaction with hospital food or postoperative wound rupture.

Statistical Methods

Data analysis was performed using SPSS statistical software (version 23.0, IBM Inc). Pearson chi-square test or Fisher exact test was used to compare categorical variables (age, gender, medical condition, telephone connection rate, follow-up rate, and feedback rate). The normality of continuous variables (session duration) was tested with a modified Kolmogorov-Smirnov test. Unpaired *t* tests were performed for those following a normal distribution. All tests were two-sided. Data were considered to be statistically significant for $P<.05$.

Results

Patient Characteristics

Patient characteristics for the two groups are shown in Table 2. Group differences in age, gender, and disease category were not statistically significant (Table 2).

Table 2. Comparison of patient characteristics in manual and artificial intelligence–assisted follow-up groups.

Characteristics	Manual follow-up group, n (%)	AI-assisted[a] follow-up group, n (%)	Chi-square (*df*)	*P* value
Number of patients	2656 (100)	270 (100)		
Age (years)			0.8 (3)	.86
<50	805 (30.3)	77 (28.5)		
50-59	480 (18.1)	47 (17.4)		
60-69	861 (32.4)	94 (34.8)		
≥70	510 (19.2)	52 (19.3)		
Gender			1.7 (1)	.19
Male	994 (37.4)	112 (41.5)		
Female	1662 (62.6)	158 (58.5)		
Disease category			4.1 (2)	.13
Spinal disease	1676 (63.1)	154 (57.0)		
Joint disease	938 (35.3)	110 (40.7)		
Other	42 (1.6)	6 (2.2)		

[a]AI-assisted: artificial intelligence–assisted.

Cost-Effectiveness

As shown in Table 3, there was no significant difference in either telephone connection rate (manual: 2478/2656, 93.3%; AI-assisted: 249/270, 92.2%; *P*=.50) or follow-up rate (manual: 2301/2478, 92.9%; AI-assisted: 231/249, 92.8%; *P*=.96) between two groups. However, the feedback collection rate in the AI-assisted follow-up group was significantly higher than that in the manual follow-up group (manual: 68/2656, 2.5%; AI-assisted: 28/270, 10.3%; *P*<.001). The approximate session duration of the manual follow-up group varied from 60 seconds to 180 seconds, according to interviews with the operators. An extra 120 to 180 seconds were also necessary for material recording and uploading. Therefore, the average time spent on each patient in the manual follow-up group was approximately 3-6 minutes. We recorded the total time that the operators spent on randomly following 100 patients (9.3 hours). The average session duration of the AI-assisted follow-up group was 87.7 (SD 39.5) seconds. However, none of this time required human resources, and the AI system generated data reports automatically. In this way, the time spent on AI-assisted follow-up was close to 0 hours. Compared with manual follow-up, the AI-assisted follow-up were of shorter duration.

Table 3. Comparison of manual and artificial intelligence–assisted follow-up indicators.

Indicators	Manual follow-up	AI-assisted[a] follow-up	Chi-square (*df*)	*P* value
Telephone connection			0.4 (1)	.50
Number of effective follow-ups + invalid follow-ups	2478	249		
Number of patients called	2656	270		
Rate, %	93.3	92.2		
Follow-up			0.003 (1)	.96
Number of effective follow-ups + invalid follow-ups	2301	231		
Number of effective follow-ups + invalid follow-ups	2478	249		
Rate, %	92.9	92.8		
Feedback collection			47.1 (1)	<.001
Number of patients with effective feedback	68	28		
Number of effective follow-ups + invalid follow-ups	2656	270		
Rate, %	2.5	10.3		
Time spent, hours per 100 patients	9.3	0	N/A[b]	N/A

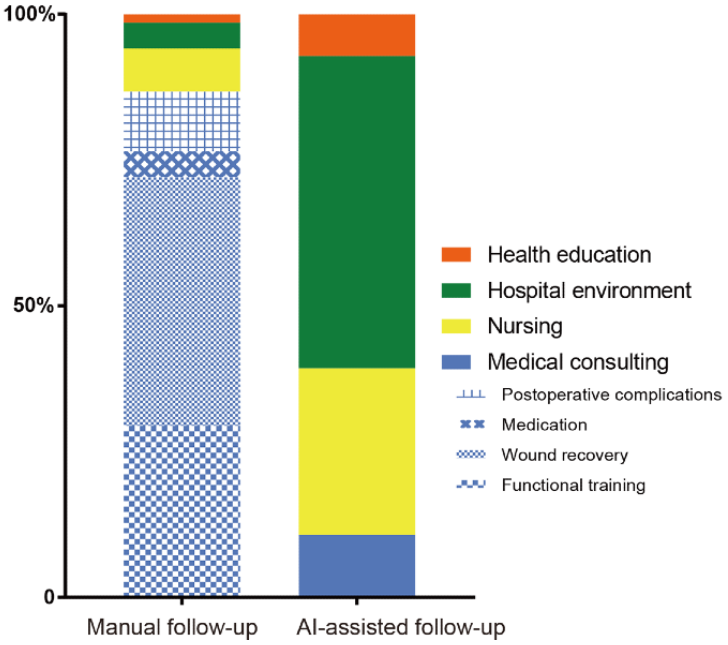
[a]AI-assisted: artificial intelligence–assisted.

[b]N/A: not applicable.

Feedback Composition

The composition of feedback content is shown in Figure 2. In the manual follow-up group, 87.0% of the feedback were medical consultation–related, including functional training, wound recovery, medication usage and postoperative complication (29.5%, 42.7%, 4.5%, and 10.3%, respectively). Feedback related to nursing, health education and hospital environment accounted 7.3%, 1.4%, and 4.3%, respectively. In the AI-assisted follow-up group, only 10.7% of the feedback were related to medical consultation and most of the feedback focused on hospital environment, nursing, and health education (53.6%, 28.6%, and 7.1%, respectively).

Figure 2. Composition of feedbacks in AI-assisted follow-up group and manual follow-up group.



Discussion

Principal Findings

In this paper, we put forward a new methodology for postoperative data collection for follow-up of patients who had undergone orthopedic surgery. The AI-assisted follow-up system is intended to facilitate follow-up efficiency via machine learning, speech recognition, and human voice simulation technology.

In the cost-effectiveness analysis, our study found that there was no significant difference in the telephone connection rate and follow-up rate between the two groups, suggesting the effectiveness of AI was not inferior to the traditional manual method. AI-assisted follow-up could replace traditional manual follow-up to some extent. At PUMCH, follow-up was traditionally completed by nurses or telephone operators where the average time spent on each patient was about 3-6 minutes. The AI-assisted system, however, was able to follow up 5-7 patients simultaneously using telephone relay technology. Thousands of patients could be followed up daily while the time spent on AI-assisted follow-up was close to 0 hours, saving a lot of manpower and human resources.

AI-assisted follow-up did improve the feedback rate, but the composition of feedback was different between the two groups. Feedback from the AI-assisted follow-up group were mainly related to nursing, health education, and hospital environment; only 11% was related to medical consulting. Conversely, this number was 87% in the manual follow-up group. After interviewing the operators, we found a possible explanation to be the telephone operator (usually nurses) were more likely to record feedback that was difficult for them to respond directly, such as medical consultation. In order to improve follow-up efficiency, they tended to respond directly to feedback related to nursing, hospital environment, and health education. This feedback would not have been recorded in the follow-up materials. It also explains why the feedback rate was lower in the manual follow-up group. Another possible explanation was that compared with AI-assisted follow-up, patients could communicate more naturally and deeply with operators. As a result, they may have been more willing to put forward professional medical consultation feedback to operators. In the manual follow-up group, medical consulting could be divided into four categories while in the AI-assisted follow-up group, medical consultation was difficult classify because it was not pertinent.

Limitations

Our work has several limitations. First, apart from phone calls, there are other communication methods that could be combined with AI, such as text messages, computer software, and smartphone apps. Anthony et al [15] invented an automated mobile phone messaging platform for orthopedic trauma patients that improved the responding rate after trauma procedures; however, many elderly patients were not familiar with texting. Therefore, texting might not be suitable for follow-up. Another option is the chatbot. It is a computer program or smartphone app based on AI that can communicate with people via auditory or text [15]. Medical chatbots have been used in disease diagnosis [16], management [17], and monitoring [18]. Recent research showed that chatbots were a convenient method to help

patients address common concerns after ureteroscopy [19]. Integrating chatbots into the telemedicine system could be used to help assess disease conditions and provide self-care recommendations for patients [20]. Therefore, future work may include developing a chatbot software or app for additional medical purposes and to provide better personal service.

The second limitation of this study is that the probation period of the AI-assisted follow-up system is not too long. It is generally believed that with the increasing of machine learning time, the AI-assisted system would become more intelligent. Therefore, we should pay more attention to this system in the future.

Conclusions

In this research, we found that the effectiveness of AI-assisted follow-up was not inferior to the manual follow-up. Moreover, human resources costs could be saved with the assistance of artificial intelligence. Compared with manual follow-up, AI-assisted follow-up obtains more comprehensive feedback, but feedback lacks depth and pertinence. Therefore, the application of an AI-assisted follow-up system in hospital ward management has the potential to improve telemedicine follow-up service and patient satisfaction.

Acknowledgments

The AI-assisted follow-up system was designed by the Beijing Qiyun Zhida Technology Co, Ltd. This system is currently used in the field of trade, finance, and medicine.

Abstract

Background: The medical tourism industry is currently popular in India, but there is no confirmation of the common perspectives among the country's medical travelers.

Objective: This qualitative research study analyzed web-based narratives from health travelers visiting India and described the themes of their experiences. This study aimed to answer the following primary question: What can we learn about health travelers' experiences in India from an analysis of their web-based narratives? The secondary questions were as follows: (1) What are the primary health care reasons for which patients in the examined narratives traveled to India? (2) What can be derived from the narratives regarding medical tourists' satisfaction with the outcome and result of the treatment they received in India? (3) What are some positive and negative factors influencing medical tourists' perceptions and overall experiences about their health travel to India? (4) What are the characteristics of medical tourists who write web-based narratives regarding their health experiences in India?

Methods: Publicly available narratives written by medical tourists who visited India were obtained from a Google search. The narratives included blog posts and discussion board posts by medical tourists. The analysis process consisted of initial open coding being conducted on the narratives to create initial codes and identify common themes with a focus on the primary research question and subquestions.

Results: Although Mumbai, Chennai, and New Delhi were not the only destination cities mentioned, these were the most popular cities patients visited for care. The medical tourists, who stated their origin country, came from one of the following continents: Africa, Europe, North America, and Oceania. Dental care, Ayurveda treatment, and eye care were the most popular types of care that medical tourists sought. The results showed that most of the medical tourists were happy with the overall experience of receiving care in India. The most popular themes with regard to the patients' satisfaction were low costs, good customer service, and services being offered that were unavailable in their home country. When negative feedback was provided, it was mainly concentrated on the overall environment of India being unorganized and unsanitary.

Conclusions: Primarily, the study's findings can benefit health care providers and patients. Providers hosting medical tourists in India can use negative feedback to improve their services; similarly, providers who are losing patients to medical tourism can identify opportunities for improvement (ie, why are we losing patients). Indian providers hosting medical tourists should keep their prices competitive and continue to provide exceptional service; however, they should do their best to lessen the crowdedness of their facilities while making sure they are esthetically pleasing. Providers losing patients to medical tourism need to identify

ways to ensure their services match the benefits that their international counterparts are providing, such as competitive pricing and expansion on the services provided.

KEYWORDS

medical tourism; India; global health; personal narratives; travel-related illness; qualitative research; patient satisfaction; delivery of health care; travel; data collection

Introduction

Background

Depending on the source, the terms "health tourism," "medical tourism," and "wellness tourism" are used very loosely and unsystematically [1]. According to Connell [2], this is most likely because the boundaries between these terms are unclear. For the purposes of this paper, the terms medical tourism and health traveler are used to define instances when a patient travels across international borders to obtain medical care. These medical tourism treatments may range from highly invasive heart surgeries to less invasive procedures such as dental work. Mutalib et al [3] stated that "medical tourism (specifically) is not a new phenomenon, what is new is actually the trend of practicing medical tourism." Lunt et al [4] explained that availability, cost, expertise, and cultural and familial reasons motivate patients to seek care abroad. The majority of medical education in India is subsidized by the government; therefore, the doctors do not have the heavy burden of student loans [5]. This helps to drive down the cost of care. Similarly, Alsharif et al [6] examined medical tourists visiting India, China, Jordan, and the United Arab Emirates and found that the most important reasons for patient travel were cost, provider's reputation, and hospital accreditation. Throughout the paper, the terms posts, narratives, and journals have been used interchangeably to represent the qualitative data analyzed to execute this research.

The internet can play a role in a prospective patient's medical tourism decisions. According to Lunt et al [4], patients consult a range of information sources before making decisions, and the internet plays a key role in providing information from informal networks. Consumers participating in web-based health care communities often reveal personal information in intricate detail [7]. As it relates to health care specifically, trust in the destination assures medical tourists who choose to visit a particular destination that the services provided will be transparent, reliable, and risk and hassle free [8]. According to Lunt et al [4], medical tourists often pay more attention to soft information than hard clinical information.

Prior Work

This study originated from the recommendations in the further research section in the study by Ozan-Rafferty et al [9] titled "A qualitative analysis of internet narratives by health travelers to Turkey". Her study analyzed web-based narratives from health travelers to Turkey and described the themes of their experiences. This study will mimic the established method of the abovementioned study but focus on India instead of Turkey.

Setting

India is roughly one-third the size of the United States but its population is about four times that of the United States [10]. India's private sector providers, along with independent medical tourist–facilitating organizations, have taken the lead in developing medical tourism [11]. The combination of India's economic liberalization, growing middle class, and the rise in medical tourism has contributed to the growth in the number of private, for-profit hospitals [12]. The primary reason for India's growing medical tourism sector is cost savings. On average, medical services provided in India cost almost half the price of those offered by any other developed country [13]. The Indian government has encouraged the growth of medical tourism by issuing special visas for medical tourists [6]. In addition, many patients are intrigued by the possibility of combining their medical treatment with a vacation [2].

There are no authoritative data on the number and flow of medical tourists between nations and continents [14]. This is mainly because there are no international standards for the transmission of information to clinicians in the patient's country of origin [15]. Bernasek [16] cited the World Health Organization's projection that 16 million Americans would travel abroad for medical care in 2017. In their study on medical tourism growing in the Indian health care market, Gupta et al [17] noted that India's Ministry of Tourism has even conducted road shows in West Asia (Dubai, Riyadh, Kuwait, and Doha) to promote medical tourism.

Similar to the research by Ozan-Rafferty et al [9], this research assumes that understanding the experiences of medical tourists will benefit the providers who service current and future medical tourists. In addition, the findings from this study can be used to assist in decision making for patients considering health travel in the future, and they may strengthen health administration education by providing insights on medical tourism [9]. In addition, this study's outcomes may lead to the development of more online communities focused on improving medical tourism. In the future, this study can help further the push of establishing a global tracking system for statistics on the number of medical tourists. More importantly, we hope that this study will encourage more research on the topic of medical tourism by way of its recommendations and drive competition resulting in a better health experience for all patients irrespective of their location.

No funding was required for this study. As per Central Michigan University's Institutional Review Board (2017), it has been determined that this project does not meet the definition of human subject research under the purview of the institutional review board (ie, exempt status). This is because no human

subjects were involved in the research, and no identifiable information was included.

Research Questions

The medical tourism industry is currently popular in India, but there is no confirmation of the common perspectives among the country's medical travelers. The questions to be answered are as follows: (1) What are the primary health care reasons for which patients in the examined narratives traveled to India? (2) What can be derived from the narratives regarding medical tourists' satisfaction with the outcome and the result of the treatment that they received in India? (3) What are some positive and negative factors influencing medical tourists' perceptions and overall experiences about their health travel to India? (4) What are the characteristics of medical tourists who write web-based narratives regarding their health experiences in India?

Methods

Recruitment

This is a qualitative research study based on a narrative analysis from Creswell's qualitative approach [18]. Narratives written by medical tourists visiting India were obtained using publicly available webpages identified via a Google search. The narratives included blog posts and discussion board posts by medical tourists who visited India for care. Data were extracted using purposeful sampling, which focuses on information-rich cases related to a specific topic [19]. Similarly, Blumberg et al [20] stated that purposeful sampling is when researchers select participants arbitrarily for their unique characteristics or their experiences. In this case, the focus was on patients who left their home countries and received care in India. The search terms used included, but were not limited to, "health travel," "medical tourism," "plastic surgery," and "wellness travel" and incorporated "India," "Mumbai," "New Delhi," and "Kolkata." Specific clinical procedures used in the search were determined based on the reviewing sites that promoted health travel to India, as well as findings from the literature review, and terms noted in initial findings.

Results from the first 10 pages of the general Google search were reviewed to find narratives that met this study's criteria, which were as follows: (1) a first-person narrative written by an individual who underwent treatment or their partner on the trip, (2) a narrative written in English, (3) a narrative that includes a description of the type of procedure, (4) a narrative that includes a personal experience of health travel to India, and (5) a publicly available narrative that does not require a password or discussion board membership to be accessed [9]. Then, following the core of the process established in the "A qualitative analysis of internet narratives by health travelers to Turkey" study, the next step limited the search results to only include discussions. Next, results from the first 10 pages of the "discussion" were only filtered results that were reviewed to determine whether there were any eligible narratives meeting the same 5 requirements listed earlier.

On the basis of the research by Ozan-Rafferty et al [9], the following review attributes were considered when collecting the narratives. Any narrative that was longer than a single sentence was added to the queue for analysis. However, some of the narratives were in a chronological story format, and some were shorter in length and outlined a specific part of a general larger experience [21]. Even though posts and blogs related to the topic of the author's health travel were included in the research, other topics written by the author were reviewed to obtain demographic or characteristic information such as the author's age, gender, or country of origin. Multimedia Appendix 1 displays the steps in the narrative process by way of a flow diagram.

On the basis of the types of medical tourism treatments identified in the research review, 256 different keyword searches were performed. These produced more than 800 million search results. Of course, this is when counting results falls outside of the first 10 pages. After the filtering process was completed, there were 53 narratives available for analysis.

Coding Analysis

For the coding process, the identified narratives were copied from the internet and posted in individual Microsoft Word (Microsoft Corporation) documents. Each document was named by using an identifier (ie, "000") that coincides with its entry number in the process and findings log. Similar to the study by Ozan-Rafferty et al [9], the narratives that included more than one entry were collected chronologically from the oldest to the newest. All the narratives combined totaled to 121 pages. The largest page count of a single narrative used was 23. There were 34 narratives that were 1 page each. As each narrative was contained in its own document, the page count was rounded off. For example, a narrative that was one and half pages long was counted as being 2 pages long.

Initial open coding was conducted on the narratives to create initial codes and identify common themes with a focus on the primary research question and subquestions [9]. The unit of reference was a sentence [21,22], and a total of 2536 units of measure were analyzed. In addition, the content of each sentence was examined to identify positive and negative opinions [22]. Written words were analyzed using narrative analysis theory principles to create primary (parent) and secondary (child) themes [9]. As the analysis occurred, notes were taken to clarify the concept behind some of the codes and sentences being analyzed. More than 40 primary themes were identified, and if necessary, memos were kept for each sentence coded to add context and keep track of concepts.

A second review was completed, and the narratives were entered into NVivo Pro Version 11 (QSR International) where the initial codes, key concepts, and themes identified in the open coding were clustered [23]. As was performed in the study by Ozan-Rafferty et al [9], NVivo was used to identify relationships with the various initial themes. Each sentence along with its corresponding code was entered into NVivo. The codes were clustered into categories, and various clusters were used to identify trends and relationships.

A final round of selective coding [23] was completed by scanning all the data and codes and reviewing all themes. Multimedia Appendix 2 displays the theme frequency count table. To confirm coding accuracy, an additional researcher was

approved by the dissertation committee, and he randomly selected 8 of the 53 narratives to review. For the random selection process, the narratives were numbered 1 to 53 but were in no specific order. The 8 narratives selected were independently coded by the additional researcher. After comparing the additional researcher's codes with the primary researcher's initial codes, there was only 96.5% reliability (reliability=number of agreements divided by the number of agreements + disagreements). It is important to note that any personal identification details of the narrator were removed and not considered in this research.

As has been mentioned, there was a committee outside of the additional researcher. This committee consisted of 3 members, and they approved all major components of the study. Given that she had prepared a similar project focusing on Turkey, Dr Ozan-Rafferty was the committee member who assured that the methods were followed correctly. Dr Sharma, originally from India, assured the accuracy of information depicted in the narratives, and Dr Johnson was the chairperson overseeing all aspects of the project.

Data Exclusion

During the search process, it was not very difficult to find weblinks in which patients were discussing their medical experiences in India. However, most of the initial findings were not eligible for this study because they were being posted for promotional purposes. For example, the direct quotes were on the webpages of hospitals that wanted people to come to their facilities for a certain procedure. The articles that quoted medical tourists but were not written by the actual medical tourists or by someone who went on the trip with them were excluded. There were many photo blogs and video blogs (vlogs); by strictly following the method established in previous research on this topic, this type of media was not considered. Adding a photo, video, or the aspect of judging a person's tone could have easily distracted from the overall word analyzation, which was the primary focus of this project. It was not uncommon to find blogs or articles written by doctors who treat medical tourists. If joining a forum or discussion group was required to obtain any narratives, obtaining membership in the discussion forum or discussion group was not done to ensure all information used is truly publicly available. A log of each narrative was created and included the web address of each post. Some medical tourists posted the exact copy of the narrative on multiple webpages, and those duplicates were eliminated from this research.

Results

Overarching Narrative Details

The entire search process took place from November 5 to 16, 2017. Narratives were reread on the web on January 8, 2018, to confirm no additional postings were added. Some search inputs garnered millions of results. Of the narratives that were used, most came from discussion forums where someone would start a thread such as, "Has anyone been to India for…," and previous medical tourists responded by sharing their stories and helping out other prospective health travelers by answering general questions. There were several blogs as well. Some of the blogs were very professional-looking (with photos and embedded videos), whereas others were simple text entries. From time to time, a narrative was found in the comments of an article about medical tourism, so it was important to read all the comments on an identified weblink. At the conclusion of the search, a total of 53 narratives were deemed eligible for analysis. Of those 53 narratives, 6 were blog posts. The remaining 47 narratives were from a discussion thread.

Of the 53 narratives collected, there were only 8 narratives in which the medical tourists' countries of origin (home countries) were unidentifiable. Table 1 displays the continent of origin and country of origin for each patient. This table is in an alphabetical descending order. With 11 narratives, the United States was the country with the highest number of medical tourists visiting India, followed by the United Kingdom and Australia (10 each). There were 3 countries with only 1 medical tourist visiting India: Morocco, Austria, and France.

Table 1. Health travelers' country of origin.

Country	Travelers, n

Narrative Content Details

Of the narratives analyzed, the most frequent procedure availed by a medical tourist was some kind of dental care. This was followed by Ayurveda treatment and Lasik eye surgery. There were a number of services that were only mentioned once across all the narratives. These services ranged from gallbladder surgery to a hair transplant. Although it did occur, it was not a common trend for patients to avail more than one medical service while in India. Table 2 consists of the detailed counts of how often a procedure was availed.

Tables 3-6 provide details regarding each patient and demographic details about where the procedures occurred. With regard to gender, 21 of the medical tourists were men and 18 were women; the gender of the remaining 14 tourists was unidentifiable. In most cases (32 narratives), there was no indicator of the patient's age. Regarding the identified ages, it is notable that 14 of the patients were older than 40 years when their initial post was made. Then, 16 of the narratives referred to a person accompanying the medical tourist while in India, and of those 16, 4 were authored by the person who accompanied the patient. Only 4 narratives mentioned that the patients used a medical tourism–facilitating organization.

Most of the narrators (n=30) only made a single post, and 11 made two posts. One narrator made 21 entries, and another made 39 entries. There were 4 narratives in which years passed between the first and last posts. However, all the other narratives consisted of posts that occurred within a year or another. In addition, 45 of the posts were made between 2010 and 2017. The oldest post analyzed was from March 2005, and the newest post was from December 2017. A total of 29 narratives mentioned the actual treatment date.

The destination city was noted in 38 of the narratives. Mumbai, Chennai, and New Delhi were the most popular cities that patients visited for care. Regarding specific facilities, 23 different facilities were listed, but only 2 were listed more than once: Asian Joint Reconstruction Institute of Chennai and MY EYE.

The authors were very open about their experiences. They shared details such as the food they ate all the way up to their personal fears (such as flying). It was similar to reading a personal journal. From a personality standpoint, very few users described themselves, but when they did, they included descriptors such as humble, self-conscious, and focused on health. Most narrators had a positive attitude rather than a negative one. This is because they stated things such as "I'm excited about the trip" or "I had been looking forward to this." Many sentences that were coded described the narrator as not having a complaining attitude, having an overall positive view on life, or being optimistic about their health's improvement after receiving treatment in India. Contributors also encouraged others. For example, a patient with Crohn disease sent this message to another person diagnosed with Crohn disease: "I really hope she feels better, and I know sometimes it can feel like there is no hope and you're willing to try everything to help alleviate the symptoms." The following sections are reasons for medical tourism, patient satisfaction, and perception influencers. These are used to highlight the significant themes identified in the narratives.

Table 2. Health travelers' primary and additional procedures.

Row labels	Count of primary procedure[a]	Count of additional procedures
Ayurveda	9	N/A[b]
Dental	13	N/A
Eyelid surgery	1	2
Gallbladder surgery	1	3
Gynecomastia surgery	1	N/A
Hair transplant	1	N/A
Heart surgery	1	N/A
Hernia surgery	1	N/A
Joint replacement	3	N/A
Lasik eye surgery	8	2
Limb lengthening	3	N/A
Physical exam	2	N/A
Physiotherapy	1	N/A
Plastic surgery	3	1
Sex reassignment surgery	1	N/A
Shot	1	N/A
Spine surgery	1	N/A
Surgery	1	N/A
Surrogacy	1	N/A
Grand total	53	8

[a]Primary procedure is the procedure the narrator noted first or mentioned as their primary reason for traveling to India for care.

[b]N/A: not applicable.

Reasons for Medical Tourism in India

The medical tourism drivers were patients attempting to receive the best care for a specific diagnosis, travelers trying to overcome home country barriers (ie, costs or unavailability), and patients seeking alternative treatments for a condition; there were a few who were just curious about the overall medical tourism experience and options. One of the more polarizing direct quotes was "No, I can't get the same treatment in America, that's why I'm here." Another stated "I have private health insurance, but I wasn't happy with the experience (or lack of) surgeons have here in carrying out the procedure."

It appeared that patients became open to the idea of medical tourism while researching one of two things. They were either looking for a provider who specialized in treating a certain diagnosis or researching procedures to treat certain conditions. A patient exploring Lasik options stated:

> *At 64 I decided that I had enough of broken glasses reading in bed. I went for a consult with a very reputable eye laser company here in Toronto. After all the tests, (no blood work) they can only restore my far vision at the cost of $6000+. I did some research and found a doctor in India…made an appointment through their site.*

In fact, there have been studies that confirm various health clinics will use the internet to advertise their services globally and that they not always clearly depict the risks of certain treatments [24].

Patient Satisfaction

The number of satisfied health travelers greatly outnumbers those who had complaints or expressed unhappiness. For example, some narrators made comments such as "happy with dental implants," "normal life regained," or just "happy with results." General problem resolution comments were the most abundant indicator that patients were satisfied with the care they received. With Ayurveda treatments, specifically, there were comments such as "found a love for yoga" or "found true self" that were not initially expected outcomes by the narrator. One Ayurveda patient said they found an "unexpected healing." A narrative, in which a patient received Lasik eye surgery, stated:

> *My sight is amazing and having had a session with Dr. Chandrakant Gaonker again this morning, he says it will get better each day.*

Another critical point surrounds the topic of desired repeat travel to receive care again. The repeat travel was not because the initial visit required any type of follow-up care, but it was because the patient was so happy with the experience, they wanted to go back to get another procedure. There was a narrator who mentioned they would only be getting their dental work completed in India moving forward. In addition, there was a narrator who considered permanently moving to India because they felt the care was highly superior to that offered in their home country for supporting specific chronic conditions.

When patients expressed negative feedback on the outcome and results, the negativity fit in the following primary categories: general bad experience, bad appearance, unresolved problem,

or issue worsened. Dental procedures most frequently garnered an unsatisfactory comment about the results, especially when relating to a narrator's appearance after care was given. After receiving a dental bridge, a patient said:

> *The curve of my finished bridge was way out of sync with my upper gum line, and the inner gum line sat too low from my gum, causing every bite I took to clog up in that space.*

One patient with Crohn disease did not mention that their condition worsened, or any corrections had to be made, but that the Ayurveda treatment had no impact:

> *Despite the doctor's assurances, it did not help much, I still had the same intolerances and same degree of inflammation.*

Perception Influencers

The influences that shaped the narrators' Indian medical tourism care experience included India's general environment. This was the noise, smells, and basic laws. One patient summarized his feelings by saying:

> *The problem is that I don't know the culture, don't speak the local dialect, have a hard time understanding the English of the average Indian, am a little intimidated by the system, and feel somewhat alone and isolated.*

Cost was another perception influencer; the costs mentioned were everything from the lodging to receiving care. Travel logistics (such as the passport and visa process), quality of care, customer service, facility condition, and follow-up care were the other main contributors that shaped narrators' opinions. For example, regarding costs, a notable trend among the narratives was that they described the payment process. Prepayment was one of the more frequent payment processes mentioned. Throughout all the narratives, there were 6 references to a prepayment requirement (before services were rendered). There was one narrator who mentioned they not only had to pay in advance, but they were required to pay cash:

> *He insists on only cash, so I handed over Rs. 98,500 (remember Rs. 1500 was paid already for the tests). I felt like I was doing some sort of underhand deal, however I fully trusted Dr. Sandip.*

Discussion

Principal Findings

Almost all the narratives came from patients seeking resolution of a health issue. There were no patients who went to India merely for exploratory purposes. Patients either felt they needed to fix their appearance (ie, cosmetic) or had a serious medical diagnosis such as a hernia. The patients found India by looking for not only the best care but also the most affordable resolution, which is consistent with the findings of the study by Ozan-Rafferty et al [9].

The general theme of all the narratives reviewed was positive. It was rare for a patient to indicate that their travel to India for care was negative. Many of the narratives focused on how affordable the care was when compared with that in the patients' home countries. An author even mentioned that he tried to give a financial tip to a provider because the care was so good and affordable. The other positive influencers were the narrators' good interactions with the health care providers in India, the modern facilities, and the resolution of their health issues. Many narrators mentioned that they would be a medical tourist in India again and encouraged others to travel to India for medical care. With that said, it is still important to state that there could be far more negative experiences, but the patients did not necessarily document their experiences on the web.

Reasons

The narrators said that a barrier prevented them from resolving their health issues in their home country and drove them to India. Some people sought procedures such as Ayurveda treatment, Desarda hernia repair, or limb lengthening that are simply not offered in all parts of the world. Some patients could not afford or did not have the type of insurance necessary to get the care they needed. A good example is the patients who went to India for dental care because they did not have dental insurance in their home countries. In fact, dental was the most common type of care the patients in this study received. There was an author who said they received a root canal at no charge.

The blog comments and discussion threads included detailed conversations between former and possible future patients just talking about medical tourism in general. It was obvious that some participants provided more insights to the readers in a more private format because they would reference a private message exchange with another user. Sometimes experiences were reconfirmed when other medical tourists commented that they had gone to India for care and had a similar story (ie, same doctor or facility).

Satisfaction Levels

As mentioned, many of the authors said their primary issue was resolved for an affordable price, and the authors encouraged others to consider medical tourism when looking to have their health issues resolved. As this study is replicated, the number of primarily negative-toned narratives is critical, similar to those highlighted in the next section; it will help to answer the question, if providers of medical tourism are improving (based on feedback) or ignoring opportunities to get better. In addition, patients' opinions, which were once positive, could change if there are any delayed side effects.

Negative Viewpoints

All of the negative comments tied back to the health issue not being fixed to the patient's satisfaction. This section will focus on two of the narrators who were the most dissatisfied. A dental patient's condition worsened as a result of bad implants, and the author realized it would be difficult for her to file a lawsuit because she voluntarily went out of her home country to get care. Another narrator said that providers spoke to each other in an unidentified language even though they all spoke English, and this made her feel excluded and uncomfortable. That same patient said she believed some of the utensils used during preoperational procedures were not clean.

Interactions With Hospitals and Providers

The number of patients and their companions who reported good encounters with the providers in India greatly outnumbered those who experienced bad encounters. The positive comments included, but were not limited to, providers being well dressed, providers having extensive experience, friendly doctors, and some patients being greeted with flowers upon arrival. There were more than a few times that a provider had good web-based reviews, which initially led the patient to the provider. In addition, patients really seemed to be comforted if the provider had experience or training in the United States, and a large number of the patients indicated the providers either spoke English or had a translator readily available.

When negative comments were made specifically related to provider and patient interaction, they seemed to be aimed at inaccurate web-based advertisements of the doctor's capabilities and specialties and general poor communication. For example, one patient landed in India only to find out their appointment had been canceled, and another narrative described a provider as being money hungry.

Challenges to Medical Tourism in India

Some of the main challenges to medical tourism in India are poor visitor experiences expressed in negative web-based reviews, travel logistics (ie, long flights, having to get passports and travel visas), lack of capital compared with other countries marketing medical tourism, and improved health care infrastructure across the globe [13]. Regarding negative web-based reviews, many of the narratives indicated that the patient completed web-based research before deciding to go to India for care, and it was not unusual for patients to remark that it was difficult to identify trustworthy information or find information about medical tourism in India. There were previous medical tourism patients who had posted negative feedback about doctors on web-based forums or blogs and urged others to avoid medical tourism. In the narratives used for this study, a dental patient said the dentist they saw in India had persuasive marketing but was not successful in resolving any of the patient's primary diagnosis. The patient said the provider deleted any bad reviews users posted on Facebook.

Although India does have a medical tourism–focused visa, the passport and visa process creates another hurdle for patients who want to go to India for care. Once the appropriate passports and visas are obtained, there can be the issue of discomfort owing to a long flight.

India is not the only country known as a medical tourism destination, and some countries are working hard to not lose patients to medical tourism. Within this study, there was a narrative in which a dental patient wrote:

> *I researched nearly every clinic in New Delhi and trust me—none of them are as well trained and professional as in the U.S. YOU GET WHAT YOU PAY FOR!!! My suggestion is to try Buenos Aires, Argentina.*

Brazil, Turkey, Mexico, Costa Rica, and Thailand are just a few of the other countries promoting medical tourism [25]. These options could be more attractive to a potential medical tourism patient if they are closer, cheaper, or do not require a travel visa.

Opportunities for Medical Tourism Improvement in India

After reviewing the narratives, three opportunities for the improvement of medical tourism in India are apparent. The first is international accreditation. Several patients did not have a process to ensure they were receiving quality service other than "everything looked up to date and clean." Although there are hospital-accrediting organizations and processes in India, the certification and approval details need to become more prominent and widely advertised. Adding to that, organizations such as Healthgrades and RateMD could expand to emphasize provider reviews specifically tailored for medical tourists.

There is an opportunity for Indian providers to partner with providers across the globe to assist with patient preparation and follow-up care. Many narratives mentioned that there was additional time spent in India to prepare for their procedure (such as x-rays, bloodwork) or get the appropriate follow-up care. Patients mentioned that they had to do substantial self-care once they went back to their home country, such as changing dressings or preparing food in a certain manner. If an Indian doctor partnered with providers in other countries, this could reassure patients that their needs could easily be met before and after their care was completed in India, eliminating the cumbersome follow-up care process.

The third item is the extremely limited availability of medical tourism insurance that covers the costs of procedures completed overseas. Although the narratives did mention huge cost savings when doing an "apples to apples" comparison (price of procedure in home country vs price in India), the patients were paying out of pocket for travel, lodging, and care. There is a huge opportunity for India to introduce insurance that would help alleviate some of the current medical tourism out-of-pocket costs.

Limitations

There are no official statistics or databases regarding how many people travel internationally to obtain health care [26]. So, there was no pool of known health travelers that could have been contacted to gather general additional insight or expedite the narrative search process.

Greenhalgh [27] pointed out that a primary limitation of narrative research is that narratives are open to multiple interpretations. With that, Bhattacharya [28] added that researchers need to be mindful of their own subjectivities; they should be aware of how their personal experiences creep into the research process and influence the way in which the researcher understands the narrations.

Following the method established in the study by Ozan-Rafferty et al [9], there were already some built-in limitations. These limitations included the chance for fictitious and biased data to be present in the narratives, and the researcher had limited methods to validate self-reported information [29]. As described in the Methods section, narratives were not used if they were posted for promotional purposes. This would include

testimonials posted on the actual webpages of providers, websites that strictly focused on consumers rating their experiences, or any post that flat out said something such as "the provider asked me to post this..." Anonymity releases authors from any consequences of their posts or behavior, but at the same time, anonymity may encourage people to share more on the web and discuss sensitive topics and issues [30]. The sample did not include individuals who lacked access to a computer or some type of internet-connected device (to post their narrative on the World Wide Web) and thus may not be representative of the general population [31]. Of the 53 narratives, only 6 were blogs. As these were not live interactions (ie, real-time interviews or conversations), the researchers were unable to clarify feedback provided by the health travelers [9].

Since Ozan-Rafferty et al [9] completed their original study related to this topic, Google has disabled the search filter that allowed users to limit search results strictly to blogs. The feature was retired in 2014 [32].

Comparison With Prior Work

It is notable that a portion of this study's results align with some of the results in the study by Ozan-Rafferty et al [9], which focuses on a completely different country. For example, Europe and North America were the top home origination countries for medical tourists. Most of the patients were content with the care they received while being abroad, and the health travelers thought fondly of the providers they saw in the host countries. One of the negative commonalities that stood out was the bad traffic described in both Turkey and India. The results of studies that follow this same method but apply it to different countries can be combined to make more precise conclusions about medical tourism, overall.

There was a contrast in the popular procedures from each study. In the study by Ozan-Rafferty et al [9], the top procedure that medical tourists availed was hair transplants. However, only 1 patient mentioned getting a hair transplant when India was studied. Ayurveda was the second most mentioned procedure in this study, but it was not mentioned at all in the analysis by Ozan-Rafferty et al [9].

Conclusions

This is not the first study to focus on medical tourism or medical tourism in India, specifically. As mentioned, it was actually birthed from the recommendations of a prior study, but it is unique in how and when the research occurred and the method that was used to study medical tourists who traveled to India for care. Although keeping technology and the medical industry constantly evolving, the core of this study's findings can be beneficial to health care providers, patients, and governments. The method can be applied to research medical tourism in other countries or even to gather consumer feedback on topics beyond health care. About 25 years ago, this study would not have been possible. The advancement of internet search engines and increased socializing on the internet has greatly helped to evolve research. Now, there are actual E-Hospitals. Hong [33] wrote about the Chinese American Physician E-Hospital's October 2015 grand opening. All physicians affiliated with this E-Hospital are bilingual Chinese American physicians who are board certified in the United States, and the website is designed specifically for the Chinese population (webpage only available in Chinese). The services provided include international transfer in the United States, saving the patients the hassle of identifying and connecting with an appropriate health service provider and also minimizing language and cultural barriers [33].

The limitations previously stated must still be considered, specifically considering the fact that there is no guaranteed way to assure all the narratives are truthful, and there is no solid estimate on how many medical tourists are actually traveling to India. However, providers hosting medical tourists in India can use the negative feedback to make corrections in the services they provide. As many patients noted disorganization was a sore point in their experience, providers can make sure to have organized lines when patients are checking in or out of the facilities. Providers who are losing patients to medical tourism can refer to this study and make service adjustments so that fewer patients are swayed to become medical tourists. For example, more providers might start practicing forms of Ayurveda, which is currently not provided in many countries outside of India. Many patients in the study specifically went to India to receive Ayurvedic care. Some narratives mentioned extending the length of trips so patients could receive appropriate follow-up care and some mentioned that follow-up care was not possible in their home countries. Providers can seek ways to enhance the follow-up care process by possibly setting up satellite offices in partnership with providers in other countries.

These results open up more options for patients. There are positives (ie, very affordable) and negatives (ie, bad traffic) about medical tourism in India. In addition, prospective patients can use altered and less-intensive versions of this study's method to research how they can resolve their specific health issues as medical tourists in India or in other countries. In addition, patients who have previously been medical tourists and review this project can add to the details provided by authors of the narratives. More participation will help increase the accuracy of future work.

Acknowledgments

This research was conducted as part of the first author's (JB) requirements for completing a Doctorate of Health Administration at Central Michigan University. The author would like to thank the Dissertation Committee Chair, JJ; Dissertation Committee Member, MO; Dissertation Committee Member, MS; and SB for coding review.

Abstract

Background: Roadside observational studies play a fundamental role in designing evidence-informed strategies to address the pressing global health problem of road traffic injuries. Paper-based data collection has been the standard method for such studies, although digital methods are gaining popularity in all types of primary data collection.

Objective: This study aims to understand the reliability, productivity, and efficiency of paper vs digital data collection based on three different road user behaviors: helmet use, seatbelt use, and speeding. It also aims to understand the cost and time efficiency of each method and to evaluate potential trade-offs among reliability, productivity, and efficiency.

Methods: A total of 150 observational sessions were conducted simultaneously for each risk factor in Mumbai, India, across two rounds of data collection. We matched the simultaneous digital and paper observation periods by date, time, and location, and compared the reliability by subgroups and the productivity using Pearson correlations (r). We also conducted logistic regressions separately by method to understand how similar results of inferential analyses would be. The time to complete an observation and the time to obtain a complete dataset were also compared, as were the total costs in US dollars for fieldwork, data entry, management, and cleaning.

Results: Productivity was higher in paper than digital methods in each round for each risk factor. However, the sample sizes across both methods provided a precision of 0.7 percentage points or smaller. The gap between digital and paper data collection productivity narrowed across rounds, with correlations improving from r=0.27-0.49 to 0.89-0.96. Reliability in risk factor proportions was between 0.61 and 0.99, improving between the two rounds for each risk factor. The results of the logistic regressions were also largely comparable between the two methods. Differences in regression results were largely attributable to small sample sizes in some variable levels or random error in variables where the prevalence of the outcome was similar among variable levels. Although data collectors were able to complete an observation using paper more quickly, the digital dataset was available approximately 9 days sooner. Although fixed costs were higher for digital data collection, variable costs were much lower, resulting in a 7.73% (US $3011/38,947) lower overall cost.

Conclusions: Our study did not face trade-offs among time efficiency, cost efficiency, statistical reliability, and descriptive comparability when deciding between digital and paper, as digital data collection proved equivalent or superior on these domains in the context of our project. As trade-offs among cost, timeliness, and comparability—and the relative importance of each—could be unique to every data collection project, researchers should carefully consider the questionnaire complexity, target sample size, implementation plan, cost and logistical constraints, and geographical contexts when making the decision between digital and paper.

Introduction

Background

Road traffic injuries (RTIs) are a major global public health problem. With over 1.35 million deaths and 20-50 million nonfatal injuries estimated each year, RTIs impact all age groups and populations of all socioeconomic backgrounds [1]. However, low- and middle-income countries (LMICs), with rapid motorization in an unsafe road environment, bear a disproportionate share of deaths and disability [1]. In addition to safe vehicles, road infrastructure, and road safety management capacity, enhancing safe road user behavior plays an important part in preventing crashes and injuries [2]. The development and successful implementation of comprehensive programs to positively impact speeding, helmet, and seatbelt wearing require rigorously monitoring the prevalence of behavioral risk factors. One such example is the Bloomberg Initiative for Global Road Safety (BIGRS), a multisectoral program that unites a consortium of partners that work together to reduce the burden of RTIs in 10 cities in LMICs [3]. Roadside observational studies have played a fundamental role in designing evidence-informed strategies, including media campaigns, enforcement, and environmental modifications to enhance road safety.

Paper-based data collection has been the standard method for primary observational studies, but due to the possibility of human errors, storage costs, and time and labor required for double data entry, digital data collection methods are gaining popularity. Two concerns frequently influence the decision to switch from paper to digital methods of data collection. First, whether digital data collection is as productive and reliable as paper data collection in a dynamic roadside environment, and second, whether digital data collection is at least as efficient as paper data collection. Recent observational studies of road safety risk factors in three different countries, using both approaches have consistently demonstrated reliable results between the two methods [4]. In LMICs, with limited resources and relatively less expensive labor costs, paper data collection has been traditionally deemed as feasible and potentially more affordable. However, the efficiency of digital data collection vs traditional paper-based approaches has not been empirically assessed in these settings.

Efficiency is a rate measure against cost, time, or accuracy, and is used to assess whether the desired output can be produced in less time, using fewer resources, or with fewer errors. Efficiency is contextual, as cost and time efficiency is tied to the availability of infrastructure or other logistical requirements, as well as human and material resources. For a researcher deciding between using digital or paper data collection, provided there is a reasonable level of reliability and comparable productivity between the two methods, the decision may be based on factors related to efficiency.

Objectives

We conducted an observational study in Mumbai, India, to understand the reliability, productivity, and efficiency of paper vs digital data collection based on three different road user behaviors: helmet use, seatbelt and child restraint use, and speeding. We also conducted a cost and time comparison to understand the relative efficiency of paper vs digital data collection across successive rounds, and to evaluate the potential trade-offs among different dimensions of efficiency (Table 1).

Table 1. Three areas of comparison between digital and paper data collection: productivity, reliability, and efficiency.

Dimensions of each area of comparison	Methods of measurement
Productivity	
Volume	• Number of observations per observation session
Precision	• Margin of error for estimation of proportions • Akaike Information Criteria in regression analysis
Reliability	
Statistical reliability	• Proportion of risk factor by date, time, and location, as well as vehicle, occupant, and environmental characteristics
Comparability of results	• Adjusted odds ratios for vehicle, occupant, and environmental risk factors
Efficiency	
Cost	• Per survey • Per dataset to achieve a certain level of precision • Per labor-hour of time (may be differential by skill level and cost of labor)
Time	• Per survey • Per complete dataset (preparation, data collection, data entry and verification, data management and cleaning)

Methods

Setting

This comparative study was conducted in Mumbai. Mumbai is India's most populous city, as well as the country's financial center and commercial capital [5]. Mumbai city has a population of approximately 12.5 million, with another 20.6 million people in the metropolitan area [6]. Mumbai has a high literacy rate, close to 90%, with 15.8 million internet subscribers [7,8]. Mumbai ranks sixth among major cities in India for number of road traffic collisions, with over 82% of all crashes resulting in at least one injury and almost 15% of collisions resulting in at least one fatality [9]. The registered vehicle fleet was 2,571,000 in 2015 [10].

Data Collection

As part of the BIGRS project, the Johns Hopkins International Injury Research Unit partnered with the Indian Institute of Technology, Bombay to conduct semiannual observational studies to measure the prevalence of helmet use, seatbelt and child restraint use, and speeding at representative locations throughout the city. The details of the roadside data collection protocol are provided elsewhere [4]. To assess reliability between the two methods, paper and digital data collection were conducted simultaneously between January-March 2018, and again between July-September 2018. In each round, 75 of 150 observation sessions had simultaneous paper and digital data collection for each risk factor, which was used for our study analysis. Consistent procedures and definitions were maintained between methods, across observation sites, and across rounds to ensure comparability of results.

Observations on helmet and seatbelt use were conducted at intersections while vehicles were stationary to allow field teams to observe the use of safety equipment, whereas speeding observations were conducted at unobstructed stretches of road. Data were captured by an observer, who kept his or her attention on the flow of traffic and reported observations to a recorder, who wrote or entered into a tablet the road safety data. During the initial years of the project, the entire data collection was paper-based, while pilot testing of digital data collection in Mumbai started in 2018.

Each observation session began by capturing information about the site and observation session. These included (1) date, time of day, and location of each observation period; (2) names of the observer and recorder for that session; (3) the weather; (4) the volume of traffic over time; and (5) the presence of any law enforcement during the session. Paper-based data collection was handwritten into forms with a predesigned grid appropriate to each risk factor. Each row captured information on a single vehicle. For speeding observations, the columns captured road safety behavior for each vehicle, whereas for helmet and seatbelt use observations, occupant position, demographics, and road safety behavior were captured in a set of columns for each occupant in the vehicle.

The digital data collection tool was developed to mirror the paper-based tool, capturing all the same information, but in a series of screens through which the recorder would swipe to record information on each vehicle and vehicle occupant. For the BIGRS project, we used KoBoToolbox for digital data collection, an open-source mobile data collection platform [11]. The digitization process involved programming digital forms that were then downloaded onto the KoBoCollect mobile app. The content of both paper and digital questionnaires was the same; however, the digital form included mandatory fields, logic checks, and constrained text entry that prevented recorders from leaving fields blank or entering unreasonable or inconsistent responses. The team used Android tablets for data collection and uploaded the questionnaire forms to a secure cloud server at the end of each session.

Local data collectors were trained for two days on study protocols, paper data entry, the use of Android tablets and the KoBoCollect app, and how to upload data to the server. Supervisors and data managers were trained to monitor field site data collection and data aggregation on the server.

Statistical Analysis

Helmet use was categorized as correctly, incorrectly, or not used. Correct helmet use was defined as using a strapped, standard helmet, whereas incorrect helmet use involved either wearing a *cap* or *tropical* helmet, or using an unstrapped helmet. Neither digital or paper data collectors would be able to distinguish an imitation or substandard helmet from a genuine standard helmet, as that would require close inspection for a standards label. Although this may slightly inflate the proportion of the sample assessed to be wearing a helmet correctly, it would not do so differentially by data collection method, and so should not affect measures of comparison between the two methods. Correct seatbelt use was defined as the use of age-appropriate restraints: seatbelts for adults and child or booster seats for children under 12 years old. Incorrect and no restraint use were grouped due to the low occurrence of incorrect restraint use. Speeding was defined as any excess of the speed limit or was grouped categorically as not speeding, speeding up to 10 kilometers per hour (kph), and speeding over 10 kph above the posted limit.

For helmet use observations, the age variable captured whether the occupant was observed to be over or under the age of 18, whereas for seatbelt use observations, a greater level of detail was captured to assess whether children under 12 years were using age-appropriate child restraints. During the analysis, we did not distinguish children under 12 by gender, as observers were not able to reliably determine a child's gender through observation. Helmet use observations categorize motorcycle riders as drivers or passengers, whereas seatbelt use observations distinguished passengers further as sitting in the front or rear seats. Sex was captured as either male or female for both helmet and seatbelt use observations. Speeding observations did not capture any occupant characteristics, as data collectors cannot accurately observe inside vehicles in motion. For speeding and seatbelt use observations, the vehicle type and ownership were captured; vehicle types were either a sedan, sport utility vehicle, pickup or light truck, minivan, heavy truck, bus, or, for speeding observations only, motorcycle. Vehicles ownership was classified as private, government, commercial, taxi, or tourist vehicles, based on markings on the outside of the vehicle,

particular to the context. Vehicle type and ownership were not included in helmet use observations, as all vehicles were uniformly private motorcycles.

We matched simultaneous digital and paper observation periods by date, time, and location. We compared the productivity of the two methods by calculating the correlation in the number of observations made on vehicles (for speeding) or vehicle occupants (for helmet and seatbelt use) per 90-min observation session. The measure for reliability was the correlation in the prevalence of each risk factor among subgroups defined by vehicle occupant, vehicle, and environmental characteristics within matching sessions. Both reliability and productivity were assessed using Pearson correlations. Although Spearman rank correlations are more conventionally used to compare proportions, we were interested in how closely the proportions exactly matched each other, rather than whether the rank ordering of proportions was similar between digital and paper data collection methods. Pearson correlations are also appropriate for proportions when the proportions are not close to 0 or 1. We also performed a precision analysis, evaluating the margin of error available with current data and the sample size that would be required to estimate a proportion within 1 and 2 percentage points.

We also wished to understand whether the method of data collection would influence the results of descriptive or inferential analysis. To achieve this, we aggregated together all observation sessions by data collection method and round of observation (January-March 2018 and July-September 2018), creating four datasets. We conducted descriptive analysis separately within each dataset and compared the prevalence of various risk factors, overall and across subgroups. We also conducted multivariable logistic regression separately using each of the four datasets and compared the adjusted odds ratios.

Covariates included in the regressions included the occupant sex, age, and position in or on the vehicle, vehicle type, and ownership. Also included were the time of day, the location, and whether the date was a weekend or weekday. Finally, environmental factors included whether there was visible police presence, camera enforcement, or, for speeding observations, speed deterrents such as speed bumps, stop signs, or crosswalks. For analysis related to speeding, occupant characteristics were not included. As the location of the observation being naturally collinear with the presence of environmental speed deterrents, we included speed deterrents in our models and omitted locations, as the effect of environmental deterrents on speeding is of interest to road safety researchers.

Cost Estimates

Personnel costs included field data collectors (observers, recorders, and field supervisors) and data entry operators, and logistical costs included staff training and transportation to observation sites. Supplies and equipment included running costs for office supplies, space for paper data entry, data plans for tablets, with one-time costs for computers for data entry, tablets and power banks, and app development. We assumed that tablets and power banks would need to be replaced every 3 years. Digital data collection running costs also included annual server costs and cloud data backup. Costs were calculated using the 2018 midyear exchange rate between Indian rupees (INR) and US dollars. Costs were calculated for only the 75 observation sessions that were simultaneously collected using both paper and digital methods.

Time Estimates

The time to complete an observation on a vehicle (for speeding observations) or on the vehicle occupants (for helmet use and seatbelt use observations) was assessed by dividing the 90 minutes of each observation session by the volume of observations in that session, and then multiplying by 60 seconds for a minute to obtain the number of seconds needed to complete an observation. Finally, we took the average number of seconds to complete an observation for each risk factor in each round of data collection.

The time to obtain a complete dataset was measured as the number of days it took until the dataset was entered, cleaned, and ready for analysis, which included all work performed by the local partners onsite, including training, field work itself, data entry and verification of paper data, and both local and offsite data cleaning and management. As only half of the paper sessions were simultaneously collected digitally, time estimates for paper data entry and verification were appropriately divided in half.

Results

Productivity Comparison

Across each of the three risk factors, paper methods showed higher productivity than digital methods, in both the winter (January-March) and summer (July-September) data collection rounds (Figures 1-3). However, the gap between digital and paper data collection volumes narrowed between the winter and summer rounds, with the correlation in productivity by observation session increasing from r=0.27 to 0.96 among helmet use, 0.32 to 0.95 among seatbelt use, and 0.49 to 0.89 among speeding observations.

The results of our precision analysis showed that the existing sample sizes in digital and paper provided precision to within 0.7 percentage points or smaller (1.4% margin of error). Conversely, the difference between paper and digital levels of precision was less than 0.2 percentage points, regardless of risk factor or round of data collection (Table 2). When comparing results from the regression analysis, digital data collection had a lower Akaike Information Criteria (AIC) in all cases except in the summer speeding data collection. This was despite digital data collection methods having a smaller sample size and the same number of variables in the models (Multimedia Appendix 1).

Figure 1. Correct helmet use: correlation between digital and paper volumes of observations by round.

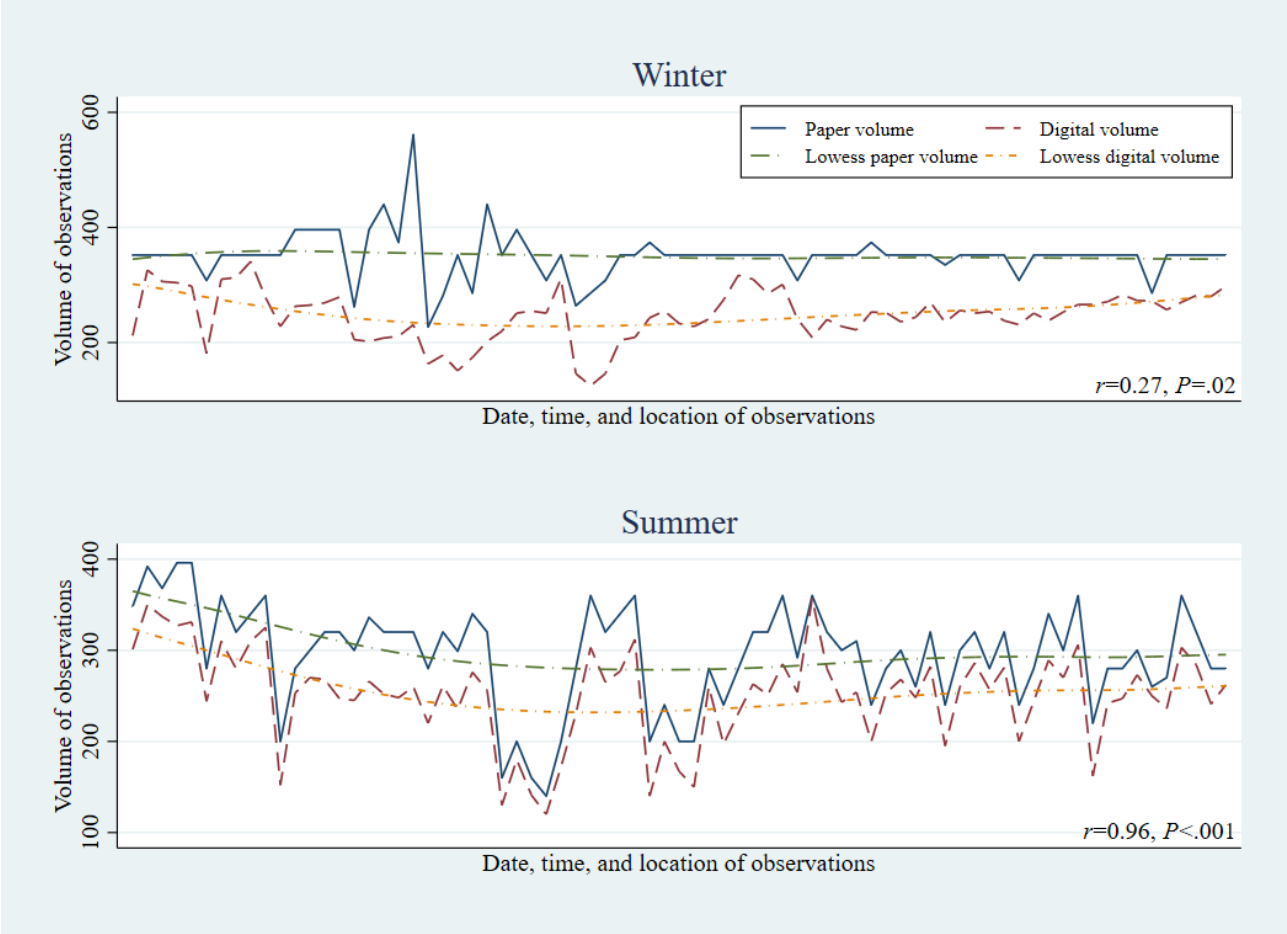

Figure 2. Seatbelt use: correlation between digital and paper volumes of observations by round.

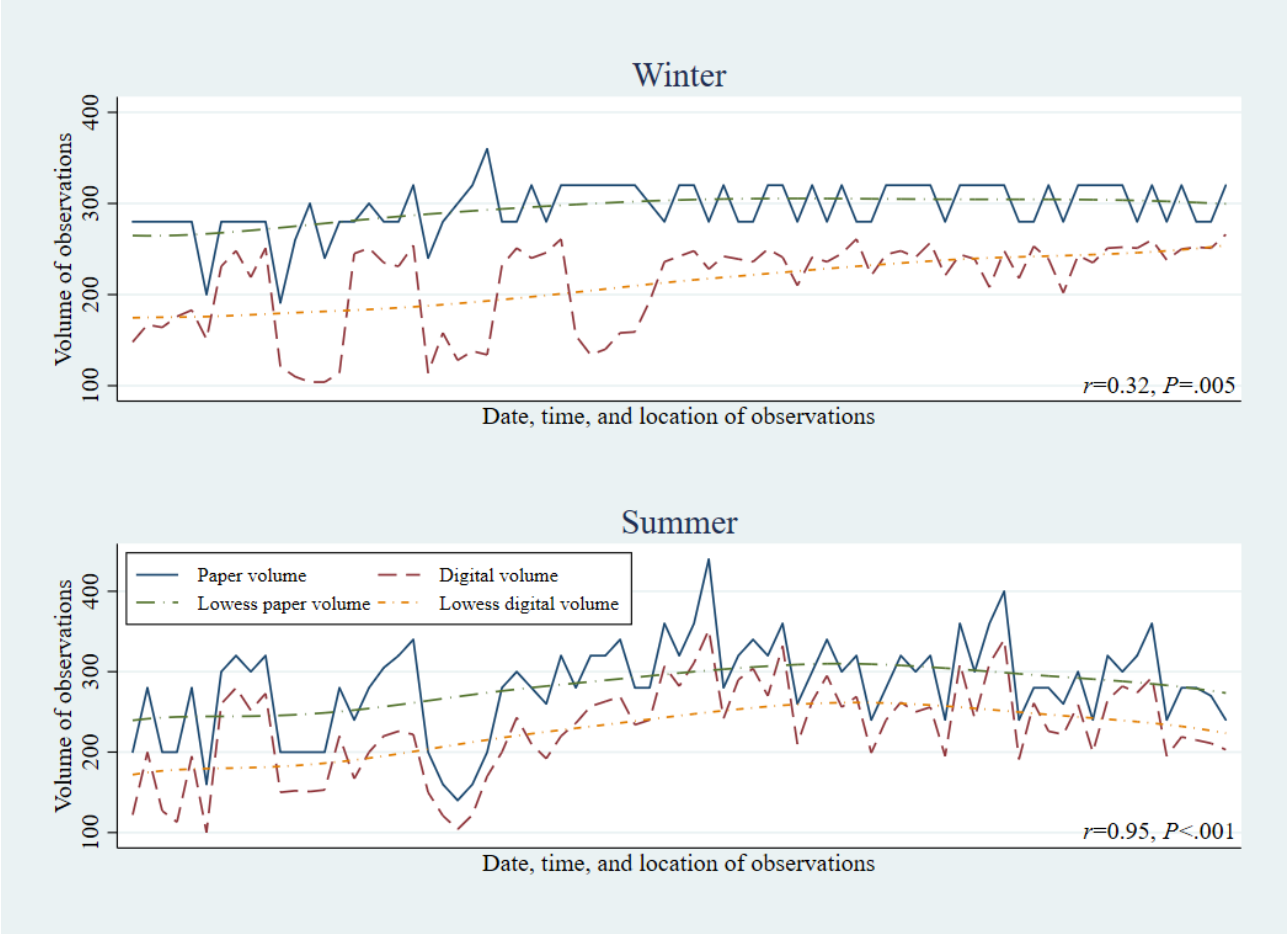

Figure 3. Speeding: correlation between digital and paper volumes of observations by round.

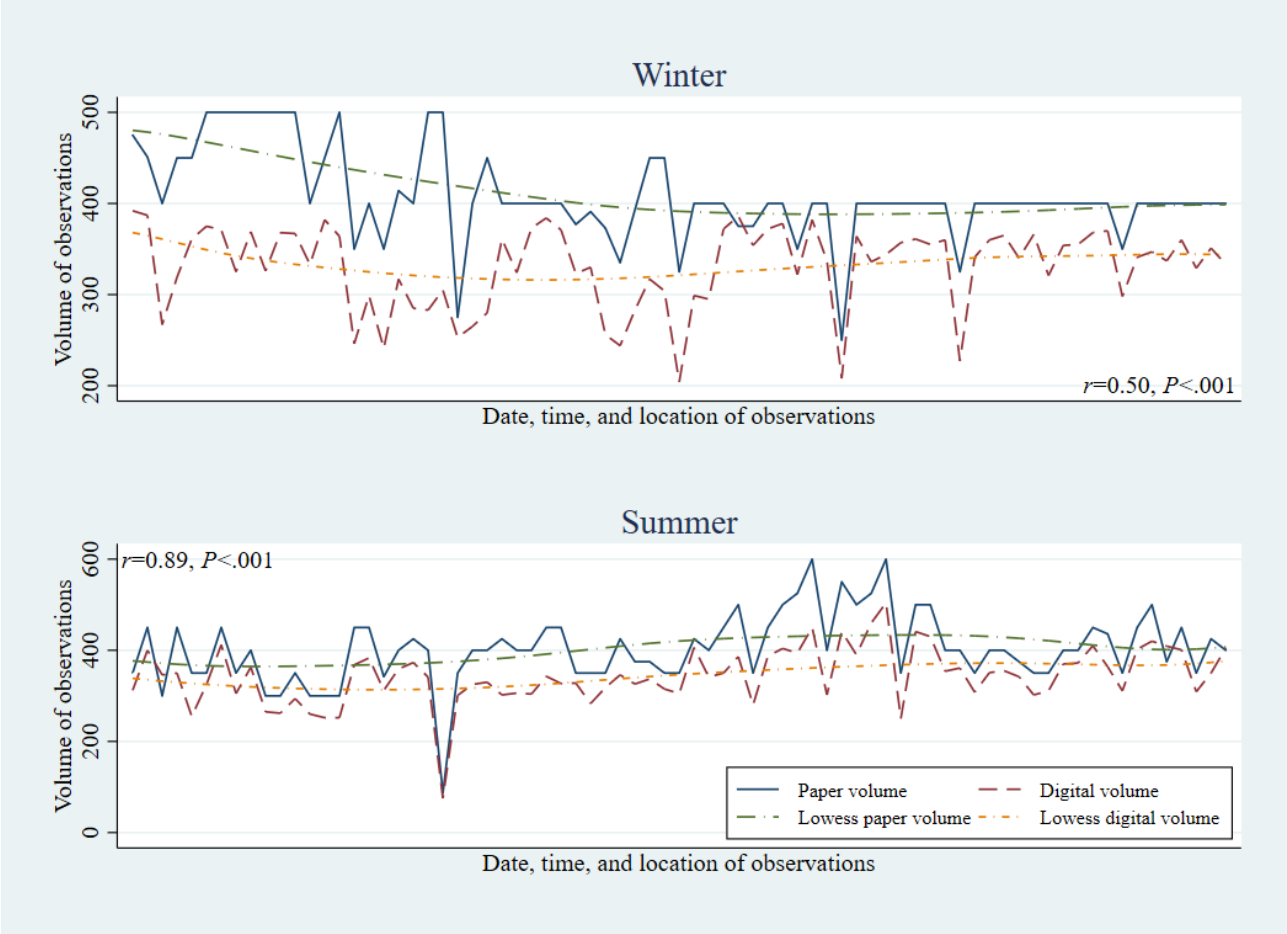

Table 2. Level of precision: current and needed sample sizes.

Risk factor and round of data collection	Paper sample size, n	Precision with existing paper sample, proportionate terms	Digital sample size, n	Precision with existing digital sample, proportionate terms	Required sample size for estimation within 1 percentage point (0.01), n	Required sample size for estimation within 0.5 percentage points (0.005), n
Helmet use						
Winter	34,309	0.006	24,283	0.007	9595	38,377
Summer	29,286	0.006	24,778	0.007	9585	38,338
Seatbelt Use

Summer	30,190	0.004	25,783	0.006	8459	33,835

Statistical Reliability

Reliability in the prevalence of behavioral risk factors matched by date, time, location, and by characteristics of vehicles and vehicle occupants showed moderate to high levels of correlation in both rounds of data collection. There were some improvements in correlations between the winter and summer rounds of data collection among all risk factors, particularly among speeding observations and in the prevalence of incorrect helmet use (Table 3).

Table 3. Reliability in behavioral risk factor prevalence: Pearson correlation and *P* value.

Risk factor	Winter		Summer	
	Correlation value (*r*)	*P* value	Correlation value (*r*)	*P* value
Helmet use[a]				
Any helmet use	0.98	<.001	0.99	<.001
Correct helmet use	0.82	<.001	0.86	<.001
Incorrect helmet use	0.79	<.001	0.92	<.001
Seatbelt use[a]				
Correct seatbelt use	0.82	<.001	0.82	<.001
Speeding[b]				
No speeding	0.73	<.001	0.80	<.001
≤10 kph[c] over speed limit	0.61	<.001	0.63	<.001
>10 kph over speed limit	0.72	<.001	0.73	<.001

[a]Matched by date, time, location, age, sex, and position.

[b]Matched by date, time, location, vehicle type, and ownership.

[c]kph: kilometers per hour.

Overall Comparison: Risk Factor Proportions

The descriptive analyses showed similar results between methods for most subgroups defined by vehicle and occupant characteristics. For helmet observations, the digital and paper datasets showed correct helmet use proportions within 2 percentage points of each other, across subgroups by age, sex, and role or position. Among seatbelt observations, digital and paper seatbelt use prevalence by vehicle type and occupant position were within 5 percentage points of each other, except for those subgroups with fewer than 200 observations. For comparisons of speeding by vehicle ownership, digital and paper percentages within each category of speeding were also within 5 percentage points of each other. Across all risk factors, the comparability decreased as the subgroup sample size decreased (Multimedia Appendices 2-4).

Overall Comparison: Regression Results

The multivariate logistic regressions for correct helmet use, correct seatbelt use, and any speeding showed more variability. Estimates for adjusted odds ratios were largely similar for the associations between occupant characteristics (age, sex, and position) and correct helmet use, regardless of method or round of data collection, adjusting for the day, time, and location (Figure 4). Passengers, compared with drivers, had consistently lower odds of using a helmet correctly, as did males, compared with females, and occupants under 18 years of age, compared with those over 18 years of age. However, the age estimate in the winter 2018 paper dataset was not significant, leading to a different inference from the digital dataset about the impact of age on helmet use between digital and paper. By contrast, the adjusted odds ratios for day of week, time, and location of data collection did not have as many overlapping CIs in either round of helmet use data collection.

As with helmet use data collection, the relationships between occupant characteristics and seatbelt use were comparable between digital and paper datasets, while adjusted odds ratios for day of week, time, and location showed more variability (Figure 5). We regressed sex, age, occupant position, day, time, location, vehicle type, and vehicle ownership onto correct seatbelt use. Seatbelt use was higher among males as compared with females, with front and rear passengers showing very low odds of seatbelt use, as compared with drivers, in both paper and digital datasets. There were similar estimates with overlapping CIs for all occupant age groups, although inferences differed between data collection methods for some age groups (12-17 years and over 60 years) in the winter round of data collection, as the paper data collection CI overlapped with the null value.

Similar to the other two risk factors, in the speeding regressions, the adjusted odds ratios for time showed some variability, controlling for vehicle type, vehicle ownership, and environmental speed deterrents (Figure 6). The effect of speed deterrents, which were only present during the winter round of data collection, showed a similar impact on reducing speeding regardless of data collection method; both the magnitude of the adjusted odds ratios and inferences were similar. Please see Multimedia Appendices 5-7 for further details on regression results for all risk factors.

Efficiency: Cost Comparison

A comparison of the initial set up and running costs for paper and digital data collection for this study is presented in Table 4. Field data collection costs for staffing and transportation were identical between methods. The field data collection for a single round was covered in 2880 labor hours for each method. Fixed costs or one-time costs, for digital and paper data collection, differed. Four android tablets with sim cards, cases, and power banks were used for digital data collection. For the paper data collection, two desktop computers with hard drives were purchased in the first round, and a laboratory space for paper data entry and storage was rented.

Variable costs or running costs for materials and supplies in paper data collection included paper printing, pens, and clipboards. For digital data collection, variable costs included monthly cellular data plans to ensure continuous connectivity and annual subscription of server space and backup storage.

The variable costs for labor were also different between digital and paper data collection methods. Data management for paper data included data entry, cleaning, and verification. Data entry required 450 labor hours divided over 5 persons, with data cleaning and verification taking an additional 180 labor hours. This could take an additional 26.25 days of work per person, an estimated 105 labor days for 4 data entry operators working 6 hours per day. Digital data management included initial app development, data cleaning, and daily server monitoring, taking approximately 12 labor hours per round.

During the first round, digital data collection cost 1.54% (US $310/20,071) more than paper data collection, driven by the fixed costs of software development and server setup. However, over both rounds in year 1, digital data collection cost 7.73% (US $3011/38,947) less than paper data collection, as with further data collection the higher variable costs in paper exceed the higher fixed costs with digital data collection. Given that the project would potentially last for multiple years, projected costs for data collection over 4 years is presented in Table 5. Over 4 years with two rounds of data collection per year, digital data collection would result in 10.03% (US $15,268/152,203) cost savings, primarily by cutting data entry and verification costs.

Table 4. Cost comparison between paper and digital data collection across rounds of data collection in US dollars.

[a]DDC: digital data collection.

[b]Includes yearly subscription of the cloud server.

[c]Includes initial app development.

[d]N/A: not applicable.

[e]This is difference between paper and digital costs as a percentage of the paper cost ([paper–digital]/paper).

[f]Assumes replacement of tablets and accessories after 2 years.

Efficiency: Time Comparison

As mentioned earlier, productivity was higher in paper collection as compared with digital data collection, with improvement in the correlation of volumes over time. With observation periods lasting 90 min in each data collection method, this higher productivity in paper data collection is due to the fact that it took field teams between 2-6 seconds longer to collect data digitally than to collect data using paper forms, on average (Table 6). Such small differences added up over the several hundred observations made per observation period and over 75 observation periods per round. Interestingly, the improvement in the correlation of productivity between the winter and summer rounds was due not only to an increase in speed in digital data collection but a slight drop in speed in paper data collection. Between the winter and summer data collection rounds, the time to complete an observation decreased or remained the same in digital but increased slightly in paper.

Although each observation took less time in paper data collection, it took less time to obtain a complete dataset with digital data collection. The time for training and field data collection were the same between digital and paper data collection methods, with 2 days for training and 15 days for field data collection. Data entry and verification in paper data took an additional 630 hours, or 26.25 days for 4 data entry operators to complete, which was done concurrently with ongoing fieldwork. Under the best conditions, this would delay receipt of data collection by a minimum of 11 days after fieldwork was complete. By contrast, digital data collection initially required 20 hours before fieldwork to develop the app and set up the server, and an average of 12 hours of data cleaning following receipt of the data before it was ready for

analysis. Switching from paper to digital data collection reduced the time to receive a clean dataset after fieldwork was completed from 630 hours to 12 hours, or from 11 days to 2 days.

Table 6. Time in seconds to complete an observation by data collection method and round.

Risk factor	Winter, time (seconds)		Summer, time (seconds)	
	Paper	Digital	Paper	Digital
Helmet use[a]	12.0	17.6	14.6	17.4
Seatbelt use[a]	11.3	17.5	12.4	16.4
Speeding[b]	13.4	16.7	14.3	16.7

[a]Observation on a vehicle occupant.

[b]Observation on a vehicle.

Discussion

Productivity

In our study, productivity was higher in paper data collection as compared with digital data collection regardless of the round of data collection or risk factor. The majority of studies comparing productivity between digital and paper data collection methods found equivalent or less time to complete a digital survey or observation, as compared with paper data collection [12-16]. Paper data collection may have taken less time in our study for several reasons. First, the data collectors had greater familiarity and experience with paper data collection, having previously completed five rounds of paper-based data collection over 3 years. Second, the act of swiping through multiple screens during digital data collection may take more time than filling in a single row in a predesigned table format on paper. Third, the digital tools used logic checks and constraints to prevent errors, which may delay recording the response. Although digital productivity did improve over time, it is not possible to project whether it would ever eventually catch up to the productivity seen in paper data collection, due to the formatting of the digital module and the logic checks imposed. Researchers and project managers may wish to spend additional time on classroom and field training with digital data collection tools, to give field staff the extra practice required to close this productivity gap as much as possible.

Despite the higher productivity in paper data collection, both digital and paper data collection methods were able to obtain a large enough sample size to estimate a proportion within ± 1 percentage point, which we judged to be a reasonable margin of error. Moreover, this higher productivity in paper did not translate into higher quality statistical models, measured using AIC.

Reliability

Similar to other direct comparisons of digital and paper data collection, we found high reliability between the two methods [15,17-27]. This high reliability was seen across risk factors, and improved between rounds of data collection, perhaps indicating improvements in data collector facility with the digital modules over time.

Overall Comparison: Risk Factor Proportions and Regression Results

The descriptive analyses showed comparable results of behavioral risk factor prevalence between subgroups defined by occupant, vehicle, or environmental characteristics, but with comparability decreasing with sample size. Other studies that conducted descriptive analyses also found similar distributions between data collection methods [12,15-28].

However, the multivariable regression analyses showed that the digital and paper datasets produced comparable results for some variables but not for others. Occupant characteristics—age, sex, and position—showed similar adjusted odds ratios, meaning that a researcher using digital data collection would have come to the same conclusions as a researcher using paper-based data collection when trying to understand the occupant-related factors associated with the use of protective equipment. However, there was less comparability between digital and paper methods in odds ratios for vehicle-related factors, or for day, time, and location, across risk factors.

Owing to smaller sample sizes in some subgroups, some age categories, vehicle types, and vehicle ownership types showed different prevalence estimates between paper and digital methods. Differences in regression results by day, time, and location, between digital and paper methods seem to be due to the nature of observational sampling and the differences in productivity between digital and paper methods. With faster data collection in paper, digital and paper data collectors do not make observations on the *same* target vehicles and their occupants. Such random differences are less pronounced for occupant characteristics (age, sex, or position), or when the prevalence of the risk factor are significantly modified by sex and occupant roles (drivers vs passengers). Differences in risk factor prevalence are less pronounced among the different locations and times of day, and therefore, random differences in target vehicle selection may have a larger effect on prevalence and odds ratio estimates. These results cannot be explained by surveyor effects, as the pool of data collectors were randomly assigned to data collection teams, and teams were randomly switched between methods and among locations, times of day, and days of the week.

Efficiency: Cost Comparison

Digital data collection had higher fixed costs and lower variable costs compared with paper data collection. In the initial round

of data collection, digital data collection was slightly more expensive, driven by the costs of purchasing tablets, but became less expensive with additional rounds of data collection. Digital data collection is significantly more cost efficient than paper when costs are annualized over several years with ongoing data collection. Digital data collection will have the greatest cost efficiency when used by projects with larger sample sizes, or multiple and extended rounds of data collections [29]. As labor, training, and transportation cost would be the same between methods, regardless of annual salary increase or inflation rate, the cost savings by digital data collection are driven primarily by savings in data management, particularly data entry. Other studies have similarly found higher fixed costs for digital data collection and lower variable costs, providing increased cost savings for larger sample sizes [13,14,16,30-33].

Cost differences between digital and paper will vary by project and context. The relative cost of labor, hardware, and electricity may differ by geographic location. Additionally, the cost of data collection platforms differs by company and by project. For example, for this project, the server space was purchased to accommodate data for all 10 cities, and hence the actual space required for Mumbai data was smaller and could have cost significantly less. Contractual agreements and price negotiations for server space could be influenced by a number of factors such as the size of the company, infrastructure and service details, promotions, packages, size and configuration of the server space, program, data security and back up arrangements, length of time, region, and location. The cost figures provided are particular to this project, and we encourage researchers for whom cost differential is a major consideration to draw up similar comparative budgets for digital and paper data collection methods for a given project. On the basis of our experience and the existing literature, for each study, there will be a sample size threshold above which digital data collection will provide cost savings, and below which paper data collection will be the more cost-effective option.

Our study was not able to directly measure a third dimension of efficiency: accuracy, or the reduction in errors achieved per resource unit expended. However, we note that the error protection built into the digital app through logic checks and constraints had two advantages. It decreased the cost of digital data collection as compared with paper, as evident by significantly fewer hours spent on verification and cleaning of data. It also decreased the size of the AIC seen in digital data collection compared with paper, even with lower sample size in digital methods. In other words, digital data collection provided our project with more precision at a lower cost.

Efficiency: Time Comparison

One of the biggest benefits of digital data collection is the real-time nature of data collection and availability: once data collection starts, the digital data are immediately available for data cleaning and analysis, while researchers using paper data collection must wait for data entry and reconciliation to be complete. It is important to note that for complex questionnaires, more time may be needed at startup for digital data collection as compared with paper-based data collection [24,34]. However, the efficiency for subsequent rounds of data collection would be significantly increased. The majority of studies comparing digital and paper data collection methods found that digital data collection reduced the time to obtain a complete dataset, as they avoided double data entry and reconciliation [14,16,33,35].

Conclusions

Our study did not face trade-offs among time efficiency, cost efficiency, statistical reliability, and descriptive comparability when deciding between digital and paper methods, as digital data collection proved equivalent or superior on these domains in the context of our project. Digital data collection provides estimates which are precise and reliable with paper data collection, with overall comparable results. Digital data collection may take longer per survey but takes less calendar time to obtain a completed dataset. The setting, context, length of the survey, and desired sample size play a role in determining the extent of time and cost efficiency. However, we may have encountered a method effect due to sampling methods for observational studies and random error.

Researchers considering using digital data collection may benefit from developing comparative budgets for each of the two methods, and pilot testing each method to understand relative productivity. When working with data collectors who are unfamiliar with handheld devices or with the chosen digital data collection app, additional classroom and field training on the digital data collection tools would improve productivity. Although this may slightly narrow the time efficiency advantage that digital data collection has over paper and increase the cost of training for digital methods as compared with paper, this additional effort would be worthwhile especially in studies relying on higher productivity. As trade-offs among cost, timeliness, and comparability and the relative importance of each could be unique to every data collection project, researchers should carefully consider the questionnaire complexity, target sample size, implementation plan, cost and logistical constraints, and geographical contexts when making the decision between digital and paper [36].

Authors' Contributions

NT and AM conceptualized the study and prepared all manuscript drafts. AM developed the digital data collection tool. NT led the data analysis and prepared results. PV and SG led the data collection in Mumbai. RP and AM participated in training and implementation of digital data collection in Mumbai. AB provided oversight of the study and critical feedback in data analysis and manuscript drafts. All authors read and approved the final manuscript.

Abstract

Background: Multiple types of mobile health (mHealth) technologies are available, such as smartphone health apps, fitness trackers, and digital medical devices. However, despite their availability, some individuals do not own, do not realize they own, or own but do not use these technologies. Others may use mHealth devices, but their use varies in tracking health, behaviors, and goals. Examining patterns of mHealth use at the population level can advance our understanding of technology use for health and behavioral tracking. Moreover, investigating sociodemographic and health-related correlates of these patterns can provide direction to researchers about how to target mHealth interventions for diverse audiences.

Objective: The aim of this study was to identify patterns of mHealth use for health and behavioral tracking in the US adult population and to characterize the population according to those patterns.

Methods: We combined data from the 2017 and 2018 National Cancer Institute Health Information National Trends Survey (N=6789) to characterize respondents according to 5 mutually exclusive reported patterns of mHealth use for health and behavioral tracking: (1) mHealth nonowners and nonusers report not owning or using devices to track health, behaviors, or goals; (2) supertrackers track health or behaviors and goals using a smartphone or tablet plus other devices (eg, Fitbit); (3) app trackers use only a smartphone or tablet; (4) device trackers use only nonsmartphone or nontablet devices and do not track goals; and (5) nontrackers report having smartphone or tablet health apps but do not track health, behaviors, or goals.

Results: Being in the mHealth nonowners and nonusers category (vs all mHealth owners and users) is associated with males, older age, lower income, and not being a health information seeker. Among mHealth owners and users, characteristics of device trackers and supertrackers were most distinctive. Compared with supertrackers, device trackers have higher odds of being male (odds ratio [OR] 2.22, 95% CI 1.55-3.19), older age (vs 18-34 years; 50-64 years: OR 2.83, 95% CI 1.52-5.30; 65+ years: OR 6.28, 95% CI 3.35-11.79), have an annual household income of US $20,000 to US $49,999 (vs US $75,000+: OR 2.31, 95% CI 1.36-3.91), and have a chronic condition (OR 1.69, 95% CI 1.14-2.49). Device trackers also have higher odds of not being health information seekers than supertrackers (OR 2.98, 95% CI 1.66-5.33).

Conclusions: Findings revealed distinctive sociodemographic and health-related characteristics of the population by pattern of mHealth use, with notable contrasts between those who do and do not use devices to track goals. Several characteristics of individuals who track health or behaviors but not goals (device trackers) are similar to those of mHealth nonowners and nonusers.

Our results suggest patterns of mHealth use may inform how to target mHealth interventions to enhance reach and facilitate healthy behaviors.

Introduction

Background

Mobile health (mHealth) includes the use of portable digital devices, such as smartphones, tablet computers, and fitness and medical wearables, to support health. Approximately 80% of US adults own a smartphone [1], which typically has one or more health-related software apps (*health apps*) preinstalled at the point of purchase. Close to 60% of smartphone owners also report installing (ie, downloading) one or more health apps onto their smartphone [2]. Wearable devices with a multitude of sensor types designed to monitor health indicators, such as activity, sleep, blood glucose, and blood pressure, have also penetrated the US marketplace [3,4]. Within the general population, wearable activity monitors (eg, Fitbit) are among the most commonly owned wearable devices and are reportedly used by about 13% of Americans [5].

Despite their ubiquity, ownership and use of diverse types of mHealth technologies for health and behavioral tracking varies. Reported use of mHealth technologies includes communicating with health care providers [6], making dietary or physical activity decisions [7,8], achieving health goals such as weight loss [9], and monitoring chronic conditions such as diabetes or hypertension [10,11]. Some mHealth intervention studies have reported that the use of mHealth technologies is associated with improved health or behavioral outcomes. These include, for example, improvements in diet and physical activity [12,13], weight loss or maintenance and blood glucose reduction [11], and higher quality patient-provider communication [14]. Although these studies suggest the potential for mHealth to enhance patient-provider communication, improve health outcomes, and facilitate behavior change, research examining how mHealth technologies are used by the US population for health and behavioral tracking is needed to understand how to target and tailor mHealth interventions to enhance their reach and efficacy across population subgroups.

Currently, there are gaps in the literature related to understanding use of mHealth technologies for health and behavioral tracking that need to be filled to advance mHealth intervention science. First, most intervention studies to date evaluate only one type of mHealth technology to address a desired health outcome or target behavior [8,15-18]. Yet, as mHealth technologies diversify in functionality, individuals have also become increasingly diverse in the types of mHealth technologies they own and use, with multiuse becoming more common [19]. Therefore, identifying the types of mHealth technologies the US population uses for health or behavioral tracking is an essential component of advancing the science.

Second, there is limited research about whether people in the United States set health goals when they use mHealth technologies for health or behavioral tracking. Goal setting can promote higher and sustained engagement with mHealth interventions [20-22]. Moreover, goal setting is strongly associated with favorable health behavior outcomes, such as increased physical activity and healthy eating in overweight and obese adults [23] and is a characteristic of efficacious mHealth interventions to improve diet, physical activity, and sedentary behaviors of children and adults in the general population [13]. Investigating whether tracking includes goal setting and assessing the characteristics of those who set these goals may increase understanding about who may be more (or less) likely to change health behavior as a result of using mHealth technologies for health or behavioral tracking and facilitate more precise targeting and tailoring of future mHealth interventions.

Finally, past studies have found that many people in the United States report not owning or using mHealth technologies for health or behavioral tracking, and that these individuals differ from mHealth technology owners and users on several characteristics such as age, gender, education, and income [5,24]. However, mHealth technologies for health and behavioral tracking continue to evolve and are adopted at different rates across population subgroups. Thus, continuing to describe and characterize mHealth nonowners and nonusers is necessary to understand patterns of mHealth use for health and behavioral tracking in the US population.

Study Aims

This paper has 3 primary aims. The first is to address gaps in the literature by describing patterns of mHealth use for health and behavioral tracking in the US population. We account for 3 factors in our conceptualization of pattern of mHealth use: (1) whether mHealth technologies are owned and used for health or behavioral tracking, (2) the types of mHealth technologies owned and used for health or behavioral tracking, namely smartphones or tablets and other digital devices such as fitness trackers or medical devices, and (3) whether health or behavioral tracking with mHealth technologies includes goal setting.

On the basis of these 3 factors, we distinguish between 5 mutually exclusive categories, or population subgroups, of mHealth owners and users and mHealth nonowners and nonusers in the United States. *mHealth nonowners and nonusers* are those who report that they do not own or use mHealth technologies for health or behavioral tracking. Among mHealth owners and users, *supertrackers* are those who report using multiple devices—a smartphone or tablet and another device, such as a fitness tracker or medical device—to track health or behaviors and goals, whereas *app trackers* report only using a smartphone

or tablet for the same purpose. *Device trackers* are those who report only using a device other than a smartphone or tablet to track health or behaviors and do not use smartphone or tablet health apps to track goals. Finally, *nontrackers* are those who report only having smartphone or tablet health apps but do not use them to track goals and do not track health or behaviors with other devices.

The second aim of this paper is to describe the characteristics of mHealth nonowners and nonusers by comparing them with people who own or use mHealth technologies for health and behavioral tracking. We consider individual-level factors such as sociodemographics—age, gender, race and ethnicity, education, income, and geographical area. We also consider factors associated with health and health behaviors, such as weight status, having a chronic condition (eg, diabetes), perceived health status, health self-efficacy, and being a health information seeker.

The third and final aim of this paper is to describe and compare the characteristics (sociodemographics, health, and health behaviors) of mHealth owners and users by pattern of mHealth use for health and behavioral tracking. Comparing mHealth owners and users by pattern of mHealth use may provide important insights about those who not only own and use different types of mHealth technologies in the United States but also use those technologies in ways that can promote improved health and health behavior outcomes (ie, goal setting). As mHealth technology development and adoption rapidly evolves, characterizing the population by pattern of mHealth use may inform how to target and tailor mHealth interventions to reach diverse US audiences and facilitate healthy behaviors.

Methods

Data

Data were merged from the National Cancer Institute (NCI)'s Health Information National Trends Survey (HINTS), HINTS 5, Cycle 1, and HINTS 5, Cycle 2. HINTS is a probability-based, cross-sectional survey of the US adult, civilian, noninstitutionalized population. Survey data were collected by paper-and-pencil self-administered questionnaires completed from January through May 2017 (Cycle 1; see Multimedia Appendix 1) and January through May 2018 (Cycle 2, see Multimedia Appendix 2). HINTS has a two-stage, stratified sample; addresses were randomly selected from a US Postal Service file of residential addresses, and a random individual respondent was selected from each sample household (HINTS 5, Cycle 1 response rate=32.4%, N=3285; HINTS 5, Cycle 2 response rate=32.9%, N=3504). Details related to HINTS methodology have been described elsewhere [25].

Sociodemographic and Health-Related Characteristics

Items included in the analysis pertaining to respondent characteristics were asked of the full, merged sample from 2017 and 2018 (N=6789). Sociodemographic variables included in analyses were gender (male and female); age (18-34, 35-49, 50-64, and ≥65 years old); race (white, black, and other race, which combines low-frequency responses for American Indian/Alaska Native, Asian Indian, Chinese, Filipino, Japanese, Korean, Vietnamese, other Asian, Native Hawaiian, Guamanian or Chamorro, Samoan, and other Pacific Islander); Hispanic ethnicity (Hispanic, non-Hispanic); education (less than high school or high school graduate, technical, vocational, or some college, and college graduate or postgraduate); annual household income (<US $20,000, US $20,000-US $49,999, US $50,000-US $74,999, and ≥US $75,000); and geographical area. Geographical area was categorized as urban or rural based on the US Department of Agriculture Economic Research Service continuum codes.

Health-related variables included BMI (normal: 18.5-24.9; overweight: 25-29.9; and obese: ≥30), perceived health status (*poor* or *fair*, *good*, *very good*, and *excellent*), health self-efficacy (*not confident at all* or *a little confident*, *somewhat confident*, *very confident*, and *completely confident*), having one or more chronic conditions (diabetes, high blood pressure, or a heart condition), and being a health information seeker. Perceived health status was evaluated with a single item, *In general, would you say your health is…* This single item includes a 5-point Likert response from *poor* to *excellent*. Health self-efficacy was measured with the item, *Overall, how confident are you about your ability to take good care of your health?* Response options were also on a 5-point Likert scale, ranging from *completely confident* to *not confident at all*. Having one or more chronic conditions was reported using a checklist that followed the question, *Has a doctor or other health professional ever told you that you had any of the following medical conditions?* In this study, respondents were classified as having a chronic condition if they selected *yes* to *diabetes or high blood sugar*, *high blood pressure or hypertension*, or *a heart condition such as heart attack, angina, or congestive heart failure*. These chronic conditions were included because self-management using digital medical devices (eg, glucometer) is common. The item, *Have you ever looked for information about health or medical topics from any source?* (*yes* or *no*), was used to evaluate being a health information seeker.

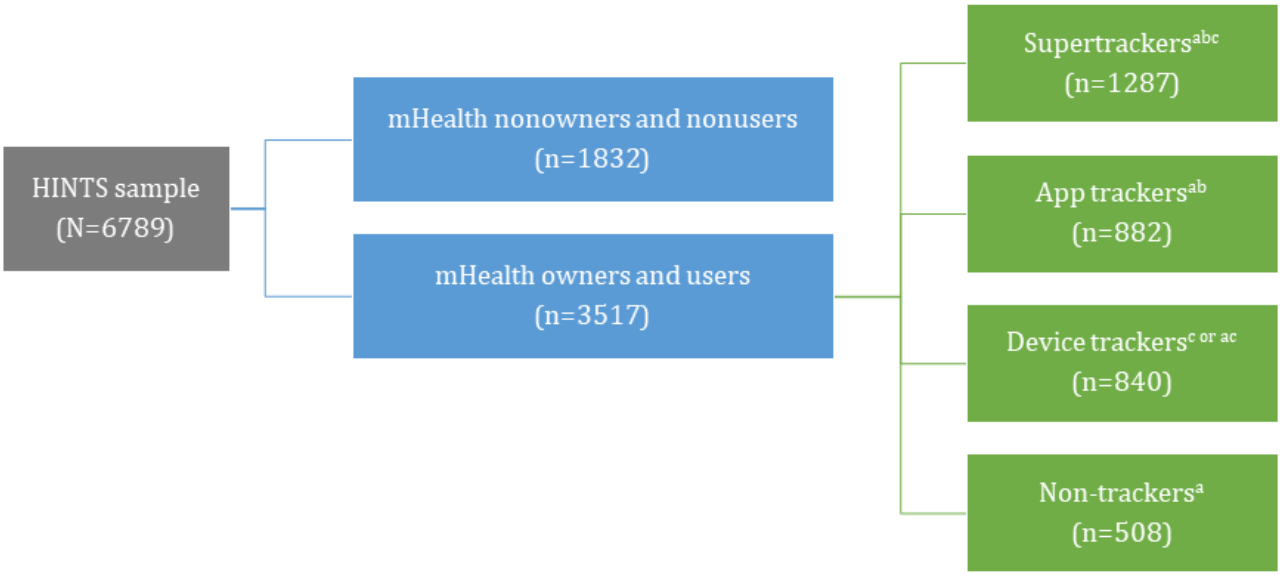
Mobile Health Technologies Owned and Used for Health or Behavioral Tracking and Goal Setting

Respondents with a smartphone or tablet computer were asked, *On your tablet or smartphone, do you have any apps related to health and wellness?* (*yes*, *no*, or *don't know*). For logistic regression analyses, this response was dichotomized to yes vs no and don't know. *Don't know* responses were collapsed with *no* responses owing to a low response frequency for *don't know* (n=285) and because not knowing whether one has health apps suggests nonuse of those apps for health or behavioral tracking. Respondents were also asked, *Has your tablet or smartphone helped you track progress on a health-related goal such as quitting smoking, losing weight, or increasing physical activity?* (*yes* or *no*). All respondents were asked, *Other than a tablet or smartphone, have you used an electronic device to monitor or track your health within the last 12 months? Examples include Fitbit, blood glucose meters, and blood pressure monitors*. (*yes* or *no*).

Operationalizing Pattern of Mobile Health Use for Health and Behavioral Tracking

Figure 1 represents our operationalization of each mutually exclusive pattern of mHealth use for health and behavioral tracking. The combined HINTS sample was divided into mHealth owners and users and nonowners and nonusers. mHealth nonowners and nonusers were defined as those who reported that they do not have or do not know if they have health apps on their smartphone or tablet, do not use a smartphone or tablet to track health-related goals, and do not use other devices to track health or behaviors (eg, Fitbit, glucose meter, and blood pressure monitor). mHealth owners and users were divided into 4 categories based on distinctive ways mHealth technologies are owned or used to track health or behaviors and goals. Supertrackers were defined as those who reported using a smartphone or tablet to track health-related goals and use other devices, such as a fitness tracker or digital medical device, to track health or behaviors. App trackers were defined as those who reported using a smartphone or tablet to track health-related goals but do not use other devices to track health or behaviors. Device trackers were defined as those who reported using devices other than a smartphone or tablet to track health or behaviors but do not use a smartphone or tablet to track health-related goals. Finally, nontrackers were defined as those who only reported having smartphone or tablet health apps but do not use them to track health-related goals and do not use other devices to track health or behaviors.

Figure 1. Operationalizing pattern of mobile health use for health and behavioral tracking. a. On your tablet or smartphone, do you have any "apps" related to health and wellness? Yes. b. Has your tablet or smartphone helped you track progress on a health-related goal such as quitting smoking, losing weight, or increasing physical activity? Yes. c. Other than a tablet or smartphone, have you used an electronic device to monitor or track your health within the last 12 months? Examples include Fitbit, blood glucose meters, and blood pressure monitors. Yes. HINTS: Health Information National Trends Survey.



Statistical Analysis

Analyses of merged HINTS 5, Cycle 1 and HINTS 5, Cycle 2 data were conducted using SAS version 9.4 (SAS Institute, Cary, NC). Descriptive statistics (frequencies, weighted percentages, and chi-square statistics) were used to examine patterns of mHealth use for health and behavioral tracking (Aim 1). Respondents with and without a smartphone or tablet were included in the mHealth nonowners and nonusers category; not having, not tracking, and not monitoring health with a mobile device was the primary criterion for inclusion. Similar to mHealth nonowners and nonusers, having a smartphone or tablet was not a criterion for inclusion in the device tracker category.

In all, 2 logistic regression models were constructed to characterize and compare US population subgroups by pattern of mHealth use for health and behavioral tracking. To address Aim 2, binomial logistic regression was performed to test the odds that respondent characteristics independently predict being in the mHealth nonowners and nonusers category, while holding the other respondent characteristics constant (reference category=all mHealth owners and users). To address Aim 3, a multinomial logistic regression model using the generalized logit was constructed to determine the predicted probability that respondent characteristics independently predict mHealth owners' and users' pattern of mHealth use for health and behavioral tracking, while controlling for the other respondent characteristics. Because a normative group of mHealth owners and users does not exist, supertrackers were chosen as the reference category for this second model as Aim 1 findings showed supertrackers made up the largest category of mHealth owners and users in the sample. Tests for significance for odds ratios and 95% CI were calculated at $P<.05$. Complete case analysis and listwise deletion were used for regression models.

Data weights were applied to provide representative US population estimates. A full-sample weight was used to calculate population-level point estimates and parameters. Replicate weights (calculated using the jackknife variance estimation method) were used to compute accurate standard errors.

Results

Sociodemographic and Health-Related Characteristics

The total combined HINTS sample was 6789. Weighted prevalence estimates were calculated for HINTS respondents' sociodemographic and health-related characteristics (see Multimedia Appendix 3). HINTS poststratification weightings adjust for inherent variations in the obtained sample by adjusting weighted totals to approximate known population characteristics. As in most health surveys, the HINTS raw sample tended to overaccumulate responses from females, older age individuals, people who are urban-dwelling, and those with more education and higher annual household income. In addition, white, non-Hispanic respondents comprised more than half of the sample. With respect to health-related characteristics, about half of the US adult population reported at least very good perceived health status, and most were at least very confident about their health self-efficacy. Most were health information seekers, overweight or obese, and had never been diagnosed with diabetes, hypertension, or a heart condition.

Mobile Health Technologies Owned and Used for Health or Behavioral Tracking and Goal Setting

Weighted prevalence estimates were also calculated for items pertaining to ownership and use of mHealth technologies for health or behavioral tracking and goal setting. Most respondents (85.22%) reported having a smartphone or tablet, close to half (46.83%) reported having a health app on one of these devices, and 43.23% reported that they use their smartphone or tablet to track progress on a health-related goal. Approximately one-third of respondents (34.66%) reported that they have a device other than a smartphone or tablet to track their health or behaviors.

Aim 1: Patterns of Mobile Health Use for Health and Behavioral Tracking

On the basis of our operationalization of pattern of mHealth use for health and behavioral tracking, mHealth nonowners and nonusers made up about one-third of the sample (34.72%). Most mHealth nonowners and nonusers were owners of a smartphone or tablet (95.15%). Nontrackers, those who reported having health apps on their smartphone or tablet but do not use them to track a health-related goal and do not use other devices to track health or behaviors, comprised the smallest percentage of the sample (8.8%).

Among respondents who reported owning or using mHealth technologies for health or behavioral tracking, supertrackers were the most prevalent (24.05%), followed by app trackers (19.5%) and device trackers (12.9%). Most device trackers reported having a smartphone or tablet (97.6%), and approximately one-third reported that they have a health app on one of those devices (35.0%). Table 1 describes the sociodemographic and health-related characteristics of respondents by pattern of mHealth use for health and behavioral tracking.

Table 1. Weighted population estimates for sociodemographic and health-related characteristics by pattern of mobile health use for health and behavioral tracking; HINTS 5, Cycle 1, 2017 and Cycle 2, 2018 (N=6789).

Characteristics	Nonowners and nonusers (n=1832; 34.72%)	Nontrackers (n=508; 8.8%)	Device trackers (n=840; 12.9%)	App trackers (n=882; 19.5%)	Supertrackers (n=1287; 24.05%)	Chi-square (*df*)	*P* value

Aim 2: Characteristics Associated With Being in the Mobile Health Nonowners and Nonusers Category

Compared with mHealth owners and users (nontrackers, app trackers, device trackers, and supertrackers), mHealth nonowners and nonusers had higher odds of being male (OR 1.38, 95% CI 1.08-1.77) and 35 years old or older, with the odds of being in the mHealth nonowners and nonusers category increasing with advancing age (35-49 years old: OR 1.55, 95% CI 1.01-2.36; 50-64 years old: OR 2.01, 95% CI 1.30-3.11; 65+ years old: OR 2.77, 95% CI 1.86-4.13). mHealth nonowners and nonusers also had higher odds of reporting an annual household income below US $75,000 (<US $20,000: OR 2.06, 95% CI 1.34-3.16; US $20,000-US $49,999: OR 1.94, 95% CI 1.33-2.83; US $50,000-US $74,999: OR 1.67, 95% CI 1.14-2.46).

In addition, mHealth nonowners and nonusers had higher odds of not being a college graduate (high school graduate or less: OR 1.88, 95% CI 1.31-2.69; technical, vocational, or some college: OR 1.36, 95% CI 1.02-1.83) and not being health information seekers (OR 1.53, 95% CI 1.15-2.04). However, they had lower odds of reporting a chronic condition (OR 0.57, 95% CI 0.45-0.72) compared with mHealth owners and users. There were nonsignificant differences for race and ethnicity ($F_{3,98}$=0.11; P=.95), geographical area ($F_{1,98}$=0.39; P=.54), perceived health status ($F_{3,98}$=0.31; P=.82), health self-efficacy ($F_{3,98}$=0.92; P=.43), and weight status (BMI, $F_{1,98}$=1.77; P=.18) when controlling all other variables (see Table 2).

Table 2. Sociodemographic and health-related characteristics significantly associated with being in the mobile health nonowners and nonusers category (n=1468). Reference category=all mobile health owners and users.

Aim 3: Characteristics Associated With Mobile Health Owners' and Users' Pattern of Mobile Health Use for Health and Behavioral Tracking

Multinomial logistic regression analysis revealed several sociodemographic and health-related characteristics associated with pattern of mHealth use for health and behavioral tracking among mHealth owners and users (reference category=supertrackers). As shown in Table 3, there were significant differences in terms of gender, age, race and ethnicity, income, having a chronic condition, weight status, and being a health information seeker. There were, however, nonsignificant differences for pattern of mHealth use by geographical area ($F_{3,98}$=1.37; *P*=.29), perceived health status ($F_{9,98}$=1.33; *P*=.23), health self-efficacy ($F_{9,98}$=0.91; *P*=.52), and education ($F_{6,98}$=1.47; *P*=.20) when controlling for all other variables.

Compared with supertrackers, the largest category of mHealth owners and users in this study, app trackers had higher odds of being male (OR 1.46, 95% CI 1.11-1.94) and lower odds of being 50 years old or older (50-64 years old: OR 0.63, 95% CI 0.41-0.96; 65+ years old: OR 0.50, 95% CI 0.29-0.88). App trackers had about 2 times the odds of reporting an annual household income in the US $20,000-US $49,999 range than US $75,000 or more (OR 2.32, 95% CI 1.61-3.33). Finally, app trackers had lower odds of reporting that they have a chronic condition than supertrackers (OR 0.62, 95% CI 0.42-0.92).

Device trackers also had higher odds of being male (OR 2.22, 95% CI 1.55-3.19) compared with supertrackers. With respect to age, device trackers had nearly 3 times the odds of being 50-64 years old (OR 2.83, 95% CI 1.52-5.30) and about 6 times the odds of being 65 years old or older (OR 6.28, 95% CI 3.35-11.79). Device trackers had about 2 times the odds of reporting an annual household income in the US $20,000-US $49,999 range than US $75,000 or more when compared with supertrackers (OR 2.31, 95% CI 1.36-3.91) and about 3 times the odds of not being health information seekers (OR 2.98, 95% CI 1.66-5.33). Device trackers had lower odds of identifying as non-Hispanic black (OR 0.48, 95% CI 0.31-0.74) and other race and ethnicity (OR 0.54, 95% CI 0.30-0.99). They had higher odds of reporting a chronic condition (OR 1.69, 95% CI

1.14-2.49) but lower odds of being overweight (OR 0.58, 95% CI 0.38-0.88) or obese (OR 0.55, 95% CI 0.35-0.86) than supertrackers.

Finally, compared with supertrackers, nontrackers had more than twice the odds of being 65 years old or older (OR 2.74, 95% CI 1.47-5.11). They also had more than 2 times the odds of not being health information seekers (OR 2.37, 95% CI 1.16-4.86). Nontrackers had lower odds of being in the other race and ethnicity category (OR 0.51, 95% CI 0.27-0.96) than supertrackers. In addition, they had lower odds of being overweight (OR 0.47, 95% CI 0.29-0.76) or obese (OR 0.43, 95% CI 0.28-0.67).

Table 3. Characteristics significantly associated with being a mobile health (mHealth) owner and user by pattern of mHealth use for health and behavioral tracking. Reference category=Supertrackers (n=1122).

Discussion

Principal Findings

The aims of this study were to examine patterns of mHealth use for health and behavioral tracking in the US population and to characterize the population according to those patterns. We found that those who do not own or use mHealth technologies for health or behavioral tracking make up a relatively large proportion of the population (about one-third). Among owners and users of mHealth technologies, being a supertracker—using multiple mHealth technologies for health or behavioral tracking and goal setting—is the most common pattern of mHealth use. Our study also confirms and extends what other studies of nationally representative samples (eg, Canada) have discovered [7]; that is, there are substantive differences among mHealth technology owners and users in terms of sociodemographics and health-related factors. The sociodemographic and health-related characteristics of supertrackers and device trackers were the most distinctive, with several characteristics of device trackers—those who track health or behaviors but not health goals—paralleling those of mHealth nonowners and nonusers. Our findings suggest that the distinctive characteristics of supertrackers and device trackers, in particular, can be used to help target and tailor future mHealth interventions.

Characteristics of Nonowners and Nonusers of Mobile Health Technologies for Health and Behavioral Tracking

People who do not own or use mHealth technologies for health and behavioral tracking make up about one-third of the US population; regardless of the high percentage of Americans who own a smartphone or tablet, ownership does not necessarily mean that these devices are being used to track health, behaviors, or goals. We found that mHealth nonowners and nonusers tend to be male, older age, and report lower education and income levels than owners and users of mHealth technologies for health or behavioral tracking, which are findings supported by other studies focused on the US population's mHealth technology usage [5,24]. In addition, our findings revealed a relationship between being in the mHealth nonowners and nonusers category and not seeking health information in general.

mHealth nonowners and nonusers also tended not to have a chronic condition, specifically diabetes, hypertension, or a heart condition, when compared with owners and users of mHealth technologies for health or behavioral tracking. These results suggest that having a chronic condition is a potential reason or motivator for owning and using mHealth technologies. Although a study of smartphone owners found that those with chronic conditions are no more likely to use health apps than people without a chronic condition [10], our analyses also accounted for respondents' use of other devices, such as Fitbits, glucometers, and blood pressure monitors. Thus, our analyses appear to have detected distinctive differences in use of mHealth technologies between those with and without a chronic condition because these diverse types of technology were included in our measurement.

Although the link between older age and being a nonowner or nonuser of mHealth technologies is consistently reported across studies, we recommend continued population-level research of mHealth nonowners and nonusers because the proportion of digital natives will grow as the population ages. In turn, this may increase the proportion of the population that trusts collecting personal health information on digital devices [26]. Perceived utility of mHealth technologies for health or behavioral tracking may also increase among nonowners and nonusers and former owners and users as mHealth technologies advance in their functionality, especially if approaches such as ensuring sociocultural relevancy [27] and person-centered design [28,29] are considered throughout mHealth technology development.

In addition, our findings related to mHealth nonowners and nonusers suggest that clinical and public health practitioners could consider alternatives to mHealth interventions to track and promote health behavior change, especially among less educated older men. However, they also call to mind the importance of ensuring that not owning or using mHealth technologies for health or behavioral tracking is not due to barriers that can be addressed, such as digital health literacy [28,30-32]. Researchers and organizations are addressing some of these issues through programs such as RecycleHealth [31,33], American Association of Retired Persons Tek workshops [34,35], and The Wellness Group [36], with measurable beneficial effects on health and behavioral outcomes [31,36].

Characteristics of Mobile Health Owners and Users by Pattern of Mobile Health Use for Health and Behavioral Tracking

In this study, we also discovered differences in the characteristics of mHealth owners and users by comparing nontrackers, app trackers, and device trackers with the largest group of mHealth owners and users, supertrackers. Supertrackers, those who use multiple devices for health or behavioral tracking and goal setting, make up approximately one-quarter of the US population. Our findings demonstrate that supertrackers, conceivably the most intrinsically interested in mHealth technologies, are younger than nontrackers and device trackers, who have in common that they do not use mHealth technologies to track a health-related goal. Supertrackers also tended to be female when compared with their tracker counterparts, device trackers and app trackers. This finding related to gender is consistent with previous studies of people who download smartphone health apps [24] and users of wearable activity monitors, such as Fitbits [5].

With respect to socioeconomic factors, when compared with supertrackers, we found that being an app tracker or being a device tracker, respectively, was associated with reporting an annual household income in the US $20,000-US $49,999 range vs US $75,000 or more. Paré et al [7] found in a Canadian sample that reporting the highest annual income level, greater than Can $80,000 (US $59968.80), was associated with being a *digital self-tracker*, someone who uses health apps, wearables, or digital medical devices. By analyzing the US population's distinctive patterns of mHealth use, we add to the literature that multiuse of mHealth technologies for health or behavioral

tracking and goal setting is associated with higher reported annual household income. In addition, level of education was not significantly associated with mHealth owners and users' pattern of mHealth use for health and behavioral tracking when controlling all other factors. Other studies have found that higher level of education is associated with having or downloading smartphone health apps [2,24,37], digital self-tracking [7], and reporting current use of a wearable activity monitor [5]. Future studies should continue to examine relationships between mHealth owners and users' specific pattern of mHealth use, education, and income, as ease of use, pricing, and accessibility will continue to evolve with the advancement of mHealth technologies.

Although we did not find that racial or ethnic identity was associated with being an mHealth owner or user vs being in the mHealth nonowners and nonusers category (see Aim 2 results), race and ethnicity was associated with mHealth owners and users' pattern of mHealth use for health and behavioral tracking. For example, non-Hispanic blacks and respondents in the other race and ethnicity category had lower odds of being device trackers than supertrackers. Future studies should explore the relationship between sociocultural factors that foster or challenge interest and motivation to use mHealth technologies and the perceived sociocultural relevancy of different types of mHealth technologies for health or behavioral tracking and goal setting [27].

We also discovered several health-related characteristics associated with mHealth owners and users' pattern of mHealth use for health and behavioral tracking. For example, we found that supertrackers tended to be health information seekers when compared with mHealth owners and users who do not use devices to track health goals (ie, nontrackers and device trackers). One explanation for this finding is that supertrackers may be relatively more attentive, interested, and curious about personal health information (evidenced by their goal-setting behavior), including collecting and recording it on digital devices [30,38]. Health information–seeking behavior and goal setting appear to be distinguishing characteristics among the US population's mHealth technology users.

Unlike the results of our analysis of mHealth nonowners and nonusers vs mHealth owners and users, we found a significant relationship between mHealth owners and users' pattern of mHealth use for health and behavioral tracking and weight status. Specifically, supertrackers had greater odds of being overweight or obese compared with nontrackers and device trackers, respectively. Krebs and Duncan [2] found that smartphone owners who download health apps are more likely to be overweight or obese, and Byuhan et al [37] also report greater odds of using health apps to track a health-related goal among obese compared with underweight individuals. Therefore, we add to the findings of these authors that being overweight or obese is associated with multiuse of mHealth technologies for health or behavioral tracking and goal setting.

Having a chronic condition (diabetes, hypertension, or a heart condition) was also associated with mHealth owners and users' pattern of mHealth use for health and behavioral tracking; however, the direction of the relationship differed when comparing supertrackers with app trackers and with device trackers. Namely, supertrackers had greater odds of having a chronic condition than app trackers but lower odds of having a chronic condition than device trackers. This result may be explained by the wide range of devices other than a smartphone or tablet that respondents might use, ranging from fitness trackers to digital medical devices, such as glucometers. On the basis of the characteristics of device trackers—male, older age, non–health information seekers, with a chronic condition—the type of mHealth technologies used by this group may be digital medical devices over fitness trackers. We recommend that future iterations of HINTS include separate items to measure use of specific types of wearables and other portable digital devices because motivations for use and individual differences of mHealth technology users likely vary considerably by the specific type of nonsmartphone or nontablet mHealth technology used.

We also recommend that mHealth intervention researchers and health care providers who study or prescribe mHealth to individuals who fit the device tracker profile consider individual-level factors that might threaten continued engagement with mHealth technologies, such as relatively less intrinsic interest in digital self-tracking, potentially low digital health literacy, and data-entry burden [2,29,36]. However, our findings suggest opportunities, not only potential challenges. For example, although device trackers in our study reported that they do not use health apps to track health-related goals, about one-third reported downloading health apps onto their smartphone or tablet. These downloads may represent implementation intentions that clinical and public health practitioners might leverage by working with device trackers to set personal health goals within their health apps. Health goal-setting and reminders embedded in mHealth technologies that stimulate habit formation may lead to *guided mastery*, which is theorized to help people with implementation intentions act on their behavioral intentions [22].

Notably, geographical area (urban vs rural), perceived health, and health self-efficacy were not significantly associated with pattern of mHealth use for health and behavioral tracking. These results are inconsistent with studies showing that mHealth technology users are more likely to reside in urban over rural areas [37]. One explanation for our findings may be the rapid increase in smartphone ownership throughout the entire United States since the time other population studies were conducted [1]. Although better perceived health status [7,10,24,29,37] and greater health self-efficacy [37] have been associated with mHealth technology use in past studies, our results highlight that other individual-level factors may be stronger predictors when mHealth technology owners and users are compared by distinctive pattern of mHealth use for health and behavioral tracking.

Limitations

This study is the largest and most current nationally representative study of mHealth ownership and use in US adults across 2 cycles of NCI HINTS. However, there are also several limitations, including reliance on self-report and cross-sectional data. Because the survey data are cross-sectional, we cannot

infer causal relationships between variables (eg, being a supertracker leads to obesity or vice versa). In addition, we cannot discern whether respondents intended to engage, reengage, or disengage from mHealth technologies following their participation in HINTS.

Given the limitations of the dataset, we could neither determine the type of devices used beyond smartphones and tablets nor discern whether respondents used a combination of nonsmartphone or nontablet devices (eg, fitness tracker plus a digital medical device). We also could not distinguish their specific reasons for tracking health or behaviors (eg, blood glucose monitoring or number of steps walked) or the extent to which they engage with mHealth technologies (frequency of use, duration of use, etc). Moreover, we were unable to evaluate their experience of mHealth technology use (eg, usability and acceptability). However, findings from this study may be used to guide development of future research focused on improving users' experience of mHealth technologies for health or behavioral tracking because we were able to capture the characteristics of the US population by diverse patterns of mHealth use.

An additional limitation of this study is that we could not determine the specific health goals respondents set in their health apps. Goals may have varied from smoking cessation to weight loss to asthma control, for example. Although the aim of this study was not to make predictions based on the specific goals of mHealth technology use, we acknowledge that making such distinctions is important for behavioral interventions.

Conclusions

This study contributes to understanding of the US adult population's ownership, use (including multiuse), and nonuse of diverse types of mHealth technologies for health or behavioral tracking and goal setting. We discovered that characteristics, such as age, gender, being a health information seeker, and having a chronic condition, are associated with specific patterns of mHealth use. Researchers and clinical and public health practitioners can apply these findings to research design, practice, and health message development to better reach intended audiences and promote health behavior change.

Although mHealth technologies have the potential to broadly reach people and facilitate behavior change, our findings suggest that an appreciation for the diverse ways mHealth technologies are used (and not used) for health or behavioral tracking and goal setting should be considered when designing as well as interpreting the results of mHealth intervention studies. Future studies could build on this work through continued surveillance of patterns of mHealth use for health and behavioral tracking and the individual-level factors associated with those patterns. Research that keeps pace with mHealth technology development is needed to understand the contextual factors that help explain variation in population-level effects of mHealth technology use on health behavior.

Abstract

Background: In chronic neurological diseases, especially in multiple sclerosis (MS), clinical assessment of motor dysfunction is crucial to monitor the disease in patients. Traditional scales are not sensitive enough to detect slight changes. Video recordings of patient performance are more accurate and increase the reliability of severity ratings. When these recordings are automated, quantitative disability assessments by machine learning algorithms can be created. Creation of these algorithms involves non–health care professionals, which is a challenge for maintaining data privacy. However, autoencoders can address this issue.

Objective: The aim of this proof-of-concept study was to test whether coded frame vectors of autoencoders contain relevant information for analyzing videos of the motor performance of patients with MS.

Methods: In this study, 20 pre-rated videos of patients performing the finger-to-nose test were recorded. An autoencoder created encoded frame vectors from the original videos and decoded the videos again. The original and decoded videos were shown to 10 neurologists at an academic MS center in Basel, Switzerland. The neurologists tested whether the 200 videos were human-readable after decoding and rated the severity grade of each original and decoded video according to the Neurostatus-Expanded Disability Status Scale definitions of limb ataxia. Furthermore, the neurologists tested whether ratings were equivalent between the original and decoded videos.

Results: In total, 172 of 200 (86.0%) videos were of sufficient quality to be ratable. The intrarater agreement between the original and decoded videos was 0.317 (Cohen weighted kappa). The average difference in the ratings between the original and decoded videos was 0.26, in which the original videos were rated as more severe. The interrater agreement between the original videos was 0.459 and that between the decoded videos was 0.302. The agreement was higher when no deficits or very severe deficits were present.

Conclusions: The vast majority of videos (172/200, 86.0%) decoded by the autoencoder contained clinically relevant information and had fair intrarater agreement with the original videos. Autoencoders are a potential method for enabling the use of patient videos while preserving data privacy, especially when non–health-care professionals are involved.

autoencoder; video-rating; machine learning algorithms; deep neuronal network; Neurostatus-EDSS

Introduction

In chronic neurological diseases, especially multiple sclerosis (MS), clinical assessment of motor dysfunction is crucial to monitor the disease in patients [1]. Traditional scales used to assess MS, such as the Expanded Disability Status Scale (EDSS), are not sensitive enough to detect slight changes in motor performance [2]. Video recordings of patient performance are more accurate and increase the reliability of severity ratings [3,4]. Moreover, when these recordings are automated, quantitative disability assessments by machine learning algorithms (MLA) can be created [5]. Machine learning algorithms are potentially more sensitive in detecting small changes between images; however, they require high-resolution images because of the high dimensionality of the data [6,7]. Creation of these algorithms usually involves non–health care professionals, which is a potential challenge for maintaining data privacy. Autoencoders can address this issue. They embed visual information into a lower-dimensional latent space that preserves information needed for algorithm development but is not visually interpretable by humans. [6]. An autoencoder consists of an encoder that creates encoded videos by creating a sequence of coded frame vectors and a paired decoder that transforms the coded frame vectors back into the original video. Videos encoded in this way can be shared with non–health care professionals, while the decoder can be used to verify if the essential information from the video has been captured. However, it is unknown whether the condensed data in the coded frame vectors contain clinically relevant data. Therefore, the aim of this proof-of-concept study was to test whether coded frame vectors of autoencoders contain relevant information for analyzing videos of the motor performance of patients with MS.

Methods

Study Design and Participants

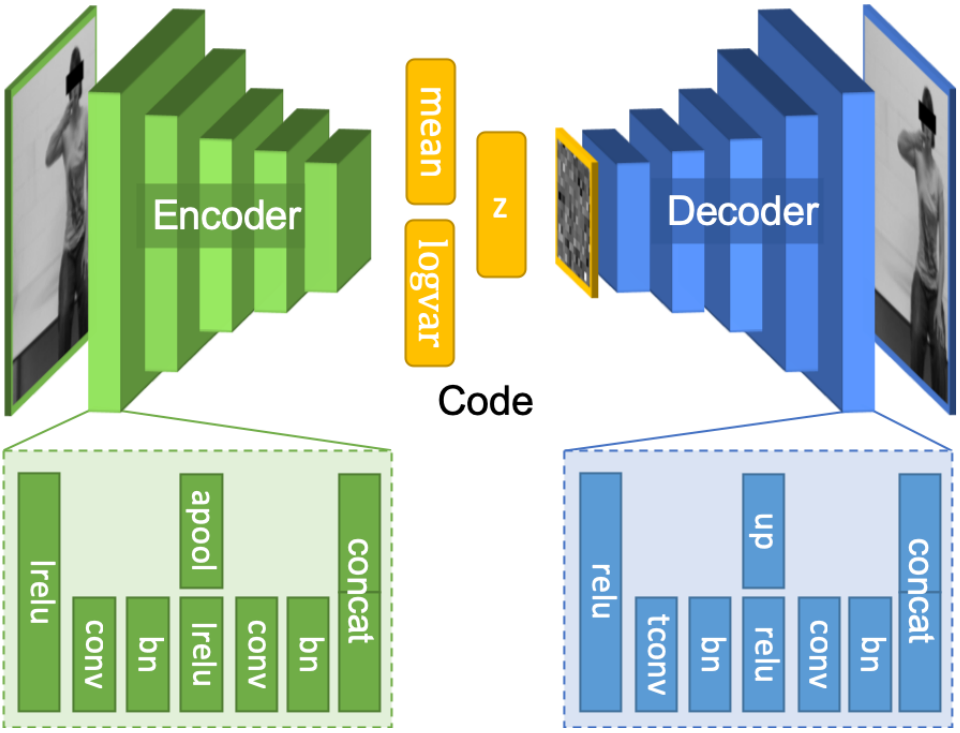
This study was a subproject of the ASSESS MS study [5] and was approved by the local ethics committees. All participants gave their written informed consent prior to inclusion. In the ASSESS MS study, 9 standardized movements were recorded on video; these movements covered overall motor function, including upper extremity function, truncal stability, and mobility. A detailed description of the movements can be found elsewhere [8]. For this study, we used recordings of the finger-to-nose test. The execution of the finger-to-nose test was standardized using a detailed protocol: Each participant was instructed to close their eyes and abduct their arms to 90° at the shoulder in full extension before touching their nose with the tip of their index finger. Both sides were tested. Original and decoded videos of 20 participants were shown to 10 neurologists at an academic MS center in Basel, Switzerland. The neurologists tested whether these 200 videos in total were human-readable after decoding and rated the severity grade of each original and decoded video according to the Neurostatus-EDSS definitions of limb ataxia [9] (subscore grade 0=no ataxia; grade 1=signs only; grade 2=tremor or clumsy movements easily seen, minor interference with function; grade 3=tremor or clumsy movements that interfere with function in all spheres; and grade 4=most functions are very difficult). The decoded videos were shown firstly, and after an interval of 2-3 weeks, the original videos were shown in the same order to minimize recall bias. The neurologists tested whether these videos were human-readable after decoding.

Autoencoder

A variational autoencoder was trained on 2230 videos comprising the 9 standardized motor performances included in the ASSESS MS study. The autoencoder was structured so that the frames of each video were encoded into a lower-dimensional space and then decoded into their original form.

Figure 1 depicts the structure of the autoencoder [10]. An encoder network was presented with a single frame from the video without further context. The frame passed through 5 encoding blocks. In each block, the input was processed in a block inspired by a densely connected convolutional network [11], wherein a skip connection was provided between the input and output layers in addition to a convolutional layer/batch normalization sequence. Each block halved the resolution of the image and doubled the feature depth. This network predicted the mean and variance of a normal distribution, which was then sampled to produce a code. The code was presented to a second network that consisted of 5 decoding blocks. Each decoding block consisted of a skip connection (which performed a simple upsampling process) and a transposed convolutional block like that used in a deep convolutional generative adversarial network [12]. Each block doubled the resolution and halved the feature depth. The network was trained using a multi-scale structural similarity–based perceptual loss function [13] with Kullback-Leibler regularization as per Kingma and Welling [10]. The input images were 256×256 RGB-D images with a code length of 256. The training hyperparameters were as follows: the learning rate was 0.001, the convolutional kernel size was 5, and the number of initial filters was 8. The model was trained for 400 epochs.

Figure 1. Structure of the variational autoencoder.



The key property of interest to us was that when a frame is in its coded form, it is computationally prohibited to decipher it without access to the decoder [6]. An autoencoder as described above reduces the dimensionality of the input data (in our case, videos) by passing the data through an "information bottleneck" [14]. The resulting coded, or latent, space sufficiently describes the data in a way that allows an accurate partial reconstruction. The shared latent embedding is optimized to represent the salient information that is similar across frames of multiple videos (in our case: the movement), whereas dissimilar aspects (eg, background aspects, details of physical features) are less well conserved. Neural networks are a machine learning approach that is inspired by biological neuronal computation; these networks have demonstrated exceptional performance in complex image-related tasks in recent years [15-17]. Given this success, in this study, we used a neural net approach called a variational autoencoder [18]. A variational autoencoder has at its center a coded vector of vastly reduced dimensionality. This is because the decoder requires millions of floating point values to be set precisely before the coded vector can be successfully decoded into an image. At the same time, the coded vector contains all the information necessary to reconstruct that frame; interestingly, due to the variational constraints during training, the frame has semantically meaningful cosine distances to other visually similar frames. This property is very useful for machine learning tasks that operate upon these coded vectors because the coded frames can be used in place of the original video frames without the possibility that a human could use it to recognize the depicted participant.

Statistics

Intrarater agreement between the ratings of the original and the decoded videos was assessed using the Cohen weighted kappa with linear weights (ie, disagreements of 1, 2, and 3 were weighted by factors of 1, 2, and 3, respectively). A Cohen kappa of 0 corresponds to chance agreement; 0-0.2, to slight agreement; 0.21-0.4, fair agreement; 0.41-0.6, to moderate agreement; 0.61-0.8, to substantial agreement; and 0.81-1, to almost perfect agreement [19]. All analyses were performed in MATLAB (MathWorks, Inc).

Results

The characteristics of the study population and the participating neurologists are summarized in Table 1.

In total, 172/200 (86.0%) videos were of sufficient quality to be ratable. The Cohen weighted kappa indicating intra-rater agreement between the original and decoded videos was 0.317. The average difference in the ratings between the original and decoded videos was 0.26, in which the original videos were rated as more severe. The inter-rater agreements of the original and decoded videos were 0.459 and 0.302, respectively. As depicted in Figure 2, agreement was higher when no deficits (grade 0) or very severe deficits (grade 4) were present. Note that most videos that were not ratable were judged so by neurologists 2 and 5.

Table 1. Characteristics of the patients and neurologists who participated in the study.

Characteristic	Value
Patient characteristics (n=20)	
Age (years), mean (95% CI)	44.4 (27-74)
Gender (female/male), n (%)	12 (63%)/7 (37%)
Disease duration (years), mean (95% CI)	13.2 (1-40)
Median EDSS[a] (range)	3.5 (0-6.5)
Type of MS[b] (RRMS[c]/SPMS[d]), n (%)	19 (95%)/1 (5%)
Neurologists (n=10)	
Gender (female/male), n (%)	5 (50%)/5 (50%)
Years of experience in neurology, mean (range)	8.8 (3 to >30)

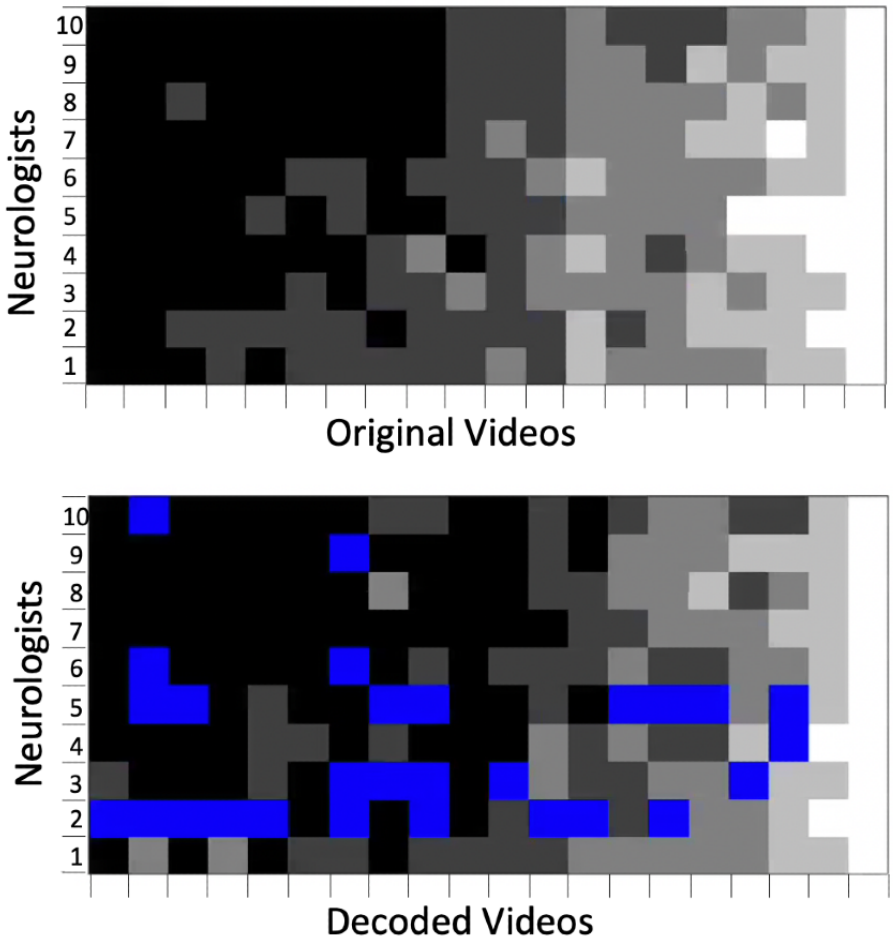
[a]EDSS: Expanded Disability Status Scale.

[b]MS: multiple sclerosis.

[c]RRMS: relapsing remitting multiple sclerosis.

[d]SPMS: secondary progressive multiple sclerosis.

Figure 2. Ratings by 10 neurologists of the original and decoded videos. The colored squares represent the different grades for limb ataxia of the finger-to-nose-test according to the Neurostatus-Expanded Disability Status Scale subscores: black=0, dark grey=1, grey=2, bright grey=3, and white=4. The blue squares represent videos that were judged as not ratable by the neurologists.



Discussion

Principal Findings

In this proof-of-concept study, 172/200 (86.0%) of the decoded videos were of sufficient quality to be ratable. We found fair intrarater agreement between the original and decoded videos. The agreement was better for minor and severe deficits in motor function.

Data security and privacy are increasingly requested by health care professionals for data capture, analysis, and storage [20]. At the same time, the use of machine learning algorithms and deep neuronal network techniques as subdomains of artificial intelligence is increasingly infiltrating all areas of health care [21,22]. The use of new technologies and electronic tools for capture and automated analysis of clinical data generally requires the involvement of non–health care professionals, which creates challenges regarding data privacy. To our knowledge, this is the first study to use an autoencoder to allow the analysis of patient videos while preserving data privacy.

Patients with MS may present with slight changes in motor performances over their disease course. Clinical assessment of these changes is notoriously difficult. Video analysis of motor performances allows automated analyses and quantification of disability by using machine learning algorithm–based analysis systems such as those used in the ASSESS MS study; however, it requires a huge data set [5]. Since the creation of machine learning algorithms usually involves non-medical collaborators, encoding of these videos is essential. The intra-rater agreement of original and decoded videos in this study was fair. It is unclear whether this is due to accordance of the video quality or the test-retest reliability of the finger-to-nose test. To our knowledge, no data are available regarding this psychometric property of the finger-to-nose test.

Limitations

A limitation of this proof-of-concept study is the class imbalance of the patient videos according to the four grades of limb ataxia for the finger-to-nose test [9,21]. Further iterations of the deep neural network are necessary to increase the intrarater reliability.

Conclusions

In this proof-of-concept study, we have shown that the vast majority (172/200, 86.0%) of videos decoded by an autoencoder contained clinically relevant information regarding upper extremity motor performance represented by the finger-to-nose test and had fair intrarater agreement. Autoencoders are a potential method for enabling the use of patient videos while preserving data privacy, especially when non–health care professionals are involved.

Abstract

Background: Point-of-care clinical photography using mobile devices is coming of age as a new standard of care for clinical documentation. High-quality cameras in modern smartphones facilitate faithful reproduction of clinical findings in photographs; however, clinical photographs captured on mobile devices are often taken using the native camera app on the device and transmitted using relatively insecure methods (eg, SMS text message and email) that do not preserve images as part of the electronic medical records. Native camera apps lack robust security features and direct integration with electronic health records (EHRs), which may limit patient acceptability and usefulness to clinicians. In March 2015, Mayo Clinic overcame these barriers by launching an internally developed mobile app that allows health care providers to securely capture clinical photographs and upload them to the EHR in a manner that is compliant with patient privacy and confidentiality regulations.

Objective: The study aimed to understand the perceptions, attitudes, and experiences of patients who were photographed using a mobile point-of-care clinical image capture app.

Methods: The study included a mail-out survey sent to 292 patients in Rochester, Minnesota, who were photographed using a mobile point-of-care clinical image capture app within a preceding 2-week period.

Results: The surveys were completed by 71 patients who recalled being photographed. Patients were seen in 18 different departments, with the most common departments being dermatology (19/71, 27%), vascular medicine (17/71, 24%), and family medicine (10/71, 14%). Most patients (49/62, 79%) reported that photographs were taken to simply document the appearance of a clinical finding for future reference. Only 16% (10/62) of patients said the photographs were used to obtain advice from a specialist. Furthermore, 74% (51/69) of the patients said they would recommend medical photography to others and 67% (46/69) of them thought the photos favorably affected their care. Patients were largely indifferent about the device used for photography (mobile device vs professional camera; 40/69, 58%) or the identity of the photographer (provider vs professional photographer; 52/69, 75%). In addition, 90% (64/71) of patients found reuse of photographs for one-on-one learner education to be acceptable. Acceptability for other uses declined as the size of the audience increased, with only 42% (30/71) of patients deeming reuse on social media for medical education as appropriate. Only 3% (2/71) of patients expressed privacy or confidentiality concerns. Furthermore, 52% (33/63) of patients preferred to provide consent verbally, and 21% (13/63) of them did not think a specific consent process was necessary.

Conclusions: Patient attitudes regarding medical photography using a secure EHR-integrated app were favorable. Patients perceived that photography improved their care despite the most common reason for photography being to simply document the appearance of a clinical finding for future reference. Whenever possible, health care providers should utilize secure EHR-integrated apps for point-of-care medical photography using mobile devices.

Introduction

Clinical Photography

Clinical photography has been standard practice in the fields of dermatology [1,2], plastic surgery [1,3] and dentistry [4] for years, and it has emerged as a useful tool for use by general practitioners [5] and emergency medicine providers [6] as well. Clinical photographs can be captured by professional medical photographers using clinic-owned equipment or by health care providers themselves using a clinic-owned camera or their personal mobile device. With personal smartphone ownership approaching nearly 3 billion, the usage of mobile devices is expected only to increase [7].

Clinical photography has many uses, and most patients seem to find it useful in the course of their care [8,9]. It can provide more vivid descriptions than a provider could detail in their written documentation, allow providers to follow progression of a disease over time, facilitate telemedicine, and allow patients or their caregivers to see clinical findings they might not otherwise be able to see themselves (eg, finding on back or intraoperative findings) [10,11].

Privacy and Confidentiality Concerns

A number of legal and ethical issues concerning patient privacy and data security arise in the course of clinical photography; for example, patients may feel uncomfortable with clinical photography that involves sensitive areas (eg, genitalia) [6]. Patient attitudes may vary when a professional-grade, clinic-owned camera is used compared with a health care provider's personal mobile phone [8,9,12,13]. Consent practices may vary [8], and the optimal method of consent (ie, implied, verbal, or written) for medical photography is unclear [2,9]. Furthermore, when patients consent to medical photography, they may assume that the photographs will only be used to provide clinical care, yet it is clear that clinical photographs may be beneficial tools for medical education [10]. The extent to which patients are comfortable with photographs being used for various educational purposes may be variable [6,8,9,12,13]. Although patients are, in general, accepting of reuse for medical care and education in small settings, they are less accepting of reuse in media that are distributed to larger audiences and the lay public (eg, social media) [6,8,9,12,13].

Legal provisions in the United States and elsewhere dictate the manner in which health care providers must keep protected health information private and secure. Although some health care providers transmit clinical photographs to colleagues using methods that lack certain privacy and security features, such as text messaging or email [2], various electronic health record (EHR) vendors have incorporated secure clinical photography modules that include patient identity management and security features within the mobile apps. Despite this, these secure mobile apps may be relatively underused. In a Canadian survey of neurosurgical residents, 45% of whom used their smartphone for clinical photography, 89% stored photos or videos of patients in the native smartphone app and only 8% used a password-protected app [9]. More concerning is that only 32% of users deleted photographs immediately after use, and 23% of them said that they do not routinely delete patient photographs on their phones [9]. At the same time, a survey of dermatologists—approximately half of whom used a smartphone for clinical photography—revealed that only 43% used a secure smartphone app that is integrated with the EHR [14]. This practice is problematic for several reasons. First, mobile devices may not be uniformly password protected to prevent unauthorized access. Second, mobile devices often automatically backup photos to a personal cloud storage service (eg, iCloud, Apple Inc; DropBox, Dropbox, Inc). These tools may not be compliant with health care data protection laws as they may lack sufficient security to prevent unauthorized viewing and there may be no reliable mechanism to ensure that patients are notified in the event of a data breech on the cloud storage service. Finally, capturing a photograph using a native app implies that the photograph will not become part of the medical record. Not only does this limit visibility by other clinicians participating in the patient's care, but it also implies that the photograph may be transmitted using insecure methods (eg, personal email, text message).

Goal

In March 2015, after legal and policy review, Mayo Clinic released an internally developed iOS-based clinical photography app named PhotoExam. The app permits any member of the health care team with clinical documentation privileges to capture photographs using their personal mobile device or a clinic-owned device and directly upload the images to the EHR. The app's features include patient identity management, Health Insurance Portability and Accountability Act (HIPAA) compliance, and confirmation that patient consent has been obtained before photography takes place. We previously reported app uptake at the 3 Mayo Clinic campuses in Minnesota, Florida, and Arizona as well as the regional Mayo Clinic Health System [11]. Considering that the existing literature largely focused on patient attitudes about medical photography performed either using a clinic-owned professional camera or a smartphone app that lacks security features and is

not integrated with the EHR, we aimed to understand how patient experience may differ with PhotoExam.

Therefore, to assess perceived patient benefit, acceptability, and privacy/security concerns, we surveyed patients who were photographed by their health care providers using the PhotoExam app.

Methods

PhotoExam App

The PhotoExam app is an internally developed iOS-based mobile app that allows health care providers to take clinical photographs of patients and incorporate them into the EHR in a manner that is secure and HIPAA compliant. Providers launch the app either from the patient's chart opened within a third-party EHR mobile app or they open the app from their home screen and then manually enter the patient's medical record. A hard-stop requires providers to verify that they have obtained patient consent, according to departmental policies, before capturing photographs. Providers then select the anatomical site(s) they will photograph and use the smartphone camera to capture up to 6 photographs per anatomical site. Photos can be immediately deleted or retaken if quality is suboptimal. After all images have been captured, the app uploads the images to the patient's medical record and provides confirmation that the images have been successfully uploaded. The photographs are then automatically deleted from the user's device after upload is complete or whenever the user closes the app—whichever comes first. Images are never made accessible outside of the PhotoExam app (eg, within the native photo gallery). Newer versions of PhotoExam allow capture of short video clips; however, video recordings were not considered for this study.

Patient Selection

We included a random sample of 300 adult patients or parents of pediatric patients (ie, aged <18 years) who were photographed using the PhotoExam app at Mayo Clinic, Rochester, Minnesota, within a preceding 2-week period and for whom a mailing address was available. Patients who refused research participation were excluded. We also excluded patients whose primary language was not English because the survey was written in English. To protect pediatric patients, we reviewed the photographs and clinical records of pediatric patients identified for potential inclusion and excluded patients who were seen for confidential visits or visits of a potentially emotionally sensitive nature. The excluded pediatric patients were substituted with another randomly selected pediatric patient (ie, aged <18 years) who had been photographed during the same 2-week period.

Survey Description

The survey included the patient's name, medical record number, and the date of the most recent clinical visit where a health care provider photographed them using the PhotoExam app. Surveys were mailed to patients at their home address. Surveys corresponding to patients younger than 18 years were addressed to the patient's parent or guardian. Patients who did not recall being photographed were asked to not answer further questions and return the survey. Questions generally related to the reason photos were taken, effect on timeliness of care, comfort level with medical photography, and the manner in which consent to photography was obtained. Patients were also allowed to share general comments or concerns about the practice of medical photography using mobile devices in free-text form (Multimedia Appendix 1). Patients who did not respond to the initial survey were sent a follow-up survey.

Statistical Analysis

Responses are reported in counts and percentages with continuous variables summarized as means or medians and standard deviations or ranges, as appropriate. In cases where patients did not respond to individual questions, percentages represent the number of patients who responded to an individual question.

Human Subjects Protection

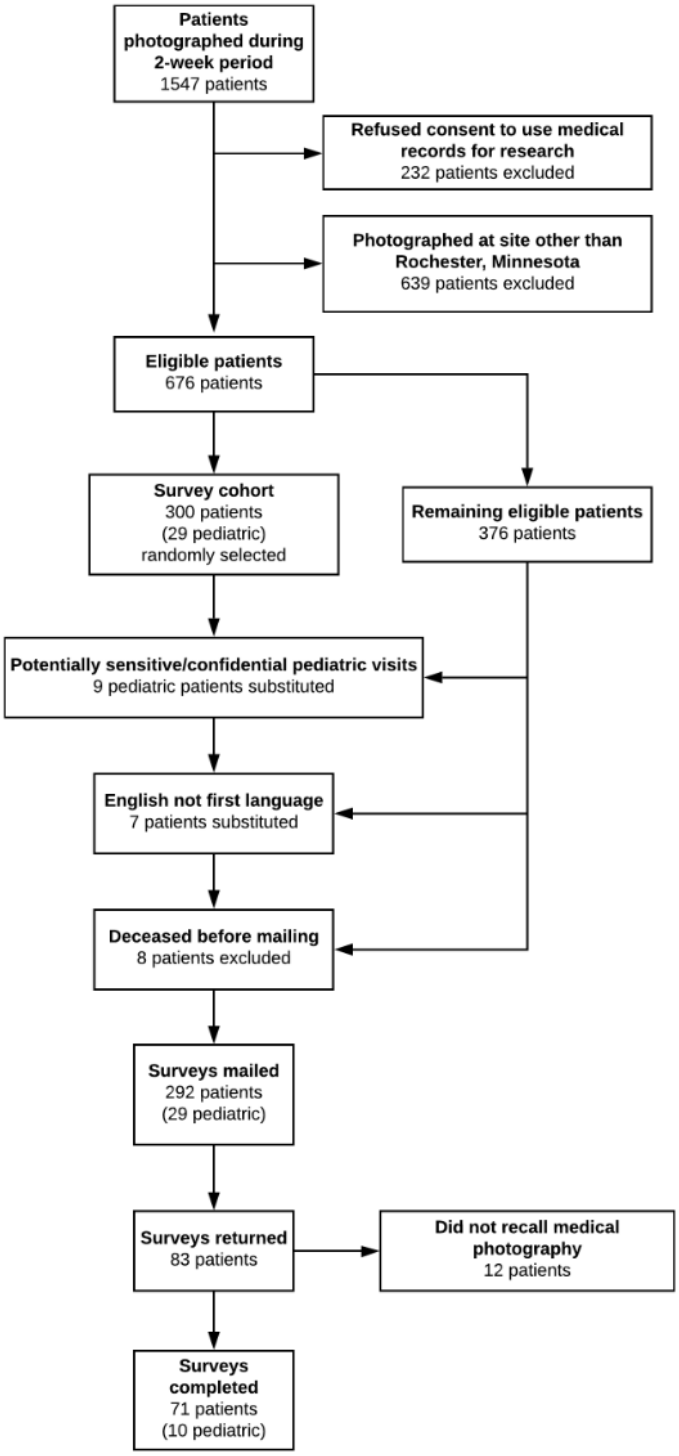
The study procedures were approved by the Mayo Clinic Institutional Review Board.

Results

Patient Selection

Patients (n=1547) who were photographed with the app within a 2-week period were identified. After ineligible patients were excluded, surveys were printed and mailed to 292 patients, 29 of whom were pediatric patients (Figure 1). Surveys were mailed 51 days after the end of the 2-week period when photos were taken. A total of 64 completed surveys were returned after the initial mailing. The second mailing was sent to nonrespondents 1 month after the initial mailing (81 days after the end of the 2-week period where photos were taken). A total of 83 total surveys were returned. In addition, 14% (12/83 of respondents willing to complete the survey) adult patients did not recall a health care provider using a mobile device to take a photograph during a visit and therefore did not complete the remainder of the survey. The remainder of respondents (n=71; 10 pediatric) recalled medical photography taking place and completed the remainder of the survey.

Figure 1. Patient selection.



Population and Demographics

The patient demographics are shown in Table 1. Patients were seen in 18 different departments, with the most common departments being dermatology (19/71, 27%), vascular medicine (17/71, 24%), and family medicine (10/71, 14%).

Table 1. Patient demographics (N=83 surveys returned).

Characteristics	Values
Age (years), median (SD)	63 (23)
Younger than 18 years of age, n (%)	10 (12)
Marital status (N=83 surveys returned), n (%)	
Single	19 (23)
Married	59 (71)
Divorced	4 (5)
Widowed	1 (1)
Race (N=83 surveys returned), n (%)	
White	82 (99)
Other	1 (1)
Number of photos taken of patient using PhotoExam during an encounter, median (range)	2 (1-9)
Number of photos ever taken of patient using PhotoExam, all encounters included, median (range)	5 (1-164)
Days between clinical visit and survey completion (days), median (range)	68 (58-224)
Eligible surveys (N=292 surveys mailed), n (%)	
Survey returned	83 (28.4)
No response after 3 mailings	177 (60.6)
Refused	24 (8.2)
Deceased (survey not sent)	8 (2.7)
Survey returned without Health Insurance Portability and Accountability Act authorization	3 (1.0)
Deceased (notified after survey sent)	2 (0.6)
Invalid mailing address	1 (0.3)
Physically/mentally unable to complete	1 (0.3)
Returned blank survey	1 (0.3)

Rationale for Photography

Patients reported that the majority of photos were taken to document the appearance of the area for future reference (49/71, 69%). Furthermore, 14% (10/71) photos were taken to send to a specialist for review. Three percent (2/71) reported that photographs were taken for educational purposes, and the remainder were unsure why photographs were taken.

Effect of Photography on Time to Diagnosis and Treatment When Specialist was Consulted

Two of the patients whose providers photographed them to obtain a specialist's assistance with making the diagnosis said the photography had no effect on the time to diagnosis and treatment, but the remaining 3 indicated that it either slightly or significantly expedited time to diagnosis and treatment.

Consent for Photography

Overall, 91% (60/66) of patients who were surveyed recalled being asked permission to take photographs, with three-fourth (45/60) of these patients providing verbal permission and the rest (15/60) providing written permission.

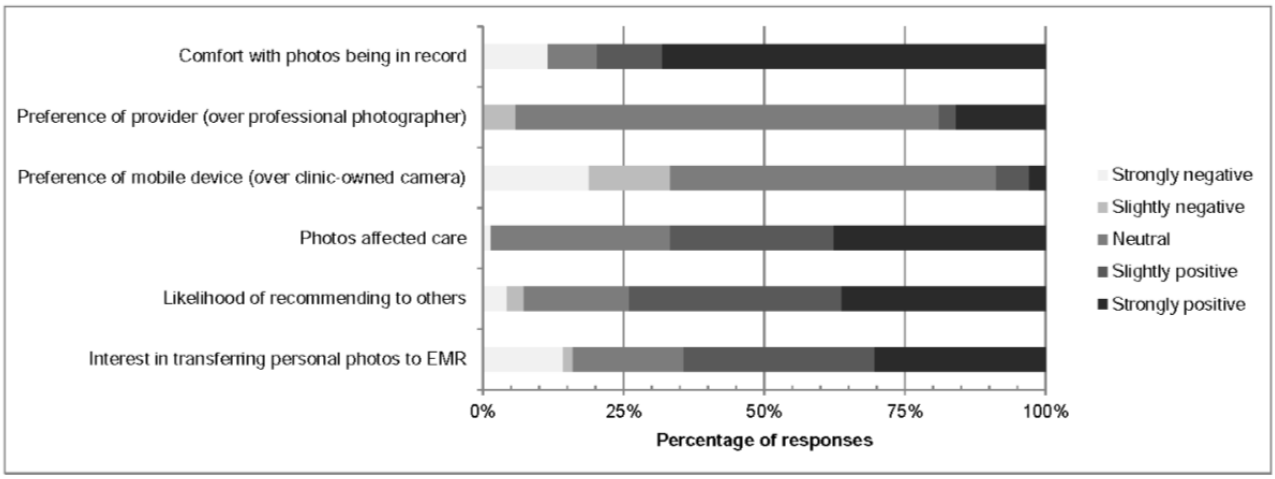
Of the patients who provided written consent, 53% (8/15) indicated that they only read a part of the consent form and 1 patient (1/15, 7%) did not read any part of the form, with the remaining 33% (5/15) patients indicating that they read the entire consent form word for word.

When patients were asked their preference for providing consent, 21% (13/63) did not think specific permission was necessary, 52% (n= 33/63) preferred verbal consent, and 27% (17/63) preferred to provide written consent, with 59% (10/17) of these patients requesting to provide written consent by signing the screen on the device used to take photos (a feature that was not available).

Attitudes Regarding Photography Practice and Process

Patients were asked a variety of questions regarding their attitudes about photography, including their comfort with photos being present in the EHR, preference of photographer, and preference of photography equipment. Patients were also asked whether photography affected their care and whether they would recommend photography to family or friends in a similar clinical scenario. Responses are shown in Figure 2, where Likert scale responses are color coded. Overall, 74% (51/69) of patients said they were likely to recommend mobile point-of-care clinical photography to others, and 67% (46/69) of patients thought the photos favorably affected their care.

Figure 2. Attitudes regarding photography practice and process. EMR: electronic medical record.



Furthermore, 80% (56/70) of patients indicated that they owned a phone with a camera, and the majority of them expressed an interest in transferring personally taken photographs into the EHR (Figure 2). Three of the patients (3/55, 5%) who owned a smartphone experienced a provider taking a photograph of a phone screen to transfer a photograph from a personal device to the EHR.

Privacy and Data Security Concerns

In total, 2 patients (2/71, 3%) indicated that they had concerns regarding privacy or confidentiality related to the photos. When asked for further explanation, one of these patients inquired whether the photos remain on the provider's phone and another explained that they believed the photos were used professionally but that they did not know the provider who took the photos. Therefore, it appeared that these concerns did not represent a belief that a privacy breech had actually occurred.

In addition, 26% (18/70) of patients recalled that security features of the app were explained by the health care provider. Furthermore, 16% (11/70) indicated that security features were not explained, and the majority (41/70, 59%) of them did not remember or were unsure if security features were explained to them.

Reuse of Photographs for Educational Purposes

Patients were asked about their comfort level with the photos that were taken being shared in various settings, provided that any personally identifying information was removed. In general, patients were supportive of use for medical education; however, comfort declined with progressively increasing audience sizes (Table 2).

Table 2. Patient comfort with reuse of photographs for educational purposes (N=71)

Reuse of photographs	Value, n (%)
One-on-one learner education	64 (90)
Large group (eg, classroom) medical learner education	57 (80)
Presentation at a national medical professional meeting	52 (73)
Publication in a medical journal or textbook	48 (68)
Publication on social media for medical education	30 (42)

Free-Text Responses

Overall, 41% (29/71) of patients provided additional written comments regarding their experiences with being photographed using a mobile device. The comments included the following:

- Requests to have a personal copy of the photographs sent.
- Indication that answers regarding comfort with the photos would have been different had the anatomical site photographed been a more sensitive area.
- Indication that the ability to have medical photographs taken prevented the need for an additional office visit.
- General questions regarding the security of the app and desire for a patient education handout regarding the privacy and security of the app.
- Indication that the ability to review images allowed patients to track the progress of their medical condition.

Discussion

Principal Findings

To the best of our knowledge, this is the first report to focus on the attitudes and experiences of patients who were photographed using a secure EHR-integrated smartphone app designed specifically for medical photography. Patients were largely satisfied with clinical photography using the app, with 74% (51/69) of patients indicating they were likely to recommend a friend or family member to give permission for medical photography using a mobile device in a similar clinical situation.

In addition, 67% (46/69) of patients perceived that the app's use improved the care they received even though most patients indicated that the photograph was taken only to document the appearance of a clinical finding that could be referenced at a future visit. This suggests that patients see benefit in the documentation of findings in a manner that may facilitate future clinical care. Indeed, in free-text responses, 2 patients shared that it helped them to track the progress of their medical condition. Although a minority of photographs were sent to a specialist, some patients shared that sending photographs to a specialist prevented them from needing an additional office visit—presumably because of the use of telemedicine.

Responses demonstrated that some patients had a desire to incorporate personally taken photographs into their medical record and revealed evidence that some health care providers had resorted to using PhotoExam to take a photograph of a photograph displayed on a patient's smartphone screen as a workaround to incorporate these photographs. EHR vendors should consider how to better integrate photograph upload functionality into their patient-facing products so that patient-taken photographs may complement those taken by providers. After the survey was administered, Mayo Clinic implemented a new commercially vended EHR that included the ability of patients to upload clinical photographs to providers with whom they have an established relationship. In the future, we will explore whether patients could be permitted to upload photographs to providers who are not already members of their care team (eg, emergency medicine provider).

The consent processes were variable. Although many patients feel that verbal consent is adequate, verbal consent processes may be problematic in that they may not elicit specific permission for all potential reuses (ie, medical education). Furthermore, even though written consent forms may ask for permission to use photographs for medical education, they may not explicitly detail various medical education uses for which patients may consent (eg, internal use one-on-one with learners vs widely distributed patient education pamphlet) and may simply include a boilerplate legal *blanket statement* seeking permission for all possible uses. We are currently evaluating the use of a 3-tiered consent form with clear language, allowing patients to consent for use of photographs for (1) clinical care only; (2) clinical care and internal education; or (3) clinical care, internal education, and external education.

Comparison With Prior Work

In our survey, most patients who recalled the consent process indicated that they provided verbal consent, and the majority of patients felt that verbal consent was adequate. In contrast, a French survey involving 158 adult patients and parents of 114 pediatric patients photographed in a dermatology clinic observed that 80% of adult patients and 89% of parents thought written consent was necessary for medical photography [8]. Another study surveyed a convenience sample of 398 patients seen in dermatology clinics in New York City and observed that 78.4% (312/398) of respondents preferred to provide written consent compared with 14.1% (56/398) who preferred verbal consent. A similar study conducted in Chicago reported 58.7% (172/293) preferring written consent over verbal consent (113/293, 38.6%) [13]. Potential explanations for the differences observed between our survey and those reported in the literature include temporal changes in patient attitudes between the survey time points (with patients gaining acceptability over time); patients' understanding of security features in the PhotoExam app; and sociodemographic differences between study populations, including the enrichment of our community with health care workers.

Patients were overwhelmingly supportive of reuse of their clinical photographs for educational purposes. Acceptability of different uses decreased as the size of the audience increased. These observations were consistent with other studies that generally reported high rates (ie, >80%) of acceptability of use of photographs for medical teaching and less comfort with widespread distribution to the lay public [6,8,9,12,13]. Despite these high levels of acceptability of image reuse, consent for reuse should always be sought (either at the time of photography or at the time reuse is desired).

We also observed, consistent with other studies, that comfort with photographs depends on the anatomical area photographed, with patients expressing discomfort with photography of sensitive anatomic areas [8,9]. A total of 3% (2/71) of actual photos in our sample were of the breast, buttock, or genitalia, and free-text comments suggested that other patients would have expressed more discomfort if they had been photographed in a more anatomically sensitive area.

More than half of patients had no preference regarding whether a provider's personal mobile device was used for clinical photography compared with a clinic-owned camera. This is in contradiction to multiple previous studies that reported poor acceptability of providers' personal mobile devices for clinical photography [8,9,12,13]. As with the differences observed regarding attitudes about the consent process in other studies, it is unclear if changes in patients' perceptions over time, the security features of the PhotoExam app, or sociodemographic differences account for the inconsistency between studies.

Strengths and Limitations

This study has several strengths. First, we included a random sample of pediatric and adult patients seen in a variety of departments who were photographed using a mobile app designed specifically for the purpose of clinical medical photography. Surveys were mailed shortly after the clinical encounter where photography occurred to maximize recall. In addition, we surveyed patients across multiple domains, including the perceived benefit, attitudes regarding use of photographs for education, preferred method of providing consent, and preferred camera type. We were also able to incorporate additional information from the medical record, including patient demographics, anatomical site(s) photographed, and the department of the specialist who photographed the patient.

Conversely, there are several limitations to this study. Although initial surveys were sent within 10 weeks of the occurrence of medical photography and most completed surveys were filled out promptly, we were surprised that 14% (12/82) of those who returned the survey did not recall that they were photographed

by their health care provider. This significantly limited our ability to gather information about these patients' experience with medical photography. It is unclear whether patients' failure to recall the photography is evidence that medical photography was viewed as an insignificant and unimportant part of their visit or whether it was perceived as standard of care and therefore not memorable. Although our response rate was low, at 28% (83/292), this was similar to response rates of similar internal patient surveys conducted at Mayo Clinic. The low response rate led to a small sample size, which limits the generalizability of the results and limits our ability to make meaningful conclusions regarding questions that only a subset of patients were eligible to respond to based on other responses.

In addition, responses were only gathered from patients, and clinical outcome measurement was limited to a patient's perception of how medical photography affected their care. Use of a formally validated survey would improve the internal and external validity of the study. Health care providers who use clinical photographs may have other insights into how clinical photography affects clinical management. To address provider experience, we plan to separately report a survey of health care providers who have used PhotoExam.

It is also important to note that our sample is biased in that we only surveyed patients who were photographed using the PhotoExam app. By nature of permitting a health care provider to photograph them with the app, patients may have preconceived notions of how the app may be beneficial or may have different attitudes regarding medical photography when compared with patients who refused medical photography with the PhotoExam app. In the authors' personal experience, refusal of consent to photograph is rare and is generally in the context of a request to photograph an anatomically sensitive area. As noted above, the patient population seen in Rochester, Minnesota, may not be representative of the broader United States. Although our population includes both local patients and those who travel from elsewhere to receive care, our local population is enriched with health care workers, whose attitudes may differ from those who do not work in health care; for example, 82% (68/83) of patients in our study were from Minnesota, with 47% (39/83) of included patients residing in Rochester, Minnesota, and an additional 7% (6/83) living outside of Rochester, Minnesota, but within Olmsted County. In addition, our patient population was 99% (82/83) white. A more racially diverse cohort may have resulted if we had provided translated surveys for non–English-speaking patients. Owing to this limitation, our current results may have failed to reflect important cultural differences in attitudes that may vary among patients.

We were encouraged that, in general, patients felt that medical photography using the app favorably affected their care, and only on a rare occasion did patients perceive it to be detrimental to their care. Concerns about privacy were rare, and patients were generally comfortable with clinical photography conducted using their provider's mobile device. These findings suggest that PhotoExam was implemented in a way that facilitates patient care and is sensitive to patients' privacy and confidentiality.

Conclusions

In summary, the PhotoExam app was well received by patients, addressed privacy and confidentiality issues, and was perceived to favorably affect patient care. We discovered no major patient-perceived barriers to implementing point-of-care clinical photography. In this regard, point-of-care medical photography is an up-and-coming best practice that we predict will become a new standard of care because of the obvious clinical benefit and ease with which photographs can be captured and entered into the medical record [15]. Future priorities include explicitly clarifying permissible educational reuses of photographs using uniform consent processes.

Acknowledgments

The authors thank the Mayo Clinic Center for Connected Care for funding to conduct the surveys. SO and JY are members of the Center for Connected Care leadership. JY provided minor suggestions regarding wording of survey questions; however, no member of Mayo Clinic Center for Connected Care otherwise played a role in the content of the survey questions. SO and JY were invited to participate as coauthors and both reviewed and approved the manuscript for publication. However, the funding source had no role in the decision to write this manuscript or submit it for publication. Furthermore, the authors thank the patients who participated in this survey and the Mayo Clinic Survey Research Center for assistance mailing surveys and compiling results.

Conflicts of Interest

All coauthors are current or former employees at Mayo Clinic, which retains intellectual property of the PhotoExam app. The app is only used internally and is not currently being licensed. Funding to distribute surveys and enter survey data was provided by Mayo Clinic Center for Connected Care, for which SO and JY are leadership members.

Abstract

Background: Laryngeal microsurgery (LMS) is often accompanied by a sudden increase in blood pressure (BP) during surgery because of stimulation around the larynx. This sudden change in the hemodynamic status is not immediately reflected in a casual cuff-type measurement that takes intermittent readings every 3 to 5 min.

Objective: This study aimed to investigate the potential of pulse arrival time (PAT) as a marker for a BP surge, which usually occurs in patients undergoing LMS.

Methods: Intermittent measurements of BP and electrocardiogram (ECG) and photoplethysmogram (PPG) signals were recorded during LMS. PAT was defined as the interval between the R-peak on the ECG and the maximum slope on the PPG. Mean PAT values before and after BP increase were compared. PPG-related parameters and the correlations between changes in these variables were calculated.

Results: BP surged because of laryngoscopic manipulation (mean systolic BP [SBP] from 115.3, SD 21.4 mmHg, to 159.9, SD 25.2 mmHg; $P<.001$), whereas PAT decreased significantly (from mean 460.6, SD 51.9 ms, to 405.8, SD 50.1 ms; $P<.001$) in most of the cases. The change in SBP showed a significant correlation with the inverse of the PAT ($r=0.582$; $P<.001$). Receiver-operating characteristic curve analysis indicated that an increase of 11.5% in the inverse of the PAT could detect a 40% increase in SBP, and the area under the curve was 0.814.

Conclusions: During LMS, where invasive arterial catheterization is not always possible, PAT shows good correlation with SBP and may, therefore, have the potential to identify abrupt BP surges during laryngoscopic manipulations in a noninvasive manner.

Introduction

Background

Laryngeal microsurgery (LMS) is often accompanied by a sudden increase in blood pressure (BP) during surgery because of stimulation around the larynx [1,2]. Laryngoscopic manipulations cause sympathetic nervous system stimulation and increase in the level of plasma catecholamines, such as epinephrine and norepinephrine [3]. Acute hypertension resulting from this process can cause complications such as ischemic heart disease, heart failure, stroke, and life-threatening arterial bleeding even in patients without predisposing factors [4,5]. Moreover, myocardial ischemia or arrhythmia can occur during the perioperative period because of the stimulation of the deep receptors of both the larynx and cardioinhibitory fibers of the vagus nerve [6]. There have been previous studies regarding the appropriate methods of anesthesia for maintaining a stable hemodynamic status in patients during LMS [7,8]. Despite a sudden change in the hemodynamic status, an abrupt BP rise is not immediately reflected in a casual cuff-type measurement that takes intermittent readings every 3 to 5 min.

Pulse arrival time (PAT), measured as the interval from the R-peak on an electrocardiogram (ECG) to the peripheral arrival of the pulse wave, has been used as an estimate for pulse transit time and may be a noninvasive marker for BP [9-14]. Recent advancements in technology enabled adjustment for confounding factors (eg, heart rate, arterial stiffness, and pre-ejection time) in estimating BP from PAT [9,15,16]. Furthermore, a cuff-less approach for 24-hour BP monitoring became possible using wearable devices [13]. Clinical application and commercialization of these wearable BP-monitoring devices are underway [17,18].

Objectives

We previously reported that beat-to-beat changes in PAT can effectively detect decreases in systolic BP (SBP) during anesthesia induction in hypertensive patients undergoing renal transplantation [11]. However, most previous studies have estimated the state of hypotensive events, but no report to date has focused on PAT monitoring to detect an abrupt BP surge. In this study, we investigated whether noninvasive PAT could be used to monitor rapid BP increases during LMS in real time.

Methods

Study Population and Anesthesia Protocol

We retrospectively analyzed the electronic records of 30 patients with vocal cord polyps or edema who were scheduled for an elective LMS under general anesthesia. Patients with cardiac arrhythmias or incomplete data were excluded.

All patients were prepared for general anesthesia according to our institutional protocol. Premedication was not given. Cardiovascular medication, including antihypertensive medication, was administered until the day of surgery, except for angiotensin II receptor blocker or angiotensin-converting enzyme inhibitor. Routine monitoring included noninvasive intermittent BP (NIBP), ECG, pulse oximetry, and end-tidal concentration of CO_2 using a multiparameter monitor (Philips IntelliVue MP70; Philips). All data were recorded simultaneously throughout the procedure. Volatile induction and maintenance of anesthesia were performed. Anesthesia was induced with 6% to 8% sevoflurane and rocuronium (0.5-1 mg/kg) and maintained with 2% sevoflurane and 50% nitrous oxide in oxygen.

Data Acquisition and Signal Processing

ECG and photoplethysmogram (PPG) waveform data were recorded with data acquisition software (Vital Recorder) [19] at a sampling rate of 300 Hz, and NIBP was measured and recorded every 3 min. The signal data were transferred via serial port from the MP70 monitor to a computer running the Vital Recorder and written to the hard drive. PAT was defined as the interval between the R-peak on the ECG and the point at which the maximal rising slope appears on the PPG [11]. The PAT of each beat was calculated using the filter function, which was built using Python code in the Vital Recorder software (Multimedia Appendix 1). When the filter function is executed, the PAT at every heartbeat is calculated from the recorded ECG and PPG waveforms by the algorithm, and the PAT values at each time point are added as a new time series variable. The PPG waveform data recorded with the data acquisition software were converted to European Data Format [20] and analyzed with signal processing software (LabChart 8; AD Instruments) to acquire features of the PPG waveform, such as height, $width_{50}$ (width at 50% height of each PPG wave peak), maximum slope, minimum slope, and area of each wave peaks [21]. These features were extracted by the peak analysis function of the software. The 1-min averages of each value just before and after laryngoscopic manipulation were calculated by the function and recorded for further analysis. All the acquired parameters during the laryngoscopic manipulation were compared. The 1-min averages of PAT just before laryngoscope insertion and at the lowest point of PAT after stimulation were used as the PAT parameters for each time point. PPG and PAT parameters were obtained simultaneously.

Statistical Analysis

All study data are presented as mean (SD), n (%), or median (IQR). A Shapiro-Wilk test was used as a test of normality. A paired *t* test or Wilcoxon signed-rank test was used to compare parameters before and after LMS. The correlation between the changes in BP and PAT and between the changes in BP and PPG-related variables at all time points were evaluated with a Pearson correlation coefficient or Spearman correlation coefficient, as appropriate. Receiver operating characteristic (ROC) curve analyses were performed to evaluate the ability of PAT and PPG-related variables to detect a 40% change in the SBP. R version 3.4.2 software (R Foundation for Statistical Computing) was used for all statistical analyses.

Ethics Approval and Consent to Participate

This study was approved by the institutional review board at Asan Medical Center (IRB No, 2017-2268). The requirement for written informed consent was waived because of the retrospective nature of the study and the anonymity of the biosignals used in this study.

Availability of Data and Materials

All data generated or analyzed during this study are included in this published paper and Multimedia Appendices 1 and 2.

Results

Changes in Hemodynamic Variables and Photoplethysmogram Variables

After data processing, 60 sets of BP, ECG, and PPG values were analyzed. The demographic data of study patients are presented in Table 1. A representative plot of SBP and PAT of a randomly selected patient is shown in Figure 1. As indicated in Figure 1, systolic NIBP showed a tendency to follow the changing trends in the inverse of the PAT at intervals of 1 to 2 min, as the cuff-type NIBP device measures arterial pressure intermittently. Laryngoscopic manipulation during LMS caused a mean 41.3% increase in SBP and a mean 13.4% decrease in PAT. The inverse of the PAT increased as SBP increased in all patients except one (Figure 2). Heart rate increased by an average of 31.3% from baseline, and morphological parameters of PPG (eg, maximum slope, minimum slope, width, and area) also changed significantly after laryngoscope insertion (Table 2).

Table 1. Demographic and clinical characteristics of the 30 study patients.

Patient characteristics and prior comorbidities	Values
Sex, male, n (%)	18 (60)
Age (years), mean (SD)	58 (14)
Height (cm), mean (SD)	161.2 (7.6)
Weight (kg), mean (SD)	65.3 (12.2)
BMI (kg/m^2), mean (SD)	24.2 (2.9)
Hypertension, n (%)	12 (40)
Diabetes mellitus, n (%)	4 (13)
Calcium channel blocker, n (%)	9 (30)
Beta blocker, n (%)	2 (6)
Angiotensin II receptor blocker, n (%)	3 (10)

Figure 1. Tracing showing the relationship between systolic noninvasive intermittent blood pressure and pulse arrival time during laryngeal microscopic surgery. Beat-to-beat changes in pulse arrival time instantaneously reflected marked perturbations of systolic noninvasive intermittent blood pressure during endotracheal intubation and the beginning of the laryngeal microsurgery procedure. The insets show the electrocardiography (upper) and the photoplethysmographic waveform (bottom) results before and after the insertion of the laryngeal microscope. The thick blue line is the smoothed line of the PAT using locally estimated scatterplot smoothing.

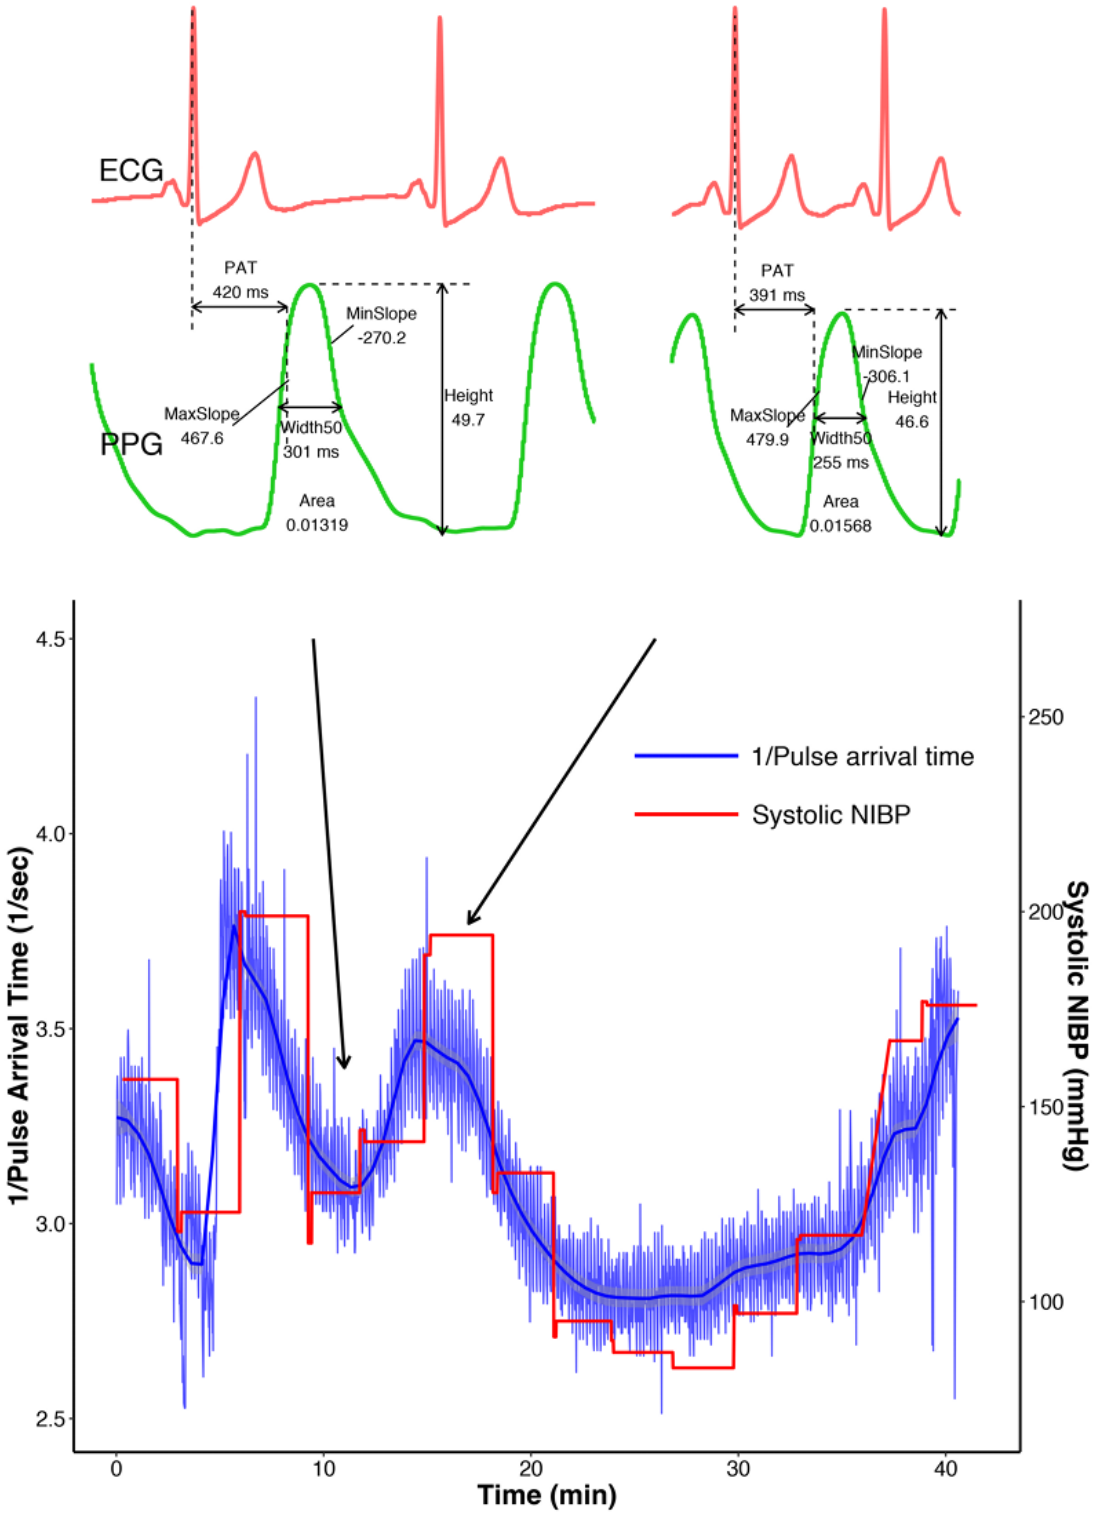

Figure 2. Changes in systolic blood pressure and pulse arrival time before and after surgical stimulation because of laryngeal microsurgery. Red dots represent changes before stimulation, whereas blue dots represent changes after stimulation.

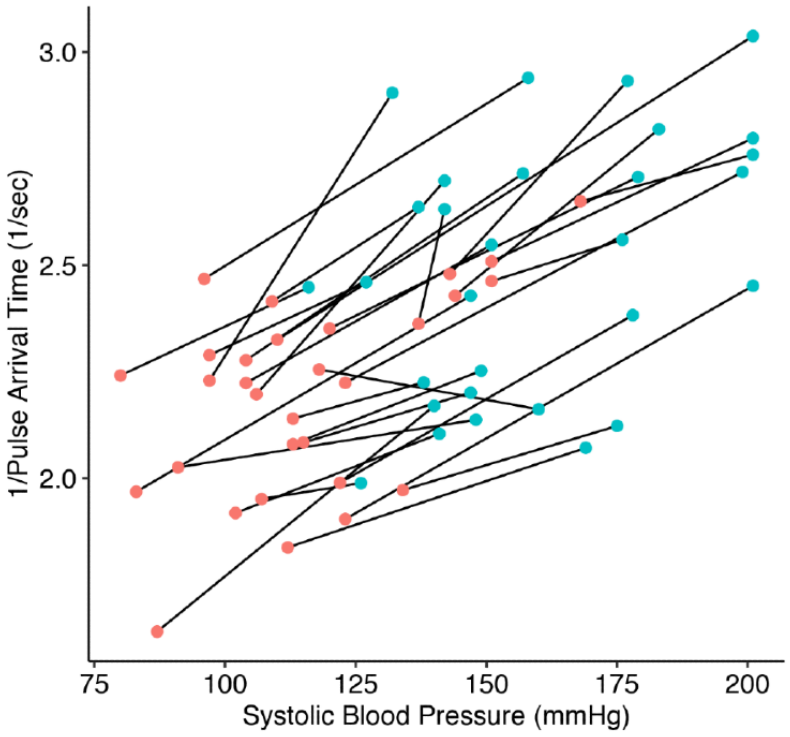

Table 2. Changes in hemodynamic, photoplethysmographic, and pulse arrival time variables during blood pressure surge (N=30).

Variables	Before	After	*P* value
Systolic blood pressure (mm Hg), mean (SD)	115.3 (21.4)	159.9 (25.2)	<.001
Diastolic blood pressure (mm Hg), mean (SD)	69.0 (14.2)	97.6 (15.6)	<.001
Mean arterial blood pressure (mm Hg), mean (SD)	79.8 (14.7)	113.2 (17.0)	<.001
Heart rate (bpm), mean (SD)	78.1 (11.7)	101.3 (12.3)	<.001
Pulse arrival time (ms), mean (SD)	460.6 (51.9)	405.8 (50.1)	<.001
PPG[a] amplitude (AU[b]), median (IQR)	45.6 (44.6-46.8)	46.3 (45.0-47.0)	.49
PPG maximum slope (AU/s), mean (SD)	485.0 (81.9)	564.3 (81.1)	<.001
PPG minimum slope (AU/s), mean (SD)	−247.2 (49.8)	−337.9 (50.3)	<.001
PPG $width_{50}$ (ms), median (IQR)	256.8 (233.3-278.4)	221.9 (209.4-240.0)	<.001
PPG area (AU·ms), median (IQR)	15.7 (14.6-16.4)	17.0 (15.9-18.5)	.001

[a]PPG: photoplethysmogram.

[b]AU: arbitrary unit.

Correlations between Hemodynamic Variables and Photoplethysmogram Variables

During the abrupt BP rise because of laryngeal stimulation, changes in the inverse of the PAT showed better correlation with the changes in SBP (r=0.582; 95% CI 0.281-0.779) than with changes in either mean arterial pressure (MAP; r=0.525; 95% CI 0.204-0.745) or diastolic BP (DBP; r=0.442; 95% CI 0.098-0.692). However, these differences in correlation coefficients were not statistically significant when compared with the coefficient between changes in the inverse of PAT and SBP using Fisher Z-transformation (correlation coefficient between changes in the inverse of PAT and MAP, P=.76; between changes in the inverse of PAT and DBP, P=.48).

When we examined the relationship between SBP and PPG-related variables, the changes in the maximum slope of the PPG showed a significant correlation with SBP changes (r=0.49, P=.01). SBP changes also showed a good correlation with changes in the inverse of PAT (r=0.582; P<.001; Figure 3). Other PPG parameters such as amplitude, minimum slope, $width_{50}$, and area did not show a statistically significant correlation with SBP changes (Table 3).

Figure 3. Correlation between the changes in systolic blood pressure and the changes in the inverse of the pulse arrival time (r=0.582, 95% CI 0.281-0.779; *P*<.001).

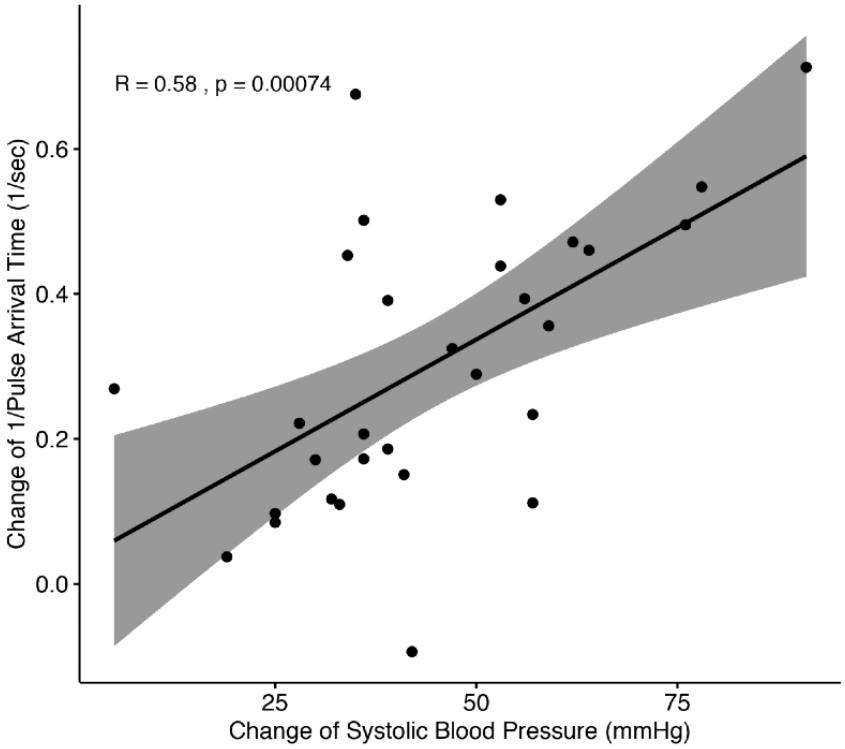

Table 3. Correlation between systolic blood pressure changes and photoplethysmogram-related variables.

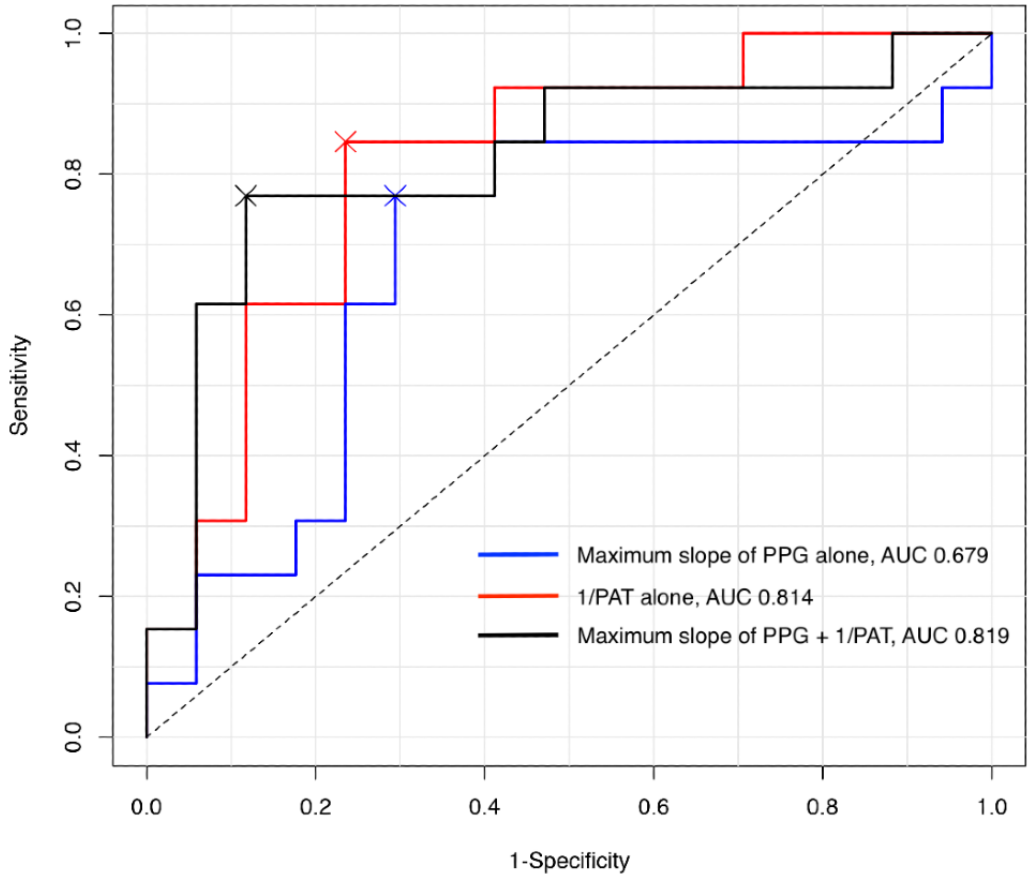
Variables	Correlation coefficient, *r*	*P* value
Δ1/pulse arrival time	0.582	<.001
ΔPPG[a] amplitude	0.338	.07
ΔPPG maximum slope	0.468	.009
ΔPPG minimum slope	−0.149	.43
ΔPPG $width_{50}$	0.049	.79
ΔPPG area	0.254	.18

[a]PPG: photoplethysmogram.

PAT and PPG maximal slope showed a significant correlation with the changes in SBP, and in ROC curve analysis, these were evaluated as measurements for detecting greater than 40% change in SBP. In total, 3 models were introduced for the evaluation. The first model detected a 40% change in BP with 1/PAT alone. The second model used the maximum slope of PPG. The last model used both. The model that used changes in the 1/PAT alone to detect 40% or greater changes in the SBP showed an area under the curve (AUC) of 0.814 (95% CI 0.656-0.973 and optimal cutoff value 11.5%), whereas the model that used changes in the maximum slope of PPG showed an AUC of 0.679 (95% CI 0.465-0.892 and optimal cutoff value 11.7%). The combined ROC curve using the changes in both 1/PAT and PPG maximum slope showed an AUC of 0.819 (95% CI 0.650-0.988), which was not significantly different from the model with 1/PAT alone (Delong test, z=−0.114; *P*=.91; Figure 4).

Figure 4. Receiver operating characteristic (ROC) curve analysis of percentage changes in the inverse of the pulse arrival time (PAT) and the maximum slope of photoplethysmogram (PPG) relative to 40% or greater changes in systolic blood pressure. Model using the maximum slope of PPG alone, area under the curve (AUC) 0.679, 95% CI 0.465-0.892, optimal cutoff value 11.7%; model using the inverse of the PAT alone, AUC 0.814, 95% CI 0.656-0.973, optimal cutoff value 11.5%; model using both inverse of the PAT and PPG maximum slope, AUC 0.819, 95% CI 0.650-0.988. Delong test for ROC curves of the model using inverse of PAT alone and the model using both inverse of PAT and PPG maximum slope, z=−0.114; *P*=.91.



Discussion

Principal Findings

We found that beat-to-beat PAT measurements using ECG and PPG are useful noninvasive indicators of BP surge in patients undergoing LMS. Specifically, changes in the inverse of the PAT and systolic NIBP show similar trends, and the inverse of the PAT changes shows a better correlation with the systolic NIBP changes than with those in the MAP or DBP. Moreover, beat-to-beat changes in the PAT reflect the BP surge 1 to 2 min earlier compared with cuff-type NIBP measurements.

Laryngoscopic manipulation in our study is clinically similar to the endotracheal intubation phase in our previous study [11]. PAT did not significantly decrease despite a 24.5% increase in SBP in the previous study. However, this study showed significant changes in SBP and PAT caused by laryngoscopic manipulation. The difference in the intensity of stimulation between LMS and endotracheal intubation might be an explanation for this discrepancy. In addition, the difference in the study population is a possible cause. All subjects of the previous study were hypertensive patients with end-stage renal disease, whereas only 40% of patients in this study had hypertension. It is assumed that the disturbances in autonomic cardiovascular regulation by chronic hypertension can cause these different responses to similar sympathetic stimulation [22].

Although changes in the maximum slope of the PPG showed a correlation with SBP changes, it did not increase the AUC of the ROC curve when it was combined with 1/PAT changes. Rather, the change in the 1/PAT value alone was sufficient to detect a 40% or greater change in the SBP, and the AUC of the ROC curve (AUC 0.814; Figure 4) was comparable with that in our previous study (AUC 0.85) [11]. This suggests that simply combining the features from the PPG signal and PAT does not further increase the diagnostic ability regarding detecting BP changes.

Clinical Applicability of Pulse Arrival Time

LMS is a hemodynamically challenging procedure for anesthesiologists. Laryngoscopic manipulation and suspension of the larynx cause plasma catecholamine levels to rise and induce hemodynamic perturbation, including hypertension, tachycardia, bradycardia, and arrhythmias [7,23-27]. These hemodynamic aberrations can potentially produce poor postoperative outcomes, including prolonged hospital stay and morbidity [28]. As LMS has a short operating time and is usually an outpatient-based procedure, it is not suitable for invasive monitoring such as arterial catheterization unless the patient has known significant preoperative risk factors. However, it is not possible to screen every patient during routine preoperative

evaluation for risks such as undiagnosed intracranial aneurysm. Even in patients without any underlying disease, unexpected changes in BP can be a potential risk for including bleeding, cerebrovascular events, or myocardial ischemia. Hence, simple and noninvasive methods of continuous monitoring are needed for early detection and quick response to unexpected BP change.

During different surgical procedures, various kinds of biosignals can be used to monitor abrupt physiological changes or to predict outcomes. PPG signals, in particular, can be used to reflect various physiological changes such as vascular compliance during hepatic graft reperfusion period following liver transplantation [29] and the success of lumbar sympathetic ganglion block [30]. There have been previous studies on the association between pulse transit time and BP. One study reported that the pulse transit time decreased as the DBP increased because of epinephrine injections in a cohort of 10 dogs [10]. In another study of 10 normal volunteers and 4 hemodialysis patients, PAT was found to correlate with SBP in normal subjects and could detect BP variations in dialysis patients [31]. Ambulatory BP monitoring based on PAT was reported to have significant accuracy in detecting BP above a threshold during nighttime [13]. In a previous evaluation of a monitoring device that estimates BP using a PAT derived by ECG and PPG, the accuracy of the instrument was comparable with that of a monitor based on oscillometry [32]. However, the relationship between BP and PAT is impaired in patients with chronic heart failure, whereas PAT is directly proportional to BP in healthy volunteers [33]. In addition to underlying heart disease, other possible confounding factors, including heart rate, pre-ejection period, and arterial stiffness, should be considered as limitations of BP monitoring using PAT [9,16,34,35]. In an earlier study of patients undergoing maxillofacial surgery, BP estimation using PAT was enhanced when two confounding factors, heart rate and arterial stiffness, were included in the multiple regression analysis model [9]. In this study, one subject showed a PAT increase from 443.4 to 462.6 ms despite a BP surge (systolic NIBP 118 to 160 mmHg; Figure 2). This was thought to be because of a decreased heart rate in this individual (102-75 bpm), which increased with an elevated BP in all other cases. This finding suggests that the refinement of the PAT-based BP-monitoring approach is necessary to reflect confounding factors.

There were some notable findings from this analysis. First, we found that BP changes could be detected 1 to 2 min earlier with PAT than with NIBP, suggesting that PAT monitoring will facilitate earlier responses to BP changes than NIBP monitoring alone. Second, changes in PPG maximum slope also correlated with SBP changes. It is noteworthy that a feature of the PPG waveform alone correlates with BP, regardless of other signals, such as ECG. On the basis of the results of this study, we developed a built-in device, which is able to monitor BP surge using ECG and PPG signal in a continuous and noninvasive manner (Figure 5). Now we are preparing for prospective research to validate the accuracy and to evaluate the usefulness of this device in real clinical practice. We also expect to apply more advanced mathematical techniques to build up a plausible physiologic model of BP estimation. In a recent study that estimated BP from features of the PPG waveform using an artificial neural network, all estimations showed a good correlation with the reference values when the algorithm was validated [36]. Additional research on features of the PPG waveform itself in the estimation of BP is also likely to be of value.

Figure 5. Development of a built-in device to monitor blood pressure surge using electrocardiogram (ECG) and photoplethysmographic (PPG) signal. Tablet personal computer as display and other biosignal sensor system were combined together and enclosed by housing. Blood pressure estimation algorithm was applied to the device, and the software was based on LabVIEW programming. Note that real-time–plotted red dots over ECG and PPG wave on display monitor indicate peak and first derivatives of those signals.

Limitations

Our study has several limitations of note. First, we used PAT measured by ECG R-wave and PPG signal to estimate actual pulse transit time, which should be measured by the time delay between arterial waveforms from two different places. Although the measurement of PAT is noninvasive and is technically easy to perform at low cost, it has been suggested that the PAT may not be a proper surrogate for the correct pulse transit time [37,38]. To calculate the exact pulse transit time, pre-ejection

period should be subtracted from the PAT. However, the pre-ejection period was not measured in this study. Future studies are needed to measure the pre-ejection time, using a method such as the cardiac bioimpedance technique [35], and to investigate its hemodynamic relationships. Second, despite the importance of the heart rate as a confounding factor in the relationship between PAT and BP [9,15,34], adjustment for the heart rate was not performed in this study. The development of techniques to make adjustments for the effect of heart rate on PAT is likely to be meaningful. Third, we used an automated oscillometric NIBP as a routine BP monitor in our patients undergoing LMS. The oscillometric NIBP may not be reliable for measuring actual BP beyond a specific range [39]. However, with advances in technology and manufacturers' efforts to meet medical standards, the accuracy of oscillometric NIBP instruments has been validated [40] and is considered to be reliable in determining BP measurements within the scope of our study. Fourth, instead of performing a calibration of PAT for NIBP, we only assessed the performance of PAT in monitoring relative changes in BP during the intubation period. PAT requires calibration to provide absolute B*P* values because both measurements have different scales and wide ranges of interpatient variability when they are converted to each other. Finally, as we conducted a retrospective analysis, selection bias or unknown confounders cannot be excluded. Well-designed prospective analyses and further device evaluation are warranted in the future.

Conclusions

There is a clear correlation between BP and PAT, which demonstrates the potential of PAT as a useful and noninvasive means of continuous BP monitoring in situations where invasive monitoring is not appropriate. Further studies to adjust for confounding factors are needed to refine the BP-monitoring approach using PAT.

Acknowledgments

The authors acknowledge Drs Hyung-Chul Lee and Chul-Woo Jung (Seoul National University) for their efforts in developing Vital Recorder, which was used to collect and process the biosignal data in this study. This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health and Welfare, Republic of Korea (grant number: HI17C2410), and was also supported by the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Science, ICT and Future Planning (grant Number 2016M3A9E8941259, 2019R1A2C4069504).

Authors' Contributions

YP was responsible for data acquisition, analysis, and drafting the article. SK designed the research plan, revised the manuscript, and organized the study resources. YL, SC, and SK contributed to the critical revision of the article. GH gave important suggestions during data interpretation and manuscript preparation.

Conflicts of Interest

None declared.

Multimedia Appendix 1
An add-on Python code for calculation of pulse arrival time which is included as a filter function in Vital Recorder software.
[TXT File , 3 KB - jmir_v22i5e13156_app1.txt]

Multimedia Appendix 2
Raw data that were analyzed in this study.
[XLSX File (Microsoft Excel File), 14 KB - jmir_v22i5e13156_app2.xlsx]

Abstract

Background: Cardiac rehabilitation (CR) is known for its beneficial effects on functional capacity and is a key component within current cardiovascular disease management strategies. In addition, a larger increase in functional capacity is accompanied by better clinical outcomes. However, not all patients respond in a similar way to CR. Therefore, a patient-tailored approach to CR could open up the possibility to achieve an optimal increase in functional capacity in every patient. Before treatment can be optimized, the differences in response of patients in terms of cardiac adaptation to exercise should first be understood. In addition, digital biomarkers to steer CR need to be identified.

Objective: The aim of the study was to investigate the difference in cardiac response between patients characterized by a clear improvement in functional capacity and patients showing only a minor improvement following CR therapy.

Methods: A total of 129 patients in CR performed a 6-minute walking test (6MWT) at baseline and during four consecutive short-term follow-up tests while being equipped with a wearable electrocardiogram (ECG) device. The 6MWTs were used to evaluate functional capacity. Patients were divided into high- and low-response groups, based on the improvement in functional capacity during the CR program. Commonly used heart rate parameters and cardiac digital biomarkers representative of the heart rate behavior during the 6MWT and their evolution over time were investigated.

Results: All participating patients improved in functional capacity throughout the CR program (P<.001). The heart rate parameters, which are commonly used in practice, evolved differently for both groups throughout CR. The peak heart rate (HR_{peak}) from patients in the high-response group increased significantly throughout CR, while no change was observed in the low-response group ($F_{4,92}$=8.321, P<.001). Similar results were obtained for the recovery heart rate (HR_{rec}) values, which increased significantly over time during every minute of recuperation, for the high-response group (HR_{rec1}: P<.001, HR_{rec2}: P<.001, HR_{rec3}: P<.001, HR_{rec4}: P<.001, and HR_{rec5}: P=.02). The other digital biomarkers showed that the evolution of heart rate behavior during a standardized activity test differed throughout CR between both groups. These digital biomarkers, derived from the continuous measurements, contribute to more in-depth insight into the progression of patients' cardiac responses.

Conclusions: This study showed that when using wearable sensor technology, the differences in response of patients to CR can be characterized by means of commonly used heart rate parameters and digital biomarkers that are representative of cardiac response to exercise. These digital biomarkers, derived by innovative analysis techniques, allow for more in-depth insights into the cardiac response of cardiac patients during standardized activity. These results open up the possibility to optimized and more patient-tailored treatment strategies and to potentially improve CR outcome.

Introduction

Cardiovascular diseases are the most prevalent noncommunicable diseases worldwide. The American College of Cardiology Foundation, the American Heart Association, and the European Society of Cardiology consider cardiac rehabilitation (CR) to be a key component within current disease management strategies, making millions of cardiac patients eligible for rehabilitation [1-3]. Unfortunately, CR programs worldwide are characterized by low implementation rates, as 33%-71% of eligible patients are not referred [4]. Notwithstanding, participation in a CR program has shown to increase cardiorespiratory fitness, thereby improving physiological responses to physical effort [5]. The improvement in functional capacity is clinically relevant as it not only improves quality of life in patients, but also serves as a powerful predictor for mortality [6]. These benefits of CR on mortality, morbidity, and quality of life have been studied comprehensively in several meta-analyses [7-10]. Moreover, the beneficial effects of CR seem to be even more pronounced when functional capacity is increased to a larger extent [11-14]. Although previous research showed that exercise-based CR has beneficial and clinically relevant effects on functional capacity, a large variability on the response to training is seen among CR patients. Recent studies have shown that *responders* are characterized by lower baseline peak VO_2 (peak oxygen uptake) values and a reduced baseline ejection fraction, while *nonresponders* have an impaired chronotropic competence, which predicts poor training response [15-17]. Other potential contributing factors to poor training response include adherence rates, exercise dose, functioning of the autonomic system, or comorbidities [18]. Nevertheless, little is known about the mechanisms causing the large variability. Therefore, Gevaert et al stated that future research needs to focus on studying these contributing factors in order to generate the best response to CR [18]. Moreover, research focusing on changes occurring during CR, and not only before or after completing the program, can contribute in the development of a more patient-tailored CR program.

The aim of this study was to investigate the difference in cardiac response, a measure of chronotropic response, between patients that showed a clear improvement in functional capacity and patients that only showed a minor improvement following CR therapy. This was done by using data captured with a wearable electrocardiogram (ECG) device during a standardized activity. Moreover, innovative analysis techniques were used to derive digital cardiac biomarkers allowing an in-depth analysis of heart rate behavior during a standardized activity test.

Methods

Study Design

A total of 129 cardiovascular patients, who were enrolled in a multidisciplinary CR program in a single tertiary-care center (Ziekenhuis Oost-Limburg [ZOL], Genk, Belgium) and representative of the typical CR population, were included. Patients over the age of 18 years with heart failure and reduced ejection fraction, with heart failure and preserved ejection fraction, and with a left ventricular ejection fraction less than or equal to 55% were eligible for the study. Patients with an inability to exercise due to orthopedic or neurological limitations were excluded from the study. The goal was to investigate the different levels of response to exercise intervention during a standardized CR program. The 6-minute walking test (6MWT) was used to follow up on the improvement in functional capacity in the course of the CR program. A wearable device was used to collect ECG data during the 6MWT. A descriptive analysis of the longitudinally collected wearable data was performed to identify patterns or trends in the dataset. To distinguish the response to rehabilitation, patients were assessed as being within a low-response and a high-response group based on a median split for the increase in distance walked throughout the CR program. Therefore, two groups with an equal number of patients were created based on the level of improvement in functional capacity measured by the 6-minute walking distance. Patients who increased more than 90 meters after completing the CR were referred to as the high-response group, while the low-response group consisted of patients who increased less than 90 meters. The study complied with the Declaration of Helsinki, and the local ethical committee approved the study protocol. All subjects gave written informed consent prior to study participation.

Multidisciplinary Cardiac Rehabilitation Program

Patients were referred to the multidisciplinary CR program following a cardiovascular-related hospital admission. The 15-week program consisted of 45 ambulatory rehabilitation sessions at a frequency of three 1-hour sessions per week. Both resistive and aerobic exercises were included in the program. Additionally, dietary sessions, psychological support, and social consultations were included in the multidisciplinary program. By standard, a cardiopulmonary exercise test (CPET) was performed at baseline and at end-of-study to assess functional capacity. A total of 14 low-response group patients out of 45 (31%) and 21 high-response group patients out of 45 (47%) had a CPET at both baseline and end-of-study. The heart rate achieved at 90% of ventilator threshold during the CPET was

chosen as the target heart rate during aerobic training. If no CPET data were available, target heart rate was set at 50%-80% of the maximal heart rate. Aerobic training consisted of 30-40 minutes, in total, of aerobic exercise on bicycle, hand bike, treadmill, and/or stepper. Resistive training was performed at 50%-80% of one repetition maximum and consisted of three sets of 15 repetitions on both the leg and arm press. Training intensity was increased every 2 weeks based on patient improvement according to the standard clinical practice of CR in our study center.

Experimental Protocol and Sensor Technology

Demographics, clinical data, medical therapy, and echocardiography data were collected from the electronic medical record. A 6MWT was performed at baseline (ie, start of rehabilitation program). Four follow-up 6MWTs were performed every 3 weeks, resulting in five 6MWTs in total. The compliance rate with the rehabilitation program between every 6MWT for both groups was calculated. Patients were expected to follow three rehabilitation sessions per week, which is equal to nine rehabilitation sessions between two consecutive 6MWT measurements. If patients attended nine rehabilitation sessions between consecutive 6MWTs, a compliance rate of 100% was obtained. The 6MWT was performed according to a standardized protocol [19]. The distance walked after 6 minutes was recorded and was used to check functional capacity during CR. During the 6MWT, all enrolled patients were equipped with a wearable device. The wearable device was equipped with the MUlti SEnsor IC (MUSEIC) chip, supporting a wide range of sensor modalities, including ECG (512 Hz sample frequency) and accelerometer data (32 Hz sample frequency) (imec the Netherlands, Eindhoven, the Netherlands) [20]. The electrodes were positioned according to lead II of Einthoven's triangle [21]. Prior to the 6MWT, patients were at rest for 5 minutes to record their resting heart rate. Additionally, a recuperation phase of 5 minutes was included after the 6MWT to record recovery heart rate.

Preprocessing and Calculation of Static and Dynamic Heart Rate Parameters

The signal was divided into three parts: a 5-minute resting phase, a 6-minute walking phase, and a 5-minute recuperation phase. First, the artefacts present in the ECG signals were automatically detected and removed by means of the algorithm proposed by Varon et al [22]. Next, an algorithm performed the initial automatic R-peak detection [23] and incorrect detections were visually corrected. The R-peaks were then used to generate the heart rate by dividing the signal into 2-minute or 16-second windows with a 4-second stride, from which the heart rate parameters were derived. The heart rate parameters derived from the 2-minute windows were used for further analysis. A distinction was made between two types of these digital cardiac biomarkers. The static, commonly used heart rate parameters that comprise the information of specific periods of time during a standardized activity are placed into a single output parameter, whereas the other digital cardiac biomarkers represent the evolution of heart rate throughout the entire time span of a standardized activity test.

The resting heart rate (HR_{rest}) was calculated by taking the mean heart rate during the final 20 seconds of the resting period. The peak heart rate (HR_{peak}) was calculated by taking the mean heart rate obtained during the final 10 seconds of the walking phase. For the recovery heart rate (HR_{rec}), the mean heart rate during every minute of recuperation following the 6MWT (ie, HR_{rec1}, HR_{rec2}, HR_{rec3}, HR_{rec4}, and HR_{rec5}) was calculated. Moreover, to study whether HR_{peak} was influenced by the difference in effort among patients, HR_{peak} was corrected for the distance walked by dividing HR_{peak} by distance ($HR_{peak\text{-}dist}$), as described previously [24]. These heart rate parameters, commonly used in practice, were calculated for each measurement session separately. The accelerometer data has been used to estimate the effort during the walking phase of the 6MWT. Effort has been previously used as a measure of physical activity intensity [25-27]. The effort has been calculated for the full 6-minute-test duration using the following formula:

in which n is the total number of accelerometer sample points considered and X_k is a vector representing the acceleration along the x-axis, while the other axes are represented by Y_k and Z_k vectors, respectively.

Four different models were used to study the heart rate behavior during a standardized activity for both patient subgroups: one-term, two-term, two-term with added coefficient, and quadratic polynomial models. The goodness of fit was determined by calculating the coefficient of determination (R-squared). The model with the best fit was used to study the heart rate behavior. The coefficients of the best fits—the digital cardiac biomarkers—were studied for differences between both groups.

Study Endpoints

This study focused on investigating the difference in cardiac response, reflected by changes in commonly used heart rate parameters and digital cardiac biomarkers, between patients with a clear increased functional capacity and patients with only a minor improvement after completing CR.

Statistics

Continuous variables are expressed as mean (SD), if normally distributed, or as median (IQR), if nonnormally distributed, and dichotomous data are expressed as n (%). Normality was checked by the Shapiro-Wilk statistic. Categorical data were expressed as numbers and percentages and compared with the Fisher exact test. Continuous variables were compared between groups with the Student *t* test or the Mann-Whitney U test as appropriate. A two-way mixed analysis of variance (ANOVA) investigated the effect of magnitude of improvement on the progression of heart rate measures throughout a CR program. Results are expressed as df_{main}, df_{error}, F, and partial η^2. df_{main} indicates degrees of freedom for the simple main effect and df_{error} indicates degrees of freedom for the error term. F indicates that we are comparing results to an F distribution and partial η^2 is a measure of effect size. If significant, a repeated-measures

ANOVA was performed to analyze the simple main effect over time and univariate analysis was performed to analyze the main effect of response groups. An independent *t* test was performed to compare cardiac biomarkers between groups at specific moments in time. Outliers were assessed by inspection of a boxplot for values greater than 3 box-lengths from the edge of the box and were removed from analysis. The statistical significance was always set at a two-tailed probability level of <.05. Statistics were performed using SPSS version 24.0 (IBM Corp).

Results

Demographics and Baseline Population

Of the 129 patients that consented to participate, 89 (69.0%) completed the total study protocol. Out of 129 patients, 40 (31.0%) were excluded from analysis upon failure to complete the CR program due to health-related problems, lack of motivation, and work or family commitment (see Multimedia Appendix 1). The 89 patients who completed the study protocol were subdivided into two groups based on their improvement in functional capacity throughout the CR. The high-response group consisted of 45 patients who improved more than 90 meters throughout the CR, while the low-response group consisted of 44 patients who improved less than 90 meters. Baseline characteristics of both groups are provided in Table 1. There was no statistical difference between the groups with respect to the demographics and baseline characteristics, except for diabetes. More often, patients in the low-response group suffered from diabetes compared to the high-response group (24.4% vs 2.3%, *P*<.01). The two-way mixed ANOVA showed a similar compliance rate between both subgroups throughout the rehabilitation program ($F_{3,255}$=1.03, *P*=.99). The low- and high-response groups showed a similar average compliance rate of 88.0% and 85.8%, respectively, during the initial 3 weeks of the program, which did not significantly change throughout the remaining 12 weeks of the program.

Functional Capacity

Patients showed an increase in functional capacity based on both the results of the CPET measurements and the results of the 6MWTs. Only 14 patients out of 44 in the low-response group (32%) and 21 patients out of 45 in the high-response group (47%) performed both a CPET at baseline and at end-of-study. Although not statistically significant, an increase of 2.23 mL kg^{-1} min^{-1} in peak VO_2 was seen between baseline and end-of-study for the low-response group (14/44, 32%, *P*=.10). The same group showed a mean significant increase of 55 meters in 6MWT distance between baseline and end-of-study (*P*<.001). The high-response group showed a significant increase of 5.10 mL kg^{-1} min^{-1} in peak VO_2 (21/45, 47%, *P*<.001) and 147 meters in 6MWT distance between baseline and end-of-study (*P*<.001).

[a]This group consisted of patients who improved less than 90 meters throughout the cardiac rehabilitation.

[b]This group consisted of patients who improved more than 90 meters throughout the cardiac rehabilitation.

[c]CPET: cardiopulmonary exercise test.

[d]VO_2: peak oxygen uptake.

[e]6MWT: 6-minute walking test.

Commonly Used Static Heart Rate Parameters

To study the difference in cardiac response between the two subgroups, commonly used heart rate parameters were derived from the ECG data. Hereto, HR_{rest}, HR_{peak}, and HR_{rec} were analyzed. For these parameters, the differences between the two subgroups for every session and the differences in progression throughout CR were studied. Figure 1 shows the evolution of HR_{rest} throughout CR for both groups. A decreasing trend of

HR_{rest} in the high-response group is observed. In addition, ANOVA did not show a difference in the evolution of HR_{rest} throughout the CR program. Nor was a difference seen in HR_{rest} between the high- and low-response groups at any point in time.

Secondly, the evolution in HR_{peak} across five sessions and, more specifically, the difference between both subgroups was investigated. Figure 2 shows the change in HR_{peak} for both the high- and low-response groups throughout CR.

Figure 1. Resting heart rate (HR_{rest}) for each group throughout cardiac rehabilitation.

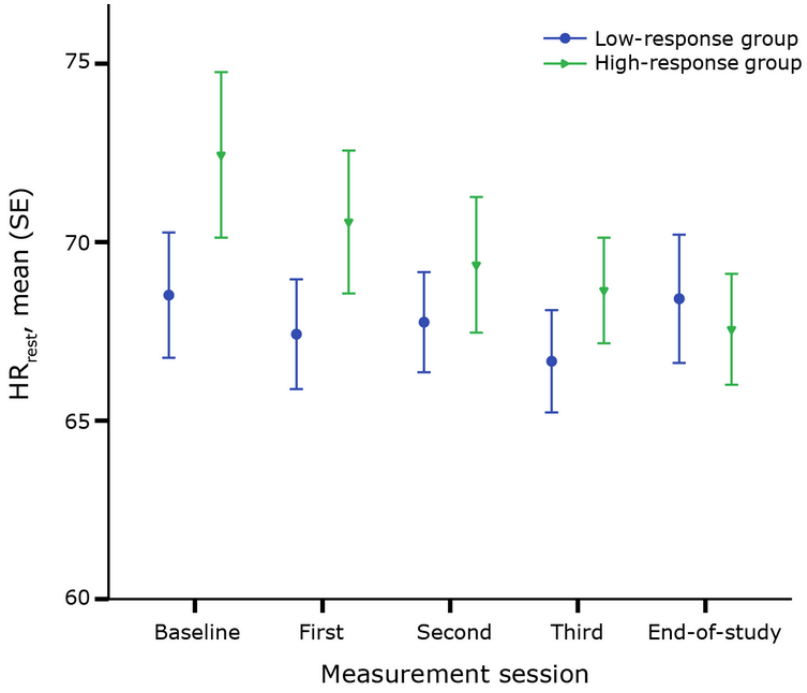

Figure 2. Maximum heart rate (HR_{peak}) for each group throughout cardiac rehabilitation. *denotes a significant change over time.

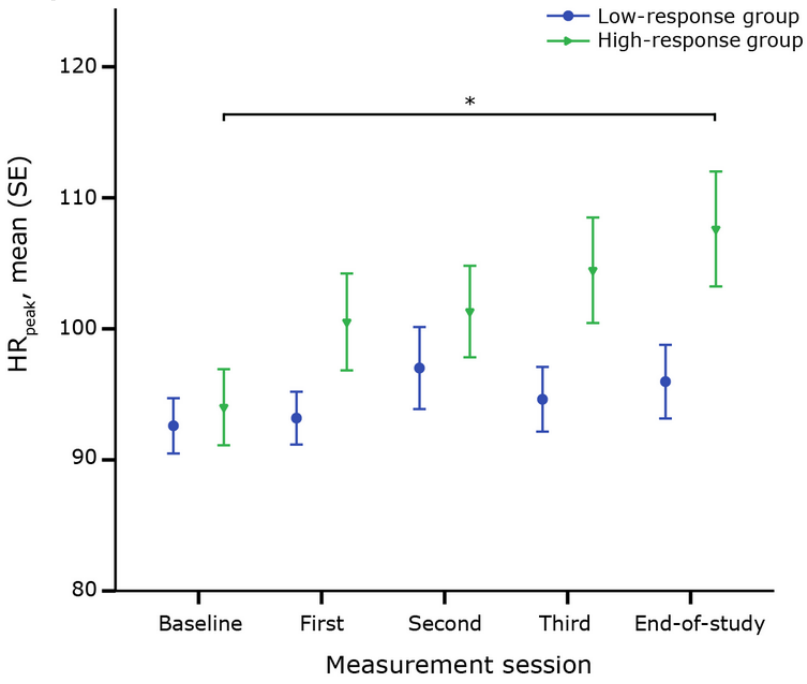

The two-way mixed ANOVA showed that the evolution of HR_{peak} throughout CR differed between the high- and low-response groups ($F_{4,216}$=3.3, P=.01, partial η^2=.058). HR_{peak} of the high-response group increased significantly throughout rehabilitation, while HR_{peak} of the low-response group remained approximately the same ($F_{4,92}$=8.321, P<.001). Although the evolution differed between both groups, no difference in HR_{peak} was seen at any point in time. HR_{peak} was corrected for distance to study whether the effort shown by patients during the 6MWTs had an influence on HR_{peak}. In Figure 3, both subgroups show a significant decrease in $HR_{peak\text{-}dist}$. However, the decrease in $HR_{peak\text{-}dist}$ was larger for the high-response group compared to

the low-response group. Additionally, a summary measure of the accelerometer data was used to compare the effort between the low- and high-response groups. Both subgroups showed a similar increase in effort throughout rehabilitation and no difference in effort between the groups was seen at any point in time ($F_{4,344}$=.668, *P*=.61).

The change in HR_{rec1} after the 6MWT throughout CR is shown in Figure 4. The evolution of HR_{rec} throughout CR differed among the response groups according to ANOVA for every minute of recuperation (see Table 2).

Figure 3. Peak heart rate corrected for distance ($HR_{peak-dist}$) for each group throughout cardiac rehabilitation. *denotes a significant change over time.

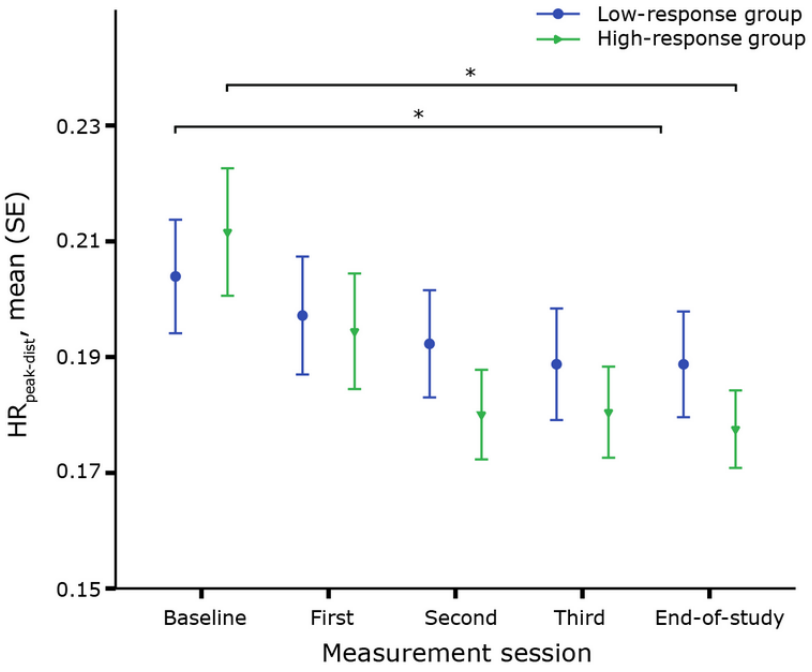

Figure 4. Heart rate recovery during the first minute (HR_{rec1}) after the 6-minute walking test for each group throughout cardiac rehabilitation. *denotes a significant change over time; **denotes a significant difference in HR_{rec1} during a measurement session between both groups.

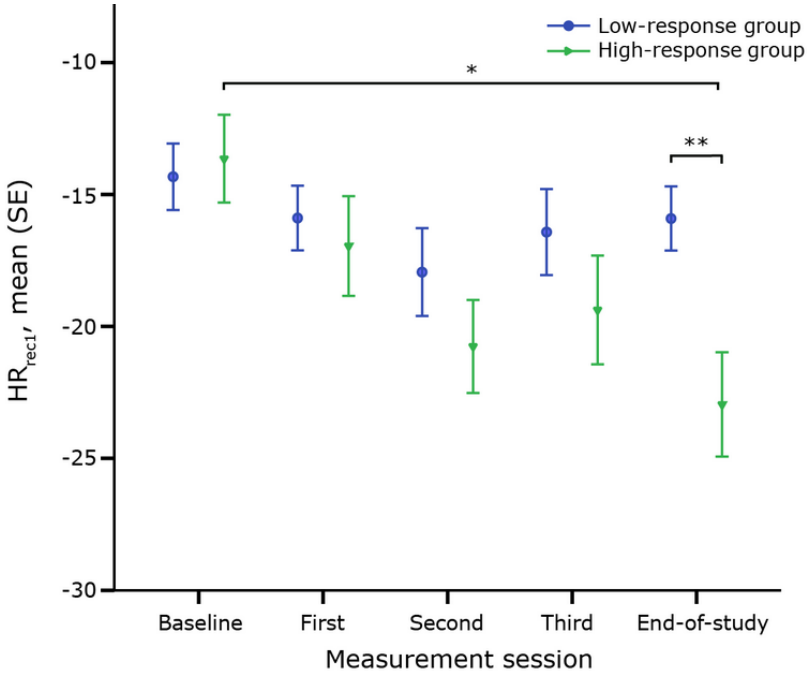

Table 2. Results from the two-way, mixed-model, analysis of variance (ANOVA) for the heart rate recovery (HRrec) during the first 5 minutes after the 6-minute walking test (6MWT).

HR_{rec}[a]	df_{main}[b]	df_{error}[c]	F[d]	Partial η^2[e]	*P* value[f]	*P* value[g]
HR_{rec1}	4	212	5.172	.089	.001	<.001
HR_{rec2}	4	212	7.288	.121	<.001	<.001
HR_{rec3}	4	212	6.634	.111	<.001	<.001
HR_{rec4}	4	212	6.092	.103	<.001	<.001
HR_{rec5}	4	208	3.967	.071	.03	.002

[a]HR_{rec}: heart rate recovery; each number in this column represents every minute of recuperation following the 6MWT.

[b]df_{main}: degrees of freedom for the simple main effect.

[c]df_{error}: degrees of freedom for the error term.

[d]Indicates that we are comparing to an F distribution.

[e]Partial η^2: a measure of effect size.

[f]Significance level for the hypothesis of no time effect × group effect.

[g]Significance level for the hypothesis of no time effect.

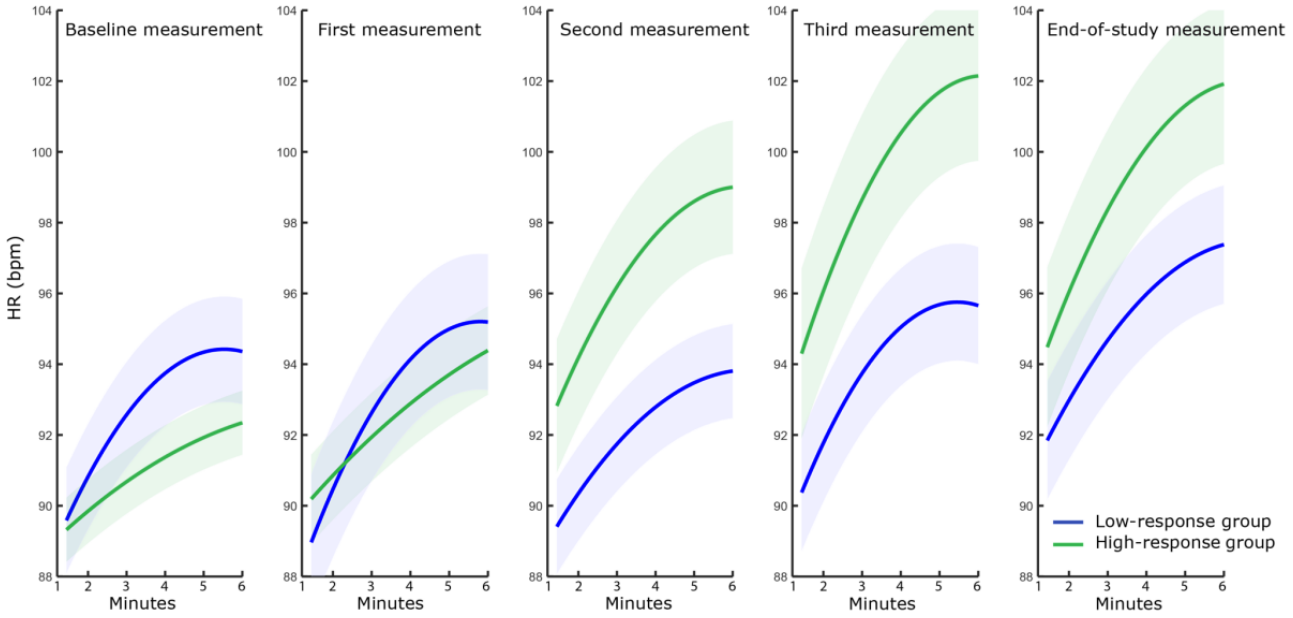
The HR_{rec} during every minute of recuperation increased throughout CR for the high-response group, while no change was observed in the low-response group (HR_{rec1}: *P*<.001, HR_{rec2}: *P*<.001, HR_{rec3}: *P*<.001, HR_{rec4}: *P*<.001, and HR_{rec5}: *P*=.02). This evolution in HR_{rec} throughout CR resulted in a higher HR_{rec} in the high-response group at the end of the study (HR_{rec2}: *P*=.02, HR_{rec3}: *P*=.02, HR_{rec4}: *P*=.03, and HR_{rec5}: *P*=.02). In other words, patients from the high-response group will recuperate faster at the end of CR.

Digital Cardiac Biomarkers to Capture the Dynamic Behavior of Heart Rate

The dynamic behavior of heart rate during a standardized exercise and subsequent recovery phase were investigated to further understand the difference in cardiac response between the groups. Hereto, four different models were fitted to the heart rate data. The quadratic polynomial fit obtained the best goodness of fit and was extracted from the heart rate data; the resulting coefficients, a_{poly} and b_{poly}, were analyzed. Both coefficients determine the shape and steepness of the curve, thereby characterizing the speed of heart rate increase during the 6MWT and, thus, the response of the heart to exercise. These innovative digital cardiac biomarkers were studied for differences between the groups during every session, as well as for the difference in their progression throughout CR.

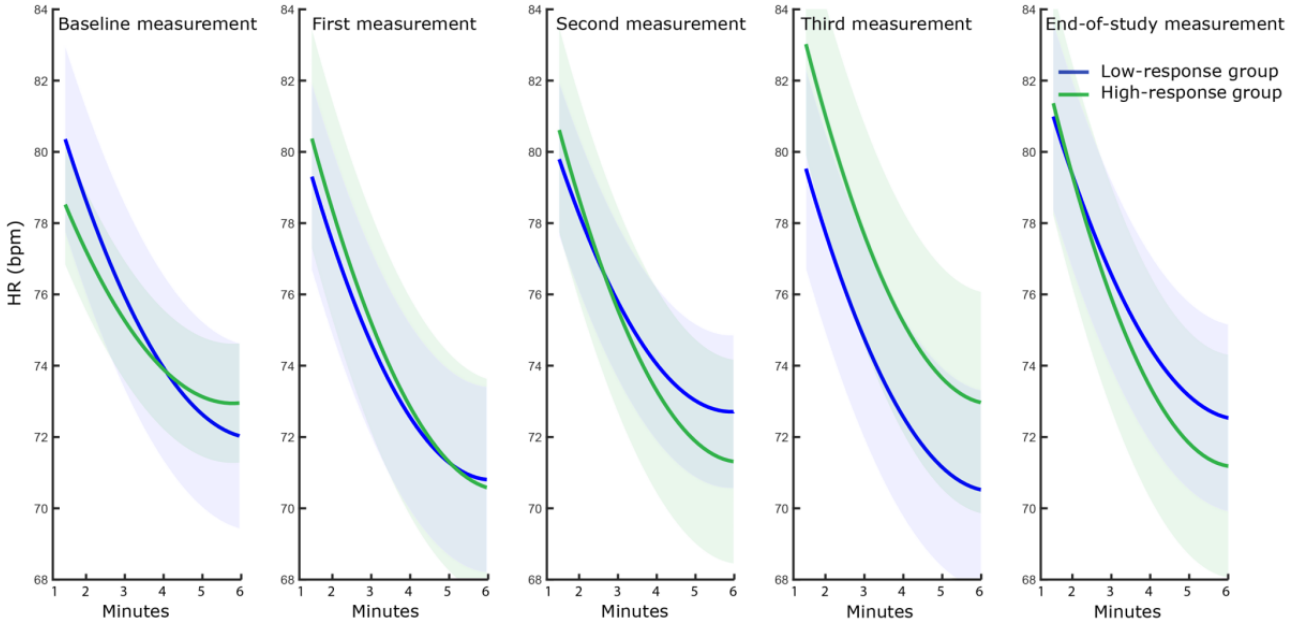
Figure 5 shows the mean quadratic polynomial fit ($f(x) = a_{poly}x^2 + b_{poly}x + c$) to the heart rate behavior during all five 6MWTs performed throughout the CR program. The behavior of heart rate measured during the walking phase evolved differently throughout CR in both groups. This is reflected in the difference in evolution for the polynomial coefficients, a_{poly} and b_{poly}, between the groups ($F_{4,96}$=5.691, *P*=.008, partial η^2=.133 and $F_{4,160}$= 4.302, *P*=.01, partial η^2=.175). The higher values of a_{poly} and b_{poly} during baseline and the subsequent 6MWT in the low-response group indicate that the heart rate of these patients increases faster at the start of CR (-.00013 vs -.000027 and .065 vs .022, *P*<.001). However, toward the end of CR, the heart rate of the high-response group shows an increase and eventually catches up with the low-response group, showing a similar heart rate behavior during walking.

Figure 5. Mean quadratic polynomial fit to the changes in heart rate (HR) during all sessions while walking. The line represents the mean fit and the shadows represent the SD. bpm: beats per minute.



The behavior of heart rate during the subsequent recovery phase was analyzed for both groups (see Figure 6). The coefficient, b_{poly}, extracted from the polynomial fit, showed a different evolution throughout CR between the groups ($F_{4,236}$=3.367, P=.01, partial η^2=.054). More specifically, the behavior of heart rate during recovery changed over time for the high-response group, while the low-response group showed no change in heart rate behavior during recovery (P<.001).

Figure 6. Mean quadratic polynomial fit to the changes in heart rate (HR) during all sessions while recuperating. The line represents the mean fit and the shadows represent the SD. bpm: beats per minute.



Discussion

Principal Findings

The findings of this observational study indicate that cardiac response to exercise in patients following a CR program plays a role in the level of their response to training in terms of distance walked. To our knowledge, this is the first study to describe the longitudinal follow-up of a CR patient population using wearable sensor technology during a repeated, standardized, submaximal activity test. Our 3-month follow-up period allows for novel in-depth insights into the cardiac response at rest, during exercise, and during recovery. Cardiac response is one of the possible confounders affecting the response to CR in patients. Therefore, investigating this cardiac response in a typical CR program aids in understanding the mechanisms behind different response rates. The wearable sensor technology enabled continuous monitoring of heart rate to derive both traditional heart rate parameters, commonly used in practice, and innovatively derived parameters that can function as digital cardiac biomarkers. The descriptive analysis of this longitudinally collected dataset investigated the difference

in cardiac response between two patient populations following CR, who are respectively characterized by low and high improvement in functional capacity during CR.

Evolution of Commonly Used Static Heart Rate Parameters Throughout Cardiac Rehabilitation

Previous research showed that the response to training depends on the cardiac output or chronotropic response, as this determines the increase in muscle blood flow during exercise [17,28]. Cardiac patients often depend on increasing their heart rate during exercise, as an increase in stroke volume is often limited due to the impaired cardiac output [29]. Heart rate parameters measured before, during, and after exercise contain information on how the heart responds to exercise. First, the effect of CR on the evolution of HR_{rest}, HR_{peak}, and HR_{rec} in patients showing a high or low response to exercise intervention was analyzed. These heart rate parameters, which are commonly used in practice, comprise the heart rate–related information from the resting, walking, and recuperation phases, respectively, into one single value.

HR_{peak} is a cardiac biomarker that evolves differently throughout CR for both response groups. The high-response group showed an increase in HR_{peak}, while the low-response group showed no significant change. At a first glance, these results might appear to be opposite of the results from previous research [30-32], which showed that an increase in functional capacity is accompanied by a decrease in HR_{peak}. However, they studied the heart rate response during a maximal exercise test, while in this study patients performed a submaximal test. The increase in HR_{peak} that we observed is accompanied by an increased distance. Hence, it is difficult to conclude whether the increased HR_{peak} is a result of the CR program or the fact that the walking distance also increases. Previous research showed that exercise intolerance causes a limitation in cardiac response in cardiac patients, as they achieved a higher heart rate compared to controls during submaximal exercise at a similar workload [33,34]. Effort is a measure of the walking intensity during the 6MWT. Both groups showed a similar effort. Although there was an increase in effort during the 6MWT throughout the CR, only the *response* group was characterized by an increase in HR_{peak}. This indicated that the cardiac response in the *nonresponse* group was limited, leading to exercise intolerance throughout the CR program. Additionally, a correction was made for the distance. After correcting HR_{peak} for distance, a significant decrease in $HR_{peak\text{-}dist}$ was seen for both groups. Thus, the results indicate that a cautious interpretation of heart rate parameters is necessary when studying the effects of CR on cardiac response during a submaximal exercise test.

The difference between the two groups in heart rate recovery, as captured by HR_{rec}, was investigated. According to Qiu et al, HR_{rec} measured after the 6MWT is considered to be a powerful prognostic indicator in cardiovascular disease [35]. Cardiovascular patients are characterized by a slower HR_{rec} due to an attenuated autonomous nervous system. This decrease in HR_{rec} can be partially restored, as following a CR program improves the impaired recovery [36]. The results showed that HR_{rec} changed differently throughout the CR program for each group. In addition, our study showed no differences between the absolute HR_{rec} values during the first four sessions, but indicated a difference in HR_{rec} between the groups during the last session. The faster recuperation toward the end of CR could indicate the positive effect on the attenuated vagal reactivation within the high-response group, while this effect is absent in the low-response group.

To summarize, these heart rate parameters show that the effect of CR on the different response groups is also reflected in differences in cardiac response. The cardiac system of the high-response group adapts better to exercise throughout CR compared to the low-response group.

Evolution of Digital Cardiac Biomarkers Throughout Cardiac Rehabilitation

To further understand the difference in cardiac response, the dynamic behavior of heart rate during the 6MWT and subsequent recuperation phase was also investigated. This innovative type of heart rate analysis allows in-depth insights by reflecting changes within shorter time spans during a standardized activity test. The heart rate response is representative of the ability of the autonomic nervous system to meet the hemodynamic demands during exercise. The heart rate acceleration at the onset of exercise is often modelled by an exponential curve [37]. Previous research showed that biphasic and sigmoidal curves are suitable to model heart rate behavior due to the increase in sympathetic activity following vagal withdrawal [38,39]. The choice to model the heart rate with exponential and polynomial curves was based on both literature and the heart rate behavior during the 6MWT, which was characterized by a steep increase followed by a steady-state phase as seen in this CR population.

The heart rate behavior during the 6MWT and subsequent recuperation phase evolved differently between the groups throughout CR. The increase in heart rate during the walking phase was steeper in the low-response group at baseline, indicating that in this phase of the CR the autonomous nervous system of these patients is characterized by a superior response to exercise in comparison to the high-response group. In the course of the CR program, the increase in heart rate steepened for the high-response group, eventually catching up with the low-response group. These results are similar to the findings of Schmid et al and Jorde et al, who indicated that the heart rate slope was blunted in subjects with an impaired cardiac response [17,40]. The ability of the *response* group to increase the heart rate slope, and the fact that the heart rate slope remained unchanged in the *nonresponse* group, indicated that an impaired cardiac response could lead to an impaired response to exercise training. Schmid et al showed that nonresponders to exercise training showed poor heart rate recovery, indicative of a disturbed cardiac autonomic status [17]. Our results confirm these findings, as both groups also showed a different evolution in heart rate behavior during the recuperation phase. The high-response group patients recuperated faster toward the end of CR, while the patients in the low-response group showed no change in recuperation rate.

To summarize, this study shows novel differences between groups, as the evolution in heart rate changes differently throughout the CR. Continuous measurements using wearable sensor technology enables the collection of traditional, commonly used heart rate parameters, but also of digital cardiac biomarkers representative of heart rate behavior during and after activity. The latter parameters were derived using a polynomial curve fitting technique, which is an innovative approach to capture heart rate evolution. Our research showed that these digital cardiac biomarkers can differentiate between the low- and high-response groups at baseline; hence, they, together with the traditional heart rate–related parameters, are valuable tools to use in short-term follow-up. Moreover, the results contribute to the development toward a more patient-tailored treatment strategy. Future research should focus on the role of these heart rate–related parameters in predicting outcome. The ability to improve and complement short-term follow-up by using these innovative techniques could make it possible to adjust treatment strategy in time and optimize outcome.

Limitations

This study is an observational study analyzing the characteristics of a typical CR population; as patients were not randomized into different groups, the results should be interpreted as hypothesis generating. A low number of patients received both a baseline and end-of-study CPET measurement. These missing values do not influence the outcome of the study, as a submaximal exercise test is used to determine the progression in functional capacity throughout CR. There are some limitations to performing a median split to divide a patient population into two groups. However, data in this observational study was investigated in the search for trends upon which to base future randomized research. Another point of discussion is that the 6MWT is an effort-dependent test and a greater increase in HR_{peak} could be a consequence of higher effort. Therefore, effort derived from the data collected by the triaxial accelerometer was used to determine whether the high-response group was characterized by a higher effort in comparison to the low-response group. Hills et al state that acceleration is proportional to the net external force involved in an activity and, therefore, more directly reflects the energy cost associated with movement [41]. Moreover, effort is a parameter that is often used in VO_2-max estimations during submaximal exercise [42,43]. Therefore, if the high-response group would have reached a higher percentage of their maximal exercise capacity during the 6MWT, this would have been reflected in a higher effort obtained during the 6MWT; however, this was not the case.

Conclusions

Following CR is, without any doubt, beneficial for cardiovascular patients. However, some patients benefit more from CR as they show a larger improvement in functional capacity in comparison to other patients. This study shows the following:

1. Continuous measurements using wearable sensor technology during standardized activity give novel insights into cardiac response between different response groups.
2. Patients showing a larger increase in functional capacity are characterized by a better improvement in cardiac response. This is in contrast to patients showing a low response to exercise intervention.
3. Innovative analysis approaches allowed us to study the difference in heart rate behavior between the response groups in more detail, showing differences in cardiac response at baseline.
4. The results from this study can be used in future research to investigate whether the outcome of CR can be predicted in order to adjust treatment strategy. Moreover, it is a first step toward the development of a more patient-tailored CR program.

Abstract

Background: Emergency physicians face the challenge of relieving acute pain daily. While opioids are a potent treatment for pain, the opioid epidemic has ignited a search for nonopioid analgesic alternatives that may decrease the dose or duration of opioid exposure. While behavioral therapies and complementary medicine are effective, they are difficult to deploy in the emergency department. Music is a potential adjunctive therapy that has demonstrated effectiveness in managing pain.

Objective: Our objective was to understand the feasibility and potential for an effect of a novel music app to address acute pain and anxiety in patients admitted to an emergency department observation unit.

Methods: This prospective cohort study enrolled patients admitted to an emergency department observation unit with pain who had received orders for opioids. We gathered baseline pain and psychosocial characteristics including anxiety, sleep disturbance, and pain catastrophizing using validated questionnaires. Participants received a smartphone-based music intervention and listened to the music in either a supervised (research assistant–delivered music session 3 times during their stay) or unsupervised manner (music used ad lib by participant). The app collected premusic and postmusic pain and anxiety scores, and participants provided qualitative feedback regarding acceptability of operating the music intervention.

Results: We enrolled 81 participants and randomly assigned 38 to an unsupervised and 43 to a supervised group. Mean pain in both groups was 6.1 (1.8) out of a possible score of 10. A total of 43 (53%) reported previous use of music apps at home. We observed an overall modest but significant decrease in pain (mean difference –0.81, 95% CI –0.45 to –1.16) and anxiety (mean difference –0.72, 95% CI –0.33 to –1.12) after music sessions. Reduction of pain and anxiety varied substantially among participants. Individuals with higher baseline pain, catastrophizing (about pain), or anxiety reported greater relief. Changes in pain were correlated to changes in anxiety (Pearson ρ=0.3, *P*=.02) but did not vary between supervised and unsupervised groups. Upon conclusion of the study, 46/62 (74%) reported they liked the music intervention, 57/62 (92%) reported the app was easy to use, and 49/62 (79%) reported they would be willing to use the music intervention at home.

Conclusions: A smartphone-based music intervention decreased pain and anxiety among patients in an emergency department observation unit, with no difference between supervised and unsupervised use. Individuals reporting the greatest reduction in pain after music sessions included those scoring highest on baseline assessment of catastrophic thinking, suggesting there may

be specific patient populations that may benefit more from using music as an analgesic adjunct in the emergency department. Qualitative feedback suggested that this intervention was feasible and acceptable by emergency department patients.

Introduction

Background

The number of opioid analgesics prescribed in the United States is now recognized as unsustainably and dangerously high [1,2], with no indication that the experience of pain among individuals has improved as a result. Three problematic consequences of increased opioid prescription are (1) overdose deaths, with over 47,000 individuals dying from opioid-related overdose in 2017 [3] (approximately 128 individuals per day); (2) an epidemic of opioid use disorder, with escalation to injection opioid use and increasing numbers of opioid-related bacterial infections [4]; and (3) an inherent conflict of clinical priorities in the emergency department (ED), where providers confront the competing pressures of reducing exposure to opioid analgesics while still managing acutely painful conditions, with limited alternatives [5,6]. Nonopioid analgesics, increasingly the first-line treatment for certain acutely painful conditions, often provide an inadequate response. Enhancing the response to nonopioid (or opioid) analgesics through adjunctive use of behavior modulatory therapies (eg, cognitive behavioral therapy) [7] or complementary medicine (eg, yoga, acupuncture) is an attractive strategy [8,9], but these therapies are difficult to deploy in the ED. Therefore, exploration of other more feasible and scalable alternative strategies is needed to reduce or replace opioid pharmacotherapy in this context.

One potential adjunctive therapy is listening to music, a nearly universal experience shared across cultures, ethnicities, and races [10]. The ubiquity of music across cultures and known human history may arise from its capacity to improve affect and mood. Functional magnetic resonance imaging studies have shown that pleasurable music listening is associated with increased dopaminergic neurotransmission in the nucleus accumbens, a common reward pathway in the brain [11,12]. Music also improves affect, with at least one study showing a beneficial effect on both pain and anxiety in the perioperative setting [13].

The favorable neurochemistry induced by listening to music may enable an innovative behavioral intervention. Machine learning has identified features (ie, musical “genes”) associated with increased dopaminergic neurotransmission and improved affect while listening to pleasurable music [14,15]. These features intrinsic to music itself have formed the basis for commercial music selection algorithms such as the music genome project [16]. Similar techniques have been applied in the development of novel music programs to create new signatures of pleasurable music to be played from a smartphone app [17,18].

Objective

The objective of this study was to evaluate the feasibility and effectiveness of a smartphone-based music intervention for acute pain in patients presenting to the ED. We specifically sought to measure changes in pain and anxiety associated with 10-minute music listening sessions delivered in either a supervised or an ad hoc fashion to patients with pain symptoms in an ED observation unit.

Methods

Participant Recruitment

In this prospective study, we recruited patients who were admitted to an ED observation unit in a quaternary, urban, level I trauma academic ED. Study staff identified potential participants by screening the electronic medical record and liaising with ED clinical staff. English-speaking patients with ED observation unit stays of up to 48 hours and who had received orders for opioid analgesia were eligible to participate. We excluded patients who had a pacemaker, had hearing loss, were on contact precautions, had previously enrolled in the study, were unstably housed, or had a significant active medical or psychiatric illness. A trained research assistant (RA) explained the study in full and gauged potential participants’ interest in the study. Interested participants provided verbal consent. The Partners Human Research Committee (Institutional Review Board of Partners HealthCare, Boston, MA, USA) approved this protocol.

Participants provided basic demographic information and underwent baseline pain and psychosocial assessments using validated measures (see section on measures) using a study phone with direct connection to a REDCap data capture system version 9.5 (REDCap Consortium) [19]. Next, participants were introduced to and given instructions for operating the novel music app on a study smartphone (iPhone 6; Apple Inc, Cupertino, CA, USA). We were interested in 2 modalities of use of the music app. First, we wanted to understand the use of music by participants if they were not given formal guidance as to how often and how long they should use music for. Second, we wanted to determine the feasibility of using a regimented prescription of music supervised by an RA. We therefore randomly assigned participants via a predetermined, computer-generated random list into unsupervised versus supervised intervention use groups. Participants randomly assigned to the unsupervised group received a smartphone with the app preloaded and paired noise-canceling headphones and were encouraged to use the music intervention app on an as-needed basis. Participants also received contact information for RAs so they could seek help to troubleshoot any potential issues with the app or the devices used. For participants

randomly assigned to the supervised intervention group, a study RA reminded and assisted the participant to use the music app up to 3 times during their ED observation unit stay (approximately every 4 hours).

Measures

We used several measures to assess baseline patient characteristics.

Pain

The Brief Pain Inventory (BPI) is a 9-item, self-report, validated measure that assesses patients' pain severity (least, worst, and average) and functional interference in the preceding week using an 11-point Likert scale with higher scores indicating greater pain or functional impact, or both [20].

Psychosocial Characteristics

We used the Patient-Reported Outcomes Measurement Information System (PROMIS) depression (8 items), sleep disturbance (8 items), and anxiety (7 items) short forms [21]. All PROMIS measures were scored on a 5-point Likert scale with higher scores indicating higher symptomatology. The Pain Catastrophizing Scale (PCS) comprises 13 items exploring individuals' pain catastrophizing divided into 3 subscales for rumination about pain, magnification of pain, and perceived helplessness to do anything about pain [22]. The PCS uses a 5-point Likert scale with cumulative scores ranging from 0 to 52. The Perceived Stress Scale consists of 10 items to measure subjective stress and uses a 5-point Likert scale for each item, where higher total scores indicate greater stress (range 0-40) [23]. We measured somatization using the 7-item somatization subscale from the Brief Symptom Inventory, where response options were scored on a 5-point Likert scale, with higher scores indicating greater somatization [24].

The Music Intervention

Participants interacted with a smartphone-based music app that used 5 separate commissioned instrumental tracks intended to be relaxing (Unwind; Bose Corporation, Boston, MA, USA) [25]. These music tracks were composed using a backbone of musical genes derived through a machine learning algorithm that selected key musical features expected to induce subjective "thrills" among individuals, combined with human-composed music. Users were presented with a preview screen that allowed them to sample 5 different tracks and select their favorite track. The same 5 tracks were presented to each participant. Next, participants used noise-canceling headphones to listen to 10 minutes of the selected track. Participants rated their *pain* and *anxiety* using a 10-point Likert scale at the beginning and end of the 10-minute music session. At completion of the study procedures, participants were guided through an RA-administered survey to assess the feasibility of operating the music app and formative reflections on using music in the ED observation unit. We collected data on the total opioid administered during the participants' ED observation unit stay from the electronic medical record and converted does to milligram morphine equivalents (MMEs). We then divided the MME amount by the number of hours the patient spent in the ED observation unit to calculate a normalized opioid utilization score (MME/h) for each participant during the study.

Data Analysis

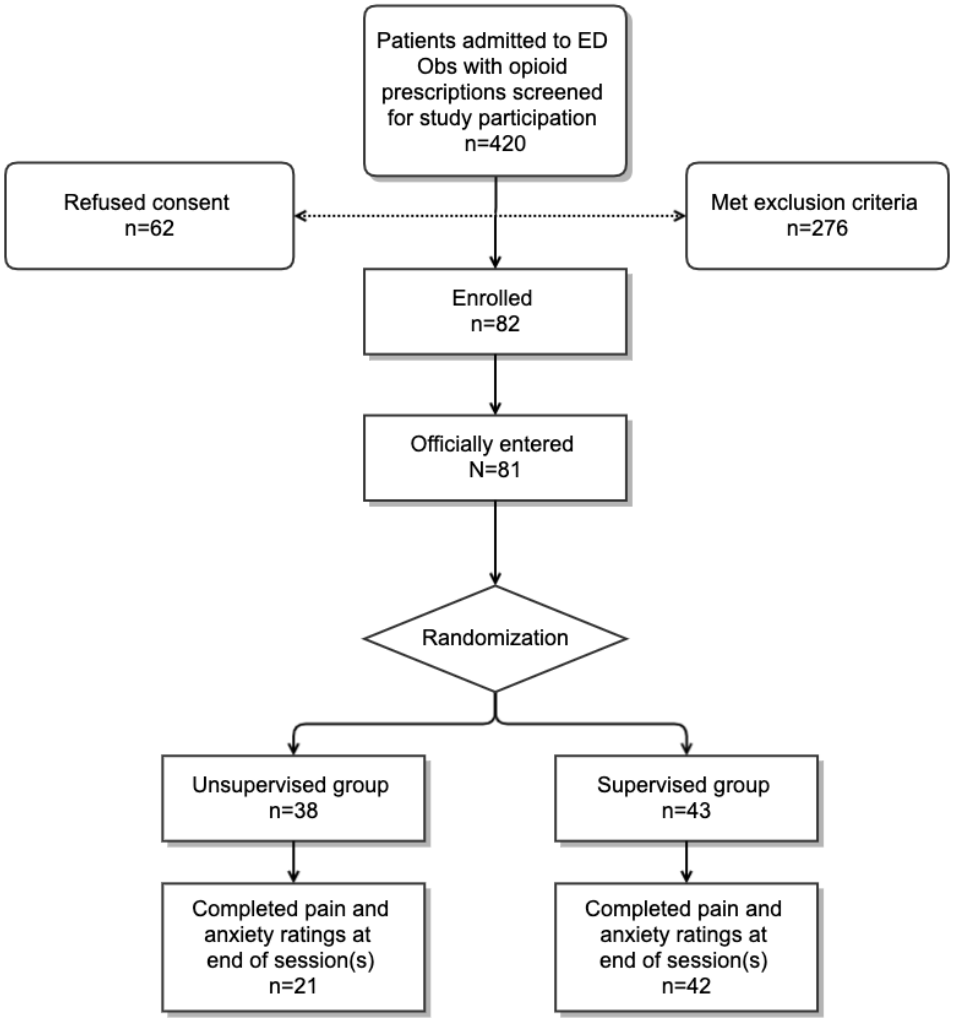
We summarized participant characteristics using frequencies and percentages for categorical variables, and mean and standard deviation or median and interquartile range for continuous variables, according to normality of distribution. For patient-reported scores of baseline and postmusic session pain and anxiety, we calculated mean values for each patient. We compared mean premusic versus mean postmusic scores using a nonparametric paired test (related-samples Wilcoxon signed rank test). We averaged the change in pain scores by subtracting mean end pain score from mean beginning pain score; we assessed this value (change in pain with music) for correlation with baseline patient characteristics, including psychosocial (anxiety, depression, catastrophizing, stress) and general pain severity and interference (BPI) questionnaires, using Spearman or Pearson correlations, as appropriate. All statistical tests were 2-tailed, and level of significance was set at Cronbach α=.05. We performed all analyses using IBM SPSS 25 (IBM Corporation).

Results

Participant Characteristics

We screened 420 individuals, of whom 144 were eligible for participation (Figure 1). Of these, we enrolled 82 patients. Common reasons for nonparticipation were lack of interest in research, other concomitant ongoing clinical assessments, and the inability to operate a smartphone.

Figure 1. Study flow diagram. ED Obs: emergency department observation unit.



The mean age of participants in the total sample (N=81) was 43.84 (SD 15) years, with a larger proportion of men (57, 70%) than women (24, 30%; Table 1). Reported pain in the previous week was high (BPI mean pain score 6.12, SD 1.8, out of 10), and at baseline 14 (17%) of participants were taking opioids on a regular basis. Participants reported relatively elevated scores on depression, anxiety, stress, and somatization (Table 1). Similarly, pain catastrophizing scores were higher than in previous reports of healthy volunteers [22] and similar to ranges reported among patients with chronic pain. We identified no difference between the supervised and unsupervised groups in terms of baseline pain or psychosocial characteristics (P>.05).

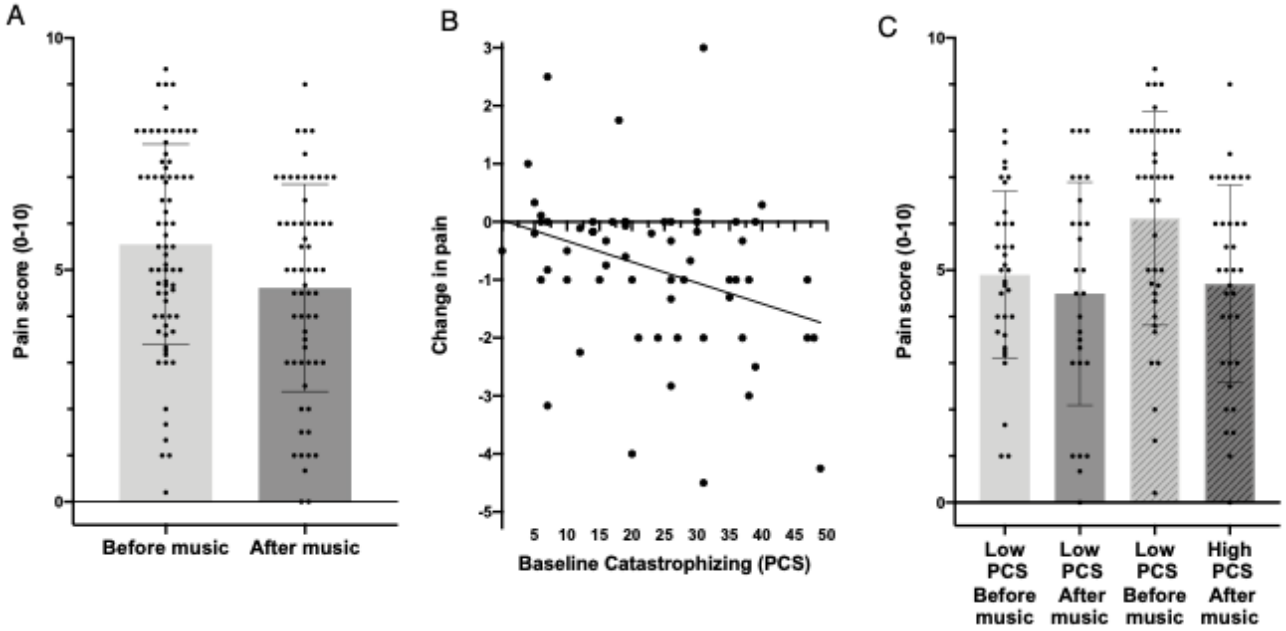
Table 1. Patient sample characteristics (N=81).

Characteristics	Values
Age (years), mean (SD)	43.84 (15)
Female sex, n (%)	24 (30)
Taking opioids at baseline, n (%)	14 (17)
Baseline Brief Pain Inventory (BPI) score, mean (SD)	
BPI current	6.17 (2.1)
BPI worst	8.61 (2.2)
BPI least	3.02 (2.4)
BPI mean	6.12 (1.8)
BPI interference	6.22 (2.4)
Patient-Reported Outcomes Measurement Information System score, mean (SD)	
Anxiety (score range 7-35)	19.13 (6.2)
Depression (score range 8-40)	17.38 (7.5)
Sleep Disturbance (score range 8-40)	29.22 (6.4)
Somatization (Brief Symptom Inventory; score range 0-35), mean (SD)	12.61 (4.0)
Perceived Stress Scale (score range 0-40)	18.83 (3.5)
Pain Catastrophizing Scale (score range 0-52), mean (SD)	
Rumination	8.35 (4.7)
Magnification	3.28 (2.5)
Helplessness	10.48 (6.4)
Total	22.11 (12.5)

Change in Pain During a Music Session

A total of 73 participants successfully attempted the music sessions, with a mean of 3 music sessions and a range of 1 to 9 music sessions per participant. We obtained fewer postmusic pain ratings than premusic ratings, with the missed postmusic ratings frequently being due to the participant falling asleep while listening to the music, as noted by RAs in supervised administrations. Comparison of mean pain scores before and after music interventions revealed a significant overall reduction in pain scores in most individuals (Figure 2, part A; related-samples Wilcoxon signed rank test, $P<.001$). The mean change in pain scores with music was modest (mean difference –0.81, 95% CI –0.45 to –1.16), with considerable variability among participants. To explore participant characteristics associated with the greatest benefit, we correlated the magnitude change in pain scores to baseline characteristics. Those with higher current pain reported on the BPI experienced greater pain relief with the use of music (Spearman $\rho=-0.37$, $P=.004$).

Figure 2. Effect of music on pain in emergency department patients. (A) Comparison of mean pain scores before and after music interventions revealed a significant overall reduction in pain scores in most individuals (related-samples Wilcoxon signed rank test, *P*<.001). The mean change in pain score with music was modest (mean difference –0.81, 95% CI –0.45 to –1.16) with considerable variability among participants. (B) Baseline Pain Catastrophizing Scale (PCS) score measured before music interventions was correlated with the amount of change in pain after music session. Higher baseline PCS scores were associated with a larger decrease in pain after music session (Spearman ρ=–0.39, *P*=.009). (C) Change in pain after music among low and high catastrophizers. Patients with high baseline PCS score (>20) had a greater decrease in pain (mean difference –1.2, SD 1.4) after music session than those with lower PCS (mean difference –0.3, SD 1.1; independent-samples *t* test=–2.9, *P*=.005).



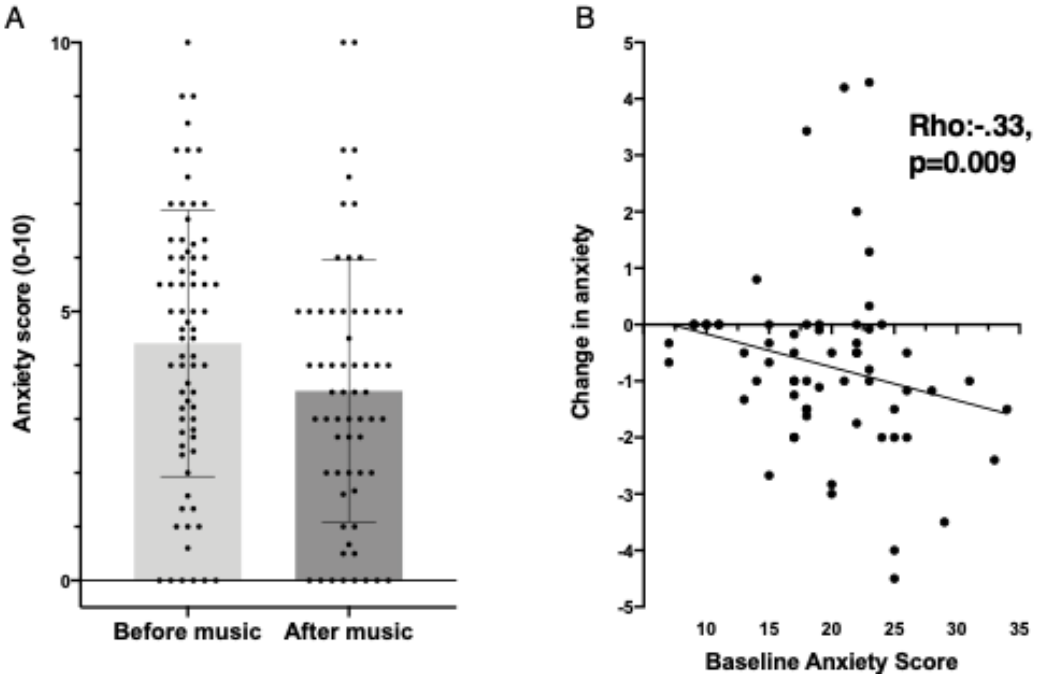
Patient Characteristics Associated With Pain Reduction

The psychosocial variables anxiety, depression, sleep disturbance, and catastrophizing showed significant intercorrelation to each other, as well as a significant association with reported acute pain (Multimedia Appendix 1). The PCS score at baseline was inversely correlated with the change in pain during the music session (difference between the end and beginning pain scores; (Spearman ρ=–0.39, *P*=.009; Figure 2, part B); participants with initial PCS scores greater than 20 were more likely to report a significant decrease in pain with the music intervention (Figure 2, part C). Other psychosocial variables (anxiety, depression, somatization, stress) were not significantly related to the degree of music-induced change in pain. Pain reduction did not differ between the supervised and unsupervised groups (*P*>.05).

Change in Anxiety During a Music Session

Comparison of mean anxiety scores reported before and after the music intervention revealed a significant overall reduction in anxiety in most individuals (Figure 3, part A; related-samples Wilcoxon signed rank test, *P*<.001). As with pain, the mean magnitude of change in anxiety scores with music was modest (mean difference –0.72, 95%CI –0.33 to –1.12), with considerable variability among participants. Greater reduction in anxiety scores significantly correlated with baseline anxiety, with those reporting high baseline anxiety also showing a greater reduction in anxiety with music (Figure 3, part B). Other psychosocial variables (depression, somatization, stress, catastrophizing) were not significantly related to the degree of music-induced change in anxiety. Change in pain was modestly related to change in anxiety (Pearson ρ=0.30, *P*=.02). Anxiety reduction did not differ between the supervised and unsupervised groups (*P*>.05).

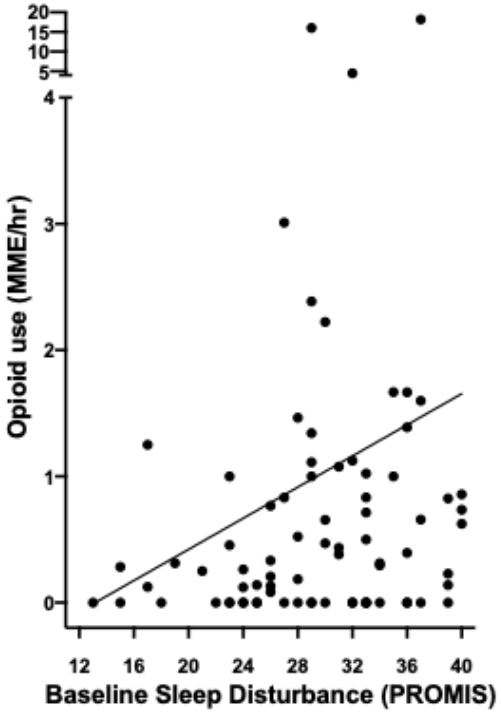
Figure 3. Effect of music on anxiety in emergency department patients. (A) Comparison of mean anxiety scores reported before and after the music listening intervention revealed a significant overall reduction in anxiety among individuals (related-samples Wilcoxon signed rank test, *P*<.001). The mean magnitude change in anxiety score with music was modest (mean difference –0.72, 95% CI –0.33 to –1.12) with considerable variability among participants. (B) Higher baseline anxiety scores were associated with a greater reduction in anxiety scores before and after the music session (Spearman ρ=0.3, *P*=.02).



Relationship of Baseline Characteristics to Opioid Use While in the ED Observation Unit

As a secondary exploratory analysis, we examined whether certain patient characteristics were associated with higher opioid use during the ED observation unit stay. A higher reported baseline sleep disturbance was associated with increased opioid consumption (Figure 4). Other baseline patient characteristics were not significantly related to changes in opioid use.

Figure 4. Variation in opioid use among participants with baseline sleep disturbance. Baseline sleep disturbance (measured by the Patient-Reported Outcomes Measurement Information System [PROMIS] short form) was associated with a higher amount of opioid consumption (milligram morphine equivalent [MME]) per hour while in the emergency department (Spearman ρ=0.24, *P*=.03).



Feasibility and User Experience

Analyses of the exit survey data revealed that most participants had used music as therapy before (43/62, 69%), and many participants had used other music apps in the past (23/62, 37%). The majority of participants reported they liked the music app (46/62, 74%), with the majority (43/62, 69%) saying they used it to relax during their ED stay, and some (15/62, 24%) endorsed using the music to sleep (Table 2). Most participants (49/62, 79%) said they would use it at home.

Table 2. Summary of the exit survey impressions of the Unwind App (n=62).

User experience	Values, n (%)
App was easy to use	57 (92%)
Liked the music app	46 (74%)
Purpose of app use: relax	43 (69%)
Purpose of app use: sleep	15 (24%)
Would use the app at home	49 (79%)

Discussion

Principal Findings

These findings suggest that music may be used to decrease pain and anxiety among individuals admitted to an ED observation unit. Individuals who had increasing catastrophizing at baseline (measured by the PCS) experienced greater decreases in pain and anxiety after listening to the music app. This demonstrates that music interventions may potentially be applied with greater effect in individuals with higher catastrophizing in the ED. Our findings are consistent with other investigations that described many other sources of music to be associated with the reduction of postoperative or procedural pain in individuals with chronic pain [26-32]. Additionally, the feasibility of using this music intervention in both a supervised and an unsupervised model suggests that this intervention can be used as a prescribed, targeted intervention in the ED or used ad hoc in individuals who may experience pain outside of the ED.

Music has several hypothesized effects on pain. First, music may modulate affect by impacting reward pathways, as changes in dopaminergic neurotransmission are associated with pleasurable or relaxing music. Music may decrease other pain-augmenting factors such as anxiety. Second, music may alter the nociceptive processing of pain by changing pain tolerance and threshold [33-35]. Alternatively, music may divert attention from acute pain to a different, pleasurable stimulus [10,18,30-33,35-38]. Regardless of the mechanism, the universality of music—every culture on the globe has some form of musical expression—coupled with the near ubiquity of personal music players, smartphones, and streaming music services makes music an attractive potential adjunctive therapy for pain.

Our data suggest that this app-based, semistructured music intervention can be employed during brief ED observation unit admissions to reduce pain and anxiety in patients with acute pain. Participants reported pain scores in real time and operated a music app in both supervised and unsupervised conditions. Additionally, participants' pain and anxiety scores were not different between the supervised and unsupervised groups. Integrated into emergency care, the use of music may afford an adjunctive treatment to those patients with higher catastrophizing and anxiety, which may be particularly relevant in emergency care settings [5].

While music reduces pain and anxiety in controlled settings [26-32], our investigation demonstrated that these effects may also exist in the midst of the unpredictable environment of the ED. These decreases in pain and anxiety, while modest, may meaningfully alter the ED experience for some individuals by serving as an adjunct to opioid analgesics. While this study was not designed to evaluate the effect of music on opioid consumption, its potential combination with other nonopioid interventions could contribute to decreased opioid use while in the ED and decrease opioid dosage units prescribed at discharge [10].

Notably, the modulation of pain produced by this music intervention was greatest in individuals with high levels of catastrophizing (negative cognitions and rumination about pain). Similarly, reduction of anxiety during the intervention was largest among those with highest baseline anxiety levels. The finding that music has a greater impact on those individuals with high levels of baseline catastrophizing anxiety is notable, as these traits are often associated with greater resistance to pharmacological manipulation, as well as pain persistence. Other previous studies among pain patients have found an association between greater catastrophizing scores and greater efficacy of behavioral interventions directed at affect, mood, and catastrophizing [39-41]. Whether the pain-sparing effect of music among high catastrophizers is due to alteration of sensory perception of nociceptive stimuli, as some laboratory-based investigations have suggested [17,18,28], or whether music modulates affect and thus indirectly decreases the impact of painful stimuli [27,36] remains to be clearly defined. Attentional modulation of (distraction away from) painful stimuli may be an important aspect of how music provides pain relief [41], although it seems unlikely to be the sole mechanism, as distraction alone has not led to pain reductions in similar populations [42].

Our exit survey data of patients at the end of the study support a possible role of affect modulation in music's effect. For example, one participant described that they continued to experience pain while listening to the music but felt "better" about their pain. Others reported decreased anxiety about their pain, while some notably reported that they preferred the use

of music over receiving an opioid. Interestingly, one observation from the study was that many participants fell asleep during the listening session, consistent with many previous studies that have noted an important connection between sleep deprivation and pain [43]. These findings suggest that the interplay between music and pain is complex. We anticipate that future investigations will address both the mechanisms in which music therapy may integrate within the biopsychosocial model of pain, and the implementation science behind operationalizing a recommendation for music to address the experience of pain.

Limitations

This study had several limitations. First, we conducted our study at a single urban academic ED. Experiences regarding complaint and psychosocial profiles of study participants and the resources available in ED observation units may be different in other types of ED settings, thus limiting generalizability to similar cohorts. Second, participants operating the app did not always rate postintervention pain and anxiety each time they used it. Anecdotally, participants reported that listening to the music made them fall asleep—itself a highly beneficial effect—thus leaving them unable to complete the postassessment, and possibly underestimating the degree of pain and anxiety reduction. This, taken together with the observation that individuals with the greatest sleep disturbance used the most opioids, suggests that future work should explore the use of music intervention to augment sleep in individuals with pain. Third, because our primary objective was the effectiveness and feasibility of using music to reduce pain and anxiety, we employed a pre-post assessment over multiple sessions, and there was thus not a control group in this study. Fourth, the use of the music app was not directly tied to opioid administration in the ED observation unit. We did not encourage participants or nursing staff to access the music app at particular times proximal to their scheduled opioid administration. Future investigations should consider offering music in strategic times near opioid administration to understand whether the analgesic effects of music can diminish the times individuals request opioids. This also made it impossible to investigate the impact of music on opioid use during the study period.

Conclusion

A smartphone-based intervention built on machine learning–based musical knowledge produced a significant decrease in both pain and anxiety among ED observation unit patients with acute pain. Participants experienced decreased pain and anxiety regardless of whether they used the music intervention on an as-needed basis for pain or under direct supervision. Individuals with higher catastrophizing scores at baseline gained more benefit from the music intervention. Further randomized, controlled studies evaluating the effect of different types of music intervention on pain modulation, pain catastrophizing, and opioid use are needed [43]. Careful assessment of baseline characteristics may help further delineate those who are most likely to derive analgesic benefit from music. Ultimately, our results demonstrate that a music intervention is a feasible adjunctive therapy for individuals who have pain in the ED, as participants willingly used a music intervention when offered to them.

Acknowledgments

Portions of this paper were presented at the 2019 Hawaii International Conference on System Sciences.

EWB received grant funding from the US National Institute on Drug Abuse (NIDA; R01DA047236); PRC received grant funding from NIDA (K23DA044874) and the Hans and Mavis Lopater Psychosocial Fund, and investigator-initiated research grants from Gilead Sciences, Inc, and E Ink Corporation; and KLS received grant funding from the US National Institute of General Medical Sciences (R35GM128691).

Abstract

Background: Continuous photoplethysmography (PPG) monitoring with a wearable device may aid the early detection of atrial fibrillation (AF).

Objective: We aimed to evaluate the diagnostic performance of a ring-type wearable device (CardioTracker, CART), which can detect AF using deep learning analysis of PPG signals.

Methods: Patients with persistent AF who underwent cardioversion were recruited prospectively. We recorded PPG signals at the finger with CART and a conventional pulse oximeter before and after cardioversion over a period of 15 min (each instrument). Cardiologists validated the PPG rhythms with simultaneous single-lead electrocardiography. The PPG data were transmitted to a smartphone wirelessly and analyzed with a deep learning algorithm. We also validated the deep learning algorithm in 20 healthy subjects with sinus rhythm (SR).

Results: In 100 study participants, CART generated a total of 13,038 30-s PPG samples (5850 for SR and 7188 for AF). Using the deep learning algorithm, the diagnostic accuracy, sensitivity, specificity, positive-predictive value, and negative-predictive value were 96.9%, 99.0%, 94.3%, 95.6%, and 98.7%, respectively. Although the diagnostic accuracy decreased with shorter sample lengths, the accuracy was maintained at 94.7% with 10-s measurements. For SR, the specificity decreased with higher variability of peak-to-peak intervals. However, for AF, CART maintained consistent sensitivity regardless of variability. Pulse rates had a lower impact on sensitivity than on specificity. The performance of CART was comparable to that of the conventional device when using a proper threshold. External validation showed that 94.99% (16,529/17,400) of the PPG samples from the control group were correctly identified with SR.

Conclusions: A ring-type wearable device with deep learning analysis of PPG signals could accurately diagnose AF without relying on electrocardiography. With this device, continuous monitoring for AF may be promising in high-risk populations.

atrial fibrillation; deep learning; diagnosis; photoplethysmography; wearable electronic devices

Introduction

Atrial fibrillation (AF) is the most common cardiac arrhythmia, and its prevalence has rapidly increased, especially in the elderly population [1]. In view of this trend, 17.9 million adults are expected to develop AF in Europe by the year 2060 [2]. The socioeconomic burdens of AF are also increasing rapidly in line with its prevalence such that annual medical expenses associated with AF have risen at least five fold in the last decade [3]. Considering the serious complications of AF, early diagnosis and proper management are important.

However, the early detection of AF is challenging owing to its paroxysmal nature [4]. This characteristic makes single electrocardiography (ECG) screening no better than pulse palpation to detect silent AF [5]. Besides, the diagnosis of early AF tends to be delayed because the condition is often asymptomatic [6]. This unmet need for early AF detection may be relieved by continuously monitoring the cardiac rhythm in high-risk populations [7]. However, the cost and invasiveness of an implantable loop recorder limit its use as a continuous monitoring device.

Recently, photoplethysmography (PPG) has been assessed to generate a novel biosignal to monitor AF [8-11]. Compared with ECG, PPG has advantages in terms of accessibility and applicability to wearable or mobile devices [12]. In contrast to an inconvenient traditional strategy to confirm cardiac arrhythmia whereby the patient needs to visit the hospital and undergo ECG, PPG can be easily performed at home using a smartphone or a wearable device. Recently, the Apple Heart Study showed that this strategy has the potential to detect underlying AF in the general population [13]. Moreover, AF detection with PPG can be accurate with deep learning analysis, without relying on ECG [14]. However, the accuracy of PPG depends on the site of measurement [15]. The finger has the highest amplitude and the smallest pulse peak time and reflection index for PPG compared with other body parts; thus, it provides maximum information that can be analyzed [16]. The finger also receives a more abundant supply of arterial blood than the wrist and is easier to affix sensors, hence improving signal quality. As a result, collection of PPG signals from the finger is likely to yield better signal quality than that from the wrist. Therefore, a ring-type wearable device may be a more suitable candidate for the acquisition of PPG signals than a wrist-type wearable device, such as the Apple Watch. Thus, we hypothesized that a ring-type wearable device monitoring PPG data would have high diagnostic performance in the detection of AF. This study aimed to develop a ring-type wearable device (CardioTracker, CART) to detect AF with deep learning analysis of PPG signals and to evaluate its diagnostic performance in patients with AF.

Methods

Study Design and Population

This was a prospective, single-center, observational cohort study conducted from 2018 to 2019. The flowchart of this study is illustrated in Multimedia Appendix 1. Adult patients (aged ≥20 years) with persistent AF who were admitted for elective direct-current cardioversion were eligible for the study. The patients were excluded from the study if their cardiac rhythm just before the cardioversion was not AF. The participants who met the eligibility criteria were introduced to the study and enrolled after obtaining informed consent. The recruitment process was consecutive, and measurements were performed in the order of consent to participate in the study.

For direct-current cardioversion, electric shocks of 100-200 J with a biphasic defibrillator were delivered by paddles under light sedation. The cardiac rhythms before and after the cardioversion were validated with 12-lead ECG read by three cardiologists. If there was a discrepancy, a senior electrophysiologist (EKC or EL) assessed the final cardiac rhythm. Both before and after the cardioversion, each participant was at rest in the supine position and PPG and simultaneous single-lead ECG were recorded over 15 min. We did not measure PPG signals after the shock delivery for those in whom cardioversion was unsuccessful. The study protocol was approved by the Institutional Review Board of Seoul National University Hospital and adhered to the Declaration of Helsinki (approval no: 1801-081-916). The study has been registered at ClinicalTrials.gov (NCT04023188).

Measurements

This study used PPG measurements by CART (Sky Labs Inc, Seongnam, Republic of Korea) and a conventional medical-grade pulse oximeter (iDAQ-400 with PPG-AMP and P400, PhysioLab Inc, Busan, Republic of Korea) as the two index tests and synchronized single-lead ECG (lead I) as the reference standard. The two devices recorded PPG signals simultaneously (CART at the proximal phalanx and the conventional device at the fingertip). The participant chose a finger that was the most comfortable for PPG measurements and wore CART. Wearing CART was not very different from wearing a conventional ring. However, to ensure proper signal quality, other fingers were selected if there were scars, thick skin, or tremors. Moreover, three different sized CART devices were prepared for proper contact between the skin and PPG sensors. The measurements of both PPG signals and the single-lead ECG were synchronized. The PPG signals from the conventional device and the single-lead ECG were tracked and recorded by monitoring equipment kept at the bedside, whereas the PPG signals from CART were wirelessly transmitted to a research-purpose smartphone in real time (Figure 1). The rhythms of PPG data were confirmed and labeled by reading synchronized single-lead ECG strips. The cardiac rhythms were classified into sinus rhythm (SR) or AF. Here, SR included a case where there existed premature atrial or ventricular beats.

During the measurement, the participant was required to lie still in bed to minimize motion artifacts.

We applied a bandpass filter (0.2-18 Hz) to the PPG signals, recorded them at a sampling frequency of 50 Hz, and exported them in XML format for preprocessing. Examples of PPG data from CART and the conventional pulse oximeter are illustrated in Multimedia Appendix 2.

For data augmentation [14,17], each 15-min PPG datum was divided into 30-s samples with 20-s overlaps. For the deep learning process, every sample was labelled as AF or SR according to the rhythm of its synchronized single-lead ECG.

Figure 1. Demonstration of photoplethysmography (PPG) monitoring by CardioTracker (CART). CART measures PPG signals at the proximal phalanx and wirelessly transmits the data to the linked smartphone, which can monitor the PPG signals in real-time, and the deep learning algorithm suggests a possible diagnosis.

Ring-Type Wearable Device

CART has been developed to collect and analyze PPG signals from the proximal phalanx. The measurement is based on the reflective method [18], using high-intensity green light-emitting diodes (LEDs) and photodiodes (PDs) embedded inside. It analyzes the PPG signals using a deep learning algorithm with a convolutional neural network (CNN) [17,19], which involves nine neural layers, where the top two are fully connected. The neural network was trained by the Adam optimizer [20]. Dropout and L2 regularization were performed to prevent overfitting [21]. The softmax outputs of the neural network were gently calibrated with temperature scaling to exhibit the diagnostic confidence of SR and AF for every testing PPG sample [22].

To compare the CNN to nondeep learning algorithms, CART also uses a linear-kernel support vector machine (SVM) [23], as it has been shown to have the best diagnostic performance among nondeep learning algorithms [24]. For the features of SVM, we used root mean square of the successive differences of RR intervals with Shannon entropy (RMSSD+ShE) [25], autocorrelation [9], and the ensemble of the previous two (RMSSD+ShE and autocorrelation).

Multimedia Appendix 3 illustrates CART and its wireless charging station. The LEDs and PDs of CART were designed to be located under the finger. CART is made of surgical steel and is waterproof and dustproof (IP58 grade). It collects PPG signals at the proximal phalanx by measuring the reflected lights under the finger. It can monitor PPG signals over 60 hours continuously and can store data for up to 10 hours. It can upload the data via Bluetooth to a mobile or cloud server and can be charged wirelessly with its cradle.

Diagnostic Performance Analysis

We evaluated the baseline characteristics of the study population, including demographics, comorbidities, use of antiarrhythmic agents and anticoagulants, CHA_2DS_2-VASc

scores, and history of AF. Multiple five-fold cross-validation processes were used to perform the training and testing processes of the deep learning algorithm. Each validation process randomly assigned 80% of the total participants for training and the other 20% for testing. The validation process was repeated 10 times for each combination of training and testing datasets, resulting in a total of 50 validation processes for evaluating overall diagnostic performance. For the deep learning process, entire 30-s PPG samples were used without pre-extracted features in training or testing. For a given PPG sample, the deep learning algorithm identified SR or AF, whichever had higher diagnostic confidence. There were no indeterminate or missing data in the two index tests and the reference standard.

To evaluate the diagnostic performance of CART according to the length of the PPG samples, we generated 25-, 20-, 15-, 10-, and 5-s PPG samples from the raw data and repeated the analysis. To investigate whether its performance is affected by the variability of peak-to-peak intervals or the pulse rate of PPG signals, we calculated both the coefficient of variation of the peak-to-peak intervals and the pulse rate for every sample. The diagnostic performance according to the variability and pulse rate was evaluated. As the use of a ring-type device for PPG measurement is not fully understood yet, we compared the two index tests (CART and conventional device) by performing the same analysis but with different PPG measurements. We also assessed the accuracy of the diagnostic performance by trying different subsets of PPG samples; a PPG sample was allowed to be tested by the deep learning algorithm only if its diagnostic confidence was higher than a certain threshold level. For external validation of CART with the deep learning algorithm, 20 healthy subjects with SR were additionally recruited. The PPG signals were measured by CART and processed according to the same protocol in each subject. Considering the random characteristics of deep learning, we repeated the testing 10 times.

Statistical Analysis

The Kolmogorov-Smirnov test was used to check for normal distribution of clinical variables. The data are presented as mean (SD) for age, median with IQR for body mass index and CHA_2DS_2-VASc score, or n (%) for other variables. We obtained cross-tabulation from the validation process and calculated the sensitivity, specificity, positive-predictive value (PPV), negative-predictive value (NPV), and diagnostic accuracy (the ratio between the number of correct cases and the total number of tests). A receiver operating characteristic curve was constructed, and the area under the curve (AUC) with 95% CI was calculated using the diagnostic confidence (CNN) or features (SVM). The mean pulse rate was compared between SR and AF samples using the Student *t* test. All statistical analyses were two-sided, and $P<.05$ was considered statistically significant. The data were analyzed using SPSS version 22.0 (IBM Corp, Armonk, New York, USA).

Results

Baseline Characteristics

The baseline characteristics of the study population are illustrated in Table 1. A total of 100 participants (81 male participants, 81%; mean age 63.8 years, SD 8.5; median CHA_2DS_2-VASc score 2) were enrolled in this study. We collected a total of 13,038 30-s PPG samples (5850 for SR and 7188 for AF) from this population, using CART. Among the 100 participants, 81 had persistent AF and the other 19 had long-standing persistent AF. In 15 participants, cardioversion was unsuccessful. The mean pulse rate was higher in AF samples than in SR samples (63.5, SD 9.9 vs 59.6, SD 9.9; $P<.001$). There were no adverse events or safety issues during the study.

Table 1. Baseline characteristics of the study population (N=100).

Characteristic	Value[a]
Demographics	
Age (years)	63.8 (8.5)
Male	81 (81.0)
Median body mass index (kg/m^2)	25.3 (23.5-27.1)
Median CHA_2DS_2-VASc score	2 (1-3)
Atrial fibrillation ablation history	7 (7.0)
Types of AF	
Persistent[b]	81 (81.0)
Long-standing persistent[c]	19 (19.0)
Comorbidity	
Congestive heart failure	15 (15.0)
Hypertension	57 (57.0)
Diabetes mellitus	27 (27.0)
Stroke or transient ischemic attack	4 (4.0)
Myocardial infarction or ischemic heart disease	6 (6.0)
Valvular heart disease	3 (3.0)
Dyslipidemia	35 (35.0)
Chronic renal failure	3 (3.0)
Chronic obstructive pulmonary disease	1 (1.0)
Hyperthyroidism	3 (3.0)
Antiarrhythmic agents	
Propafenone	17 (17.0)
Flecainide	10 (10.0)
Pilsicainide	3 (3.0)
Sotalol	0 (0)
Amiodarone	64 (64.0)
Beta-blocker	24 (24.0)
Nondihydropyridine calcium channel blocker	27 (27.0)

[c]Atrial fibrillation history for more than 1 year.

Diagnostic Performance According to the Algorithms

The performance of CART according to the algorithms is presented in Table 2 and Figure 2. Combined with the CNN algorithm, it showed the highest performance for all the diagnostic parameters, with diagnostic accuracy of 96.89%, sensitivity of 98.96%, specificity of 94.34%, PPV of 95.55%, NPV of 98.67%, and AUC (95% CI) of 0.993 (0.992-0.993). Among the nondeep learning algorithms, SVM with the ensemble method had the highest results for all the parameters, except sensitivity and NPV, with diagnostic accuracy of 91.49%, sensitivity of 91.29%, specificity of 91.74%, PPV of 93.14%, NPV of 89.55%, and AUC (95% CI) of 0.983 (0.982-0.983). Adding RMSSD and ShE to autocorrelation as features did not significantly improve the performance of SVM (Figure 2).

Table 2. Diagnostic performance of the ring according to algorithms.

Algorithm	Accuracy, mean percentage	Sensitivity, mean percentage	Specificity, mean percentage	Positive-predictive value, mean percentage	Negative-predictive value, mean percentage	AUC[a] (95% CI)
Convolutional neural network	96.89	98.96	94.34	95.55	98.67	0.993 (0.992-0.993)
SVM[b], ensemble[c]	91.49	91.29	91.74	93.14	89.55	0.983 (0.982-0.983)
SVM, autocorrelation[d]	91.37	92.15	90.4	92.18	90.36	0.982 (0.981-0.982)
SVM, RMSSD[e]+ShE[f] [g]	84.11	90.65	76.07	82.31	86.88	0.887 (0.885-0.889)

[a]AUC: area under the receiver operating characteristic curve.

[b]SVM: support vector machine.

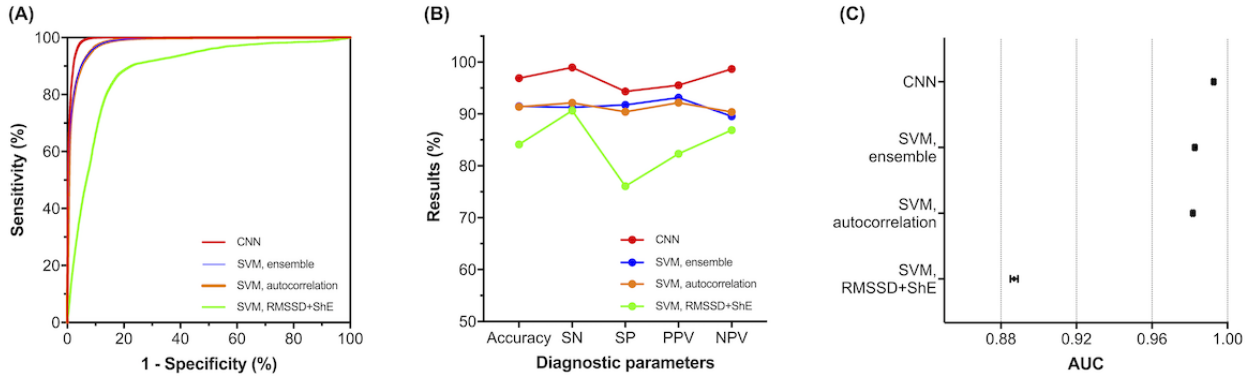
[d]SVM with autocorrelation as a feature.

[e]RMSSD: root mean square of the successive differences of RR intervals.

[f]ShE: Shannon entropy.

[g]SVM with RMSSD and ShE as features.

Figure 2. Diagnostic performance of CardioTracker (CART) according to the algorithms. CART with the deep learning algorithm achieved the highest results for all diagnostic parameters. (A) ROC curves, (B) Diagnostic parameters, and (C) AUCs according to the algorithms. AUC: area under the curve, CNN: convolutional neural network, NPV: negative-predictive value, PPV: positive-predictive value, ROC: receiver operating characteristic, SN: sensitivity, SP: specificity, SVM, autocorrelation: support vector machine with autocorrelation as a feature, SVM, RMSSD+ShE: support vector machine with root mean square of the successive differences of RR intervals and Shannon entropy as features, SVM, ensemble: support vector machine with all three features.



Impact of Sample Length

The association between sample length and the diagnostic performance of CART is presented in Figure 3 and Table 3. The figure only presents the results of CART with CNN. As expected, all diagnostic parameters decreased as sample length shortened. Using 10-s PPG segments, CART achieved diagnostic accuracy of 94.72%, sensitivity of 97.46%, specificity of 91.35%, PPV of 93.26%, NPV of 96.69%, and AUC (95% CI) of 0.985 (0.985-0.986).

Figure 3. The diagnostic performance of CardioTracker according to sample length. In general, longer lengths of photoplethysmography samples had higher diagnostic performances. AUC: area under the curve, NPV: negative-predictive value, PPV: positive-predictive value, SN: sensitivity, SP: specificity.

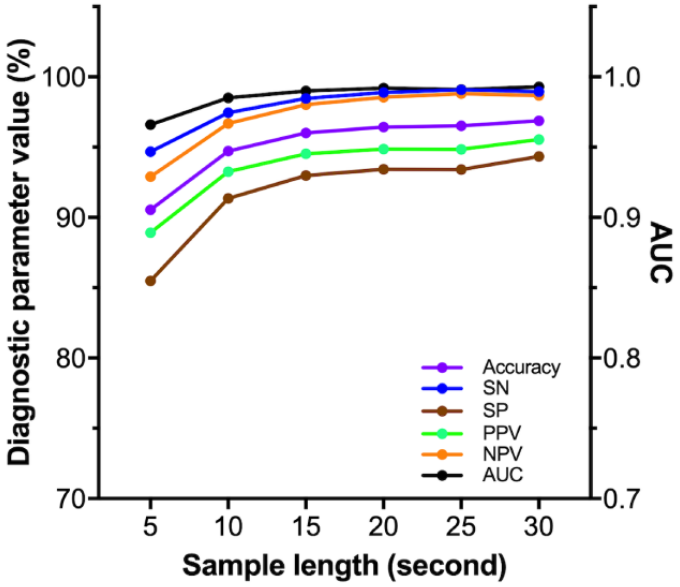


Table 3. Diagnostic performance according to sample length.

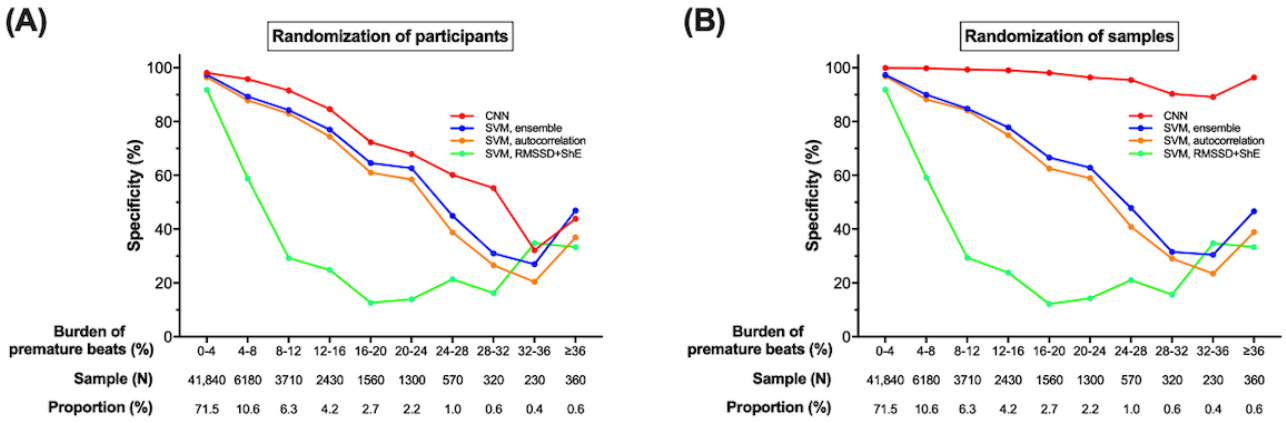
Duration (s)	Accuracy, mean percentage	Sensitivity, mean percentage	Specificity, mean percentage	Positive-predictive value, mean percentage	Negative-predictive value, mean percentage	AUC[a] (95% CI)
30	96.89	98.96	94.34	95.55	98.67	0.993 (0.992-0.993)
25	96.53	99.08	93.40	94.85	98.80	0.991 (0.990-0.991)
20	96.44	98.89	93.43	94.87	98.56	0.992 (0.992-0.992)
15	96.01	98.47	92.99	94.52	98.02	0.990 (0.990-0.990)
10	94.72	97.46	91.35	93.26	96.69	0.985 (0.985-0.986)
5	90.55	94.68	85.49	88.91	92.90	0.966 (0.965-0.966)

[a]AUC: area under the receiver operating characteristic curve.

Impact of Premature Beats

Each SR-labelled PPG sample may have a record of atrial or ventricular premature beats, which can be confirmed by evaluating synchronized ECG. We evaluated the specificity of our device by assessing the burden of premature beats (Figure 4). The total number of samples was 10 times the number of SR samples (58,500), as the validation processes were repeated 10 times. When participants were randomized for the five-fold cross-validation processes such that the algorithm always encountered new participants in the testing, higher burdens of premature beats deteriorated the specificity of CART, regardless of the algorithm. Among the algorithms, CNN maintained the highest results for most cases of premature beat burdens. When samples were randomized such that the algorithm might encounter the same participants in testing, there was an improvement in CNN performance, especially for higher burdens of premature beats, and CNN maintained overall consistent results, regardless of the burden. As this validation process simulates a situation with a sufficiently large number of participants in the training dataset, this finding implies that the performance would improve with an increasing population, regardless of the burden of premature beats.

Figure 4. The specificity of CardioTracker according to the burden of premature beats. (A) The five-fold cross-validation process with randomization of participants. There was a decreasing trend of specificity according to increasing burden of premature beats. However, the convolutional neural network (CNN) maintained the highest results for most cases. (B) The five-fold cross-validation process with randomization of samples. The CNN improved specificity in especially high burden of premature beats. SVM, autocorrelation: support vector machine with autocorrelation as a feature, SVM, RMSSD+ShE: support vector machine with root mean square of the successive differences of RR intervals and Shannon entropy as features, SVM, ensemble: support vector machine with all three features.

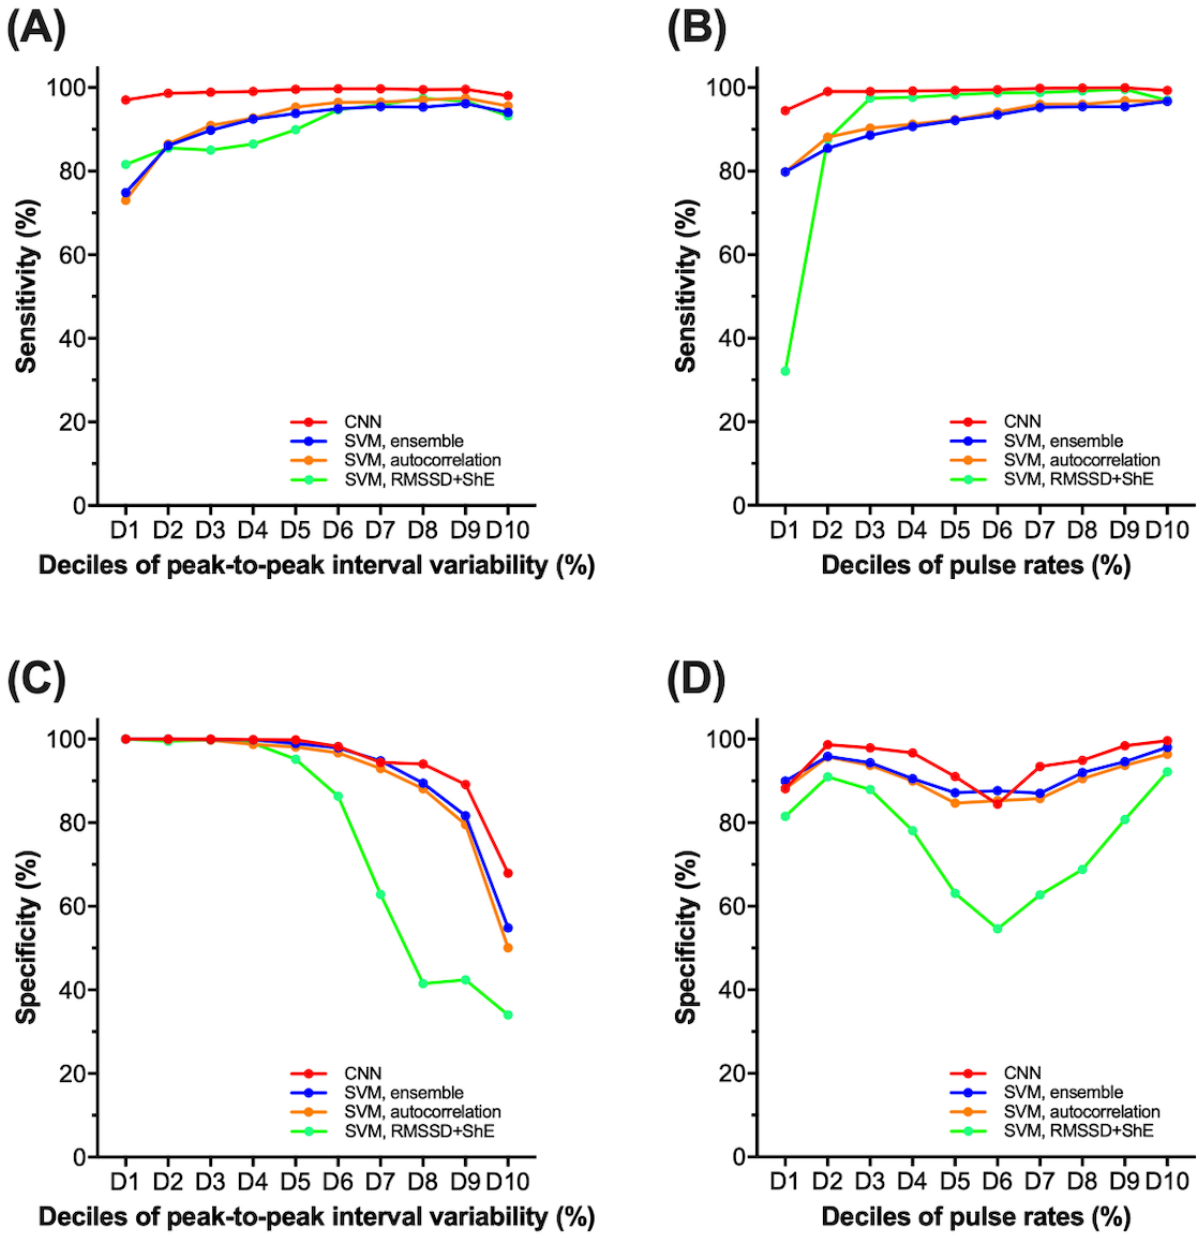


Impact of the Variability of Peak-to-Peak Intervals and the Pulse Rate

The performance of CART can be affected by the characteristics of the PPG samples. We evaluated whether the variability of peak-to-peak intervals and the pulse rate affected the performance (Figure 5). For sensitivity, higher peak-to-peak interval variability and faster pulse rates were associated with higher sensitivity for SVM. However, for CNN, neither peak-to-peak interval variability nor pulse rate had such a relevant association with sensitivity. This finding suggests that CART with a deep learning algorithm is less affected by peak-to-peak interval variability or the pulse rate of AF.

For specificity, the performance of CART decreased with higher peak-to-peak interval variability regardless of the algorithm. However, for CNN, only the extremes of the variability (the ninth and the tenth deciles) had decreased specificity less than 90%. This finding was expected, as SR with higher peak-to-peak interval variability mimics AF to a great extent. There was a nonlinear association between specificity and pulse rate, and in general, the results were the highest with CNN. The complicated association between specificity and pulse rate can be mostly explained by evaluating the association between the burden of premature beats and the pulse rate (Multimedia Appendix 4). For example, lower specificity for the sixth decile of the pulse rate can be due to the higher burden of premature beats.

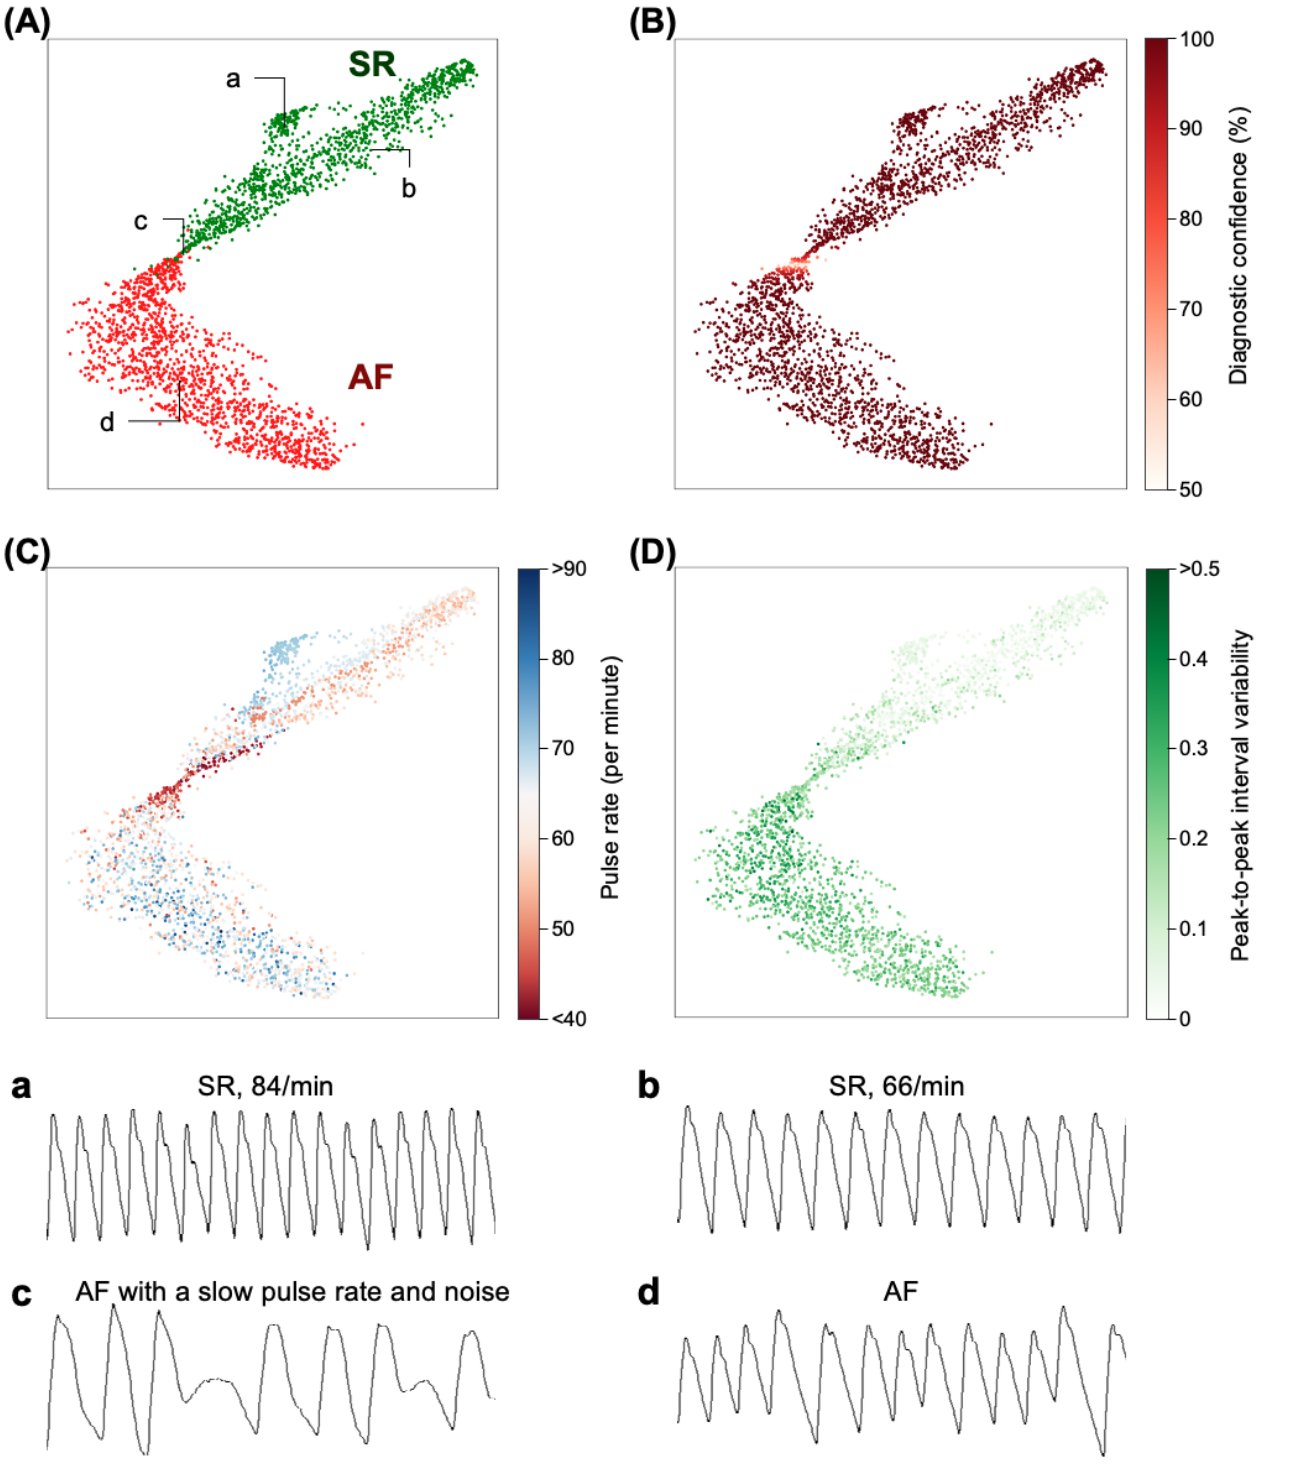
Figure 5. The sensitivity and specificity of CardioTracker according to the characteristics of samples. (A) and (B) With the deep learning algorithm, there were no definite associations between the sensitivity and peak-to-peak interval variability or the pulse rate. (C) The specificity generally decreased with higher peak-to-peak interval variability. (D) There was generally a U-shape association between specificity and the pulse rate. CNN: convolutional neural network, SVM, autocorrelation: support vector machine with autocorrelation as a feature, SVM, RMSSD+ShE: support vector machine with root mean square of the successive differences of RR intervals and Shannon entropy as features, SVM, ensemble: support vector machine with all three features.



Visualization of Deep Learning Analyses

The deep learning analyses for CART are illustrated in Figure 6 by mapping extracted features from the deep learning algorithm into two-dimensional space. According to the t-distributed stochastic neighbor embedding plot, the cluster of AF was well differentiated from the counterpart of SR. In the region where the two clusters overlapped, lower diagnostic confidences were observed, which suggests that the deep learning algorithm mostly failed when the PPG samples belonged to this region. When we applied heatmaps with the pulse rate and peak-to-peak interval variability, this region had characteristics with lower pulse rates and modest variabilities. When we inspected the actual PPG data, this region also exhibited noisy signals. Therefore, PPG samples with lower pulse rates, modest variabilities, and noise would likely have low diagnostic performance. The cluster of AF was homogeneous in terms of the pulse rate, whereas the cluster of SR had distinctive subportions according to the actual pulse rate.

Figure 6. Visualization of deep learning analyses. The deep learning analyses of CardioTracker are plotted with the t-SNE method. The upper panel: (A) The two clusters of AF and SR were well differentiated from each other, leaving a small overlapped potion. (B), (C), and (D) The overlapped region showed low diagnostic confidence, low pulse rates, and modest peak-to-peak interval variability. The lower panel: typical examples of photoplethysmography samples. AF: atrial fibrillation, SR: sinus rhythm, t-SNE: t-distributed stochastic neighbor embedding.



CardioTracker and the Conventional Pulse Oximeter

We evaluated the two index tests in parallel and observed the changes in diagnostic performances according to the threshold level of diagnostic confidence. Compared with the conventional pulse oximeter, CART showed comparable diagnostic performance (Table 4). In both devices, all the diagnostic parameters improved with increasing threshold levels (Multimedia Appendix 5). This finding is expected, as the diagnosis would become more accurate for samples with higher diagnostic confidence. However, this improvement was counter-balanced by increasing the proportion of filtered samples (not tested by the deep learning algorithm). From these findings, CART appears to be comparable to the conventional pulse oximeter when used as a PPG measurement device. Moreover, the performance of CART can be tuned by applying different threshold levels.

Table 4. Comparison of diagnostic performance between CardioTracker and the conventional pulse oximeter at the fingertip (control).

Device	Accuracy, mean percentage	Sensitivity, mean percentage	Specificity, mean percentage	Positive-predictive value, mean percentage	Negative-predictive value, mean percentage	AUC[a] (95% CI)[b]
CART[c]	96.89	98.96	94.34	95.55	98.67	0.993 (0.992-0.993)
Control	97.50	99.66	94.89	95.95	99.56	0.995 (0.995-0.995)

[a]AUC: area under the receiver operating characteristic curve.

[b]The standard error by the binomial exact test was less than 0.01.

[c]CART: CardioTracker.

External Validation of CardioTracker in Healthy Subjects

A total of 1740 PPG samples were obtained from 20 healthy subjects with SR. Among these samples with repeated testing 10 times, 94.99% (16,529/17,400) of the testing cases were correctly identified with SR.

Discussion

Principal Findings

This prospective observational cohort study evaluated the diagnostic performance of a ring-type wearable device (CART) to detect AF. To the best of our knowledge, this is the first clinical study to analyze the performance of a ring-type wearable device designed for detecting AF with PPG. The study had several findings. First, we found that the deep learning algorithm can maximize the performance of CART solely based on PPG. Second, a PPG measurement period of about 10 s may be sufficient to detect AF. Third, the data from a sufficiently large number of participants may further improve the performance of CART by enhancing the deep learning process, especially for difficult cases in which the high burden of premature beats mimics AF. Fourth, among the diagnostic parameters, sensitivity may be maintained at a consistently high level regardless of the variability of peak-to-peak intervals or the pulse rate of PPG signals. Fifth, although CART measures PPG at the middle of the finger, which is not the location where a conventional pulse oximeter measures the impulse, its performance is comparable to that of a conventional device. Lastly, we performed external validation of CART with the deep learning algorithm in healthy subjects and observed that the CNN algorithm can diagnose SR accurately.

Screening for Atrial Fibrillation in a High-Risk Population

AF is known to cause about 10% of the total cases of stroke, and it has been shown to increase the risk of stroke even when discovered incidentally through screening [26]. AF screening is beneficial in an appropriate setting for patients in all localities. Therefore, early diagnosis of AF with appropriate anticoagulant therapy is expected to reduce the risk of ischemic stroke. However, early diagnosis is challenging because paroxysmal or asymptomatic episodes are common. Therefore, further research is needed to find more convenient and effective screening methods. Based on this aspect, PPG has recently attracted attention as a method of AF screening because it can be continuously monitored with appropriate equipment and its measurement is convenient.

Utility of Photoplethysmography to Detect Atrial Fibrillation

This study used PPG signals measured from CART to detect AF. As there is a good correlation between each pulse of PPG and the corresponding QRS complex on ECG, it is feasible to diagnose AF with PPG. Considering that PPG has limited capability to detect atrial electrical activity, many PPG algorithms have been studied to detect AF using the randomness of peak-to-peak intervals [27,28]. Two issues should be addressed. First, there is uncertainty as to the choice of algorithm used to detect AF. For detecting AF with PPG, deep learning algorithms have been known to achieve the highest diagnostic results so far [14]. The possible reason is that nondeep learning algorithms use only specific data features, which are invented by humans, whereas deep learning algorithms analyze the entire dataset without human guidance. Second, the optimal anatomical location for PPG measurement is debatable. Multiple studies have evaluated the diagnostic value of PPG measured at various sites, including the wrist and face [8,10,12]. However, a recent study showed that the finger has the highest quality of PPG signals [16]. Therefore, to diagnose AF more effectively, it is probably best to analyze PPG signals from the finger. In summary, the most effective AF diagnosis is possible when analyzing PPG signals from the finger and using deep learning algorithms.

Wearable Devices to Detect Atrial Fibrillation With Photoplethysmography

The method for screening AF should be not only supported by sufficient diagnostic precision but also convenient for patients. The strategy of carrying a portable device involving point-of-care testing is not only inconvenient but also ineffective in that it can miss the diagnosis when AF is asymptomatic. In this context, a wearable device that continuously monitors PPG signals in the background without user intervention would be easy to use and efficient for diagnosis. If CART is worn all day, PPG signals can be continuously monitored; therefore, more AF episodes could be detected. However, continuous monitoring might increase the chance of collecting other signals, such as noise caused by movements in daily life, leading to a decrease in the accuracy of diagnosis. To resolve this problem, we need engineering technology for estimating and correcting motion artifacts through the use of accelerometer sensors in addition to PPG signal analysis. Second, various atrial tachyarrhythmia episodes other than AF could be detected more frequently, which might lower the diagnostic performance for AF detection by

CART. Sufficient data should be collected for various atrial tachyarrhythmias in addition to AF to improve machine learning analyses.

Besides, when PPG signals are continuously monitored, various atrial tachyarrhythmia episodes can occur in addition to AF, which may lower the diagnostic performance of CART. If atrial tachyarrhythmia episodes occur frequently, the irregularity of the PPG signal is expected to be similar to that for AF, and in this case, the diagnostic performance of CART may deteriorate. To solve this issue, sufficient data should be collected for various arrhythmias in addition to AF to improve machine learning analyses.

Although wearable devices may not have become popular due to their availability and cost-effectiveness, the usefulness of such devices in the detection of AF has been studied [29]. The wrist-type device is one of the most widely studied wearable devices [13,30,31]. However, the WATCH AF Trial also reported that a high proportion (22%) of PPG signals from smartwatches had an insufficient signal quality for evaluation [31]. Therefore, measuring PPG signals on the wrist may lead to poor signal quality. In order to resolve this issue, other types of wearable devices are necessary, and the ring-type device, which measures PPG signals from the finger, might be ideal. Therefore, a ring-type wearable device could be useful as a new diagnostic tool for high-risk populations in the future.

Limitations

There are some limitations in this study. First, noise in PPG signals, such as motion artifacts, might affect the analysis. However, motion artifacts were minimized as every participant was required to lie still on the bed during the PPG measurement. The diagnostic performance of CART in an ambulatory setting will be tested, but a sophisticated deep learning algorithm should be developed beforehand to deal with motion artifacts. Second, the performance of CART was not assessed for other arrhythmias. Future studies should analyze the diagnosis of other arrhythmias using PPG signals. Third, the duration of monitoring was relatively short. Longer monitoring times would allow further deep learning training and subsequently yield better results than our results. Fourth, we did not compare performance between CART and other commercially available wrist-type wearable devices. Further studies will provide insights into this issue. Fifth, economic assessment of CART cannot be performed yet. However, in the case of AliveCor, it was shown that a wearable device could be cost-effective for AF screening [29]. Likewise, CART is also expected to reduce the economic burden of diagnosing AF if its market price is reasonable. This economic evaluation requires further research. Sixth, since a 20-s overlap existed between consecutive samples obtained from a subject during data augmentation, it is possible that even if different samples existed in the training and testing datasets, some sections were the same, and thus, the diagnostic performance was improved. Seventh, AF diagnosis by PPG only has limitations. Adding the on-demand recording function of single-lead ECG, similar to an Apple Watch, to CART may compensate for the limitations that arise in diagnoses based on PPG signals. In this case, if AF is suspected during PPG monitoring, a notification can be sent to the user to check the electrocardiogram, so that the user can more clearly check for AF. The validation of such a function would be performed in future research. Lastly, even though there were no adverse events of CART, potential safety issues in long-term use should be addressed in a subsequent study.

Conclusions

In this study, we validated the performance of a ring-type wearable device (CART) to diagnose AF using PPG signals. The deep learning algorithm aimed to analyze PPG rhythms and suggested a dichotomous diagnosis of either AF or SR. CART with deep learning analysis of PPG signals had good diagnostic performance without relying on ECG. Moreover, as a PPG measurement device, CART generated results comparable to those of a conventional medical-grade pulse oximeter. This new device may be promising for the detection of AF in high-risk or asymptomatic populations.

Acknowledgments

We would like to thank Dajeong Heo, who helped in the photoplethysmography measurement processes during the study. This work was supported by Sky Labs Inc, Seongnam, Republic of Korea, and by the grant no. 0320202040 from the Seoul National University Hospital Research Fund.

Authors' Contributions

SK and JH have made equal contributions to the design of the study, acquisition, analysis, and interpretation of data, creation of figures and tables, and draft of the manuscript. EKC and YY contributed equally in correspondence to the study and revision of the manuscript.

Conflicts of Interest

SK, JH, EL, and SO: None declared. EKC, ERJ, BKK, and YY: Stockholders of Sky Labs Inc, Seongnam, Republic of Korea. BL and CB: Employees of Sky Labs Inc.

Abstract

Background: There are a range of perceived gaps and shortcomings in the publicly funded Canadian health system. These include wait times for care, lack of public insurance coverage for dental care and pharmaceuticals, and difficulties accessing specialist care. Medical crowdfunding is a response to these gaps where individuals raise funds from their social networks to address health-related needs.

Objective: This study aimed to investigate the potential of crowdfunding data to better understand what health-related needs individuals are using crowdfunding for, how these needs compare with the existing commentary on health system deficiencies, and the advantages and limitations of using crowdfunding campaigns to enhance or augment our understanding of perceived health system deficiencies.

Methods: Crowdfunding campaigns were scraped from the GoFundMe website. These campaigns were then limited to those originating in the metropolitan Vancouver region of two health authorities during 2018. These campaigns were then further limited to those raising funds to allow the treatment of a medical problem or related to needs arising from ill health. These campaigns were then reviewed to identify the underlying health issue and motivation for pursuing crowdfunding.

Results: We identified 423 campaigns for health-related needs. These campaigns requested CAD $8,715,806 (US $6,088,078) in funding and were pledged CAD $3,477,384 (US $2,428,987) from 27,773 donors. The most common underlying medical condition for campaign recipients was cancer, followed by traumatic injuries from collisions and brain injury and stroke. By far, the most common factor of motivation for crowdfunding was seeking financial support for wages lost because of illness (232/684, 33.9%). Some campaigns (65/684, 9.5%) sought help with purchasing medical equipment and supplies; 8.2% (56/684) sought to fund complementary, alternative, or unproven treatments including experimental interventions; 7.2% (49/684) sought financial support to cover travel-related costs, including in-province and out-of-province (49/684, 7.2%) travel; and 6.3% (43/684) campaigns sought help to pay for medication.

Conclusions: This analysis demonstrates the potential of crowdfunding data to present timely and context-specific user-created insights into the perceived health-related financial needs of some Canadians. Although the literature on perceived limitations of the Canadian health system focuses on wait times for care and limited access to specialist services, among other issues, these campaigners were much more motivated by gaps in the wider social system such as costs related to unpaid time off work and travel to access care. Our findings demonstrate spatial differences in the underlying medical problems, motivations for crowdfunding, and success using crowdfunding that warrants additional attention. These differences may support established concerns that medical crowdfunding is most commonly used by individuals from relatively privileged socioeconomic backgrounds. We encourage the development of new resources to harness the power of crowdfunding data as a supplementary source of information for Canadian health system stakeholders.

crowdfunding; exploratory analysis; Canada; health system

Introduction

Background

A core aim of the Canadian health care system—and many other publicly funded health systems—is universal coverage for medically necessary services [1]. Nonetheless, Canadian health care users and policy makers report a range of perceived or experienced deficiencies in this system that impose financial costs on its users. These deficiencies include barriers to accessing care that motivate the use of private medical treatment and out-of-pocket costs when accessing publicly funded treatment [2,3].

Public reporting on systemic barriers to accessing care in Canada often focuses on wait times and health human resource shortages in key areas. A 2013 survey of Canadians found that waiting for a medical appointment and difficulty getting an appointment were the most common problems cited by those reporting access barriers. These barriers were greatest in relation to accessing specialist care, nonemergency surgery, and diagnostic testing. Canadians who were aged younger than 65 years, females, immigrants, people with some postsecondary education, and those with specific health needs were more likely to report barriers to accessing care than other groups. Geographically, Canadians in Quebec and the Western provinces, including British Columbia, were more likely to report access barriers than those living elsewhere in the country [4].

The Canadian Institute for Health Information has found that access barriers because of wait times vary by location and treatment sought. They report that 30% of Canadians perceive facing wait times for access to surgery for hip replacement or cataracts that are longer than recommended. At the same time, hip fracture repair was provided within the recommended wait times for 88% of Canadians, and 97% received timely radiation therapy [5]. British Columbia performs below the Canadian average in all wait time categories, with 67% of residents accessing hip replacement treatment within the recommended wait time, 59% for knee replacement, 85% for hip fracture repair, 64% for cataract surgery, and 93% for radiation therapy [6]. These perceived barriers to accessing care have been cited as factors motivating the expansion of private insurance in Canada and private payment for treatment domestically and abroad via medical tourism [7-9].

In addition to these perceived barriers to accessing care, several key gaps in coverage for services that are not covered under the Canada Health Act and thus are not part of the publicly funded health system have been identified [1]. These gaps include lack of or inadequate payment for prescription drugs, eye care, and dental care, which may be met by other social programs or private health insurance, depending on one's income, place of residence, and employment [10,11]. Other nonreimbursed out-of-pocket expenses encountered by Canadians include parking payments at hospitals, medical devices used at home, accommodations while accessing nonlocal care, complementary and alternative treatments, home accessibility modifications, physical rehabilitation, in-home care, and travel costs [12-15]. Limited public coverage of prescription drugs, in particular, has received significant academic, policy, and political attention [16].

Some Canadians who are facing these perceived deficiencies in the Canadian health system are turning to medical crowdfunding to assist them with raising funds to support options such as seeking treatment abroad or paying for care and services that are not covered by the health and social care systems. Medical crowdfunding is a practice whereby individuals seek funds for health-related needs from their social networks via Web-based fundraising platforms. By far, the largest medical crowdfunding platform, GoFundMe, has been growing by 300% per year in 2016 and has raised funding from 25 million donors through 2 million crowdfunding campaigns [17]. In 2017, it was reported that it had raised US $3 billion since 2010 and has been raising US $140 million per month in donations. [18] More recently, the total raised by GoFundMe was reported as US $5 billion and growing [19].

Objectives

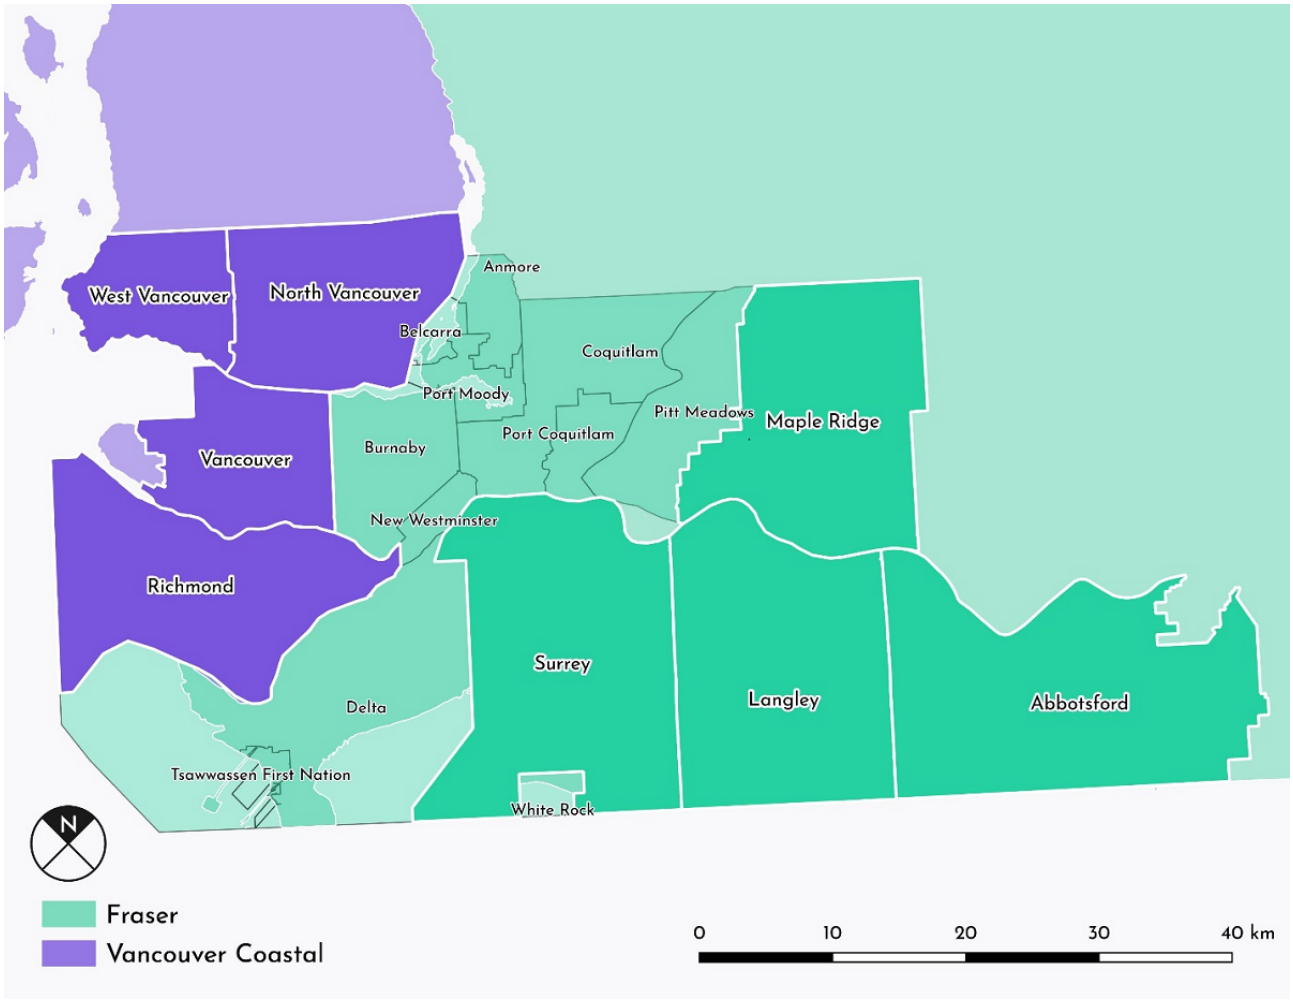
Working from the premise that medical crowdfunding campaigns may provide unique user-focused insight into local health system gaps and deficiencies, in this exploratory analysis, we examine campaigns from two administrative regions of British Columbia. These administrative areas cover a range of communities, including dense urban centers, suburban regions, and less densely populated rural areas, all geographically contiguous and with access to extensive health system infrastructure. Our aim in undertaking this analysis was to better understand what health-related needs individuals in this area are crowdfunding for, how these needs compare with the existing commentary on health system deficiencies, and the advantages and limitations of using crowdfunding campaigns to enhance or augment our understanding of perceived health system deficiencies. We further aimed for this analysis to serve as a model for other analyses using crowdfunding data to enhance understanding of health-related needs.

Methods

We used an automated Web scraper to extract campaign data from GoFundMe.com. This scraper, the Crowdfunding for Health Research Portal, began recording data from GoFundMe crowdfunding campaigns in April 2019 using the GoFundMe.com sitemap. Information for every campaign listed on the sitemap was recorded at that time, including the title, text, updates, number of donors, money requested, money pledged, number of Facebook shares, and campaigner location. All campaigns listing locations in the Fraser Health Authority (FHA) region (n=2772) and metropolitan Vancouver portion of Vancouver Coastal Health Authority (VCHA) region

(Vancouver, Richmond, North Vancouver, and West Vancouver; n=1971) were selected and recorded on a shared spreadsheet (see Figure 1). These regions are relatively densely populated geographically contiguous areas that are home to extensive health system infrastructure.

Figure 1. A map of campaigner locations.



These campaigns were then restricted to fundraising categories, most likely to be health related (emergencies, family, medical, and uncategorized), and initiated in 2018.

After campaigns were extracted from the portal, the second author reviewed the campaigns, including those raising funds to allow treatment of a medical problem or related to needs arising from ill health. All authors independently reviewed 50 of the included campaigns and met to identify categories of health-related needs motivating crowdfunding, understood as needs triggered by, exacerbated by, or otherwise related to the underlying health condition. Included campaigns were then coded by JS and MZ for the requested health-related need, and the second author recorded the underlying health problem for each campaign. The fourth author then reviewed any codes flagged as uncertain by the first 2 reviewers and audited 5% of the coded campaigns to ensure consistency. Any disagreements were discussed and resolved by these reviewers. Given the exploratory purview of this analysis, sums were generated for the coded categories to allow for descriptive statistics to be generated.

Results

We identified 423 campaigns for health-related needs between VCHA and FHA. These campaigns requested Can $8,715,806 (US $6,088,078) in funding and were pledged Can $3,477,384 (US $2,428,987) from 27,773 donors and shared 120,665 times on Facebook (see Table 1). In the FHA, campaigns were located most commonly in the cities of Surrey (47/275, 17.1%), Abbotsford (45/275, 16.4%), Langley (31/275, 11.3%), and Maple Ridge (26/275, 9.5%). In the VCHA, campaigns were divided between Vancouver (108/148, 73.0%), North Vancouver (27/148, 18.2%), Richmond (10/148, 6.8%), and West Vancouver (3/148, 2.0%; see Table 2). The most common underlying medical condition for campaign recipients was cancer, followed by traumatic injuries from collisions, and brain injury and stroke (see Table 3).

Table 1. Campaign engagement.

Category	Fraser Health Authority	Vancouver Coastal Health Authority	Total
Campaigns, n	275	148	423
Amount requested (Can $)	5,982,654 (US $4,178,944)	2,733,152	8,715,806
Money pledged (Can $)	1,939,932 (US $1,355,062)	1,537,452	3,477,384
Percentage pledged, %	32.4	56.3	39.9
Donors, n	15,826	11,947	27,773
Facebook shares, n	78,966	41,699	120,665

Table 2. Campaign location.

Location	Number of campaigns (N=423), n (%)	Population [20] (N=2,916,414), n (%)
Vancouver	108 (25.5)	672,963 (23.08)
Surrey	47 (11.1)	569,065 (19.51)
Abbotsford	45 (10.6)	151,923 (5.21)

After discussion, 13 categories of health-related needs motivating crowdfunding were identified. Campaigners were motivated by seeking funding for a variety of issues related to the recipient's health needs (see Table 4). Of the 685 motivations recorded, including multiple motivations in several instances, by far, the most common was seeking financial support for wages lost because of illness (232/684, 33.9%). These included instances of income lost because of taking time off of paid employment because of the effects of illness, needing to take time off of paid employment for treatment, and needing to relocate for treatment. Such needs were often prompted by recipients reaching the limits in unemployment insurance coverage, as for the campaigner who wrote that "employment insurance does not cover much and only lasts for 10 weeks."

Table 4. Motivation.

Motivation category	Fraser Health Authority (N=444), n (%)	Vancouver Coastal Health Authority (N=231), n (%)	Total (N=675), n (%)
Lost wages	153 (34.5)	79 (34.2)	232 (34.4)
Local travel expenses	35 (7.9)	14 (6.1)	49 (7.3)
Out-of-province travel	29 (6.5)	20 (8.7)	49 (7.3)
Medical equipment and supplies	43 (9.7)	22 (9.5)	65 (9.6)
Home accessibility improvements	16 (3.6)	3 (1.3)	19 (2.8)
Lack of travel insurance	0 (0.0)	2 (0.9)	2 (0.3)
Private care because of wait times	3 (0.7)	4 (1.7)	7 (1.0)
Private care because of quality of service	3 (0.7)	3 (1.3)	6 (0.9)
Medications	28 (6.3)	15 (6.5)	43 (6.4)
Caregiver expenses	11 (2.5)	1 (0.4)	12 (1.8)
Complementary, alternative, or unproven treatments	34 (7.7)	22 (9.5)	56 (8.3)
Elective or uninsured direct medical expenses	36 (8.1)	22 (9.5)	58 (8.6)
Unspecified or other direct medical costs	53 (11.9)	24 (10.4)	77 (11.4)

Other common motivations for crowdfunding for health-related expenses included elective or uninsured direct medical expenses (68/685, 9.9%). The treatments sought included diagnostic testing, fertility treatments, physiotherapy, and dental treatment, among others. Some campaigns (65/685, 9.5%) sought help with purchasing medical equipment and supplies. This equipment was typically intended for home use after discharge from hospital. Other campaigns (56/685, 8.2%) sought to fund complementary, alternative, or unproven treatments including experimental interventions. These requests ranged from complementary cancer treatments such as acupuncture to naturopathic treatment for Lyme disease and unproven stem cell interventions abroad. Seeking financial support to cover travel-related costs was another common motivation for crowdfunding, including in-province (49/685, 7.2%) and out-of-province (49/685, 7.2%) travel. Those traveling in-province typically needed help with gas expenses and parking for medical appointments or relocation to be closer to a medical center. Out-of-province travel included help relocating within Canada or, more commonly, travel abroad to privately purchase medical care. Help paying for medications was requested in 6.3% (43/685) campaigns. These were typically prescription medications, as in the case where “some of my medical issues require prescriptions that are not covered which means that I can't get them.” Unspecified health-related expenses were the second largest category (77/685, 11.2%). All other motivation categories were under 5% of all instances.

Discussion

Principal Findings

Our exploratory findings show the scope of crowdfunding in one metropolitan region in Canada. Despite universal public insurance coverage for Canadian residents, at least 423 individuals living in the areas covered by FHA and VCHA initiated crowdfunding campaigns in 2018, raising nearly Can $3.5 million (US $2,541,886). These campaigns impacted a wide network, as they received nearly 28,000 pledges of donations and were shared on Facebook over 120,000 times. Given that these campaigns may have been shared on other social media platforms and each share is viewed by multiple individuals, the impact of these campaigns is considerable.

As has been reported elsewhere, seeking funds to assist with addressing the costs of treating and managing cancer is by far the most common underlying health issue motivating crowdfunding by Canadians [21]. Other medical conditions linked to the crowdfunding campaigns reviewed in this analysis are less discussed in this literature, including trauma injuries because of collisions, brain injury and stroke, heart disease, and spinal injuries. This may reflect specific health needs in the region analyzed or broader crowdfunding trends across Canada.

Our findings demonstrate that out-of-pocket expenses incurred by people who were accessing care provided by the publicly funded health system were by far the most commonly cited reasons for using medical crowdfunding. Lost wages because of illness and accessing treatment was by far the most common motivation, appearing in 54.8% (232/423) campaigns. This may indicate insufficient access to or other limitations in employment benefits for residents. Indirect expenses such as in-province and out-of-province travel to access care (98/423, 23.2%), purchasing medical equipment and supplies (65/423, 15.4%), and making home accessibility improvements were also common (19/423, 4.5%). Although some people sought funds to cover the cost of privately-paid-for medical care, the overwhelming majority of campaigns was effectively illustrating the limits of the support available to those accessing the public system.

The extant literature on barriers to Canadians accessing medical care focuses on wait times for care. And there is some concern that these wait times drive Canadians to privately purchase care domestically or abroad. Meanwhile, this motivation was rarely found in the campaigns reviewed in this analysis, appearing in only 1.0% (7/100) instances. Similarly, accessing care privately because of the perceived (low) quality of care in the publicly funded system appeared only 0.9% (6/700) times. When the direct provision of care motivated crowdfunding, it was generally not to access private care more quickly but to afford elective or other uninsured forms of care (68/423, 16.1%), complementary or alternative care not covered by insurance (56/423, 13.2%), and medication not covered by insurance (43/423, 10.2%).

These findings demonstrate that campaigns exhibit spatial differences regarding crowdfunding requests between those living in the FHA and VCHA areas. Although both FHA and VCHA campaigns listed cancer as the most common underlying health condition motivating the campaign, FHA and VCHA contained 44.3% and 33.6% of cancer-related campaigns, respectively. Similarly, heart and circulatory diseases and kidney disease were much more common in FHA. Conversely, 7.9% of FHA campaigns involved accident trauma injuries compared with 12.3% for VCHA, and 4% of VCHA campaigns were for gender affirmation treatments compared with 0.4% for FHA. Motivations for engaging in crowdfunding were generally consistent across this region, although home accessibility improvements were nearly three times more common in FHA and private care because of wait times was more than twice as common in VCHA. Usage of crowdfunding varied greatly across metro Vancouver and the Fraser Valley as well, with higher usage rates compared with the underlying population for Abbotsford and Maple Ridge and lower usage rates for Richmond and Surrey. These differences merit continued exploration, as they could reflect spatially specific difficulties in meeting health-related needs.

The most striking difference between these two regions was in terms of success in meeting crowdfunding goals. FHA campaigns were pledged 32.4% of their requests compared with VCHA’s 56.3%. Evidence is emerging that crowdfunding campaigns may increase inequities by linking fundraising success to socioeconomic advantages and disadvantaging marginalized communities [22,23]. Average total annual income per person is Can $93,808 (US $65,417; Vancouver) and Can $83,850 (US $58,472; Richmond) in the VCHA vs Can $84,023 (US $58,593; Fraser East), Can $90,386 (US $63,031; Fraser North), and Can $97,301 (US $67,853; Fraser South) [24]. Statistics Canada distinguishes these two health authorities as falling into distinctly separate peer groups, with FHA having greater rates of visible minorities compared with VCHA (very

high vs high) and Aboriginal residents (low vs very low) [25]. Life expectancies in VCHA and FHA are 84.4 and 82.8, respectively, and the infant mortality rates for VCHA and FHA are 3.0 and 3.3, respectively [26]. These socioeconomic and health inequality differences may be significant factors driving the differences in meeting campaign goals between those living in the FHA and VCHA regions. More generally, these findings raise questions as to whether the socioeconomic differences between regions are associated with differences in crowdfunding campaign success. However, this falls outside the scope of the current analysis and thus raises important implications for future research directions.

These findings can be used to support some existing arguments regarding the impact of insurance gaps and indirect medical expenses as pressing needs facing Canadians. Given current debates over medical prescription costs and PharmaCare expansion, this analysis demonstrates that such expenses are pushing some Canadians to turn to others for financial support to meet drug costs [27]. The prevalence of lost wages and travel expenses in these crowdfunding campaigns also show why indirect medical expenses must be part of the conversation of the social costs of ill health and gaps in social insurance. For example, this reflects public debates in British Columbia, where fees for parking costs at hospitals have been criticized as exploitative and unfair [28]. In total, 56 (13.2%) campaigns sought complementary and alternative medical interventions that, in some cases, are not evidence based, potentially risky to patients, and contain misinformation that is spread via these crowdfunding campaigns [29]. This finding can help inform debates about public funding for complementary and alternative treatments and confusion about their relationship to traditional, evidence-based treatment [30].

It is notable that some underlying health needs were largely not represented in these campaigns despite a prominent place in local discussion of the health system. Much recent discussion has taken place in metropolitan Vancouver around the opioid crisis, mental health and addiction issues, and the lack of adequate access to treatment to address these health needs [31]. However, these conditions were represented in only 1.6% (7/438) of the campaigns reviewed. This suggests that we should use campaigns to complement ongoing local dialog about health care but not replace other sources. Moreover, some of the most pressing health system priorities are a clear reflection of the socioeconomic gradient in communities. Noting that people were not crowdfunding for this care may add support to the literature that suggests that those who crowdfund are more educated and have higher socioeconomic status than the community at large.

Limitations

This analysis has two main limitations, given the data used. First, crowdfunding data are self-reported and may be inaccurate. For example, the location of the campaign reflects the location of the campaign maker, who may be different from and in a different location than the campaign recipient. Campaigns were carefully reviewed to exclude cases where the recipient was clearly outside of the geographic area of interest. Second, because crowdfunding campaigns can be deleted, and data were collected in early 2019, many campaigns from the VHA and VCHA regions were likely not included in our findings. Thus, the findings here likely represent an undercount of the total crowdfunding activity in the FHA and VCHA.

Conclusions

This analysis demonstrates the potential of crowdfunding data to present timely and context-specific user-created insights into the perceived health-related financial needs of some Canadians. Such insights can complement those generated by other sources, such as administrative and census data and even media and public discussions about health system reforms. New crowdfunding campaigns are being generated on an ongoing basis campaign-based data can be used to identify trends in perceived health-related financial needs as they develop as well as service gaps. These data are also context specific and thus can help to inform policy makers, patient advocates, health workers, and other stakeholders' perceived health system deficiencies that lead to financial burdens for residents of Canada. Importantly, not all of the health-related needs described in these campaigns should be interpreted as identifying health and social system gaps that must be addressed. That said, a better understanding of trends around practices that fall well outside the scope of the Canada Health Act, such as accessing unproven medical interventions and traveling abroad for care, are also useful for health system stakeholders. This is because practices such as these have been shown to potentially introduce health system burdens and create ethical challenges for physicians [32].

We encourage the development of new resources to harness the power of crowdfunding data as a supplementary source of information for Canadian health system stakeholders. Although the findings of this study demonstrate the potential of these data to shed additional light on perceived health system deficiencies, they also show that context is of great importance in using these data. Despite their geographic proximity, the crowdfunding campaigns from these two health regions showed noteworthy differences between the percentages of requested funding that received. This finding lends support to existing questions about what factors determine crowdfunding success and whether this reflects larger social inequities. Finally, more research on crowdfunding campaigns across Canada, including those in rural settings, will allow regional differences in crowdfunding motivations and success to be identified.

Authors' Contributions

All authors reviewed the data, identified motivation themes, and edited the manuscript. JS wrote the manuscript. MZ cleaned and coded all data.

Abstract

Background: There is increasing interest in shared decision making (SDM) in Australia. Question prompt lists (QPLs) support question asking by patients, a key part of SDM. QPLs have been studied in a variety of settings, and increasingly the internet provides a source of suggested questions for patients. Environmental scans have been shown to be useful in assessing the availability and quality of online SDM tools.

Objective: This study aimed to assess the number and readability of QPLs available to users via Google.com.au.

Methods: Our environmental scan used search terms derived from literature and reputable websites to search for QPLs available via Google.com.au. Following removal of duplicates from the 4000 URLs and 22 reputable sites, inclusion and exclusion criteria were applied to create a list of unique QPLs. A sample of 20 QPLs was further assessed for list length, proxy measures of quality such as a date of review, and evidence of doctor endorsement. Readability of the sample QPL instructions and QPLs themselves was assessed using Flesch Reading Ease and Flesch-Kincaid Grade Level scores.

Results: Our environmental scan identified 173 unique QPLs available to users. Lists ranged in length from 1 question to >200 questions. Of our sample, 50% (10/20) had a listed date of creation or update, and 60% (12/20) had evidence of authorship or source. Flesch-Kincaid Grade Level scores for instructions were higher than for the QPLs (grades 10.3 and 7.7, respectively). There was over a 1 grade difference between QPLs from reputable sites compared with other sites (grades 4.2 and 5.4, respectively).

Conclusions: People seeking questions to ask their doctor using Google.com.au encounter a vast number of question lists that they can use to prepare for consultations with their doctors. Markers of the quality or usefulness of various types of online QPLs, either surrogate or direct, have not yet been established, which makes it difficult to assess the value of the abundance of lists. Doctor endorsement of question asking has previously been shown to be an important factor in the effectiveness of QPLs, but information regarding this is not readily available online. Whether these diverse QPLs are endorsed by medical practitioners warrants further investigation.

KEYWORDS

question prompt list; shared decision making; environmental scan

Introduction

The role of shared decision making (SDM) as a part of patient-centered care in clinical consultations is being increasingly recognized as having positive outcomes for patients [1]. Internationally, there are efforts to make SDM a part of routine health care [2]. The National Safety and Quality Health Service Standards (Second Edition) developed by the Australian Commission on Safety and Quality in Health Care include a statement that "Integral to the process is encouraging patients to be more involved and ask their doctor more questions during consultations" [3]. To facilitate patient question asking as a part of SDM, question prompt list (QPL) tools have been developed, and some have been evaluated and published in the peer-reviewed literature, some of which are available via the internet [4,5].

Increasingly, people are turning to the internet for health information [6]. Search engines are the predominant tool used by people to search for health information online [7]. In 2018, 78% of Australian adults reported using the internet to find health-related information [8]. Online QPLs are being used, and those using online question lists have been shown to prefer questions that specifically support SDM [9]. Physician endorsement has been found to be key to the successful implementation of QPLs into practice [4]. Similarly, a dominant factor for patient online health information seeking on the doctor-patient relationship is the doctor's willingness to discuss the information [10].

With an increasing focus on question asking in consultations, many websites include lists of questions for someone to take to their doctor as an additional resource [11-13]. While there has been some research into the implementation of QPLs into practice, there has not been an assessment of the prevalence of such lists available online [5]. Given that online material can be created and hosted by anyone and there is no regulation of the quality of information or available tools, a study of these QPLs is warranted [14]. Assessing the readability of QPL resources as well as their prevalence is important in addressing usefulness.

Adequate literacy and health literacy of patients are important in the use of tools to support question asking and SDM [15]. In their systematic review published in 2012, Sørensen et al [16] identified several competencies of health literacy around having the ability to access, understand, and use information to make decisions about health. Supporting people with lower health literacy by making such tools readable and accessible is one way to increase access to SDM [15]. Several standards exist for the readability of patient information and other SDM tools such as decision aids, to increase the accessibility of materials for target audiences [17].

While standards exist for assessing the quality of patient information resources, such as the adaption of DISCERN for internet information [18,19], there is ongoing difficulty in assessing the quality of online medical information and resources as well as how users perceive and use that information [20-23]. In addition, there are factors other than the information itself that influence information preferences, such as domain bias [24] and webpage design [21]. For example, the extension ".com" is used for commercial sites, while ".edu," ".gov," and others denote non-commercial or government sites. Domain extensions have some bearing on how users view the information provided and their trust in the source [24,25].

Environmental scan processes have previously been used to assess available online decision aids and risk calculators [26,27]. They allow a real-time snapshot of the availability of online resources available to users. The aim of this study was to conduct an environmental scan to describe and assess the number and readability of QPLs readily available to health consumers in the online environment.

Methods

Overview

We used a previously published methodology to conduct an environmental scan to search Google.com.au for question lists relating to patient-doctor clinical interactions [27]. Google.com.au was chosen as it is the most frequently used search engine in Australia (94.11% as of Dec 2018) [28]. To assess the number of question lists available to health care consumers online, 2 stages were needed. A third stage involved the assessment of the readability of a sample of QPLs and their instructions.

Stage 1: Choice of Reputable Websites and Search Term Development

The authors have expertise and backgrounds in nursing and medicine; knowledge of organizations and websites used by health professionals and consumers was used to identify a range of reputable organizations' websites to reflect the clinical areas in which QPLs have been studied [4]. The aim was to ensure that selected sites included both disease-specific lists (eg, cancer websites, parent information about their child's attention deficit hyperactivity disorder) as well as sites with more generic lists, such as those with consumer health information. We also aimed to ensure a mix of local (Australian) and international organizations with patient-focused information. The final list of 22 URLs for these organizations was decided by consensus between the authors (Table 1). These websites were accessed via the URLs to confirm that they referred to, or included, QPLs.

Using previous systematic reviews of QPLs and citation snowballing, we found 11 terms in the published literature that have been used to describe patient question lists [4,29]. In addition, the reputable organization list websites were accessed to find the language and terms used to describe QPLs on these sites; there were a further 9 terms found. Using these 2 sources, we had a total of 20 search terms for use in Stage 2 of the scan (Table 2).

Table 1. URLs of the 22 selected reputable websites.

Site or organization type, organization	URL
Consumer-directed organizations	
Healthdirect Australia Ltd.	healthdirect.gov.au
Consumers Health Forum	chf.org.au
Information about medicine or prescribing	
National Prescribing Service – Choosing Wisely	choosingwisely.org.au/home

Patient question asking support tool	Literature

[a]NPS: National Prescribing Service.

[b]NSW: New South Wales.

Stage 2: Search Strategy

A systematic search of Google.com.au using each of the 20 search terms was then conducted by 2 independent researchers (MT and PP), one term at a time after clearing the browser cache. The first 100 URL results for each term searched were downloaded to Excel spreadsheets and included in the first round. Users of Google have a strong bias to the order of results presented by Google [30], and few users look for a result beyond the first results page [31]. There are only 10 results displayed on the results page with Google's default settings. We aimed to assess the breadth of lists available with our search terms, which was the reason for assessing the first 100 results for each term.

Inclusion Criteria

Websites, accessed via search URLs, included in the evaluation needed to meet the following criteria: provide a list of questions; question lists were described as for use by patients, carers, or parents in medical consultations (general practitioner or specialist medical consultations); lists were freely accessible (without registration or requiring payment); lists were written in English; and lists were visible as part of the website, not requiring downloading to be viewed, such as video files.

Exclusion Criteria

Websites or lists were excluded if the question list stated it was for doctor's use; the use of the question list required additional supporting software, such as third-party document viewers; the website required registration or incurred a cost to access the question list; the list was on a sponsored site, such as a paid site that appears before the search results; the list required downloading to be able to be viewed, such as video files; the list was provided in an academic paper, unless the journal was aimed at consumers and the list was visible; and questions list was not focused on general practice and specialist consultations (eg, counselling for entry into clinical trials). URLs blocked by the university security software system were also not included as they were deemed a potential threat.

The inclusion and exclusion criteria were then applied to the data by opening each of the URL links, again by MT and PP. Discrepancies regarding inclusion were resolved using a third reviewer (HS). Where there were duplications of lists, such as where the question list was identified on the website as sourced from another site or the webpage linked to a list already included in the review, these sites were then excluded to ascertain the final number of unique lists.

Further data about the URLs, websites, and lists were also collected. All URLs were assessed for the URL domain extension (ie, .edu, .com, .org). A sample of 20 lists was collated

to consist of 10 URLs from the reputable organizations and, for comparison, a further 10 lists from other sites were selected using random number generation and matching to URLs from the Excel spreadsheet. The sample lists were assessed for the date of creation, review, or update, if available (copyright date for the website was not considered to be an indication that the website material had been reviewed); any evidence of review of the page, such as the name of a writer or reviewer; and an assessment of the number of questions in the lists.

Stage 3: Readability

To assess the readability of the QPLs and their instructions for use, we utilized the Flesch Reading Ease (FRE) and Flesch-Kincaid Grade Level (FKGL) scores. The FRE is one measure of the complexity of a piece of text and is a score between 0-100 calculated using average sentence length and the average number of syllables of words in the text [32]. The higher the FRE score, the easier the text is to read. The FKGL uses the same data with different weightings with a result that equates to the number of years of schooling (in the United States) required to read the text [33]. We applied these formulae to the sample lists. Each of the 20 URLs were accessed again, and both the online instructions for use (or the available preamble to the question list) and then the list of question(s) were copied into separate documents. The readability tool was then applied to the copied texts to calculate FKGL and FRE scores (Table 3).

Table 3. Description of reading ease scores, reproduced from Flesch [32].

Flesch Readability Scores (reading ease), points	Description of style
90-100	Very easy
80-89	Easy
70-79	Fairly easy
60-69	Standard
50-59	Fairly difficult
30-49	Difficult
0-29	Very confusing

Results

Following removal of duplicates from the 4000 URLs and 22 reputable sites and the application of the inclusion and exclusion criteria, there were a total of 235 lists. A further review of websites revealed 62 instances of list duplication (eg, links to reputable lists and multiple uses of a list within an organization). Using our search method, 173 unique lists were identified. See Figure 1 for the study diagram of the search. There were 15 websites that had lists used, referred to, or had links to them from other websites; 9 of these were from our reputable website list, which accounted for 46 links.

We noted a wide range in the number of questions in resources, from a single question to over 200 questions in a single resource. The most common URL domain extension was .org (115/235, 48.9%), followed by .com (63/235, 26.8%), .gov (24/235, 10.2%), .edu (11/235, 4.7%), and country code extensions such as .uk and .ca (18/235, 7.7%). More detailed analysis of the sample of 20 lists found that the number of questions ranged from 3 to 56 (mean 20.5 questions, mode 3 questions, median 18 questions; Table 4). Half (10/20, 50%) of the sample lists had a date of creation or review, with the range being 2002 to the date of the preliminary review, October 29, 2018. Evidence of authorship of the QPL was available for 80% of the reputable sample sites and 40% of the other sample sites.

Table 4 also shows the readability data scores for the 20 sample lists and their online instructions. The FRE scores were higher for lists from the reputable sites compared to other sites and for question lists compared to instructions. Similarly, the grade level required to read question lists was lower than for the instructions, with reputable sites also requiring lower grade levels for readability of instructions than for other sites.

The readability was found to be easier on the reputable websites compared to the other websites, with scores showing content ranged from “very easy” to “fairly easy” for question lists and from “easy” to “difficult” for the instructions.

Figure 1. Search strategy and results.

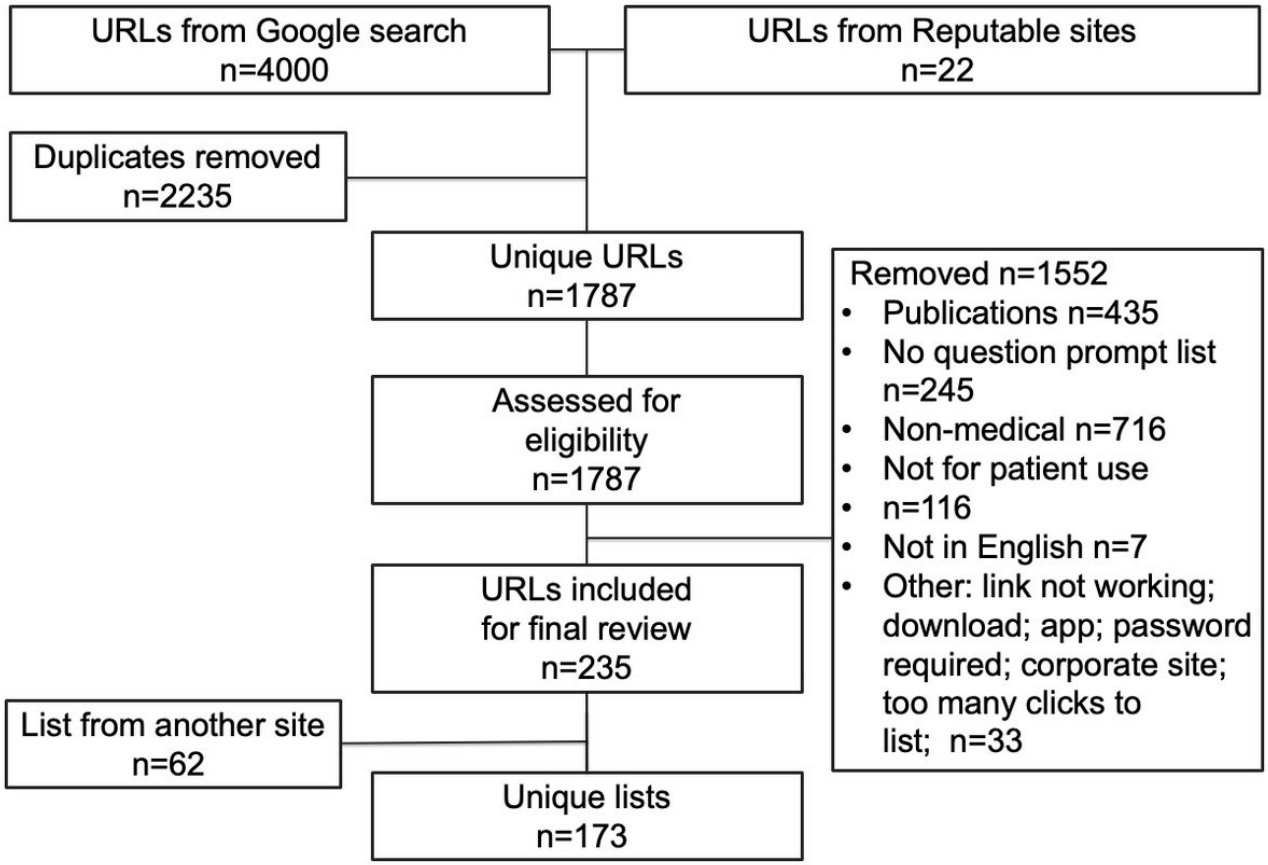

Table 4. Sample list data: readability of instructions and question lists, number of questions, source/author information, and date of creation or review.

Organization or website	Instructions and/or introduction for list		Question list		Number of questions	Evidence of source or author	Date of creation or review

Discussion

Principal Findings

This environmental scan of the internet for patient QPLs designed for use by patients to ask questions when seeing a doctor identified 173 unique lists on 235 websites. Of the lists found in our search, 15 lists had been used by other websites, with the majority (9/15) of these lists from our original list of reputable websites. The remaining duplicated lists were also from websites we regarded as reputable. In addition, there remained an abundance of advice to users about questions they could, or should, be asking at medical appointments from a wide variety of sources.

We noted that question lists appeared in a wide variety of types of websites, both from the categories of our reputable websites, such as government health information websites (eg, Healthdirect Australia) and disease-specific websites (eg, Cancer Council Australia and America), and from news websites (eg, globalnews.ca), commercial sites and blogs (eg, yourgpsdoc.com), sites of charities (eg, thebraintumourcharity.org), and educational institution websites (eg, sydney.edu.au). URL domain extensions do not always reflect the type of institution publishing the site and materials, yet they influence the user perception of site information [23]. While the source of medical information has not been shown to correlate with the accuracy of medical information [23,34], we noted the majority of lists came from .org extensions, which are generally associated with non-commercial organizations.

While there are detailed and extensive guidelines for the development of decision aids [17], there are currently no accepted standards that apply to QPLs. Many indicators of the quality of patient health information websites have been used in the past, with few variables showing any correlation to information quality, as measured by the accuracy or currency of information presented [34]. Display of creation and update dates, the age of the site, authorship, and URL extension have not been found useful in assessing sites. Our findings of these "quality" indicators were similar to other investigations of online patient materials in these respects. The sample QPL websites had higher rates of display of creation or update dates than those in previous studies of health information on the internet [23,34]. Display of some form of authorship or attribution of the sample materials was also higher than in similar studies of online health resources [23,34]. This is likely due to at least half of the sample being what we regarded as reputable.

In our environmental scan for online QPLs for use when attending a medical appointment, it was unclear in most cases whether doctors endorsed the questions for use in consultations. Prior research has shown that doctor endorsement significantly improves the use of QPLs by patients [4]. There were a couple of exceptions where the lists were placed on the website of particular practitioners where it could be assumed that the doctors in that practice supported patients using the questions included in the lists. In general, however, we were not able to ascertain specific endorsement by medical practitioners for the lists in practice. Further qualitative research to determine doctors' views on implementing such a wide variety of QPL resources into practice is needed.

Our results show that there is room for improvement in the readability of instructions for using online QPLs. International Patient Decision Aid Standards recommendations for reading grade level for decision aids is a less than an 8th grade level [35]. While all the QPLs in the sample we tested had a grade level that met the International Patient Decision Aid Standards recommendations, accompanying instructional text was often well above this level, especially in our "other" website category.

Strengths and Limitations

By utilizing the strengths of the environmental scan method, we were able to rapidly assess the online environment, where most Australians look for health information, for the presence of QPLs. While literature reviews have been able to show the benefits of QPLs in practice, no assessment has been made of the number and availability of similar tools in the real-world environment. The online environment changes rapidly, and this scan provides a survey at a point in time of what is available to users. Our search tool was Google.com.au; hence, a similar search strategy in other countries might yield different results. We also limited our search to sites in English.

We noted website updates occurring even as we reviewed the websites; if the scan was to be replicated in the future, the results may be different. Further assessment of the quality of the lists beyond readability would provide additional information. Some proxy measures were used to assess sites, even though the presence of, for example, a date and authorship has been shown to have little correlation with quality. It is not clear which, if any, QPLs we discovered have been evaluated for their efficacy in improving patient and doctor outcomes in consultations.

It is unlikely that Google users might search specifically for question lists using the search terms we used. We were not testing the utility of terms to find QPLs; rather, the intent of our search and choice of search terms were to find as many as possible of the question lists available to users. Research into how users actually access, assess, and use these resources is warranted.

Conclusions

People seeking information on Google.com.au have a vast number of question lists available to them to use in consultations with their doctor. Surrogate markers of the quality or usefulness of various types of online QPLs have not yet been established, which makes it difficult to assess the value of the abundance of lists. Quality measures for QPLs should follow further assessment of usage and endorsement.

Physician endorsement has been shown to be an important factor in the usefulness of QPLs, but there is little information to suggest whether the QPLs found in this scan would be endorsed by physicians. Whether these diverse QPLs are endorsed by medical practitioners warrants further investigation.

Ensuring that online QPLs and the instructions for their intended use are accessible to patients is important. To improve usage of online QPLs, instructions for their use should have an equivalent readability or at least be accessible to the majority of people in the target groups for which the lists have been created.

Abstract

Background: Theoretical models help to explain or predict the adoption of electronic health (eHealth) technology and illustrate the complexity of the adoption process. These models provide insights into general factors that influence the use of eHealth technology. However, they do not give hospitals much actionable knowledge on how to facilitate the adoption process.

Objective: Our study aims to provide insights into patient portal adoption processes among patients and hospital staff, including health care professionals (HCPs), managers, and administrative clerks. Studying the experiences and views of stakeholders answers the following question: How can hospitals encourage patients and HCPs to adopt a patient portal?

Methods: We conducted 22 semistructured individual and group interviews (n=69) in 12 hospitals and four focus groups with members of national and seminational organizations and patient portal suppliers (n=53).

Results: The effort hospitals put into adopting patient portals can be split into three themes. First, inform patients and HCPs about the portal. This communication strategy has four objectives: users should (1) know about the portal, (2) know how the portal works, (3) know that action on the portal is required, and (4) know where to find help with the portal. Second, embed the patient portal in the daily routine of HCPs and management. This involves three forms of support: (1) hospital policy, (2) management by monitoring the numbers, and (3) a structured implementation strategy that includes all staff of one department. Third, try to adjust the portal to meet patients' needs to optimize user-friendliness in two ways: (1) use patients' feedback and (2) focus on optimizing for patients with special needs (eg, low literacy and low digital skills).

Conclusions: Asking stakeholders what they have learned from their efforts to stimulate patient portal use in hospitals elicited rich insights into the adoption process. These insights are missing in the theoretical models. Therefore, our findings help to translate the relatively abstract factors one finds in theoretical models to the everyday pragmatics of eHealth projects in hospitals.

KEYWORDS

patient portal; adoption; adoption processes; eHealth

Introduction

Electronic health (eHealth) technology is generally considered promising for improving both the well-being and health of patients and the efficiency and effectiveness of the health care organization [1]. However, several studies show that its promise is not always fulfilled [1] and the results on the benefits gained are diverse [1,2]. This also applies to patient portals [2], which have sparked the interest of researchers, government policy makers, and health care organizations.

Previous studies define a patient portal in various ways [3-7]. Some consider them the same as a personal health record (PHR) [3]. Others regard them as a class of PHR [4]: whereas health care organizations own and control patient portals, PHRs are owned and controlled by patients themselves [5]. Grünloh et al

[6] define patient portals as "provider-tethered applications that allow patients to access, but not to control, certain health care information (eg, their EHR [electronic health record]) and provide communication and administrative functions (eg, secure messaging, appointment booking, and prescription refill requests)." Wildenbos [7] adds the possibility of authorizing informal caregivers to share access to patient portals.

Despite its technological focus and aim, the success or failure of a patient portal relies on how it is used by patients and staff, such as health care professionals (HCPs), managers, and administrative clerks [1,2,8]. A systematic review shows often-limited use by patients and HCPs for seven nontechnical reasons [2]: (1) patients worry about the confidentiality of their personal health data, (2) patients are unaware of the portal, have no digital access, or think it will not be useful, (3) patients have low health literacy or find using the portal too complicated, (4) HCPs worry about increased workload and disruptions to their usual tasks, (5) HCPs lack the digital skills to interact with patients, (6) HCPs worry that they cannot respond fast enough to patients' questions, and (7) HCPs are concerned that they can be held liable [2]. All seven reasons hinder the adoption of patient portals [2].

Researchers have developed theoretical models to explain or predict the adoption of eHealth technologies, including patient portals. Two systematic reviews on information technology adoption both mention three frequently used acceptance and adoption models [9,10]. Strikingly, these three general models are applied in all societal domains, not just health care [9]. Table 1 details these most-used models to facilitate an understanding of their ideas on the adoption process [9-20]. The table also includes the recently developed NASSS (nonadoption, abandonment, scale-up, spread, and sustainability) framework [21,22].

Table 1. Theoretical acceptance and adoption models.

Model	Developer	Year	Theoretical basis	Central constructs	Points of critique	Extended models
TAM[a]	Davis [9,11,12]	1985	Cognitive psychology [13]	Describes elements to predict the degree to which a person plans to perform specific future behavior. It suggests that perceived usefulness, perceived ease of use, and attitude (ie, intention to use) can explain user motivation [12]. It is a way to predict the intended use of a technology.	Mainly conceptualized for the acceptance of individuals and is not useful for explaining acceptance of electronic health (eHealth) technologies by organizations [11,14].	TAM2 (by Venkatesh and Davis) and TAM3 (by Venkatesh and Bala) [9,12]
DOI[b]	Rogers [9]	1995	Diffusion research [18]	Explains the characteristics of innovation. Observability, trialability, complexity, relative advantage, and compatibility are the primary determinants of innovation diffusion, which help explain the different rates of adoption [9,15]. Diffusion starts with recognizing the user's need. It spreads by knowledge acquisition, persuasion, decision (ie, adopt or reject), implementation (ie, routine use, reinvention, and conformation), promotion, and evaluation [15].	There is little focus on the organizational context [14,16,17].	The unifying theoretical model of Greenhalgh et al [16] and the Consolidated Framework for Implementation Research (CFIR) of Damschroder et al [17,18]
UTAUT[c]	Venkatesh et al [9,19]	2003	Cognitive psychology [13]	Builds on TAM and focuses on perceptions and assumptions of people, resulting in the intention to use technology. States that constructs like performance expectancy, effort expectancy, social influence, and facilitating conditions influence intention and ultimately behavior [19]. These four constructs are moderated by gender, age, experience, and voluntariness of use [19].	Does not deal with hindrances to actual use [13]. Excludes users' cognitive, affective, and physical ability to use technology [20] and ignores technological factors that might influence the decision to use an application [20].	UTAUT2 by Venkatesh et al developed in 2012 [9]
NASSS[d] framework	Greenhalgh et al [21,22]	2017	Complexity theory [21,22]	Points to aspects explaining the complexity of technological innovations in health care, which according to all the described models influence the adoption. Includes the value proposition (ie, supply-side and demand-side values) as an important factor, in contrast to many implementation theories that do not [14,21].	Not found yet	Not found yet

[a]TAM: Technology Acceptance Model.

[b]DOI: diffusion of innovations.

[c]UTAUT: Unified Theory of Acceptance and Use of Technology.

[d]NASSS: nonadoption, abandonment, scale-up, spread, and sustainability.

All four theoretical models include two key concepts—acceptance and adoption—which are either ill-defined or used interchangeably. The concept of acceptance focuses on if, how, and when intended users would use a technology [23], and adoption is the actual use of an eHealth technology. Different stages in an adoption process can result in the actual use of an eHealth technology [16]. During an adoption process, users of eHealth technology develop feelings about the technology, gain experience, find meaning or do not find meaning in its use, and evaluate the functions of the technology [16]. Thus, there is a difference between intended use (ie, acceptance) and actual use (ie, adoption) [13].

The complexity of the adoption process of eHealth technologies is underexposed in all four theoretical models. The literature reports that adoption is a highly complex process and that results cannot be *made* or even predicted [13,16]. Greenhalgh et al highlight specific prerequisites for each of the three adoption process stages for innovations [16]: (1) in the preadoption stage, intended adopters should know about the innovation: in this case, the patient portal, (2) in the early use stage, intended adopters should be supported in using the innovation and learn how to fit or blend it into their daily routines, (3) in the adoption stage, established users arise if they gain an understanding of the consequences of using of the innovation and if they have the opportunity to refine and improve it: in this case, a patient portal [16]. The theoretical models provide no clarity on the pragmatics of efforts in the adoption process. For instance, they do not show how hospitals can encourage patients and HCPs to adopt a patient portal. Therefore, we studied the introduction of patient portals in 12 Dutch hospitals, using a multi-actor perspective to gain a broad understanding of the experiences and views on adoption. Our empirical study focuses on the pragmatics of stimulating the adoption of a patient portal. This paper answers the following research question: How can hospitals encourage patients and HCPs to adopt a patient portal?

Methods

Design and Setting

In this qualitative study, we asked participants from various backgrounds how they encouraged users to adopt a patient portal and what they had learned from their efforts, in order to understand what stimulated or hindered the adoption process. We conducted 22 multi-actor, semistructured group interviews and held four structured focus groups to check, enlarge, and enrich our findings [24-26]. Table 2 lists the different forms of data collection.

Table 2. Data collection.

Type of data collection and participants	Number of participants (N=122), n (%)	Data collection moments (N=26), n (%)
Individual and group interview		
Patients	22 (18.0)	22 (85)
Health care professionals	16 (13.1)	22 (85)
Organizational staff	31 (25.4)	22 (85)
Focus group		
Project leaders and staff 1	14 (11.5)	2 (8)
Project leaders and staff 2	28 (23.0)	2 (8)
Patient portal suppliers	5 (4.1)	1 (4)
Macro stakeholders	6 (4.9)	1 (4)

All interviews, both group and individual, and focus group sessions took place in a hospital or online. All the hospitals included in this study are participating in a national program—VIPP (Versnellingsprogramma Informatie-Uitwisseling Patiënt en Professional) [27]—initiated by the Dutch Hospital Association and the Dutch government. VIPP is the Dutch government's financial incentive program to support information exchange between patients and professionals through patient portals. The aim of the VIPP program is to give patients online access to their medical data, either through a patient portal or a PHR [27]. Information technology (IT) suppliers with a commercial interest deliver patient portals and PHRs. Given that Dutch hospitals are free to choose any supplier for their patient portals or PHRs, the hospitals in this study use different patient portals. The portals might differ in their available functionalities, but they all offer patients online access to their personal health information [6]. Additionally, hospitals had different aims for their patient portals; only the VIPP program aims were similar for all Dutch hospitals. Hospitals receive financial support based on their achievement of specific national VIPP aims; for example, "In the past 30 days, 25% of all patients (based on DRG [diagnosis-related group] contacts) logged in to the patient portal or the link to a PHR" [28]. How hospitals achieve these aims is left up to the hospital.

Recruitment and Participants

There are three categories of Dutch hospital: academic, teaching, and general. Academic hospitals were excluded from our study because at the time they were not participating in the VIPP program. We first determined inclusion criteria for general and teaching hospitals, aiming for a diverse study group. Based on user statistics of patient portals (low and high), geographical differences (rural areas and cities), variation in patient portal suppliers, and usage of the patient portal (more or less than one year), the researchers (PH, AMWJ, and BP) made a selection of targeted hospitals.

In total, 15 of 64 Dutch hospitals (23%) were approached, of which 12 (80%: 10 teaching and 2 general) agreed to participate. Reasons for not participating included "already participating in another study" (n=1) and "too busy with implementation and fear of not meeting VIPP deadlines," which would mean losing financial support (n=2).

At each hospital or via the Zoom online platform [29], the researchers arranged individual and group interviews in close collaboration with the person running the implementation of the patient portal at that particular hospital. Most often, this person was the project leader who selected participants according to a predefined list of three roles:

1. Patients: patients and client council members (n=22).
2. HCPs: physicians, Chief Medical Information Officers (CMIOs), nurses, Chief Nursing Information Officers (CNIOs), pharmacists, and outpatient clinic staff (n=16).
3. Organizational staff: project leaders, project staff, communication advisors, legal policy makers, and managers (n=31).

In total, 69 participants were included (see Table 2) if they were older than 18 years and had experience with developing and/or using a patient portal. The researchers emailed invitations to participants of the individual and group interviews; groups ranged from 2 to 6 participants. In 10 of the participating hospitals, we organized one or two group interviews; in the remaining two hospitals we conducted one individual interview for logistical reasons.

The aim of the focus groups was to check, enlarge, and enrich our results. Two of the four focus groups were held with project leaders and project staff of hospitals. They joined one of two self-selected focus groups organized during an educational meeting of the VIPP program (n=14 and n=28, respectively). For the other two, we used targeted sampling, selecting experts from patient portal suppliers (n=5) for the third group. The fourth group included macro stakeholders: Ministry of Health, NICTIZ (Nationaal ICT Instituut in de Zorg), the center of expertise for eHealth, health insurance companies, and scientific experts (n=6). All focus group members were invited to take part by email.

Data Collection and Analysis

Qualitative data were collected on-site in the hospital (n=59) or online via the Zoom platform [29] (n=10) in the fall of 2018. The Zoom platform enabled the inclusion of hard-to-reach, geographically dispersed participants [30]. Group interviews lasted an average of 72 minutes (range 53-88) and the individual interviews lasted an average of 53 minutes (range 44-65). One researcher (PH) conducted all the interviews, following a predefined topic list (see Multimedia Appendix 1) [31] that was based on a search of the literature and discussed among the research team.

The four focus groups lasted an average of 82 minutes (range 71-88) and were steered by a Microsoft PowerPoint presentation explaining the findings of our study. No revisions were made in the presentation between focus group sessions, ensuring that varying opinions were heard before conclusions were drawn [32]. Each focus group was run by two researchers (PH and BP or PH and AMWJ) complementing each other: one moderating and the other taking notes.

During both group interviews and focus group sessions we encouraged the exchange of heterogeneous views that provided insights into similarities and differences in the opinions and experiences of the various stakeholders [26,30,31]. We also invited the participants to challenge each other's views [33], to explore the implications of their thinking, and to articulate their sometimes-implicit assumptions about the adoption process. This method generated new insights through group interactions.

We audio-recorded the on-site interviews and focus groups and video-recorded the online sessions. All interviews were transcribed verbatim. Analysis, comprising six phases [34], was not linear but a recursive process. First, each individual researcher gave the transcripts a close reading. Second, one researcher (PH) developed codes for the interesting parts of the data. Next, three researchers (PH, AMWJ, and BP) independently developed themes, reaching consensus on a list of relevant themes (eg, communication channel, ambassadors, and patient participation [35]) through discussion. Fourth, one researcher (PH) read the transcripts again. Fifth, using the list of themes, one researcher (PH) performed thematic coding, which two other researchers (AMWJ and BP) checked. In the final phase we (PH, AMWJ, and BP) started writing the results [34].

Ethical Approval

The Medical Ethics Review Committee of Erasmus Medical Center (Erasmus MC) approved our research proposal (MET-2018-1531) and checked if we were General Data Protection Regulation (GDPR) compliant. All participants were asked to sign an informed consent form.

Results

Overview

Our study aims to provide insights into the adoption process of a patient portal by patients and HCPs. The efforts of hospitals to stimulate the use of patient portals can be categorized under three themes: (1) informing patients and professionals about the patient portal, (2) embedding the patient portal in the daily routine of HCPs, and (3) adjusting the portal to patients' needs in the initial and continuous development process. Below we present our empirical findings for each of these themes.

Informing Patients and Health Care Professionals About the Patient Portal

Overview

Participants agreed that communication about the patient portal is very important for the adoption of patient portals. The hospitals require the involvement of communication experts to inform patients and HCPs. We identified four objectives to support patient portal adoption using the informing of patients and HCPs as the basis. Here we explain them one by one. Participants mentioned using 23 communication channels to reach their audiences (see Table 3).

Table 3. Channels (N=23) used to achieve four communication objectives to inform patients and health care professionals.

Channel	Knowing about the portal	Knowing how the portal works	Knowing that action is required on the portal	Knowing where to find help with the portal
Pocket tickets	x[a]			
Promotion leaflets	x			
Press releases	x	x		
Posters	x			
Banners	x			
Screen in waiting room	x	x		
Social media	x			
Video on website	x	x		
Explanatory leaflets	x	x		
Students or volunteers in central hall for a week	x	x		x
Physical point with employees and volunteers	x	x		x
Health care professionals	x	x	x	x
Letter with request (before or after appointment)			x	
Text message with request			x	
Mail with request			x	
Staffed desk				xxx
Informative meetings	xx			
Interactive meetings	xxx	xxx		
Internal website	xx			
Peer to peer	xx	xx	xx	xx
Training	xx	xx	xx	
Newsletter	xx			
Goodie bag with explanation	xx	xx		

[a]Key: x = patients; xx = professionals; and xxx = patients and professionals.

Objective 1: Knowing About the Portal

First, participants argued that it is obviously necessary to make sure that patients and HCPs know about the patient portal; otherwise, they cannot use it. Meeting this objective means that patients and HCPs will have a general idea of what the portal is and what it looks like. The hospitals used various mass-focused channels most frequently to communicate the existence of the portal to patients and HCPs. These channels include leaflets and posters, banners hung in the corridors, messages on social media, and placing volunteers in the central hall of the hospital to point patients to the portal. Using multiple channels to reach patients is considered important because patients have different preferences, but it is probably a bit inefficient, as these quotes illustrate:

> *I am not inclined to take leaflets from the hospital. If it's really important, I think I will be reminded.* [Participant #0.4, client council member]

> *All those freebies [goodie bags], I don't like them. They won't get me to look at the portal.* [Participant #14.2, patient, informal caregiver, and former client council member]

> *Still, it works for others.* [Participant #11.4, client council member]

Looking at the channels used to reach HCPs, we see hospitals organizing informative presentations for medical and nursing staff and department meetings. Participants felt that informing only the team leaders and managers is not enough; it is important to directly inform the HCPs. According to participants, effective channels that reach broad groups of professionals include department meetings, the hospital intranet, and the staff newsletter. Reaching out by email is considered inefficient because HCPs receive a lot of email and particular messages can be easily missed or skipped.

Objective 2: Knowing How the Portal Works

Second, participants argued that patients and professionals need to know how the patient portal works. Hospitals can meet this objective by (1) using video screens in waiting rooms, (2) putting explanatory videos on the hospital website, and (3) placing volunteers in the central hall of the hospital to teach patients how the portal works.

Hospitals asked professionals who are already successful portal users to explain how the portal works to their peers (ie,

peer-to-peer information). One hospital gave their professionals a goodie bag with explanatory flyers during portal training, but only a few hospitals organized training sessions on new functionalities for HCPs. However, the participants said that HCPs need to know how the portal actually works as patients sometimes turn to them for help with portal questions:

> *So often I hear that people can't log in to the patient portal. I think that as staff we should be looking into the portal far more. How does it actually work for the patient in practice?* [Participant #1.2, staff member]

If the HCP has to tell the patient that they do not know how to help, this can be a disappointment. One participant reflected the following:

> *Lots of patients say, "I'm logged in but then I don't know [what to do]." Many colleagues say, "I don't know either." If you can't help the patient, they'll drop out immediately.* [Participant #5.5, senior doctor's assistant]

Objective 3: Knowing That Action Is Required on the Portal

A third objective is to entice patients and HCPs to visit the portal. Hospitals did this by sending specific calls to action, including personal letters, text messages, or emails asking the recipient to read through an online brochure on their treatment before their hospital appointment or to fill in a questionnaire:

> *Your appointment letter also asks you to complete the pre-operative screening questionnaire at home.* [Participant #9.1, communication advisor]

Hospitals encouraged HCPs to use the patient portal by asking them to respond to e-consults (ie, messages sent by the patient) and by showing them functions that will save their time or make their work more efficient. Time-saving functions like preoperative screening questionnaires on the patient portal are easy to embed in the daily routine of professionals. One participant explained the following:

> *We built the pre-operative screening questionnaire in such a way that [the information the patient provides] gets entered directly into the anesthesiologist's outpatient file. [This means] that the moment the anesthesiologist starts the consultation with the patient, the data are already in the system. The outpatient clinic started using the questionnaire right from the go-live.* [Participant #12.1, project leader]

Objective 4: Knowing Where to Find Help With the Portal

The fourth communication objective is to ensure that patients and HCPs know where to look for help when they have a problem using the portal. Hospitals organized a help desk, publishing its phone number and email address in leaflets, letters, on the hospital website, and on the portal itself. Some hospitals organized a service point clearly visible in the central hall of the hospital, where patients receive face-to-face service. Outpatient clinic staff can tell patients about this service point. HCPs can ask their colleagues for help (ie, peers).

Reviewing these hospital communication strategies, three findings are worth a mention:

1. The texts used to inform patients and HCPs have a promotional tone. Hospitals choose to stress the benefits and hardly mention the potential disadvantages or risks of portal use.
2. Mass communication is preferred because it is less labor intensive. However, it is also less personal and less in line with the needs of an individual. Personal communications, such as letters, text messages, and emails, have the advantage in that they probably make patients and health care professionals feel personally addressed.
3. Hospitals struggle with the timing of starting their communication efforts, for example, having a silent "go-live" or starting a campaign directly after launching the portal.

Our participants explained that most hospitals do not inform patients about the go-live, because this gives them the opportunity to solve start-up problems and technical issues signaled by the first users. After some two to three months they will use a cross-media approach to communicate on the portal. Our participants expressed concern that if a hospital initiated a communication campaign straight after launching the portal, the hospital could be making promises that they cannot keep.

Embedding the Patient Portal in Daily Routines

Overview

In the previous section we showed how communication strategies support patient portal adoption processes. HCPs worry that using the portal is time-consuming and will disturb their daily routine. They regard explaining how the portal works and communicating with patients on the portal as extra tasks and expect that helping non-computer-literate patients (eg, the elderly and people with low literacy) will be especially time-consuming. One participant explained the following:

> *If a patient says, "I don't use the computer," I won't ask if they have a son or daughter who'd like to share their access. I don't start with that, it costs too much time, really.* [Participant #5.5, senior doctor's assistant]

Our data show three ways to support embedding the patient portal in the daily routine of HCPs and management: (1) hospital policy, (2) management by monitoring the numbers, and (3) a structured implementation strategy that includes all employees in the department, termed a specialism-focused approach. According to our participants, all three ways require changing work processes and routines.

1: Hospital Policy

The first way to embed patient portals is by developing hospital policy on digitalization. Our participants revealed that some hospitals lack hospital-wide agreements, resulting in a lack of coherence for the patient. One such hospital-wide agreement could set the maximum time that HCPs have to respond to an

e-consult. According to our participants, the CMIO and the CNIO can play an important role in setting hospital-wide agreements and explaining new work routines to their colleagues (ie, peer influence). Our participants also said that some hospitals set no obligation or targets to use the portal:

> *How can we make sure the patient portal lands properly in the outpatient clinic? Good question... Well, it may have landed, but there is still no obligation [to use it] and that's the real problem.* [Participant #1.1, communication advisor]

For example, it is not clear within which time frame HCPs need to respond to patients' e-consults or how many patients per specialism should be using the portal. Responses to patients should be prompt, and the professionals need time to incorporate their responses into their daily work processes on the portal. One participant explained the following:

> *If you have to explain something to the patient on the portal or send them an email within four hours, then we need to think about how to get that complex planning process in the system. The professionals need time to think about it too. So that's development; and you need even more time to implement.* [Participant #13.2, CNIO]

2: Management by Monitoring the Numbers

The second way to embed patient portals is by ensuring that management monitors information on portal use or response time. Most hospitals lack management control of portal use. Some hospitals, however, monitor the numbers of new patient accounts and users on a dashboard or monitoring system. In one hospital, outpatient clinic employees must ask all patients presenting themselves at the desk if they are interested in opening a patient portal account. Hospital management uses this monitoring information to talk with staff who do not seem to be encouraging enough patients to sign up for the portal. One participant revealed the following:

> *Staff must register whether or not they have asked if a patient is interested in having a portal account. Now we can run reports on the employee level... We do that sometimes and then we can see that, say, Marie scores 100% on "not interested." Of course, ... then you'd have to start the conversation.* [Participant #5.4, care and operations manager]

Our participants said that fear is possibly a reason why HCPs do not motivate patients to sign up for the portal. Professionals need to overcome their own unfamiliarity and prejudices by experiencing the benefits of the patient portal. One participant declared the following:

> *Of course, we do it for the patient, but let's see where it helps the physician. Then you'll get them to at least use the patient portal.* [Participant #8.7, internist]

3: Specialism-Focused Approach

A third way to embed portals in daily routines is to apply a specialism-focused approach—a structured implementation strategy—that includes all the staff in the department. This involves a multidisciplinary project team (eg, communication advisor and project leader), management, and HCPs temporarily collaborating on changing work processes to benefit the incorporation of the patient portal into daily routines. Not trying to convince just one physician, but the whole department (eg, the outpatient clinic team), makes it easier to embed the patient portal. Working closely with project staff gives the HCPs support that is based on their needs or wishes. This approach requires giving HCPs the time to discuss their problems, share their experiences, and experiment. One participant explained the following:

> *Using this approach, we've really looked in depth at the points where the portal can be embedded better in their work process. For example, we've supported the specialism of rheumatology. They have very clear ideas about using the portal. Now we'll work actively with the health care professionals in the coming period to increase the use of the patient portal within their specialism.* [Participant #11.2, communication advisor]

According to our participants, using this approach supports giving professionals an understanding of how the portal works and how they can use it in their daily routines. However, they said that it is labor intensive for everyone involved, which slows down the adoption process hospital-wide.

Another implementation strategy is for hospitals to start off the portal adoption processes with keen, intrinsically motivated HCPs. Hospitals put effort into these professionals. They are seen as ambassadors, as *game changers*, who will convince other HCPs by setting a good example. One participant said the following:

> *I believe that starting out with the enthusiastic specialists is the most successful strategy and that's why we're starting with people who want it. We're not setting out with the difficult ones who don't want it.* [Participant #11.3, CMIO]

Adjusting the Portal to Meet Patients' Needs

Overview

Our participants said that in the continuous development process, adjusting the portal to meet the patients' needs is important. For example, enhancing user-friendliness ensures repeated use of a portal. As well, asking patients for feedback on the portal can reveal points of improvement that the project staff might not spot, as our participants explained:

> *An example: a patient tests the portal, first on a dummy and later on their own file. Someone remarks: "It's in chronological order, but the most recent is at the bottom. Why don't you put the most recent at the top of the page?"* [Participant #4.2, project leader]
>
> *It's as simple as that. You don't notice that when you are so involved.* [Participant #4.1, advisor of functional management]

According to our participants, another reason they find it important to adjust to patients' needs is because the perspectives of the patient and the communication advisor may differ:

> *I'm against all those abbreviations... Why not explain what they are? I guarantee you that half the patients won't know what the abbreviation means. Add an abbreviation list.* [Participant #10.6, patient and client council member]
>
> *It's my choice. I can write the term in full, I can explain it the abbreviation. But when I write it out completely, it becomes a very long sentence.* [Participant #10.2, communication advisor]

Our participants mentioned two methods hospitals use in the effort to optimize portal user-friendliness: (1) patient feedback and (2) focus on optimizations for patients with special needs (eg, low literacy, visually impaired, and low digital skills).

1: Patient Feedback

The first way to adjust to patients' needs in the continuous development of patient portals is to set up a panel of patients to act as a sounding board or to survey patients on their experiences and wishes. One participant reported the following:

> *We have a panel of 150 people. We sent these people a questionnaire on the patient portal and how they would like to use it.* [Participant #3.2, client council member]

Another way is to organize sessions with patients to test portal functionalities (eg, access to data, an e-consult, and filling in questionnaires). To illustrate, one hospital organized a test session for feedback and observations:

> *We invited a few patients from our patient panel. We gave them a test version of the portal and asked them to do a few assignments and fill in a questionnaire. For example: look at the patient portal and see if you get it. Give as much feedback as possible about the things that could be improved... There was one-on-one guidance. We had a large number of employees involved, so that we could sit next to the patients and get as much feedback as possible. So, we could also see how things went.* [Participant #7.1, project employee]

Hospitals also asked for feedback and reused questions, comments, and complaints patients express to the helpdesk. One participant said the following:

> *We now actively request feedback from patients. The helpdesk also receives feedback and phone calls and we can use the input obtained.* [Participant #1.1, communication advisor]

2: Focus on Optimizations for Patients With Special Needs

A second way to adjust to patients' needs is by optimizing the portal for people with special needs. For example, language experts check the language used on the portal and written information on how to use it, removing jargon and abbreviations and simplifying texts for patients with low literacy. They make more use of visuals (eg, icons, pictograms, and infographics):

> *You can summarize in pictograms, which makes it much easier for patients with low literacy. Visuals work better and faster.* [Participant #9.2, patient]

Another example of optimizing portal use for people with special needs is when hospitals collaborate with organizations offering general computer courses, such as the municipality, community centers, and libraries, for patients with few digital skills. Hospitals ask those organizations to blend the patient portal into their course and teach patients to work with it. Also, hospitals may refer patients to this course if they do not have computer skills and need to learn how to work with the Dutch national identity authentication method (DigiD). Participants report that the DigiD is not easy to use and its log-in process requires many steps:

> *I find the accessibility of the patient portal a real problem. Logging in with your DigiD is difficult.* [Participant #3.3, functional manager]
>
> *We look for courses on using the DigiD subsidized by the municipality. They organize courses in the community centers for people having trouble with DigiD and then these people can practice logging in on the patient portals.* [Participant #11.2, communication advisor]

Despite the importance of adjusting to patients' needs in continuous development, hospitals sometimes hesitate to include patients, because they may not be able to act on the patients' feedback. For example, if patients miss functionalities, it can require time and money to add them to the portal and, therefore, this cannot be easily fixed. Participants mentioned the importance of explaining to patients what the hospital does with their feedback and why some feedback points cannot be solved in the near future (eg, technologically impossible or too expensive). Otherwise, patients will feel that the hospital is not taking their feedback seriously. The following quote shows how hospitals struggle to let patients participate in the continuous portal development, even though they find patient input invaluable:

> *If we invite the panel group for testing, then we have to show that we have improved the portal based on their feedback... Otherwise they will think "nothing happens with our input." If we organize patient participation, you can only say "we're too busy" once.* [Participant #4.1, advisor of functional management, and participant #4.2, project leader]

One of the challenges of acting on patient feedback stems from the collaboration with the suppliers of patient portals. Suppliers will undertake to improve or develop new functionalities when multiple hospitals make the same request. Surprisingly, however, suppliers (n=5) said that they include no patients in their development process. The suppliers see it as the responsibility of their customers—the hospitals—to give voice to patients' wishes.

Discussion

Principal Findings

This qualitative study focuses on patient portal adoption processes by patients and HCPs in a Dutch hospital context. Overall, our results show that the adoption of patient portals is more dynamic than presented in theoretical models and the literature. Greenhalgh et al's linear adoption stages (ie, preadoption, early use, and established users) [16] seem useful in studying adoption by individuals, but hospital patients and HCPs are in different adoption stages. Consequently, an organization cannot simply move through sequential stages; it needs ongoing effort to be put into informing, embedding, and adjusting to patients' needs. Their focus on individuals rather than the organizational context is also a criticism levied at the theoretical models (see Table 1) [14,16,17].

All participating hospitals seem to be experimenting with stimulating adoption of the patient portal. They are trying to create effective communication strategies, looking for the best way to embed the portal in daily routines and adjust to its patients' needs. As yet, they have not found the best way of encouraging portal use by patients and HCPs. Here we explain the implications of our results.

Our study shows that hospitals are experimenting with many communication channels (N=23), mostly ones that are already in use. Despite efforts by communication departments, it seems that portal adoption is still quite a challenge. It seems that hospitals do not know which channels are most effective for which target audiences and what the right timing is for their communication campaigns. Looking at their communication strategies, we found that hospitals choose to emphasize the benefits of portal use and hardly mention the potential disadvantages or risks. According to Greenhalgh et al [16], intended adopters must know the consequences of adopting a patient portal to become established users. If intended adopters are not informed of the potential disadvantages, then they cannot oversee all the consequences of using the portal, for example, the risks. However, the financial incentives of the VIPP program may explain the positive promotion strategy. If hospitals do not attain a certain adoption percentage (ie, 10% or 25%) they will have to repay their VIPP grant.

Our results show that hospitals invest in HCP adoption through peer-to-peer influence. However, focusing on the enthusiastic HCPs can mean that the less-motivated HCPs will lag behind. That a patient portal often does not reduce the burden of HCPs (ie, it only means extra work) and that it is not embedded properly in work routines can hinder adoption. The specialism-focused approach offers a way of encouraging patient portal adoption by HCPs. This experiment with portal embedding would be interesting to study in other contexts to see where and how it could lead to better embedding of the patient portal. A possible disadvantage of this approach could be that patients will not understand why specialisms are in different adoption stages (ie, patients can make an online appointment with one specialism but not for another).

Another principal finding is that hospitals are struggling to adjust the portal to meet patients' needs in their continuous development process, although all seem to find this important. According to Greenhalgh et al [16], it is vital that intended users get the opportunity to refine the portal so that they will not drop out in the early adoption stage. Hospitals are using various ways to adjust to the patients' needs in ongoing portal development, without knowing which one is most effective in which phase and for what purpose. It would be interesting to do more research on how patients can participate in portal development, including efforts to stimulate adoption.

Nonusers of patient portals could be studied further. Previous studies show that nonusers have various reasons for not adopting the portal [36,37], including a preference to speak directly to their HCP, the level of their communication skills [36], and their concern for privacy and information security [36]. Such studies would show that hospitals are taking nonusers' concerns seriously and, at the same time, could produce insights valuable to exploring whether and how the patient portal could be made useful to them.

A remarkable finding is that portal suppliers do not include patients in their development process. The suppliers see it as their clients' responsibility to give voice to patients' wishes, but the focus group discussion did make them rethink this. This means that hospitals must explain to the supplier how they should make the portal more user-friendly for patients. Because of the variation in hospital context and portal suppliers, this could explain the disappointing adoption by patients.

Limitations

Our study has four limitations. The first is that the adoption processes in the hospitals we studied might be somewhat unusual due to the financial incentives of the national VIPP program. Conducting similar research in other countries would, therefore, be interesting and could also teach us more about the contextual, including cultural, factors that influence hospitals' efforts to stimulate adoption.

The second limitation is the way we recruited hospital participants. Using our own research networks may have biased our sample. However, our recruiting process resulted in a good variation in the mix of included hospitals.

The third limitation is that we only included teaching and general hospitals, given that academic hospitals follow another implementation program. Also, during the study period they were not participating in the VIPP program and, therefore, could not be compared. However, the inclusion criteria context of the studied hospitals varied greatly to include different kinds of hospitals and patients.

Last, this descriptive study shows the efforts that some Dutch hospitals have made to stimulate adoption of a patient portal. We did not study whether the undertaken efforts led to an actual increase of the adoption of patient portals. A further study on the effectiveness of these efforts is recommended.

Comparison With Prior Work

In recent years, many theoretical models on the adoption of information technology have been developed [9,10]. These

models show which variables are important for the adoption of a technology; for example, *perceived ease of use*, defined in the Technology Acceptance Model (TAM) as "the degree to which the person believes that using the particular system would be free of effort" [12]. However, these models are not explanatory and do not provide the know-how to stimulate patient portal adoption [9,10]. Consequently, we suggest future research should not focus on models, including new ones, but should deal with actionable knowledge for practice [38]. Action research can be used to study the adoption process and the embedding of patient portals in daily practice [39].

Communication experts support the hospitals' choice to use a cross-media promotion to inform patients and HCPs about the patient portal [40]. Explaining the benefits of using a patient portal is especially important for promotional messages [41]. However, open dialogue among HCPs and project leaders and staff is also vital because it illuminates the professionals' perspectives on portal development [41]. Earlier research shows that ignoring doubts while trying to convince others to use a technology may produce negative energy and a reluctance to use the portal [41,42]. Further research is required to find the most effective hospital communication strategies for encouraging patient portal adoption for patients and HCPs.

Our study showed that embedding a patient portal in the daily routine of HCPs requires changing their work processes. Earlier studies suggest that hospitals need to make extra time available to HCPs so that they can change and learn new work processes [41]. Research shows that portal use by patients may increase when HCPs are active on the patient portal and it is embedded in their work processes [43]. Research suggests training can benefit the adoption process [41], yet only some hospitals organize courses that explain how the portal works. As a result, some HCPs lack familiarity with portal functionalities [42].

The literature reports several ways of using feedback to adjust the portal to patients' needs in the continuous development of patient portals. These studies could help hospitals struggling with this. It is important to include patients at the beginning of ongoing development of patient portals [1,44,45]. Examples include co-design, where patients help identify the project based on personal experiences in collaborating with the clinician [45], and participatory stakeholder co-design, where patients and clinicians are equal stakeholders in the whole project [45]. Vulnerable patient groups, such as disadvantaged older adults, should be given special attention in the process of cocreation and user testing [7]. This is an important issue for future research.

Conclusions

Patient portal adoption processes are not just about implementing the technology. They require human interaction in a multitude of ways. Our study reveals three key findings for the adoption process: (1) informing patients and HCPs about the portal, (2) embedding it in the daily routine of HCPs, and (3) adjusting it to patients' needs in the continuous development of the portal. Our paper provides rich insights into the complexity of the adoption process and gives examples of efforts to stimulate the adoption of patient portals. Our findings help to translate the relatively abstract factors mentioned in the theoretical models to the everyday pragmatics of eHealth projects in hospitals.

Acknowledgments

The study was commissioned by the Dutch Hospital Association. We would like to thank our participants and the members of our scientific group. We are grateful for the helpful comments and insightful suggestions by our colleagues, especially Marcello Aspria and Louis Ter Meer.

Abstract

Background: Although electronic medical record (EMR)-tethered patient portals are common in other countries, they are still emerging in Canada.

Objective: We aimed to report user satisfaction and the effects of a patient portal on medical appointment attendance in a Canadian cohort of patients within our publicly funded health care system.

Methods: Two surveys were deployed, via email, at 2 weeks and 6 months following the first recorded patient portal access. Database audits of visit attendance were used to supplement and cross reference survey data.

Results: Between January 2016 and July 2018, 4296 patients accessed the patient portal. During the study, 28% (957/3421) consented patient portal users responded to one or more semistructured electronic surveys. Of respondents, 93% (891/957) reported that the patient portal was easy to use, 51% (492/975) reported it saved time when scheduling an appointment, and 40% (382/957) reported that they had to repeat themselves less during appointments. Respondents reported patient portal–related changes in health system use, with 48% (462/957) reporting avoiding a clinic visit and 2.7% (26/957) avoiding an emergency department visit. Across 19,968 visits in clinics where the patient portal was introduced, missed appointments were recorded in 9.5% (858/9021) of non–patient portal user visits, compared with 4.5% (493/9021) for patient portal users, representing a 53% relative reduction in no-show rates.

Conclusions: Early experience with an EMR-tethered patient portal showed strong reports of positive patient experience, a self-reported decrease in health system use, and a measured decrease in missed appointment rates. Implications on the expanded use of patient portals requires more quantitative and qualitative study in Canada.

KEYWORDS

patient portal; patient satisfaction

Introduction

Canadians desire electronic access to their health information and have an expectation of managing their health system interactions digitally [1]. Increasingly, that access is provided through electronic medical record (EMR)-tethered and standalone web-based patient portals [2-12]. Patient portals can deliver digital access to secure messaging, health information (eg, test results, lists of medications and allergies), scheduling functions, and self-management of health issues such as weight, blood glucose, and blood pressure. Early studies of patient portals reported patient benefits including enhanced satisfaction,

better relationships with their care providers, more efficient medication refills, and improved understanding of their health information [3,4,11,13-16]. Health system benefits include fewer missed clinic appointments (no-shows), lower postage costs related to decreased mailing of paper records to patients, and less time answering phone calls related to appointments [3,4,11,13-16]. A recent systematic review of patient portals concluded that there is an urgent need for more outcomes data and reporting on organizational and provider context, as well as implementation processes [17].

Fully interactive patient portals that share detailed health information, messaging, and scheduling capability are relatively rare in Canada, and mostly allow patients limited interaction with a single health care facility or clinic [2,18-22]. A number of provinces provide standalone portals that aggregate laboratory and diagnostic imaging results, but few employ patient portals that allow self-scheduling or health management across a large population. Alberta Health Services (AHS) had a limited production rollout of a patient portal tethered to an EMR in the Edmonton zone from 2016-2019. The objectives of our study were to examine the effects of this tethered patient portal on patient satisfaction and health system usage.

Methods

Design

For this study, we employed surveys and system audit logs. This combination of longitudinal semistructured user surveys and administrative data audit was used to identify user-reported outcomes triangulated with possible clinical outcomes of interest in a cohort of users attending clinics allowing access to a patient portal. The University of Alberta's Health Research Ethics Board (Pro00066287) approved the study.

Patient Portal Development and Adoption

The patient portal that we studied is tethered to a shared EMR known as eCLINICIAN (an AHS branding of EpicCare Ambulatory 2014 from Epic Systems), used at the time by approximately 1110 physicians, residents, and students, and approximately 6000 nurses, allied health professionals, and other staff. The adaptation of this patient portal to the AHS context took about six months, the bulk of which was spent achieving consensus (including patient, clinical, administrative, legislative, and regulatory college input) on policy decisions and functions (Textbox 1). Consensus was reached to release most high-value data in real time (ie, those data required to manage active or chronic disease), with higher stakes information (ie, results of hepatitis or biopsies) delayed by ten days (Textbox 2).

Textbox 1. Patient portal features.

- Secure bidirectional messaging between patient and care team
- Display medical information (medications, problems, past history, allergies, immunizations)
- Create, select, view, and modify scheduled appointments (varies by clinic)
- View appointments and receive reminders sent to patient mobile devices
- Complete previsit questionnaires and patient-entered flowsheets
- Enter and track home data (eg, blood pressure, glucose)
- iOS and Android mobile apps
- Integration with Alberta Personal Health Portal
- Email signup process to reduce initial 2-factor login issues for patients

Textbox 2. Results release framework.

Results released in real time (hourly)

- Hematology (complete blood count, white blood cell count), electrolytes, renal function, liver function, lipids, diabetes monitoring (glucose, HbA_{1C}), coagulation profile (international normalized ratio, prothrombin time test), cardiac tests (troponin, B-type natriuretic peptide), sexually transmitted infection results, bacterial cultures

Results released after 10-day delay (or earlier if provider does so manually)

- Pathology reports, diagnostic imaging reports, genetic testing (newborn screening, specific diagnostic testing (eg, for angioedema, protein C deficiency, carrier testing, prenatal testing, preimplementation testing), cytogenetics, histocompatibility, serology, molecular diagnostics, HIV serology, hepatitis C serology, cancer-related markers (eg, prostate-specific antigen, carcinoembryonic antigen)

Study Setting and Population

AHS is a provincial health system responsible for the delivery of inpatient and ambulatory care services. Edmonton is the capital city of Alberta, with a population of approximately one million. In January 2016, an EMR-tethered patient portal was introduced in the Edmonton zone, and was evaluated between January 2016 and July 2018. During this phase, the patient portal was introduced in one family practice clinic and four specialty clinics (rheumatology, inflammatory bowel disease, multiple

sclerosis, and diabetes). These specialty clinics are part of a large academic health campus, accept patients initially via referral for specialty care, then follow them for their chronic disease management. Inclusion criteria for the survey study were the following: patients who had (1) visited 1 of the 5 aforementioned clinics between January 2016 and July 2018, and (2) signed up for patient portal access. A total of 3421 patients met inclusion criteria for the survey during the study period.

Patient Survey Instrument

A novel 30-question survey instrument (Multimedia Appendix 1) was developed by members of our research team using a modified Delphi [23] approach. Four overarching themes were identified: (1) satisfaction with the patient portal, (2) utility of the patient portal, (3) impact of the patient portal, and (4) demographic characteristics. Proposed questions were refined by the research team and then pretested with 6 members of our patient portal working group. After further refinement, which included changes and clarification of wording and question structure, the survey tool was piloted and sensibility-tested with a small group of patients, leading to a final survey with 5 (satisfaction, utility) to 12 (impact) questions per theme. The survey required about 10-15 minutes to complete.

During the sign-up process for the patient portal, patients consented to be contacted via their email address, which was routinely recorded as part of the sign-up process. Patient portal users were emailed a voluntary link to the survey which contained Likert scales, multiple-choice questions and free-text questions. The free-text answers were collated and thematically coded by two authors (TG, SA). Coding discrepancies were resolved by consensus. Surveys were administered at 2-week and 6-month time points relative to each participant's first successful access to the patient portal, as this was felt to represent an adequate period of time for participants to access and become comfortable with using the patient portal. Respondents were made aware that their responses would not impact their clinical care, that no incentives were provided, and that their responses would only be studied in collated form. Respondents were permitted to skip any question they wished.

Appointment Attendance Records

To determine the no-show rate, the numerator of scheduled appointments recorded as no-show was divided by the denominator of total scheduled appointments. No-show rates were calculated for users with an active patient portal account at the time of the visit and compared to rates for users attending the same clinics without a patient portal account at the time of the visit. Audit log analysis included attended and no-show visit rates, basic patient demographic data, and the patient's contact email address.

Statistical Analysis

Categorical data (eg, sex, age) were summarized with frequency distributions. Respondent demographic characteristics were compared to the wider user population with respect to sex and age. No-show rates were compared for patient visits where a patient portal account was active at the time and patient visits in the same clinic with no active patient portal account between November 2015 (just before the patient portal was introduced) and July 2018. Each respondent's final answer across the 3 time points to questions of a more summative nature were included for statistical testing. Statistical differences were detected at a *P* value of less than .05. Chi-square testing for each of these comparisons was conducted using R statistical software (version 3.4.3, R Core Team, R Foundation for Statistical Computing). We included users who enrolled to use the system between May 2016 and May 2018. An additional 875 new users signed up for patient portal access between May and July of 2018. To avoid biasing the estimate of the proportions of users toward the early users, these users were included in the user population but not in survey analysis.

Results

Demographic Characteristics

A total of 5629 electronic surveys were transmitted to 3421 patients between January 2016 and July 2018. The final administration of the survey was completed in May 2018 to allow users 2 months to respond to the survey. Overall, 957 patients responded 1916 times, and 28% (957/3421) of users receiving an invitation to participate replied to at least one survey. In addition to accessing their own health information, patient portal users reported using the patient portal for their children (36/957, 4%) or their spouse (131/957, 16%). Of 174,298 login sessions, 70% (122,648/174,298) were from a computer browser, 20% (34,205/174,298) were from an iPhone, and 10% (17,445) were from an Android device.

Table 1 describes user and respondent demographics and comfort with computer use; the majority of respondents (834/957, 87%) reported being either comfortable or completely comfortable using computers).

Table 1. Patient portal user and respondent demographics.

Characteristics	Respondent frequency, n (%), (N=957)	User frequency, n (%), (N=4296)	*P* value
Sex			>.99
Female	537 (56.1)	2347 (59.3)

No answer	34 (3.6)	N/A	

[a]N/A: Not applicable.

Satisfaction, Impact, and Utility

Patient portal users reported a high degree of usability and general satisfaction: 93% (891/957) of respondents felt the patient portal was easy to use, 83% (794/957) said it made communication more convenient, and 75% (716/957) indicated it saved time when scheduling an appointment.

Among survey respondents, 48% (460/957) stated the patient portal had helped them avoid a clinic visit. In February 2016, we added an additional question regarding emergency department or urgent care visit avoidance, and of users who answered this, 14% (26/188) answered that the patient portal allowed them to avoid such a visit.

There were 4 free-text questions available based on the themes of requested improvements, preferred features, how the patient portal helped avoid a health care visit (if applicable), and self-reported cost savings related to the patient portal (Table 2). Over two-thirds of respondents identified that access to laboratory and diagnostic imaging results was the most preferred feature of the patient portal. The most frequently reported concerns were related to a cumbersome sign-in process and a desire for more explanation of results. It should be noted that the patient portal was launched with an authentication method that was acknowledged to be overly complex at the time of implementation but was required for local technical and security reasons. Less common requests included a wider availability of data, including physician notes on the chart, an explanation of the meaning of the results, and the timeliness of the reports in the system.

Table 2. Respondents' view on the patient portal.

Participant responses[a]	Frequency, n (%)
Requested improvements (n=558)	
Less cumbersome login authentication	144 (25.8)
More data types and wider spread availability	143 (25.6)
Like it/love it in current state	94 (16.8)
Better instructions/explanation of results	47 (8.4)
Reports delayed or incomplete	43 (7.7)
Other[b]	108 (19.4)
Most preferred features (n=173)	
Lab and diagnostic imaging results	119 (68.8)
Feeling of health empowerment	23 (13.3)
Scheduling features	21 (12.1)
Communication features	14 (8.1)
Other[c]	4 (2.3)
Factors resulting in self-reported avoidance of an emergency department/urgent care center visit (n=129)	
Access to results meant a visit could be avoided	76 (58.9)
Chronic disease–specific management	22 (17.1)
Question answered via secure message[d]	21 (16.3)
Other[e]	50 (38.8)
Reported cost savings by avoiding a health care visit (n=112)	
General convenience and less waiting in clinic	43 (38.4)
Not paying for parking and gas	25 (22.3)
Overall improved efficiency for the health system	19 (17.0)
Not paying for meals/hotels	10 (8.9)
Other[f]	2 (1.8)

[a]There was more than one answer permitted per category.

[b]Other included general usability and results management (n=41), adding and updating health information (n=20), view diagnostic imaging images (n=14), secure messaging and notifications (n=14), patients able to upload pictures and documents (n=11), and better phone/tablet experience (n=8).

[c]Other included access to health information decreases anxiety (n=7), can view medications (n=7), proxy access to family member's chart (n=4), and previsit questionnaires (n=1).

[d]Secure messaging was done through MyChart and answered a question from the user.

[e]Other included visit more efficient because informed (n=9), health empowerment (n=8), and preferred to get results in person (n=3).

[f]Other included not paying for meals/hotels (n=10), not missing work (n=7), and not paying for childcare (n=2).

Health System Usage

We studied the proportion of patients who had a no-show to an appointment, as it related to patient portal user status. From January 2016 to July 2018, there were 19,968 no-shows across the 5 clinics that participated. Of these visits, 9021 did not have an active patient portal account at the time of the visit. The number of no-shows amongst these visits for patients without a patient portal was 858 (9.5%, range: 3.7%-16.6%). Of the remaining 10,947 visits for patients with an active patient portal account, 493 (4.5%) no-show visits were recorded (range: 3.1%-10.4%). No-show rates for patients with no patient portal were 11.9% (386/3257) for the specialty clinics and 8.2% (472/5764) for the family practice clinic, whereas the rates for patients with patient portal access were 4.9% (194/3943) and 4.3% (299/7004), respectively. This represented a 53% relative reduction in the no-show rate overall (P<.001).

Discussion

Overview

In our study, patients were surveyed about their perceptions of an EMR-tethered patient portal. Patients had high general satisfaction, with over 90% reporting that it was easy to use, and almost half reporting that it saved them a medical visit. Respondents reported that access to results and advanced features, such as messaging and scheduling, improved

communication with their care providers. Additionally, self-reported reductions in health system use implied improved utilization of scarce health system resources. Finally, objective data from clinic visits demonstrated an over 50% relative reduction in no-show rates.

We decided to focus on patient-centered indicators of patient portal utility rather than tracking health outcomes in our study. As with any technology, the benefits will accrue only if the technology itself is working and is being used as expected [24]. Although it is assumed that just having access to health information is of benefit, there is little evidence that access to lab tests will improve health outcomes. However, we believe that more advanced features, such as scheduling and secure messaging, in combination with access to test results and clinical notes are more likely to result in long-term health system benefits. In 2014, Goldzweig et al [17] performed a systematic review and found that there were a limited number of studies about patient portals, with heterogeneous designs making it difficult to draw strong conclusions about a new technology. Additionally, they found that improved outcomes (eg, for chronic disease such as diabetes, hypertension, and depression) tended to involve portal use in conjunction with case management [17]. They also found mixed data about the effect of portals on health care utilization and efficiency. Based on the success of the patient portal in our study, planning is underway to expand patient portal use across all AHS clinics. This expansion is targeted at the notion that patients having access to their own information in conjunction with the ability to interact with the health system digitally will contribute to increasing health system efficiency, including reductions in no-show rates and clinic and emergency department (ED) visits, increased patient satisfaction and empowerment and, in the longer term, improved health outcomes. The latter assumes that the patient portal is not only widely available, but actively being used as intended.

The 53% relative reduction in the no-show rate seen in patient portal users in the 5 pilot clinics may be widely relevant. Across the Edmonton zone of AHS, about 200,000 appointments are scheduled monthly**.** Of these**,** about 40,000 appointments are rescheduled, and 2000 appointments are considered no-shows. Patients who miss appointments often use emergency departments as sources of both primary and chronic care, driving up costs and straining hospital systems [23-25]. Missed appointments can compromise continuity and quality of care for both the patients who no-show and others who would have been scheduled in those appointment slots [25]. If the decreased no-show rates scale up to a wider set of users, patient portals may have significant positive impact on wait times and clinic efficiency. Access to scheduling functions in a patient portal may also be associated with decreased urgent care visits, although studies are not consistent [26,27]. In the current work, 2.7% of respondents reported being able to avoid one or more ED or urgent care visits, and 48% reported avoiding a clinic visit due to being able to communicate electronically. ED overcrowding is an ongoing and seemingly intractable problem; any strategy to safely decant these pressures in the Canadian context warrants further exploration.

In the near future, patients will expect web-based and mobile app–based access to their health data, and the ability to manage their health and interact with the health system digitally. In some jurisdictions, this access is not only related to tests and scheduling, but extends to transparent access into the complete medical record including progress notes [28]. Future studies will include interviews of care providers and patients to get a deeper understanding of the pros and cons of an EMR-tethered patient portal, its effect on clinic workflows, and the potential savings, whether that be in terms of time saved not waiting on hold during a phone call, or travel costs saved by replacing an inpatient visit with a secure message.

Limitations

Our study evaluated a single patient portal in a large group of patients attending 1 of 5 clinics, in a single city, where the clinic leads were keen to implement it. It is not clear whether the results would be broadly generalizable. However, the study population did include both family medicine and specialty clinics, representing some diversity of needs and practice. Self-reported data is subject to recall bias, which we attempted to limit by sampling at different times after a user's first successful patient portal access. The correlation between patient portal use and no-show rates may be partly the result of more diligent or engaged patients at the clinics participating in the study. Although we were able to compare survey respondent versus non-respondent demographic characteristics for all patients that had patient portal access, we did not have the ability to do the same for those with patient portal access versus those without. The analysis includes visits from non–patient portal users who eventually obtained patient portal access, which may underreport the effect size. The respondent population reported a high degree of comfort with computers, which may not hold true elsewhere, although it may reflect increasing competence with technology in general.

Conclusions

Early experience with an EMR-tethered patient portal showed decreased no-show rates for appointments, high patient satisfaction, and self-reported changes in health system use. Implications on the expanded use of patient portals requires further study in Canada.

Abstract

Background: Understanding how health organizations decide on information technology (IT) investments is imperative to ensure successful implementation and adoption. There is a high rate of failure and a tendency to downplay the complexity of implementation progression. Alberta Health Services introduced a patient portal called MyChart. Although MyChart allows patients to view appointments and selected laboratory results and to communicate with their providers, its uptake varies.

Objective: The study aimed to examine the institutional decision-making processes that shaped the development and implementation of MyChart.

Methods: A historical study was conducted based on the 7-step framework, where one engages in a rigorous archival critical analysis (including internal and external criticism) of documents and analysis of interviews. We reviewed and analyzed 423 primary and secondary sources and interviewed 10 key decision makers.

Results: Supportive leadership, project management, focused scope, appropriate technology and vendor selection, and quick decision making were some of the facilitators that allowed for the growth of proof of concept. The planning and implementation stages did not depend much on the technology itself but on the various actors who influenced the implementation by exerting power. The main barriers were lack of awareness about the technology, proper training, buy-in from diverse system leaders, and centralized government decision making.

Conclusions: Organizational priorities and decision-making tactics influence IT investments, implementation, adoption, and outcomes. Future research could focus on improving the applicability of needs assessments and funding decisions to health care scenarios.

(J Med Internet Res 2020;22(5):e17505) doi:10.2196/17505

KEYWORDS

patient portals; information technology; decision making; investments

Introduction

Backgound

Aging populations, increased prevalence of chronic conditions, and consequent rising costs significantly challenge health care systems worldwide. One proposed solution to these challenges has been health information technologies (ITs) that empower patients to be partners in their care, support evidence-based, individualized care, and monitor population health [1]. Understanding how health organizations decide on IT investments is imperative to ensure successful implementation and adoption. There is a high rate of failure and a tendency to downplay the complexity of implementation progression.

The literature shows that the majority of health IT investments are struggling to achieve the hoped-for improvements in quality of care and economic benefits [2-5]. Furthermore, these technologies tend to run over budget because of inadequate preparation for the complexities of implementation [6,7]. There is a need to understand the implementation and adoption of such technologies through a life cycle approach for the technology rather than as a decision at a single point in time. Understanding the events and actors involved in each stage of the cycle provides for better future planning for the successful implementation of IT investments such as patient portals [8]. Alberta Health Services (AHS) introduced a patient portal called MyChart through a proof of concept (PoC).

Aim and Objectives

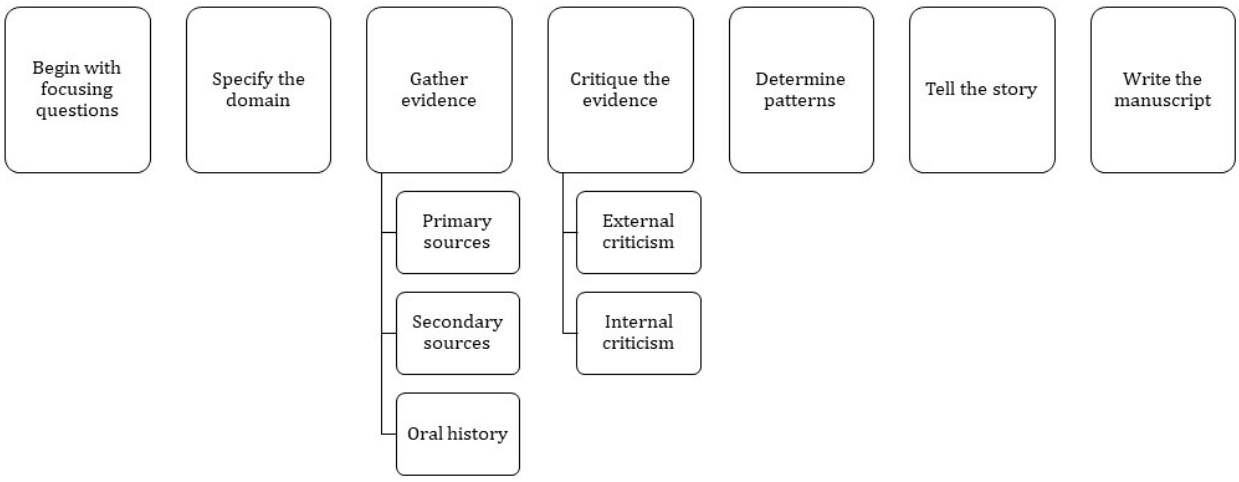
This study aimed to investigate and describe the process by which health IT, in this case, a patient portal, was introduced into the provincial health system of Alberta, Canada. The focus was on the process of decision making and the chronological timelines that led to the pilot of the patient portal, with an emphasis on the conceptualization, development, and implementation processes: need (why), process (how), decision makers (who), decision (what), setting and context (where), and timelines (when).

Methods

Study Design

A historical research approach was used to trace the history of the development and implementation of a patient portal in several clinics in Alberta [9-13]. Specifically, the 7-step methodology framework developed by Mason et al [9] for studying medical information systems was used, as shown in Figure 1. This entails a rigorous archival critical analysis (including internal and external criticism) of numerous documents (contracts, meeting agendas and minutes, training and marketing materials, reports, decision requests, etc), analysis of key informant interviews, and development of the narrative [9].

Figure 1. Mason et al (1997) 7-step framework.



Historical research includes the methodical collection and appraisal of data to recognize, understand, explain, illuminate, and accurately reconstruct past events, actions, and decisions [10-12]. Organizations may associate IT solutions with *awesome potential* and lose track of concerns and problems, resulting in repetitive regurgitation of ideas and being victims of IT fads and fashions. Mason et al [9] pioneered a framework to describe how a solution and its identified need may be adopted when it encounters the organizational context, including the connections and roles of change agents working to mitigate resistance. History allows for understanding and acknowledging what has worked and what has not worked previously [9]. It is important to outline that studying IT through the historical method is not about understanding the technology. It is about the connections and roles that impact how the technology is implemented and eventually used [9]. The framework developed by Mason et al [9] allows for an in-depth understanding of the organization' s current practices, how cultural and environmental conditions impacted the decisions, how the need and the problems were identified, shedding light on the resistance, the process of change, and the actors that led the change.

Study Setting

Alberta Health (AH) is the Alberta government department accountable for ensuring the delivery of health care services and setting and assessing compliance with policy and legislation

[14]. Health care service delivery is funded through AHS and primary care networks (PCNs). PCNs coordinate the delivery of primary health services [15,16]. AHS was established in 2008 and delivers care through 400 facilities throughout the province [17]. The focus of this historical study is the MyChart PoC that took place in Edmonton, Alberta.

Study Context

Planning for a patient portal in Alberta began in the early 2000s led by AH. However, it was not until 2016 that one was introduced into the province, with the launch of a PoC study of MyChart (AHS branding of EpicCare Ambulatory from Epic Systems, 2014 version) by AHS. MyChart was developed by Epic and customized to meet the needs of AHS, allowing patients to view appointments, medical test results, and medication therapies, and to communicate with their providers. It is connected to the central AHS electronic medical record (EMR), named eClinician.

This study received ethics approval from the Research Ethics Board at the University of Alberta (Study ID: MS1_Pro00072286).

Search Strategy

Information on the introduction of patient portals in Alberta was gathered by first identifying relevant sources. Primary sources, including oral histories (key informant interviews), are materials that provide firsthand accounts of the event of interest [18-20]. Oral histories are considered a primary source, as the interviews are *for the record* and tend to confirm the events outlined in written documents [21]. Secondary sources are reports, materials, books, or articles written on the topic of interest by people who were not directly involved [10,21]. They provide additional *depth and meaning to a topic* [22].

We developed a search strategy to identify any sources of the development and/or implementation of a patient portal in Alberta. As the implementation of patient portals was conducted internally, government archives were searched in February 2018, and it was identified that AHS and Alberta Health maintained the sources. Requests were submitted, and the AHS project leadership agreed to provide the documents. In addition, MA (lead researcher) contacted the provincial and AHS archive departments, but the archivists found no documents on this topic. It was expected that most of the written data sources (both primary and secondary) would be internal documents; thus, an agreement was signed with AHS for document access.

In addition, we conducted a Web-based search of academic electronic databases (PubMed [MEDLINE and non-MEDLINE] references and Cumulative Index of Nursing and Allied Health Literature). The search focused on the term *Alberta patient portal* with the intent of identifying articles that had any descriptions about the development of a patient portal in Alberta.

Sampling Procedure

Purposive sampling was used to recruit key informants from the AHS and AH. The names of possible participants were identified through meetings with AHS and Alberta Health representatives and a search of government directories. Both Alberta Health and AHS individuals were interviewed because of their role in planning for a patient portal. This sampling approach is common in historical studies, as the researcher requires information from individuals with firsthand knowledge of the topic under investigation. Furthermore, this approach was *selected because of the representativeness and uniqueness of their experiences, not because of the generalizability of the findings* [23].

Potential participants were sent an information letter and consent form, giving full details of the study. Once a contacted individual had agreed to participate, an interview was scheduled with each person individually. In total, 19 individuals were approached, and 10 agreed to participate in a semistructured interview. All data were analyzed and reported anonymously. In order to ensure that the participants' current positions were not jeopardized because of the opinions they offered, the names and specific positions of participants were kept confidential.

Data Collection Procedure

Selecting Relevant Sources

We considered documentary sources relevant if they described any information about patient portals in Alberta. They included project management documents, scope or function documents, decision requests, presentations, organizational charts, user manuals, privacy documentation, meeting minutes and follow-ups, contracts, briefing notes, and correspondence. We also included sources that discussed electronic health records (EHRs) or EMRs systems and potential vendors. Sources that were not related to patient portals and/or EHRs or EMRs were excluded. A total of 423 sources were included.

Documents underwent external and internal criticism by MA and were reviewed by PP (co-researcher). External criticism considers the validity of the documents by confirming where the document came from and who had documented the fact that the source existed. Internal criticism looks within the data itself to try to determine truth, even considering the motives of the person providing the data [21]. This process of trustworthiness and credibility was performed for each retrieved source [22,23].

Interviews

The interviews were conducted face-to-face or by telephone by MA and were recorded and transcribed *verbatim*. Participants were given an alphanumeric label to protect their identity. The interviews provided an opportunity to clarify various written sources and eyewitness accounts. A generic description of the positions of the key informants is presented in Table 1.

Table 1. Organizational designation of key interview participants.

Organization and designation of key interview participants	
Alberta Health	• Executive-level participant 1 • Executive-level participant 2 • Executive-level participant 3 • Senior-level participant 4
Alberta Health Services	• IT senior-level participant 5 • Senior-level participant 6 • Executive-level participant 7 • Senior-level participant 8 • Senior-level participant 9 • Clinician senior-level participant 10

Each interview lasted for 45 min and 1 hour. The interview sessions began with clarification of the objective of the study, and a description of the information was sought. The interview questions and discussions focused on the need for a patient portal in Alberta, intended outcomes, facilitators, and barriers to the design and implementation processes, stakeholders, policies and legal factors, and future recommendations.

Data Extraction and Synthesis

The sources were numbered from 1 to 423 for ease of data extraction and referencing. We developed a data extraction form to record any information about the development and implementation processes of any patient portal in Alberta. The final form included items related to source type, date of creation, author position and affiliation, summary of source information, impact of source, possible quotes, and related sources. The primary and secondary sources were grouped by year (2005-2019) and type (planning, decision requests, agendas, minutes, presentations, contracts, scoping documents, and optimization documents). MA conducted the data extraction overseen by PP.

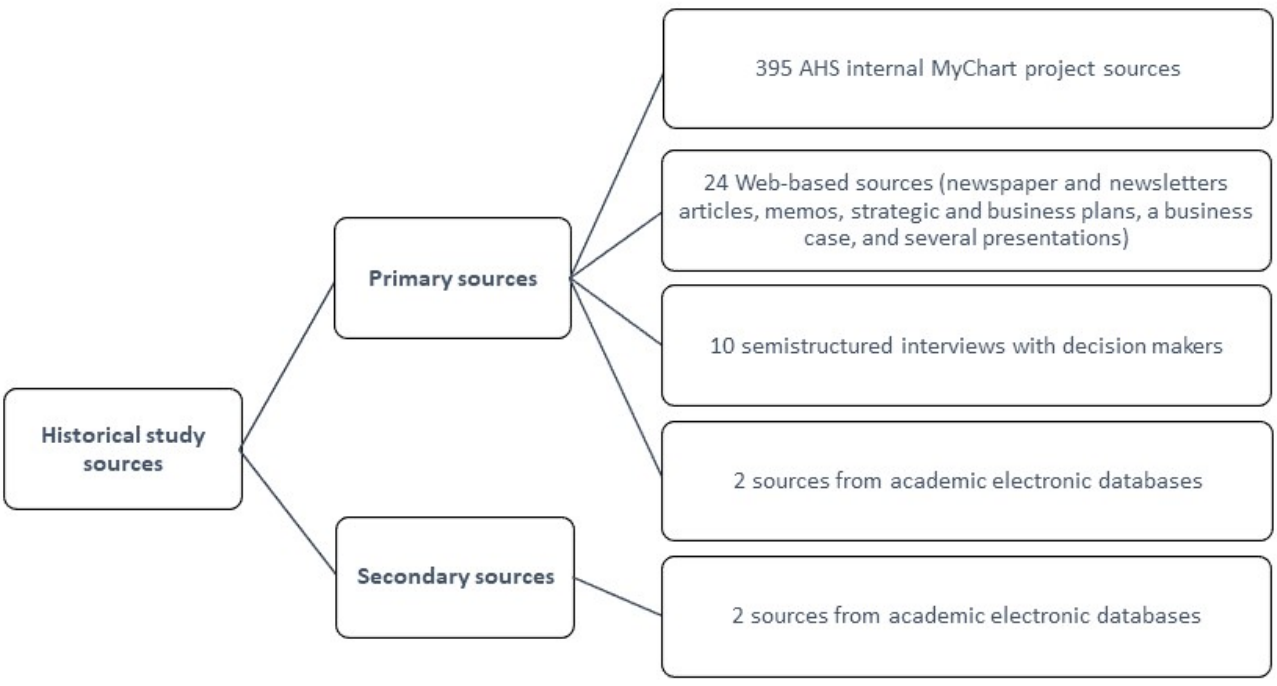
The transcription of the interviews was done by MA and overseen by PP and KO (co-researcher). In historical research, interviews are not analyzed to develop themes but to juxtapose the insights provided by the oral interviews with the *official* documents. The interviews were entered into NVivo (version 11), which was used to track the analytical process through memos and notes. Interview data extraction related to events and actions was connected with patient portals. In addition, potential quotes were identified as being related to various events.

Results

Data Collection Overview

Figure 2 shows the number of selected primary (including interviews) and secondary sources.

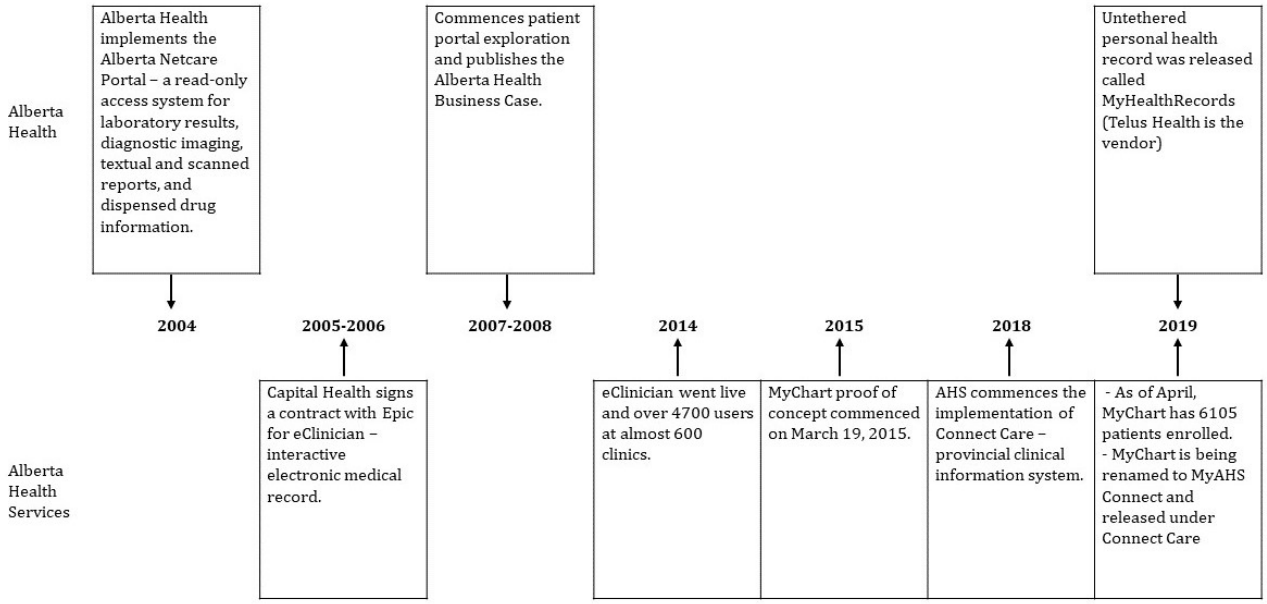
Figure 2. Overview of data collection strategy.



The following sections describe the events based on the extracted data from these sources.

An overview of the Alberta Health and AHS timelines is shown in Figure 3.

Figure 3. Timeline of the development of patient portals in Alberta. EMR: electronic medical record.



The Unmet Need

Before 2005

Alberta's first EMR implementation planning began in 1997 (before the creation of a single province-wide health services delivery organization) with the directive to develop and deliver a single province-wide EMR [24]. This led to the implementation of the Alberta Netcare Portal (ANP) in 2004, which was a read-only access system for laboratory results, diagnostic imaging, textual and scanned reports, and dispensed drug information [25].

2005/06: Capital Health and the Need for a Different Electronic Medical Records

In 2005, Capital Health (1 of the 7 regional health authorities at that time) issued a request for proposals (RFPs) for a different EMR system to replace the ANP system. Epic Systems Corporation (from now on referred to as Epic) was awarded the contract in September 2006. The new EMR system, which was developed and customized for Alberta, was called eClinician.

2007/08: The Alberta Health Business Case

Although Capital Health and later AHS were working on implementing eClinician, AH commenced a patient portal discovery phase based on reports from the United States about the potential for health ITs to be cost saving (business case: personal health portal [Advice to the Minister]). This led Alberta Health to develop a business case that represented the first official document produced by a government body in Alberta that described the need for patients to have access to their personal health records. In addition, patients were *falling through the cracks*, as they were unaware of their test results or if specialist referrals were being made (AH executive-level participant 4).

Although in 2008, AH planned to have a portal deployed within a few years, this did not occur until 2019. Several executive leaders confirmed a description of events during this time when delays resulted from inappropriate planning, changes in vendors, and changes in AH leadership. In addition, individuals involved in managing the personal health record (PHR) project were not equipped with the appropriate technical knowledge as described by an interview participant:

> *So what happened was we ended up in the development mode we're not in the software business. We are not in development business.* [AH executive-level participant 1]

The portal planning undertaken by AHS during 2008 was also seen as a reason for delays:

> *I also think that the culture of AHS has worked against us because they didn't want something separate from their clinical information system. They wanted it to be something that they controlled and part of the software that they would be purchasing. I believe that that culture and that resistance was evident through the whole journey.* [AH executive-level participant 1]

It appears from the key informant interviews and documents that between 2005 and 2008, numerous activities established foundational components for a patient portal in Alberta. It is difficult to judge whether the commitment to meet the identified technology need was rushed or whether the task was more complicated than expected. It took more than 11 years for AH to finally release a PHR system in March 2019 [26]. During these years, an apparent or actual lack of coordination between AH and AHS resulted in tension due to their two patient portal systems appearing duplicative, being established within the same health care system.

2014-2019 Alberta Health Services and the Race to Deliver a Patient Portal

The delays that occurred between 2008 and 2014 were caused by the restructuring that occurred in Alberta when 12 separate health regions and 3 health boards were merged into Canada's first province-wide, fully integrated health system known as AHS. The AHS' patient portal journey was a continuation of what had been initiated by Capital Health (one of the former health regions) by its implementation of eClinician. As AHS was planning the implementation of a provincial inpatient clinical information system, eClinician was meant to serve as a bridge that would ease the gap in terms of the identified need for a provincial EMR and an interactive way for patients and health care providers to access information. In 2014, the eClinician Working Group, with input from various stakeholders, developed a document outlining the AHS health information–sharing prioritization principles that described the need for cost-saving measures based on patients having access to their health care information. In 2014, eClinician went live with over 4700 users at almost 600 clinics or sites [27]. It is important to point out that the AH ANP EMR was still being used in Alberta during the implementation of eClinician.

The eClinician system was intended to support *one person, one record*, and had the capacity to deliver the MyChart patient portal through which patients could access their record, communicate with their provider, and book and cancel appointments. The MyChart PoC, led by a clinical Working Group (MyChart Working Group) reporting to the AHS Ambulatory Oversight Council, was planned in phases that were meant to reflect a forward-thinking plan to align with both the AH PHR and the upcoming AHS Clinical Information System.

> *As a small project team what we did is we created a Clinical Guidance Working Group it was called the MyChart Working Group and on there we had a number of different users on board. We had physicians, nurses, allied health, from different sites and we had managers on there as well.* [AHS senior-level participant 8]

The MyChart PoC implementation was planned as an incremental change in order to minimize resistance by clinicians and patients (eClinician prioritization principles). It was decided that at the conclusion of the PoC, the Working Group would validate the solution against physician's expectations, assess the true performance of the patient portal in a controlled environment, identify areas for improvement, identify implementation tips and traps, and lessons learned, measure key performance indicators and determine the return on investment (eClinician link PoC scope August 21, 2015).

The results from the PoC would be used to determine any future approaches for deployment, long-term expansion, or modifications of the health IT. Thus, between 2014 and 2019, AHS planned, developed, customized, and implemented a patient portal—a process that has been characterized by intricate agenda-setting and decision-making processes. The following sections will describe the technology and what needed to be done to commence the PoC and the subsequent successful implementation and adoption.

MyChart: The Change

The AHS MyChart was a customizable Web app that offered patients easy access to their medical records via controlled access to the same eClinician medical records used by their physicians. It provides self-service functions that have the capacity to reduce administrative costs and increase patient satisfaction. It also offers various features that organizations can select to meet their identified requirements (MyChart Recommendations: Core Features). Each function is implemented based on the need and cost.

Patients participating in the MyChart PoC were able to view their health summaries (problem list, medications, allergies, and immunizations), laboratory and diagnostic imaging test results, previous and upcoming appointments, and letters sent from clinics they have attended. In addition, patients were able to send nonurgent messages to their health care team, request appointment dates and times, complete health assessment questionnaires, and enter information (ie, vital signs or blood glucose measurements).

Before deciding on how the PoC will evolve and if MyChart was the right technology, the work was precipitated by extensive engagement with various stakeholders, as described in Figure 4 (MyChart summary report). This wide consultation process allowed the MyChart Working Group to build credibility in the work they undertook.

Before the PoC started, the MyChart Working Group had to plan and consider all possible variables, tasks, and situations that might arise, and this work was guided by the Epic team (weekly status report for eClinician foundation—eClinician MyChart). The planned PoC phases are shown in Figure 5.

The PoC was deployed by ensuring that the best *bang for our buck* was achieved by only working with health care providers that were willing to be part of the study and implementing functions that were going to be utilized (MyChart summary report). The vision for MyChart PoC was *better health, powered by information, supported by technology* (MyChart monthly CIS project status report, August 2015). The estimated PoC implementation cost (more than US $873,600) was based on the cost of staff to support the PoC, and the purchase of the required software and hardware (MyChart PoC scope, September 9, 2015). By April 22, 2015, the PoC was up and running. The initial goal was to engage 500 patients participating across clinics, with significant measurement and benefits realization activities.

Figure 4. Stakeholder involvement in the MyChart planning and implementation. AHS: Alberta Health Services; IT: information technology.

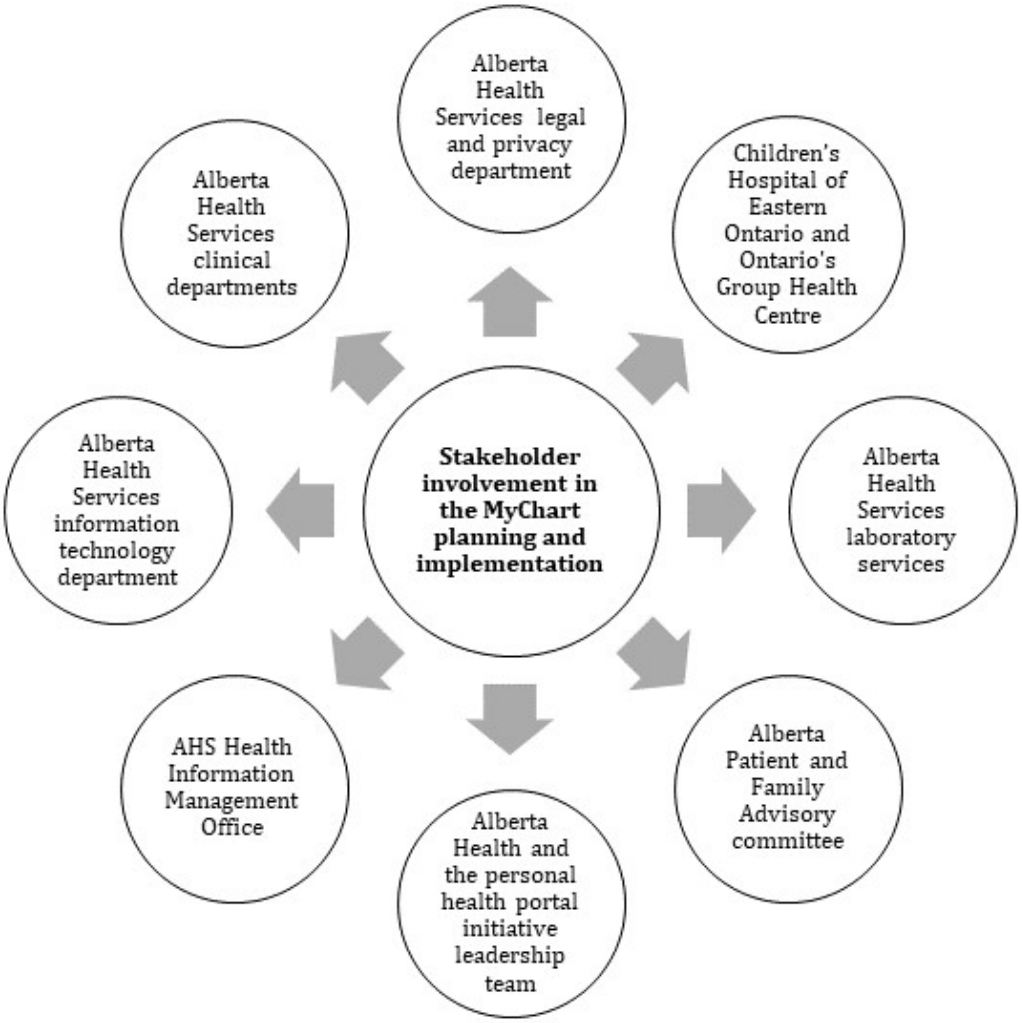


Figure 5. Planned MyChart proof of concept phases. PHR: personal health record.

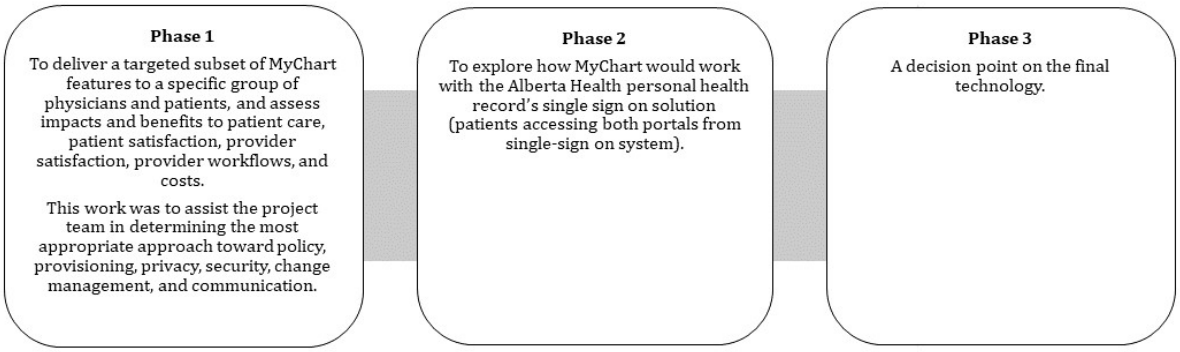

Making the Case for MyChart

The launch of the MyChart PoC required several components that were determined to be crucial for success, such as the recruitment of clinics and health care providers, customization of the portal, and an understanding of how MyChart would align with the AH PHR initiative.

The MyChart Working Group established project management principles to guide them through the planning and implementation process, guided by charter principles as shown in Textbox 1 (eClinician: Lessons learned in context MyChart project).

Textbox 1. MyChart proof of concept charter principles.

- Keep it simple
- Keep the focus on the patient
- Have clear communication with each other and with the task force group
- Let us work together, collaborate, and take joint responsibility for getting it done (no finger pointing)
- Listen to Epic! (Let us not waste time reinventing the wheel, Alberta Health Services is not all that different)

In making the case for MyChart, the MyChart Working Group outlined several cost-saving assumptions, such as a decrease in no-show appointments due to MyChart reminders and the opportunity to implement Web-based scheduling. In addition, with secure messaging, there would be less need for mailing letters to patients, and fewer visits to the emergency department for nonemergent issues, as patients would have immediate access to their health care team. Given that patients would have access to their medical records and test results, the number of follow-up visits was also expected to decrease (eClinician MyChart PoC).

Costs were calculated for the license fees and maintenance of the MyChart app. For each new user who accesses MyChart at least once, there would be an ongoing cost of US $4.05 per year (eClinician MyChart PoC). These costs were offset by the savings realized through the avoidance of unnecessary medical visits.

The Working Group members considered the MyChart PoC as a *bottom up initiative* based on the notion that clinicians had asked for their patients to have access to their medical records (MyChart Epic care AMH, December 3, 2015). Furthermore, the process of *customizing* the patient portal from the American version to a version that worked within the legislation and privacy requirements in Alberta was a long process. There were many decision requests to change how the processes and functions worked, with the intent to create a system that was patient centered and would meet all legislative requirements of Alberta's Health Information Act.

Gaining Support from the Providers

As described by AHS senior-level participant 9,

> *because we wanted to be successful, we sort of chose a group of willing clinics and physicians who we knew were knowledgeable, that reassured us that the clinic was committed and that they were willing to help us. The Working Group didn't want to force anybody that did not want it to participate in the PoC.* [AHS senior-level participant 9]

The recruitment of participating health care providers was a challenging process due to the uncertainty of what a patient portal would mean for them:

> *There were some physicians who were absolutely horrified at the idea of patients being able to view their own results and their own information especially in the case where some decisions were made to release lab results immediately. They were horrified at the idea that the patient might see the results before the physician had a chance to see the result.* [AHS senior-level participant 9]

Health care providers were concerned because MyChart would not replace anything but instead add to the workflow. The MyChart Working Group wanted to ensure that the initiative would be seen as useful and necessary for the enhancement of patient-centered care. The Working Group decided that the best way to commence the PoC was to find health care providers who were given the autonomy to decide which patients were appropriate candidates for MyChart.

During the promotional and exploratory processes for participating clinics, the Working Group selected 5 clinics in Edmonton to participate in the PoC, as shown in Textbox 2, and offered the opportunity to the health care providers from these clinics to participate or not to participate in the PoC. As of April 2019, MyChart was used at 10 clinics.

- AHS Kaye Edmonton Clinic (KEC) Multiple Sclerosis
- AHS KEC Diabetes
- AHS KEC Rheumatology

Navigating Between the Two Patient Portals

The leading concern about the future of MyChart and the need for a PoC hinged on processes related to deciding how the AH and the AHS patient portals were ultimately going to *work together*:

> *The AH PHR is essentially access to read-only database of health information. If you want to break it down to most basic stuff, PHR is for reviewing health information, while MyChart is a tool for viewing health information. These are all things that the PHR can never do. It is helpful to say that they*

> *are two different things, the problem is that if the patients are coming into MyChart and they can do all these things, why would they bother going to the PHR? That's the problem.* [AHS IT senior-level participant 5]

As the introduction of the MyChart PoC idea, tensions between AH and AHS in terms of the portal delivery have increased, leading to a *competition-type* delivery of service, as the two systems appeared duplicative.

> *There were a lot of pull and retain, and a lot of political sensitivities given the amount of money that Alberta Health, the time and effort and money had invested in the PHR. So to get the MyChart® pilot going, we had to escalate it up out of our zone to the IT leadership and medical leadership at AHS first. Then, we had to get permission from the deputy minister level of Alberta Health to do our pilot. We weren't allowed to advertise.* [AHS executive-level participant 7]

From the early planning days of the MyChart PoC, it was determined that the MyChart portal provided more functionalities than the planned PHR.

> *We knew that we could offer more complete functionality using the Epic MyChart, basically out of the box. So the public portal that they're building, there was a lot of configuration, they had to build the software. There was a lot of configuration to that kind of thing. And then the software platform that they were building on it was no longer being supported by Microsoft. So we knew that we could surpass their functionality out of the gates in some ways using eClinician MyChart.* [AHS executive-level participant 7]

Regardless of what was going to be decided, there was a feeling that AH has had the opportunity since 2009 to deliver a patient portal. The sentiment expressed by some participants was that money has been spent, and patients were yet to have access to their health care records. MyChart was seen as a portal that had the potential to be delivered on the identified need.

> *And for clinicians and patients alike this is a real game changer. There's something that really changes the way we operate in health care. It takes responsibility for health care and it gives it to me, to the patients, they can take responsibility for their own health care, which in theory is everything driven by the physician and dictated by the physician in terms of why he thinks the patients need to know and understand.* [AHS senior-level participant 9]

The planning for MyChart had to incorporate components as to how the two portals will eventually work together.

Proof of Concept Scope and Functions

The most challenging component of the implementation process was determining the MyChart functions, as there were many options but limited funding and personnel. Organizational policies had to be established for a help desk, customer service requests, key performance indicator report analyses, a MyChart utilization dashboard, and a *go-live* strategy (Epic MyChart project plan, February 2, 2015). There were many functionalities from which to select; therefore, the Working Group had to decide what was important during the PoC.

Then, 1 participant described:

> *we just sat down in committee meetings and went through the potential futures and whether it was feasible and useful and did we want. And that's how we kind of made our decisions.* [AHS executive-level participant 7]

The Working Group focused on developing the sign-up process and implementing the following functions: two-way communication, real-time scheduling, release of test results, proxy access, notifications, appointment scheduling, and questionnaires, as described in Table 2.

Decisions on how to proceed were made collaboratively as the Working Group saw this as an opportunity to bring a patient portal in Alberta. As 1 participant described:

> *so it is this step wise process that we went through and we just sat down in committee meetings and crack through the potential futures and whether it was feasible and useful and did we wanted and our environment. And that's how we kind made our decisions* [AHS executive-level participant 7]

Therefore, some functions were selected, whereas others were not. Furthermore, when the MyChart PoC was planned, it was decided that the goal would be to offer MyChart to about 500 patients. However, as the PoC evolved and more health care providers decided to participate, it became clear that the milestone of 500 patients was no longer adequate (eClinician MyChart PoC). After considering the positive feedback to date, the AHS agreed to allow for the number of patients participating in the MyChart PoC to be increased up to 5000.

Although there were a great number of anticipated challenges with bringing a patient portal in Alberta, AHS and the MyChart Working Group concluded that not proceeding with this PoC was not an option.

Table 2. Planning and development of functions during the MyChart proof of concept.

Function	Planning and development process
Sign up process	• The sign-up process was a source of significant grievances by patients and health care providers, "because we put so much security on it and made them use passwords, we made it quite complex" (AHS clinician senior-level participant 10). • A two-factor authentication process was designed to comply with privacy legislation. Some never tried to create a MyChart account again after an unsuccessful initial attempt. • When MyChart was first introduced, the sign up was based on a process whereby a provider would print a letter containing a MyChart activation code, and then the patient would take it home and sign up for the account at his or her convenience. Although this process seemed simple, many patients had issues with the code, remembering to set up the account, or losing the printed paper. • There were numerous discussions on how to improve this process and make it more efficient (MyChart activation workflows—pros and cons). • After considering the various options for sign up and soliciting advice from Epic, the MyChart Working Group decided on an email process. • Once a provider had introduced and discussed MyChart with the patient, and he or she agreed to sign up, the provider clicked the MyChart status icon on the patient header in eClinician [Decision Request 11: Create option for MyChart activation letter to be sent to patients via email]. This initiated an email containing an activation letter that was directly sent to the patient's email address documented in MyChart. The email included general instructions about MyChart and the patient's MyChart activation code. The patient had to enter his or her personal health care number, date of birth, and activation code. • The sign-up process included attaching a label to all patients offered MyChart, which indicated whether they were *active* (account used on regular or as needed basis), *inactive* (patient signed-up but never used), *pending* (a patient starts the sign-up process but does not complete it), and *declined* (patient declines to sign up). These labels were as a way of keeping track of patients (Decision Request 238: Add MyChart status to patient header).
Two-way communication	• MyChart included two-way patient-provider secure communications for nonemergent issues. This function required many modifications and decisions because it had not been tested before the PoC, and participating clinicians had expressed skepticism. It was also one of the main reasons many health care providers within the participating clinics decided not to participate in the PoC. Providers assumed that they would be inundated with a large number of messages, and there was no compensation plan in place to remunerate them for their time. • This function was seen as time saving not only for providers but also for patients. • To effectively evaluate the two-way communication, clinics had to decide on the message routing, and how responses would be managed, although the clinics agreed to a process, and each adapted to meet their needs. In some clinics, clinicians monitored the messages directly, whereas in other clinics, nurses or the front office staff managed messages.
Real-time appointment scheduling	• For the real-time scheduling function to be applied, participating clinicians had to enter their availability in the system, which would allow patients to select from the available slots. Once a patient selected a slot, the clinic's office would receive a message. If the booking was done incorrectly or the slot changed, the office staff would call the patient and modify the booking. • This function allowed patients to not only book appointments, but also cancel them at their convenience. Although this function was available to all clinics during the PoC, only 1 clinic (community-based family clinic) gave their patients access to real-time scheduling.
Release of test results	• Release of test results required the lengthiest deliberations because it needed to comply with the legislative requirements of the Health Information Act. • Three options were discussed: auto release (immediate release of all nonsensitive results), time-delayed auto release (some results to be released after a 7-day delay), and no release (results of sensitive tests with the potential for security and privacy concerns). • Each was explored, although Epic recommended automatically releasing as many results as possible, the MyChart Working Group decided that results would be released after 10 days. • Patients would receive an email notification once the results were posted in MyChart.

Function	Planning and development process
Proxy access	• Alberta Health Services determined that although proxy access was challenging due to the Health Information Act, this function would be piloted. • Proxy access allowed MyChart users to permit others to access their MyChart record by establishing a proxy relationship (eg, parent to child, adult to elderly parent). Proxy access was seen as *breaking new ground* and therefore required careful monitoring and clear guidelines. "So proxy was essentially a precedent issue," as no service provided by Alberta Health Services had this available electronically (AHS IT senior-level participant 5). • When initially introduced during the PoC, proxy access was granted through a manual paper-based process that was found to be very cumbersome and time-consuming. It was later replaced by an electronic proxy access via eClinician. Another issue was that in order to receive proxy access to another patient's MyChart account, the designated proxy had to first have their own personal MyChart account. This was not always possible, as many family members requesting proxy access were not part of the same clinic that was on eClinician. • The Working Group established a *shell* MyChart account containing no personal health information for those that have been approved proxy access to another patient's MyChart account, but do not have their own MyChart account (AHS IT senior-level participant 5). Although clinics found the proxy sign-up process cumbersome, the benefits of having proxy access appeared to outweigh these concerns, as patients reported positive benefits.
Questionnaires	• Although several participating clinics wanted to utilize MyChart for questionnaires and surveys, the MyChart Working Group decided for only 1 specialty clinic to proceed with this function. • It was agreed that if this function was deemed successful, it would be recommended for wider implementation.

Discussion

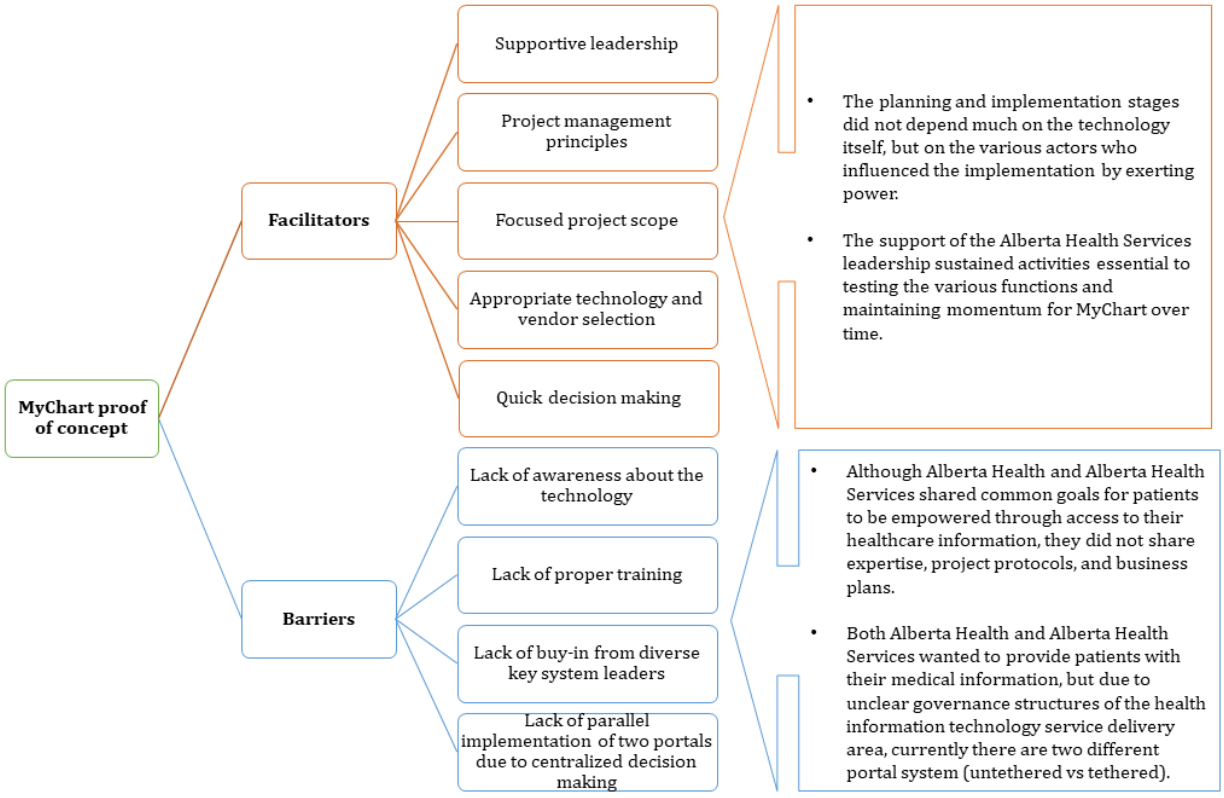
Principal Findings

We have presented an overview of the various environmental and contextual factors that influenced the MyChart PoC during the planning and implementation stages. The MyChart PoC was a complex undertaking of design transformation, adjustment, implementation and deployment, collaboration and compromise, and problem solving with the intent to learn about the necessary elements needed to ensure successful wider implementation. The PoC leadership team agreed that the "technology was the easiest part," as they focused on foundational features with very minimal customization (AHS IT senior level participant 5). The problem-solving processes were impacted by various environmental, social, and professional factors.

Despite extensive research in the area of patient portals, implementation and subsequent adoption of these systems is a convoluted process, which tends to impact settings and practices in different ways [28]. This complexity is clearly shown in MyChart PoC. Furthermore, regardless of the type of setting, these systems require a substantial investment of time, resources, and determination, and not all care settings have the same capacity to contribute equally. As the PoC proceeded, the Working Group saw a difference in the enrollment numbers between the clinics that alluded to differences in uptake.

Through this research study, we wanted to determine what it took to implement a patient portal and what were some of the elements that are necessary not only for successful implementation but also for the successful adoption and optimization of the technology. The review of primary and secondary sources and insights from the interviews explicated several facilitators and barriers that affected the process, as described in Figure 6.

Figure 6. Facilitators and barriers that impacted the MyChart proof of concept during the planning and implementation stages. AH: Alberta Health; AHS: Alberta Health Services.



MyChart Proof of Concept Facilitators

Supportive leadership and quick decision making, project management and focused project scope, and appropriate technology and vendor selection were some of the facilitators that allowed for the commencement and growth of the PoC.

Supportive Leadership and Quick Decision Making

The MyChart Working Group comprised leaders who had the capacity to make decisions in support of making the implementation more manageable and without unnecessary delays. It was not only that the leadership was effective, but they also used real and relevant cases to make the case for the portal and garner support. These observations were also confirmed by an interview participant:

> *I found that in some way, so from concept to deployment it took us what around 6 to 8 months with MyChart. And the reasons I think we were successful is we had strong leadership at the level of the MyChart pilot. And there was medical leadership but also operational leadership. We explicitly had use cases. So we developed a little framework about what are you actually going to use it for, explicitly. That is very helpful and having understanding of the high level concepts. And then we were prepared to make quick and rapid decisions and live with those decisions. And we had clinical input to help us make the decisions.* [AHS executive-level participant 7]

Leadership was able to try improvements and become leaders in innovations, as they had

> *own internal executive approval to kind of go for it and try new things and create some precedent.* [AHS IT senior-level participant 5]

Furthermore, the working Group

> *had to set the stage when it came for the precedent setting stuff since they considered this project as a PoC and they were given a little bit more leeway.* [AHS IT senior-level participant 5]
>
> *The project leadership was able to create a pull for the technology and created an environment where the demand was greater than the supply.* [AHS IT senior-level participant 5]

The findings show that the planning and implementation stages did not depend much on the technology itself, but on the various actors who influenced the implementation by exerting power.

> *The proof of concept was ultimately a learning exercise.* [AHS IT senior-level participant 5]

As described by AHS executive level participant 7:

> *We were successful because we had strong leadership at the level of the MyChart pilot.*

The support of the AHS leadership sustained activities essential to testing the various functions and maintaining momentum for MyChart over time (eClinician: Lessons learned in context MyChart project).

Project Management and Focused Project Scope

The MyChart Working Group developed the PoC based on project management principles. These principles were upheld

through various meetings and discussions. Furthermore, the Working Group developed many discussion documents to identify the most suitable scope for the MyChart PoC. As confirmed by AHS IT senior-level participant 5:

> *first got scope, and once we got clear understanding of who is going to be involved, resources. So scope, resources, finance, and then we could build the schedule. That schedule looked at basically at half dozen clinics and we rolled out everything in a very short period of time.*

Appropriate Technology and Vendor Selection

The MyChart Working Group saw Epic as the necessary guide in this PoC as they possessed the skills and knowledge on how to implement this type of technology. The assumption was that Epic had done this in many different settings and they had the expertise to understand what was required and what AHS needed to do in order to have a successful PoC. The relationship with Epic was not only for the implementation of eClinician, but also for future partnerships.

> *So it wasn't really because of the former relationship with them on eCLINICIAN deployment on anything like that, it was more of a perceived ability for them to help us in the future as a partner to deploy the full Connect Care suite of options.* [AHS executive-level participant 7]

The partnership between the MyChart Working Group and Epic has continued and grown.

MyChart Proof of Concept Barriers

The main barriers were lack of awareness about the technology, proper training, buy-in from diverse key system leaders, and parallel implementation of two portals due to centralized government decision making.

Lack of Awareness About Technology

Although the project team decided not to impose the MyChart PoC on any clinic, various documents show that there was a substantial "lack of awareness" (AHS senior-level participant 6) about what patient portals are and what they would do.

There were barriers relating to communicating with the clinics and getting buy in. There was the fear that getting patients their own information would lead to increased work for the physicians in particular. [AHS executive-level participant 7]

Therefore, there was a fear

> *that patients wouldn't be ready, would get really scared and this would cause a lot of extra work for physicians.* [AHS executive-level participant 7]

Lack of Proper Training

The MyChart Working Group acknowledged that the clinic staff should have received more detailed training. Clinicians perceived MyChart as an add-on and thus did not see training as something needed. This issue was amplified by the fact that the Working Group, due to the small funding, did not have the capacity to establish dedicated staff to assist with any technical and user issues. Although training was not deemed as valuable, as the PoC progressed, clinicians and other clinic staff realized the need for proper training on how the portal works and how patients interact with the system.

Buy-In From Diverse Key System Leaders

Buy-in was a challenge due to

> *fear that giving patients their own information would lead to increased work for the physicians in particular.* [AHS executive-level participant 7]

Furthermore, there was a lack of different key system leaders and champions. The MyChart Working Group comprised influencers, but they needed additional leaders to expand their spheres of influence.

> *I think you need for any successful innovation you need champions both within and outside the system but within the system is absolutely critical and fundamental. If you don't have internal champions, it's not going to go anywhere. And I think you really need in most instances health clinician champions.* [AH executive-level participant 2]

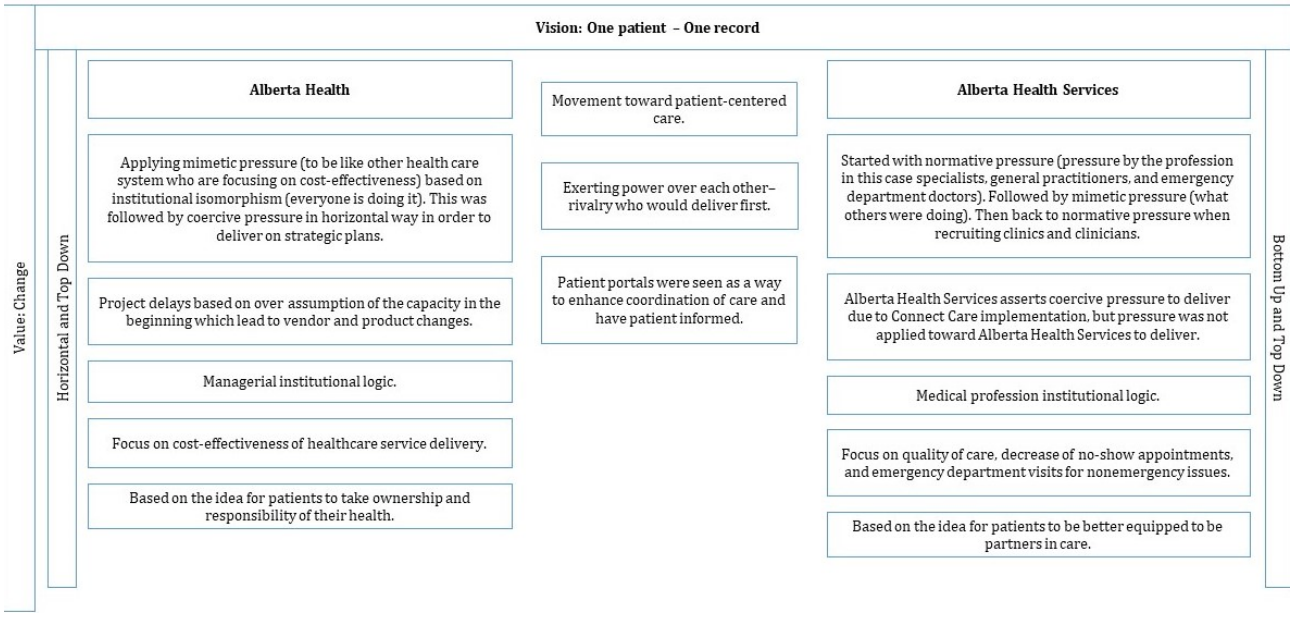
Leadership change also affected the MyChart PoC in negative ways. There were several documents called *handover succession checklists*, which described the complex process of anytime individuals changed (Enhancement PoC eClinician portals: MyChart and eClinician link—Handover succession checklist).

> *So when you have senior leader change in charge of a project that makes for a challenge as well in terms of transition thing.* [AHS clinician senior-level participant 10]

Parallel Implementation of the Two Patient Portals

Although AH and AHS shared common goals for patients to be empowered through access to their health care information, they did not share expertise, project protocols, and business plans. In addition,, the two approaches described in Figure 7 show the impact of the parallel implementation of the two portals.

Figure 7. The vision to change. AHS: Alberta Health Services.



As described by an interview participant:

> *there are two because neither have fully developed themselves out to be the one that is preferential and two, not everyone was involved.* [AHS senior-level participant 6]

Convergence of the two portals seems to be a natural progression, described as follows:

> *Convergence has to happen. Someone somewhere eventually has to figure it out.* [AHS executive-level participant 7]

Both AH and AHS wanted to provide patients with their medical information, but due to unclear governance structures of the health IT service delivery area, currently there are two different portal systems (untethered vs tethered) [29]. These bureaucratic governance complexities will continue to impact how services are planned and delivered in Alberta until there is a better governance structure [30].

The MyChart PoC facilitators and barriers show the complexities that exist within the decisions to implement health IT within different health care settings.

Comparison With Current Literature

Several studies have focused on identifying facilitators and barriers to patient portal implementation, but only a few have touched on understanding the organizational impact [31-33]. Kooij et al [31] focused on understanding how organizational factors impact the implementation process of patient portals by focusing on several hospital settings and identified a number of facilitators and barriers. Their findings are similar to what we found in terms of a lack of perceived value and willingness to change by health care providers. These findings are also similar to those of Koivunen et al [32] and McGinn et al [33]. However, these latter studies focus on understanding the facilitators and barriers from the perspectives of different stakeholders (providers, managers, IT providers, and patients), whereas our focus has been on understanding the internal organizational facilitators and barriers that impact the planning and implementation stages of a patient portal system. Our intent was to understand the internal drivers of change and how decisions were made to support implementation.

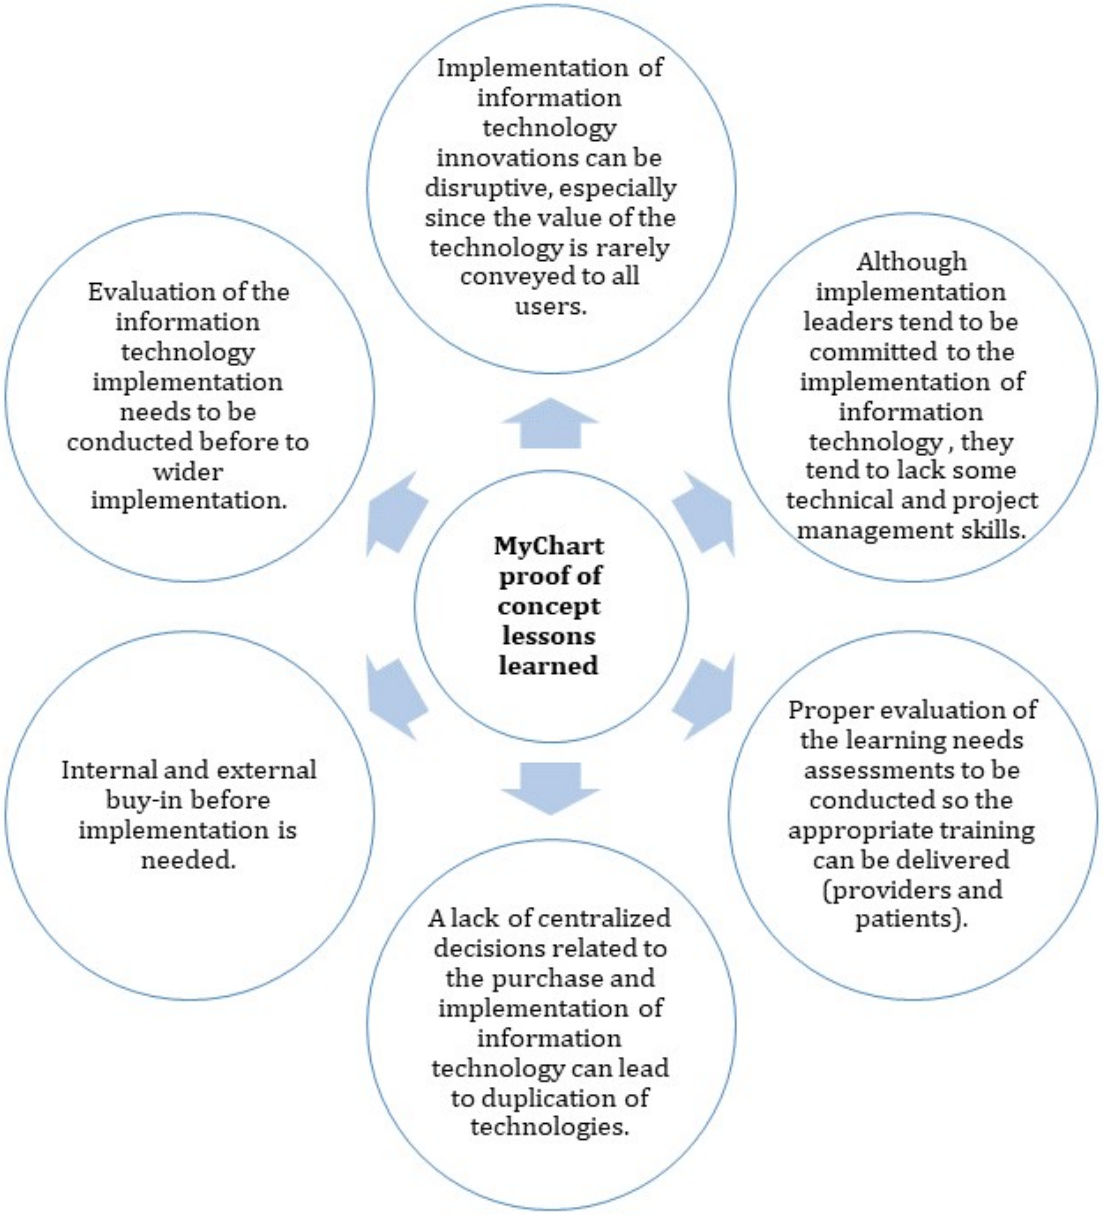
In this study, we found that incorporating project management principles led to a more focused scope that was aligned with the limited funding. These principles (vision and mission, objectives, standards of engagement, intervention and execution, organizational alignment, and measurement and accountability) allowed the implementation team to maintain a detailed record and track progress in real time. The Working Group incorporated project management principles for each project stage (planning, development, implementation, optimization, evaluation, and adoption). Studies by Richer et al [34] and Aubry et al [35] confirm that projects that have the potential to impact organizational change provide benefit not only by incorporating project management principles but also by establishing a project management office and central decision making to improve resource allocation.

According to the US Office of the National Coordinator for Health Information Technology, *the challenge of narrowing a large field of available options to a manageable number of vendors can be daunting, but it is a critical step* [36]. It is not only about selecting the best vendor but also selecting a vendor that *is willing to make commitments to gain new business* [37]. In this study, we were able to gain an in-depth understanding of how the vendor selection process evolved. The vendor section was based on the perceived ability of Epic to help in the future as a partner to deploy the provincial clinical information system.

Implications and Lessons Learned

Although many aspects of what occurred during the MyChart PoC processes are considered common with the implementation of health ITs, there are several features with broad implications for planning and delivering patient portals in a large public health care system that were evident during the MyChart PoC in Alberta, as described in Figure 8.

Figure 8. MyChart proof of concept lessons learned. IT: information technology.



First, the implementation of IT innovations can be disruptive, especially as the value of the technology is rarely conveyed to all users [38,39]. *Value, by definition, includes both costs and benefits* [40]. This is confirmed by several reviews [40-43]. One review concluded, the *human element* is critical to health IT implementation [42]. Although these IT innovations are seen as a *key component of health care transformation to reduce costs and improve quality*, their adoption *proceeds at a snail's pace* [40]. Furthermore, there tends to be a lack of properly *selecting which IT projects are of most value* [43]. Selecting the right technology requires an understanding of the value that the technology has the capacity to deliver and the ability to convey that value to all end users [44,45]. As the literature points out, health IT implementation should be considered as a complex intervention and that *complex interventions may work best if tailored to local circumstances rather than being completely standardized* [46]. Second, although implementation leaders tend to be committed to the implementation of IT, they tend to lack some technical and project management skills [47]. These types of implementation require appropriate skills to ensure successful utilization [46,48]. Third, proper evaluation of the learning needs assessments to be conducted so that appropriate training can be delivered (providers and patients) [49-52]. Quick presentations or Web-based technical training did not seem to resonate with the health care providers during the MyChart PoC. Fourth, a lack of centralized decisions related to the purchase and implementation of IT can lead to duplication of technologies [47,53-55]. Fifth, internal and external buy-in before implementation is needed [47,56,57]. Studies have shown that without the proper buy-in from providers, patients lack information about the opportunities to access their medical records [58]. Without the proper buy-in, providers and decision makers tend to doubt the usefulness of the technology [39]. Sixth, evaluation of IT implementation needs to be conducted before wider implementation [59,60]. Furthermore, evidence from pilots is rarely used when planning the implementation

on a wide scale [60]. According to Houston et al [61], *the domain of Health Informatics is at risk for too rapid implementation as external pressures continue to promote adoption*. Although decisions are made to invest in the purchase and implementation of patient portals, the evidence of utilization and adoption has produced mixed results [41,62,63]. There is a rapid desire to implement patient portals without clear evidence that these technologies have the desired impact on the target populations in terms of effectiveness and safety [61].

The findings in this study highlight the importance of understanding internal organizational and decision-making approaches that have the capacity to hinder the planning and implementation of patient portals. It shows how organizations decide on IT investments, the intricacies of the decision processes, and factors affecting decisions at each stage to provide better future preparations for the successful implementation of technologies. Furthermore, our findings also document the effect of various social and political spheres on the development and implementation of MyChart and identify key factors that government and health care organizations may wish to consider before funding IT in health care.

Limitations

There are several limitations to this study. First, we were unable to receive archival information from AH to describe their patient portal development process in its entirety. Second, although many efforts were made, we were unable to interview any AHS individuals who were considered IT technical experts.

Conclusions

Implementing patient portals is a complex undertaking, as “it’s much more about the people who are using it that actually can make an impact on care” (AHS senior-level participant 6). The results of this study document the effect of various social and political spheres of influence on the development and implementation of MyChart and identify key factors that government and health care organizations may wish to consider before funding IT in health care. This study supports decision makers in understanding and managing the necessary organizational change and managing the individual expectations when implementation technologies have different types of usage by different groups.

Acknowledgments

The authors would like to thank each of the interview participants who took the time to participate in this study. Their participation ensured that we were able to verify the validity of various documents. They would also like to thank the MyChart Working Group for sharing the documents with us. Without access to these internal documents, the story could not be told.

Conflicts of Interest

None declared.

Abstract

Background: Personal health record (PHR) systems let individuals utilize their own health information to maintain and improve quality of life. Using PHRs is expected to support self-management in patients with lifestyle-related diseases.

Objective: The aim of this study was to identify predictors of the willingness to use PHRs among patients who are prescribed medications for lifestyle-related diseases.

Methods: We recruited pharmacy patrons, aged 20 years or older, who had received at least one medication indicated for hypertension, dyslipidemia, or diabetes. Participants completed self-administered questionnaires regarding their previous diseases, awareness of health care, experience in using PHRs, willingness to use PHRs, and barriers to using PHRs. Data were analyzed using multivariate logistic regression models.

Results: Of the 3708 subjects meeting eligibility criteria, 2307 replies (62.22%) were collected. While only 174 (7.54%) participants had previous PHR experience, 853 (36.97%) expressed willingness to use PHRs. In the multivariate analysis, *considering exercise to be important for health management* (odds ratio [OR] 1.57, 95% CI 1.12-2.21; *P*=.009), *obtaining medical information from books or magazines* (OR 1.23, 95% CI 0.96-1.59; *P*=.10), and *obtaining medical information from the internet* (OR 1.45, 95% CI 1.13-1.87; *P*=.004) were newly identified predictors. These were in addition to known predictors, such as being employed, owning information terminals, and previous PHR experience.

Conclusions: Patients who have an active and positive attitude toward health seem to be more willing to use PHRs. Investigating willingness should contribute to the development of more useful PHRs for self-management among patients prescribed medications for lifestyle-related diseases.

Introduction

Hypertension, type 2 diabetes, dyslipidemia, and obesity are referred to as lifestyle-related diseases and are major risk factors for coronary heart diseases and strokes if left untreated. The goal of treating lifestyle-related diseases is to maintain good control for a long period of time, staving off mortality. With lifestyle-related diseases, improving diet and exercise and maintaining good medication adherence are crucial [1,2] but doing so for a long period of time can be hard. Adherence to diabetic diet therapy and regular exercise was reported in one study to be 69% and 19%, respectively [3]. For patients with lifestyle-related diseases in general, low medication adherence has been reported [4-6].

Recently, tools that enhance information and communication technology (ICT) have garnered much attention for effectively supporting self-management of lifestyle-related diseases [7]. Prominent in such technology are personal health record (PHR) systems, which consist of information coordination that allows patients to manage and apply their personal health, medical care, and nursing information. The use of PHRs is expected to help prevent progression of lifestyle-related diseases by improving patients' lifestyles and medication adherence [8,9]. The reported benefits of PHRs were engaging patients in their health behavior, improving their ability to self-manage, and improving communication with health care providers [10,11]. Self-monitoring blood pressure or blood glucose level by using PHRs makes it possible to give patients more specific and direct feedback [10]. A number of PHR systems were developed to support self-management in diabetes patients and were shown to be effective for improving glycemic control [12-14].

We had previously investigated the willingness of diabetes patients to use ICT-based self-management tools and identified predictors of willingness, such as current use of ICT devices or previous dropout from diabetic care [15,16]. However, the role of awareness of health management or medication adherence in this process was not understood, especially among the older population, which accounts for a large percentage of patients with lifestyle-related diseases. Recently, the importance of understanding technology-based behavior in the older population has been emphasized [17,18]. However, little has been understood about willingness and barriers to using PHRs for self-management in the older population. Therefore, we conducted an exploratory study that investigated willingness to use PHRs and awareness of health management in a larger population of patients prescribed medications for lifestyle-related diseases and identified predictors of willingness. Understanding the predictors of willingness to use PHRs may help identify the target population and develop more user-friendly PHRs that could be useful for self-management.

Methods

Study Design and Participants

Between February 6 and March 4, 2017, patients who visited any of the 85 Nihon Chouzai pharmacies in Kanagawa Prefecture, Japan, were recruited for the study. Eligibility criteria were being 20 years of age or older and having been prescribed at least one medication typically associated with treatment for hypertension, dyslipidemia, or diabetes (ie, for hypertension, receiving calcium channel blockers, angiotensin II receptor blockers, angiotensin-converting enzyme inhibitors, diuretics, beta adrenergic blockers, or alpha-beta adrenergic blockers; for dyslipidemia, receiving 3-hydroxyl-3-methylglutaryl-CoA reductase inhibitors [ie, statins], fibrate, anion exchange resin, Niemann-Pick C1-Like 1 inhibitor, probucol, nicotinate, or eicosapentaenoic acid; and for diabetes, receiving biguanide, thiazolidine derivatives, sulfonylurea, glinide, dipeptidyl peptidase-4 inhibitor, alfa-glucosidase inhibitor, sodium glucose cotransporter 2 inhibitor, insulin, or glucagon-like peptide-1 receptor agonist [19]). All participants provided written informed consent.

Exclusion criteria were inability to communicate, visiting the pharmacy on behalf of someone else, being judged by pharmacists as inappropriate, receiving in-home treatment, or being admitted to a nursing home.

Of those scheduled to visit the pharmacy during the 4-week study period, 29,771 who met the eligibility criteria were targeted. To assure the collection of questionnaires from 10% of the patients, 5000 were preselected randomly, positing an estimated response rate of 60%. The number of preselected patients at each pharmacy was in proportion to the number of patients who had visited a corresponding pharmacy during the 3 months immediately prior to the study period.

The targeted patients were given both a verbal and written explanation of the study; PHRs were explained both verbally and in writing as "systems such as electronic prescription records or health management apps to manage one's own medication and health information using electronic devices, including personal computers or smartphones." Those who responded with written informed consent were asked to complete a self-administered questionnaire. The pharmacists checked questionnaires for completion and collected them.

Questionnaire Contents

Each questionnaire elicited the following: (1) basic data, including gender, age, and occupation; (2) medical history, including the disease currently being treated, hospitalizations (with time of stay), and diagnosis of metabolic syndrome; (3) awareness of health management, including what patients considered important for maintaining health, their health information sources, the number of regularly prescribed medications, number of doses, their understanding of their diseases, use of pharmacies, and medication adherence; and (4) PHR-related data, including whether they own an information

terminal, their use of PHRs, and their willingness to use a PHR (see Multimedia Appendix 1). All information including medical history was self-reported and diagnoses were not validated by medical records.

Statistical Analyses

The differences between the two groups determined by their willingness to use PHRs were tested for statistical significance using the Fisher exact test. Correlation coefficients between two variables were calculated by the Spearman rank correlation test and were confirmed to be <.8 in all combinations.

The variables were analyzed using univariate logistic regression models. Those variables with an alpha significance level of .10 were considered candidates for explanatory variables in multivariate analyses.

Multivariate logistic regression models were built by stepwise model selection using Akaike's information criterion. The multivariate analyses included 2020 participants with no missing data in the variables that would comprise the final models.

All statistical analyses were carried out using EZR (Easy R) (Saitama Medical Center, Jichi Medical University, Saitama, Japan) [20].

Data Exclusion

A few questions on the questionnaire were excluded from the analyses because participants presumably misunderstood them; for example, "use of the family pharmacist system" and "use of Okusuri Techo Plus," which is an electronic prescription record application for smartphones and personal computers developed by Nihon Chouzai that has various functions, such as sending prescription information to the pharmacy, recording test results, management of medication adherence, and health information distribution.

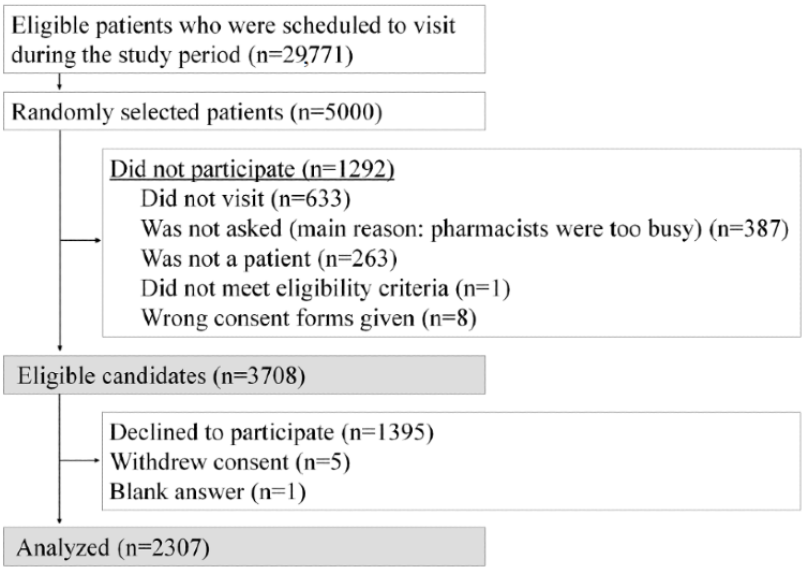
Although only 20.66% (1033/5000) of the preselected candidates had registered with a family pharmacist, 43.43% (1002/2307) of the participants responded that they used the family pharmacist system. Similarly, although the actual usage ratio of Okusuri Techo Plus stood at only 5.92% (296/5000) among preselected candidates, 45.08% (1040/2307) answered that they used it.

Results

Study Population

As described in the Methods section, 5000 patients were preselected. A total of 633 people did not visit the pharmacies with preselected patients' prescriptions during the study period. In total, 387 people were not given an explanation about the study, mainly because pharmacists were too busy, and 263 were excluded because they came to collect someone else's medication. Among the patients who gave written informed consent, 9 were excluded: 1 was not of age and 8 were given the wrong consent forms by their pharmacists. Overall, 3708 were considered eligible candidates. In total, 1395 declined to participate, 5 withdrew from the study before completing the questionnaire, and 1 turned in a blank answer form, leaving a final number of 2307 valid responses. That made the valid response rate 62.22% (2307/3708) (see Figure 1).

Figure 1. Flowchart of participants in this study. Random selection from a population of patients prescribed medications for lifestyle-related diseases, confirmation of eligibility, informed consent, and questionnaire collection.



As shown in Table 1, out of 2307 respondents, 1269 (55.01%) were male, 1636 (70.91%) were 60 years of age or older, and 924 (40.05%) were employed; 1345 (58.30%) reported they had hypertension, 705 (30.56%) had diabetes, and 432 (18.73%) had dyslipidemia. Out of 2307 respondents, 345 (14.95%) who reported neither hypertension, diabetes, nor dyslipidemia were included in the analysis, though some of them may have been treated for other diseases using the same medications used to treat hypertension, diabetes, and hyperlipidemia. Out of 2307 respondents, 1302 (56.44%) owned either a personal computer, smartphone, or tablet, with 899 out of 2307 (38.97%) having a smartphone. Out of 2307 respondents, 174 (7.54%) answered that they had experience using a PHR and 853 (36.97%) expressed willingness to use a PHR.

Table 1. Univariate models of willingness to use personal health records (PHRs).

Characteristic	Total (N=2307), n (%)[a]	Willingness to use PHRs (n=2155), n (%)[b]		Odds ratio (95% CI)	*P* value
		Yes (n=853)	No (n=1302)

[b]Percentages are out of 853 (for *Yes*) or 1302 (for *No*); because of missing responses, the percentages may not add up to 100%.

Univariate Analysis

Factors associated with willingness to use PHRs were identified by univariate analysis (see Table 1). Among the basic characteristics, being male (odds ratio [OR] 1.81, 95% CI 1.51-2.17; *P*<.001), and being employed (OR 2.57, 95% CI 2.15-3.09; *P*<.001) were positive predictive factors, while being 60 years of age or older (OR 0.36, 95% CI 0.30-0.44; *P*<.001) was a negative predictive factor.

Regarding medical history, having dyslipidemia (OR 1.37, 95% CI 1.10-1.72; *P*=.004) and having been diagnosed with metabolic syndrome (OR 1.73, 95% CI 1.40-2.13; *P*<.001) were positive predictive factors, while having hypertension (OR 0.81, 95% CI 0.67-0.97; *P*=.02) was a negative predictive factor.

Regarding what patients considered important for their health management, positive predictive factors were exercise (OR 1.98, 95% CI 1.50-2.64; *P*<.001), diet (OR 1.84, 95% CI 1.33-2.57; *P*<.001), and sleep (OR 1.39, 95% CI 1.15-1.70; *P*<.001). Other positive predictive factors were sources of medical information, such as doctors (OR 1.37, 95% CI 1.06-1.77; *P*=.01), pharmacists (OR 1.45, 95% CI 1.15-1.83; *P*=.001), books or magazines (OR 1.35, 95% CI 1.08-1.68; *P*=.007), and the internet (OR 3.98, 95% CI 3.28-4.84; *P*<.001), while nurses, dieticians, acquaintances, family, newspapers, and television were not. Negative predictive factors were *regularly taking three or more types of medicine* (OR 0.75, 95% CI 0.61-0.91; *P*=.003), *taking medicine twice or more per day* (OR 0.80, 95% CI 0.67-0.96; *P*=.02), and *good adherence to taking medicine* (OR 0.76, 95% CI 0.61-0.94; *P*=.01).

Regarding understanding of diseases, positive predictive factors were *understanding one's diseases or symptoms well* (OR 2.61, 95% CI 1.83-3.79; *P*<.001), *understanding treatment methods well* (OR 1.39, 95% CI 1.15-1.68; *P*<.001), and *understanding how to deal with deterioration of health* (OR 1.30, 95% CI 1.07-1.59; *P*=.009). In contrast, *entrusting doctors with disease and health-related matters* (OR 0.81, 95% CI 0.68-0.97; *P*=.02) or *not paying much attention to one's disease* (OR 0.60, 95% CI 0.38-0.91; *P*=.01) were negative predictive factors.

Regarding PHR-related factors, owning a personal computer (OR 3.54, 95% CI 2.94-4.27; *P*<.001), smartphone (OR 4.19, 95% CI 3.47-5.07; *P*<.001), or tablet device (OR 3.44, 95% CI 2.63-4.51; *P*<.001) were positive predictors, while owning a basic cell phone (OR 0.63, 95% CI 0.52-0.77; *P*<.001) was a negative predictor. Having experience using a PHR (OR 30.30, 95% CI 15.92-64.79; *P*<.001) was a strong positive predictive factor.

Multivariate Logistic Regression Analyses

Multivariate logistic regression analyses were performed. The final model was identified as male (OR 1.52, 95% CI 1.22-1.90; *P*<.001), employed (OR 1.30, 95% CI 1.03-1.64; *P*=.03); having dyslipidemia (OR 1.25, 95% CI 0.97-1.62; *P*=.09); considering exercise important for health management (OR 1.57, 95% CI 1.12-2.21; *P*=.009); obtaining medical information from doctors (OR 1.36, 95% CI 1.01-1.83; *P*=.04), pharmacists (OR 1.63, 95% CI 1.24-2.13; *P*<.001), books or magazines (OR 1.23, 95% CI 0.96-1.59; *P*=.10), or the internet (OR 1.45, 95% CI 1.13-1.87; *P*=.004); understanding one's diseases or symptoms well (OR 1.37, 95% CI 0.92-2.05; *P*=.13); entrusting doctors with disease and health-related matters (OR 1.21, 95% CI 0.98-1.51; *P*=.08); owning a personal computer (OR 1.85, 95% CI 1.46-2.35; *P*<.001), smartphone (OR 2.04, 95% CI 1.61-2.59; *P*<.001), or tablet device (OR 1.36, 95% CI 0.99-1.86; *P*=.06); and having experience using a PHR (OR 16.60, 95% CI 8.52-32.20; *P*<.001). All these were positive predictors for the willingness to use a PHR (see Table 2).

Table 2. Univariate and multivariate logistic models of willingness to use personal health records (PHRs).

Characteristic	Univariate model (N=2307)		Multivariate model (n=2020)	
	Odds ratio (95% CI)	*P* value	Odds ratio (95% CI)	*P* value

[a]N/A: not applicable; variables were considered candidates in the multivariate analyses (*P*<.10) but were discarded from the final model.

[b]N/A: not applicable; variables were not considered candidates for explanatory variables in multivariate analyses (*P*>.10).

Experience and Willingness to Use Personal Health Records

Participants who answered that they had used a PHR (174/2307, 7.54%) were asked the following question about their experience: Which applications had they used? The most common responses were *prescription records* (129/174, 74.1%), *activity amount recorders* (43/174, 24.7%), *blood pressure management* (37/174, 21.3%), and *weight management* (27/174, 15.5%) (see Table 3).

Table 3. Type of personal health record (PHR) application used by participants.

Type of application	Participants (n=174), n (%)
Prescription records	129 (74.1)
Activity amount recorders	43 (24.7)
Blood pressure management	37 (21.3)
Weight management	27 (15.5)
Information on sleep	13 (7.5)
Glycemic control	10 (5.7)
Menstrual management	4 (2.3)
Others	3 (1.7)

The types of information that respondents had most commonly managed through the use of a PHR included *medication prescription details* (76/174, 43.7%), *medication adherence* (54/174, 31.0%), and *home blood pressure values and body weight, etc* (50/174, 28.7%). When asked what types of information they wanted to manage, many responded with answers related to medication, such as *medication prescription details* (84/174, 48.3%) and *medication adherence* (75/174,

43.1%), as well as those related to test values, such as *test results at medical institution* (82/174, 47.1%) and *home blood pressure values and body weight, etc* (76/174, 43.7%) (see Table 4). It was found that while many people expressed a desire to manage test results at medical institutes using a PHR, they were not actually doing so (82/174, 47.1%, vs 20/174, 11.5%; *P*<.001, Fisher exact test). We also found a gap between participants' expressed desires and reality as to *home blood pressure values and body weight etc*, *medication adherence*, *record of the date of hospital visit*, *medical history*, and *meal content* (see Table 4). The most common sources of information about PHRs were *pharmacy staff* (107/174, 61.5%), followed by *the internet* (53/174, 30.5%) (see Table 5).

Table 4. Type of information that personal health record (PHR) users wanted to manage, or did manage, by PHR.

Information type	Participants (n=174), n (%)		*P* value
	Wanted to manage	Managed	
Medication prescription details	84 (48.3)	76 (43.7)	.45
Test results at medical institution	82 (47.1)	20 (11.5)	<.001
Home blood pressure values and body weight, etc	76 (43.7)	50 (28.7)	.005
Medication adherence	75 (43.1)	54 (31.0)	.03
Record of the date of hospital visit	40 (23.0)	21 (12.1)	.01
Medical history	35 (20.1)	8 (4.6)	<.001
Meal content	24 (13.8)	9 (5.2)	.010
Record of immunization	10 (5.7)	3 (1.7)	.09
Surgery record	6 (3.4)	2 (1.1)	.28
Medical history of the family	4 (2.3)	2 (1.1)	.68
Others	3 (1.7)	3 (1.7)	>.99

Table 5. Sources of information about personal health records (PHRs).

Information source[a]	Participants (n=174), n (%)
Pharmacy staff	107 (61.5)
Internet	53 (30.5)
Family	13 (7.5)
Poster	8 (4.6)
Television	6 (3.4)
Hospital staff	5 (2.9)
Newspapers	2 (1.1)
Books or magazines	2 (1.1)
Acquaintance	1 (0.6)
Others	8 (4.6)

[a]Participants who had previous PHR experience were asked where they got information from; multiple answers were allowed.

The 1302 participants who expressed unwillingness to use PHRs were asked why. The main reasons were *it needs more time and effort* (509/1302, 39.09%) or *the need is not felt* (465/1302, 35.71%), followed by *concern over security* (199/1302, 15.28%) (see Table 6).

Table 6. Reasons for unwillingness to use a personal health record (PHR).

Reasons[a]	Participants (n=1302), n (%)
More time and effort	509 (39.09)
The need is not felt	465 (35.71)
Concern over security	199 (15.28)
Cannot use mobile devices	35 (2.69)
Have no mobile device	17 (1.31)
Other	86 (6.61)
No answer	131 (10.06)

[a]Respondents who expressed unwillingness to use PHRs were asked the reasons why; multiple answers were allowed.

Discussion

Principal Findings

Among the predictive factors identified in this study, owning a personal computer, smartphone, or tablet and having experience using a PHR were consistent with prior reports that ICT literacy is associated with willingness to use a PHR [15,16,21-23]. While older age was reported to be a negative predictor in some studies [24,25], others reported that current use of ICT devices was more associated with willingness than age [21,23]. Consistently, in this study, although univariate analysis showed that older age was a negative predictor of willingness to use a PHR (see Table 1), that factor was discarded from the final model of the multivariate analysis (see Table 2). The ownership rate of personal computers, smartphones, and/or tablets was 88.7% (580/654) among participants under 60 years of age, but it was only 43.89% (718/1636) among participants 60 years of age or older (see Multimedia Appendix 2), clearly demonstrating the digital divide between generations. While 55.5% (363/654) of the participants under 60 years of age expressed willingness, only 29.83% (488/1636) of those 60 years of age or older did so (see Table 1). However, among participants 60 years of age or older, 48.1% (345/718) of those who owned ICT devices expressed willingness to use PHRs, compared to only 16.4% (136/831) of those who did not own these devices (see Multimedia Appendix 2). Being employed was identified as a predictor of willingness to use PHRs in this study, consistent with the previous reports [15,26].

While most of the previous reports suggested that gender was not a predictor [21,22,25,27], being male was identified as a predictor in this study. Consistently, the users of GlucoNote—an app for type 2 diabetes and prediabetes patients that we recently developed and released—were mostly men [28]. In contrast, studies in the United States and Europe reported that being female was a predictor of electronic health (eHealth) use [26,29]. These differences in results may be explained, at least partly, by different gender roles in each country; it was reported that a persistent gender gap in ICT use and skills was observed in Japan but not in the United States after adjusting for employment status [30].

The finding that participants who consider exercise important for their health management are more willing to use PHRs (see Table 2) was novel, as was the finding that patients who obtain medical information from doctors, pharmacists, books or magazines, and the internet are more willing to use PHRs. In contrast, obtaining medical information from newspapers or television was not associated with that willingness (see Table 2).

Regarding what the participants consider important for their health management, *diet*, *exercise*, and *sleep* were all positive predictors in the univariate analysis of willingness to use PHRs (see Table 1). However—and strikingly—only exercise remained a strong predictor in the multivariate analysis (OR 1.57, *P*=.009) (see Table 2), while diet and sleep were discarded from the final model. It was reported that for type 2 diabetes patients a health behavior change in physical activity was less common than with a change in healthy diet, and that changing motivation for a healthy diet was higher than that for habitual physical activity [31]. Exercise is different from eating and sleeping behavior in that one has to actively make an effort to implement it [32], so patients who value exercise may have a greater tendency to actively pursue health. Similarly, people who collect medical information from books, magazines, and the internet may be more active in pursuing health than those who obtain information from more passive media like newspapers and television. This is consistent with the previous report that a health-related information-seeking personality was a significant predictor for willingness to undergo online treatment [21].

Interestingly, while *considering exercise important for their health management* was a positive predictive factor, *is willing to incorporate exercise into daily life for health management* was not a significant predictor in the multivariate analysis in this study (see Table 2). According to the Transtheoretical Model, health behavior change consists of sequential stages: precontemplation, contemplation, preparation, action, and maintenance [33]. Although questionnaire choices in this study do not precisely correspond to the stages of change in the Transtheoretical Model, people who *consider exercise important for their health management* are thought to be in one of the contemplation, preparation, action, or maintenance stages, while people who are *willing to incorporate exercise into daily life for health management* are thought to be in the action or maintenance stage. Those who *consider exercise important for their health management* but are not *willing to incorporate exercise into daily life for health management* are likely to be in the contemplation or preparation stage. The result that

considering exercise important is a significant predictor of willingness to use PHRs—while *willing to incorporate exercise into daily life for health management* is not (see Table 2)—matches our previous report that diabetes patients who are in the contemplation or preparation stage of change in exercise are more willing to use ICT-based self-management tools [15]. Therefore, PHRs equipped with the function of stage-matched intervention for contemplation and preparation stages, such as understanding their own state, goal setting, or identification of barriers to behavior change, will lead the users to take action for health management, as stage-matched intervention was shown to be effective for improving glycemic control, hypertension control, and physical activity [34-37].

Because it was reported that health literacy was one of the key variables explaining a willingness to adopt a PHR [23], we expected that people who understand their disease well would be more willing to use a PHR. As expected, *understanding one's diseases or symptoms well*, *understanding treatment methods well*, and *understanding how to deal with deterioration of health* were all positive predictive factors for willingness to use PHRs, while *entrusting doctors with disease and health-related matters* and *not paying much attention to one's disease* were negative predictive factors in univariate analyses (see Table 1). In a multivariate analysis, however, *entrusting doctors with disease and health-related matters* was identified as a positive predictor, along with *understanding one's diseases or symptoms well*. The reason for this seemingly paradoxical result is that multiple answers were allowed: people who answered *I entrust doctors with disease and health-related matters* were also likely to have chosen *I understand treatment methods well* and *I understand how to deal with deterioration of health*, both of which were strong positive predictors in univariate analyses.

While people who had high health literacy were found to be more willing to adopt a PHR [23], those with a low health literacy level might benefit most from a PHR. Plainly, educating people about the benefits of using PHRs will be important.

People who had used PHRs were asked about their usage. Although 94.3% (164/174) of them were willing to use PHRs (see Table 1), gaps between the contemplated and actual use were found (see Table 4). While many people wished to manage information using a PHR, they were not doing so (see Table 4). Future tasks include developing a PHR equipped with functions desired by the users, with the hope that the additions will help trigger usage. The most frequently managed information using PHRs was prescription details, with which there was no gap between the desired and actual function (see Table 4); this may be due to the fact that this study was done in pharmacies, where staff encouraged patients to use electronic prescription records as described above.

As noted, our results showed that 1302 out of 2307 participants (56.44%) expressed no willingness to use a PHR (see Table 1). Consistent with previous reports [38], the main reason for this disinclination was that using PHRs requires too much time and effort (see Table 6). It might be possible to capture the interest of such holdouts if there was a function that made information management quick and easy—perhaps something like auto-linking data on the order of inspection values between patients and medical institutions.

Other frequently mentioned reasons for unwillingness to use PHRs include no need being felt and concern over security. This points to the need for further efforts to inform people of the merits of using PHRs, as well as improvements in security.

This study suggested that the most prevalent information source regarding PHRs was the internet, if we eliminate the potential bias of the fact that the study was conducted in pharmacies where pharmacists encouraged patients to use electronic prescription records (see Table 5). This means that only people with high ICT literacy were able to get enough information about PHRs. Obviously, the visibility and usability of PHRs must be improved so that even citizens with low ICT literacy will find it easy to use.

Limitations

There are several limitations to this study. First, because of the cross-sectional design of the study, the results do not reflect the long-term status of willingness to use PHRs, which might change drastically over time as the technology disseminates and comes into common use. Future tasks include updating the survey to follow the temporal changes in willingness.

Second, the survey was done in a geographically limited area: all the pharmacies were located in the Kanagawa Prefecture of Japan, considered part of the Greater Tokyo Area. Japan has the highest aging rate in the world with relatively high ICT literacy, so the results might not be valid for other regions with different age structures and levels of ICT literacy. Moreover, the eligibility criteria were determined by prescribed medications, which do not always correspond to a diagnosis. A previous study on claims-based algorithms for chronic conditions demonstrated that the sensitivity and specificity for identifying people with hypertension, diabetes, and dyslipidemia by using medication codes were 75.0% and 97.9%, 78.6% and 99.5%, and 34.6% and 97.2%, respectively [19]. Although the specificity is high, as expected, the sensitivity is relatively low, so the survey results cannot be generalized to the entire population with lifestyle-related diseases.

Third, because this was a self-administered questionnaire, some of the information such as the disease currently being treated may not be fully precise. As described above, 345 out of 2307 (14.95%) patients responded they were treated for neither hypertension, diabetes, nor dyslipidemia, even though all the participants were prescribed medication for at least one of the three diseases. Some of them may have been prescribed these medications to treat other diseases, but most of them presumably failed to self-report their diseases. Consistently, a previous report suggested that sensitivity of self-report questionnaires compared to pharmacy insurance claims was 92.4%, 82.6%, and 86.2% for hypertension, diabetes, and dyslipidemia, respectively [39]. Moreover, the intent of some questions may not have been fully understood or may have caused misunderstanding by the respondents, as it was not a structured interview. Importantly, although the concept of PHRs was explained both verbally and in writing as described in the Methods section, it is possible that the participants' insufficient

understanding or unfamiliarity with PHRs contributed to the lack of willingness, given that only 174 out of 2307 (7.54%) had experience using a PHR. Showing the participants actual examples of PHRs, such as health care management apps, prior to providing the questionnaire might help them better understand the concept of PHRs and properly determine the willingness to use PHRs.

Fourth, because the study was conducted at outlets of a dispensing pharmacy company whose staff encouraged patients to use electronic prescription records, there may have been biased results for some questions.

Conclusions

We identified factors predicting a willingness to use a PHR by patients prescribed medication for lifestyle-related diseases. Patients with an active attitude toward health, such as those who consider exercise important for health management or who obtain medical information from books, magazines, or the internet, seem to be more willing to use a PHR. The main barriers to using a PHR were time and effort required and lack of perceived necessity, followed by concern over security. Analyzing these predictors and barriers will prove useful in identifying suitable candidates as PHR users and in developing more helpful tools for self-management by patients with lifestyle-related diseases.

Abstract

Background: Smartphone-based learning, or mobile learning (m-learning), has become a popular learning-and-teaching strategy in educational environments. Blended learning combines strategies such as m-learning with conventional learning to offer continuous training, anytime and anywhere, via innovative learning activities.

Objective: The main aim of this work was to examine the short-term (ie, 2-week) effects of a blended learning method using traditional materials plus a mobile app—the iPOT mobile learning app—on knowledge, motivation, mood state, and satisfaction among undergraduate students enrolled in a health science first-degree program.

Methods: The study was designed as a two-armed, prospective, single-blind, randomized controlled trial. Subjects who met the inclusion criteria were randomly assigned to either the intervention group (ie, blended learning involving traditional lectures plus m-learning via the use of the iPOT app) or the control group (ie, traditional on-site learning). For both groups, the educational program involved 13 lessons on basic health science. The iPOT app is a hybrid, multiplatform (ie, iOS and Android) smartphone app with an interactive teacher-student interface. Outcomes were measured via multiple-choice questions (ie, knowledge), the Instructional Materials Motivation Survey (ie, motivation), the Profile of Mood States scale (ie, mood state), and Likert-type questionnaires (ie, satisfaction and linguistic competence).

Results: A total of 99 students were enrolled, with 49 (49%) in the intervention group and 50 (51%) in the control group. No difference was seen between the two groups in terms of theoretical knowledge gain (P=.92). However, the intervention group subjects returned significantly higher scores than the control group subjects for all postintervention assessed items via the motivation questionnaire (all P<.001). Analysis of covariance (ANCOVA) revealed a significant difference in the confusion and bewilderment component in favor of the intervention group (P=.01), but only a trend toward significance in anger and hostility as well as total score. The intervention group subjects were more satisfied than the members of the control group with respect to five out of the six items evaluated: general satisfaction (P<.001), clarity of the instructions (P<.01), clarity with the use of the learning method (P<.001), enough time to complete the proposed exercises (P<.01), and improvement in the capacity to learn content (P<.001). Finally, the intervention group subjects who were frequent users of the app showed stronger motivation, as well as increased perception of greater gains in their English-language competence, than did infrequent users.

Conclusions: The blended learning method led to significant improvements in motivation, mood state, and satisfaction compared to traditional teaching, and elicited statements of subjective improvement in terms of competence in English.

KEYWORDS

learning; teaching; students, health occupations; mobile apps; education

Introduction

Smartphone-based learning or mobile learning (m-learning), a term that highlights the type of device used, has become a popular learning-and-teaching strategy. It has been defined as the ability to access educational resources, tools, and materials anytime and from anywhere, using a mobile device, such as a smartphone [1]. With respect to health professionals and their education, Dunleavy et al describe m-learning as "any intervention using handheld, mobile devices connected through wireless connections to deliver educational content to pre and postregistration health professionals in order to extend the reach of learning and teaching beyond physical space and distance" [2]. M-learning thus provides a self-directed learning environment that affords continuous access to knowledge, information, and practice tools.

M-learning is being increasingly used by undergraduate and postgraduate students undertaking specialty or continuous training in the health sciences [2,3]. A recent review and meta-analysis showed that m-learning is equally or more effective than traditional learning in this field, although the authors also comment on the need for further research into its value [2]. Given the rapid evolution of mobile technologies in general, and of m-learning in particular, up-to-date evidence is required for the effectiveness of these strategies to be determined.

Motivation is an important factor in learning and performance [4]. Motivation levels can vary depending on learning-and-teaching style. A positive relationship has been reported between motivation and academic performance and learning, while a negative association is associated with dropping out from education [5]. Thus, motivation can be increased if the learning-and-teaching style is appropriate [6,7]. M-learning incorporates different activity options, which students can choose depending on their personal learning preferences or circumstances. This can encourage motivation, engagement, and learning success, positively influencing mood status [6,7].

New technologies may, however, also have a negative effect on learning. A recent study [8] highlights how students believed that new technologies in the classroom might affect their concentration and ability to learn. However, other investigations have found that students using electronic devices during a lecture returned results in learning that were similar to those who did not use these devices [9]. In other work, using electronic devices as learning tools while listening to a teacher was reported to not be distracting [10]. Clearly, the impact of the use of m-learning needs to be further investigated.

Blended learning that combines m-learning with conventional learning to seek the benefits of both [11,12] can also improve the educational experience [13], allowing conventionally taught material to be revisited whenever and wherever the student wishes [12,14]. Previous investigations into blended learning have returned positive results [15,16]. The main aim of this work was to examine the short-term effects of a blended learning method using traditional materials plus a mobile app on specific outcomes among students enrolled in a health science first-degree program. It was hypothesized that, compared to traditional learning alone, a 2-week blended learning program would improve knowledge uptake, student motivation, mood, and satisfaction and would improve competence in English.

Methods

Study Design and Sample Size

This study was a two-arm, prospective, single-blind, randomized controlled trial (ClinicalTrials.gov identifier: NCT03335397). The study subjects were 99 students in their first year of a health sciences degree at the Faculty of Health Sciences, University of Granada, Spain.

The sample size calculation was based on a previous study [17] and a demand of 90% power to detect a difference of 1.70 points in knowledge gain (see Main Outcomes section), while assuming a type 1 error (alpha) of 5% and a type 2 error (beta) of 10%, determined using G*Power software, version 3.1.9.3 (Heinrich-Heine-Universität Düsseldorf), for Mac OS X [18]. The required sample size was estimated at 40 subjects each for the intervention and control groups. Contemplating a dropout rate of 25%, as it is common for health science students to migrate to medicine in the first semester of their first academic year, 50 subjects were enrolled per group.

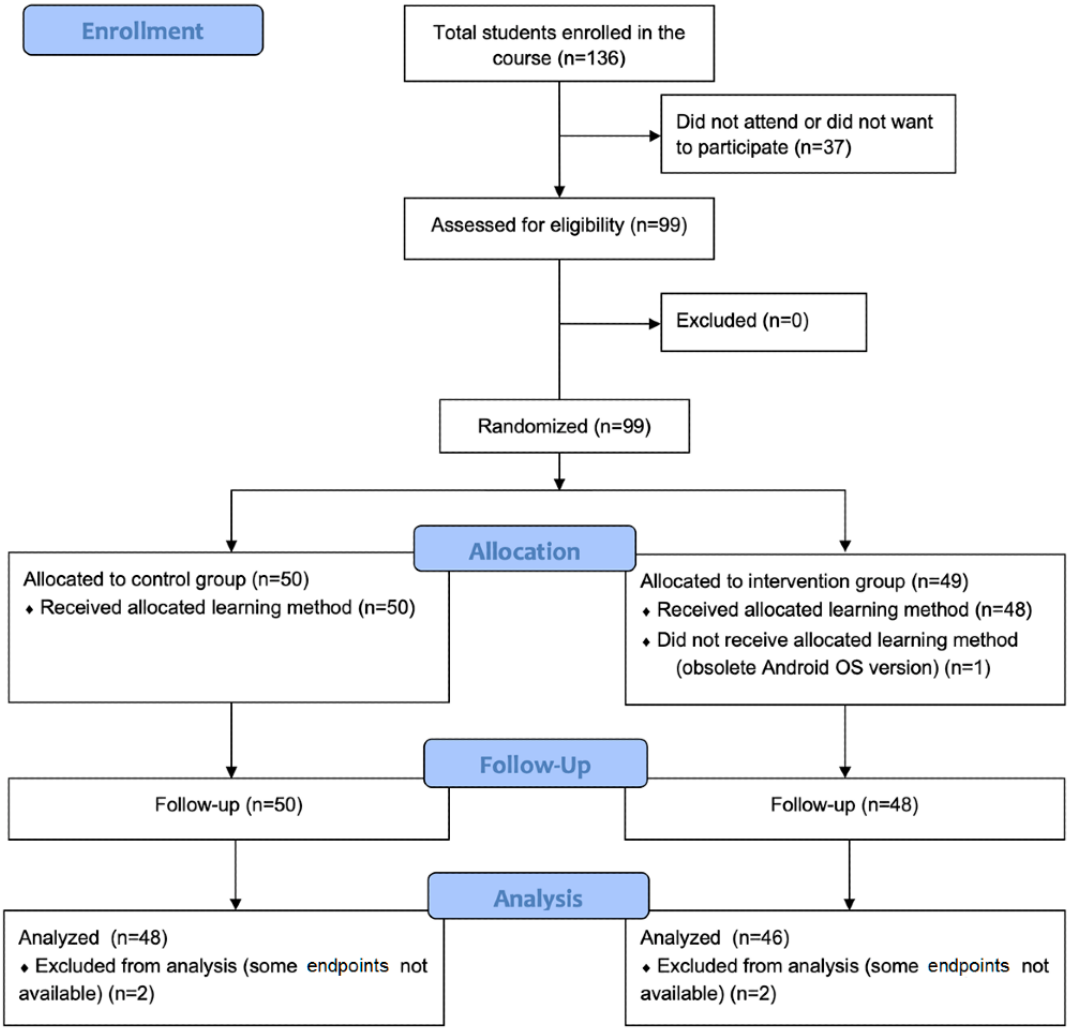
Recruitment

Subjects were recruited via a talk given on the first day of the course unit entitled Basic Health Science, a unit lasting one semester. It was emphasized that no assessment made during the trial would have any effect on final grades and that participation was totally voluntary. To be included, the subjects had to (1) possess basic skills in handling mobile apps, (2) have a smartphone running either Android operating system (OS) or iOS software, (3) install the iPOT mobile learning app, (4) be enrolled in the above course unit, and (5) have a basic knowledge of English, accredited or not. In addition, all subjects had to provide informed consent to be included. Students repeating the unit were excluded.

Randomization

Subjects who met the inclusion criteria were randomly assigned to either the intervention group (ie, blended learning, involving traditional learning plus m-learning via the use of the iPOT app) or the control group (ie, traditional on-site learning). Figure 1 shows a flowchart of the recruitment and randomization process. Subjects were allocated to these groups via the computer generation of a random number list and the subsequent production of a subject allocation sequence using SPSS statistics software, version 22.0 (IBM Corp). The subjects then met with the evaluator who would conduct the forthcoming assessments; this evaluator was blinded to all group assignments.

Figure 1. Flow diagram of the recruitment and randomization process. OS: operation system.



Experimental Procedure

This study was conducted over 2 weeks in the first semester of the 2017-2018 academic year. For both groups, the educational program involved 13 lessons on basic health science. The subjects of both groups were progressively introduced to conventional learning materials (ie, books, PowerPoint presentations, and journals available in the university library). The subjects in the intervention group, however, also received the iPOT app to reinforce the educational program; it provided no additional material. Both the intervention and control subjects were free to reinforce the taught information using any of the traditional sources available. All subjects in the intervention group received a QR (Quick Response) code to provide them access to the Apple App Store [19] or the Google Play store [20] as required. Subjects then installed the iPOT app. A lecturer involved in the project was present at this time to help solve any technical problems that might arise. All the intervention group subjects were provided a personal password linked to their institutional email account that allowed them to access the app, but were also assured each person's log-in information remained confidential and nonexchangeable with subjects in the control group; the system itself was enabled to detect irregular connections. However, given that students in the control group might borrow the devices of the intervention group members in order to try the app out, all subjects were requested to respect the protocol and told they would have unlimited access to the app at the end of the study. The iPOT app included a permanently available video tutorial (see Multimedia Appendix 1), accessible through the *Help* tab, to assist users in familiarizing themselves with the app and its operation. In addition, a WhatsApp group was established for the 2 weeks of the experimental period in order to resolve any incidents that might arise. Two smartphones were available to

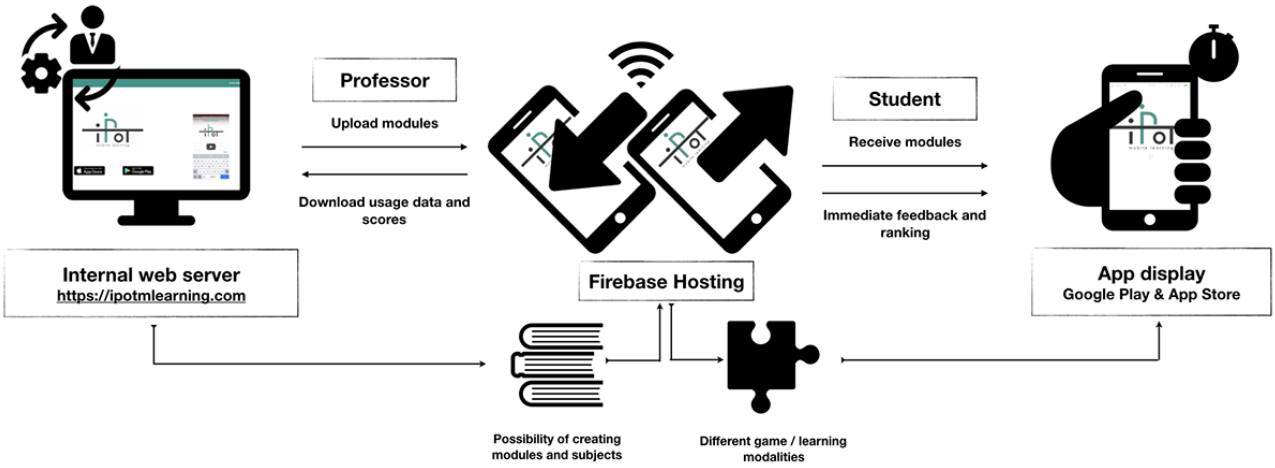
loan to students who wanted to participate but who had devices with compatibility problems.

M-learning lessons were enabled in the app over the last 2 weeks of the teaching period, allowing the intervention group subjects to review the information previously taught. Students were instructed to review each lesson via the six learning modalities available—quizzes (multiple-choice questions), alphabet soup (word search), hangman, hieroglyphics, puzzles (word sorting), and word-coupling activities—and were encouraged to use them; differences in use time were accounted for (see The iPOT Mobile Learning App: Internal Design and Technical Specifications section). It is important to highlight that during these 2 weeks, the control group subjects were encouraged to review the taught material via the above-mentioned books, PowerPoint presentations, and journals.

The iPOT Mobile Learning App: Internal Design and Technical Specifications

The iPOT app was designed by a research group composed of lecturers in health science and an internship student of computer engineering, all at the University of Granada. The app is a hybrid, multiplatform (iOS and Android), smartphone app with an interactive teacher-student interface (see Figure 2). Its architecture involves Firebase, a Google cloud-based development platform that handles user authentication, file storage, and database management. The app interface gives users access to different game modes and allows them to complete different activities and find platform-related information. The app also has an administration console, developed using Angular and Angular Material development tools (Google), that gives administrators the possibility of managing users, all app modules, game-related data, and graphic resources by adding an abstraction layer between the administrator and Firebase. For the deployment of the administration console, it was decided to use Firebase Hosting, a static, rapid hosting service that includes a Secure Sockets Layer (SSL) by default, ensuring safe access.

Figure 2. Top-level view of the iPOT app system.



The user interface shows the user profile, allowing access to personal data and providing the opportunity to change one's nickname; ranking (ie, position in terms of game scores; designed to help increase motivation via a sense of competition); and a start button to allow users to begin playing. As an incentive, each time a correct answer was given in any of the app's modalities, points were added to the user's score. Each user's scores, as well as the number of modules completed, were recorded via the system.

Outcome Measures

Knowledge and mood state were assessed for both the intervention and control groups before and after the 2-week experimental period. Motivation, satisfaction, and English-language competence—the latter only measured in the intervention group—were assessed after this period.

Knowledge

Theoretical knowledge was evaluated at baseline (ie, the beginning of the 2-week study period) and at the end of the study period using 20 multiple-choice questions [21]. This tool has been used in other educational studies [22,23]. Scores were recorded on an 11-point scale, ranging from 0 to 10, with higher values representing better outcomes. This test was developed by two external lecturers who were not involved in the study.

Motivation

Motivation was assessed using the Instructional Materials Motivation Survey (IMMS) [24]. The terminology used by the tool was adapted to the learning methods employed in this study. The survey can be used to estimate the motivation and attitudes of students in situations of self-directed learning (ie, printed, virtual, or online courses). It contains 36 questions in four domains: attention, relevance, confidence, and satisfaction. Each question is scored on a 5-point Likert scale; therefore, total scores range from 36 to 180. Higher scores denote higher levels of learning motivation. The tool has been shown to be highly reliable (intraclass correlation coefficient [ICC]>.96) [25] and has been previously used in Spanish populations [26,27].

Mood State

Mood is a short-term state of feeling; it may fluctuate within minutes or over days. Unlike emotions, moods are more transient, often unrelated to external events, and are of varying intensity [28]. Subject mood state was assessed via the Profile of Mood States (POMS) questionnaire [29], validated for use in Spain [30]. This self-reported survey contains 65 questions, each scored on an increasing 5-point Likert scale, ranging from 0 to 4, that together measure six mood components: (1) tension and anxiety (nine items that refer to an increase in musculoskeletal tension, somatic tension, and observable psychomotor manifestations); (2) depression and melancholy (15 items that reflect a depressed state along with a feeling of sadness or guilt); (3) anger and hostility (12 items that represent feelings of anger and antipathy toward others); (4) vigor and activity (eight items that allude to a state of euphoria or high energy); (5) fatigue and inertia (seven items that refer to a mood of depression or a low level of exercise); and (6) confusion and bewilderment (seven items referring to disorientation or multiplicity of thought). The total average score of all the components (ie, the Total Mood Disturbance [TMD] score) was recorded. There are no cutoff points in any domain. Subjects were asked to fill in the questionnaire indicating how they felt lately. Lower values indicate a better general mood state [31]. The test is reliable; the ICC is close to .90 for all six components [29].

Satisfaction

Subjects' satisfaction with the learning methods to which they were exposed was evaluated via a questionnaire based on that reported by Brewer et al [32], with six items that assess satisfaction variables: general satisfaction, the clarity of instructions, whether the final assessment reflected the course syllabus, clarity with the use of the learning method, whether there was enough time to complete the proposed exercises, and improvement in the capacity to learn content. Each item was scored on an increasing 5-point Likert scale, ranging from 1 to 5. Higher values represent better outcomes. Subjects were also asked to report the number of hours per day, as well as the number of days per week, that they used the app and which mode of the app they preferred.

Linguistic Competence

The subjective improvement in English-language competence (ie, a general feeling of improvement and of improvements in written comprehension, written expression, vocabulary, and global perception) was measured at the end of the study via an ad hoc questionnaire, scoring answers on an increasing 5-point Likert scale, ranging from 1 to 5. Higher values represent better outcomes. To determine the subjects' prior English-language competence, they were asked about any official English certificates they possessed before starting the study.

Statistical Analysis

The normal distribution of data was verified using the Kolmogorov-Smirnov test. Results are presented as mean (SD) values. The Student *t* test and Mann-Whitney U test or the chi-square test and Fisher exact test were used as required to examine differences in continuous and categorical variables, respectively, between the two groups (eg, sociodemographic characteristics, knowledge, and mood state) and in postintervention differences (eg, motivation, satisfaction, and English-language competence).

Differences between the groups in terms of the preintervention-to-postintervention change in knowledge and mood state were analyzed by repeated-measures analysis of covariance (ANCOVA), adjusting for the effects of those variables showing significant differences between groups at baseline (ie, the covariate *POMS-vigor and activity*). Missing values were few (<5% of the total number); in such cases, these can be considered *missing at random* and inconsequential [33]. For this reason, a list-wise deletion method was chosen; no multiple imputation was necessary. Significance was set at $P<.05$. All calculations were performed using SPSS statistics software, version 22.0 (IBM Corp), and Stata statistical software, release 14 (StataCorp).

Ethical Approval

The study was performed in accordance with the ethical standards of the appropriate national and institutional research committees, and adhering to the Declaration of Helsinki [34]. Ethical approval was granted as required by Spanish Law 223/2004, of February 6, establishing subject confidentiality under the terms of Spanish Law 3/2018, of December 5 [35]. The study was also approved by the Quality, Innovation and Planning Unit of the University of Granada, Spain (Plan FIDO UGR 2016-2018). For ethical reasons, once the experimental phase of the project was complete, the app was made available to all subjects who took part.

Results

User Statistics

A total of 99 students were enrolled, with 49 (49%) in the intervention group and 50 (51%) in the control group. The mean age of the students was 19.76 years (SD 2.74) in the intervention group versus 20.00 years (SD 3.98) in the control group ($P=.97$). A total of 38 of the 49 subjects (78%) in the intervention group were women compared to 35 out of 50 subjects (70%) in the control group ($P=.39$). A total of 37 of the 49 subjects (76%) in the intervention group used mobile phones with the Android OS compared to 31 out of 50 subjects (62%) in the control group ($P=.14$). No significant differences were seen between the members of the two groups in terms of their baseline levels of English ($P=.69$) or baseline knowledge of the material to be taught ($P=.43$) (see Table 1). English levels were determined according to the Common European Framework of Reference for Languages: Learning, Teaching, Assessment [36]. The intervention group lost one subject (1/49, 2%) to follow-up—a dropout due to the subject's phone running an old OS that did not support the iPOT app—leaving a final initial sample size of 48. Another 2 subjects were lost from both groups due to incompletion of the final assessments (see Figure 1).

Table 1. Sociodemographic characteristics of the study subjects at baseline: the beginning of the 2-week study period.

Characteristic	Control group (n=50)	Intervention group (n=49)
Age (years), mean (SD)	20.00 (3.98)	19.76 (2.74)
Gender, n (%)		
Male	15 (30)	11 (22)
Female	35 (70)	38 (78)
English level, n (%)[a]		
Not certified	25 (50)	22 (45)
A2 (elementary)	4 (8)	2 (4)
B1 (low intermediate)	14 (28)	15 (31)
B2 (high intermediate)	5 (10)	9 (18)
C1 (advanced)	2 (4)	1 (2)
Mobile system, n (%)		
iOS	19 (38)	12 (24)
Android operating system (OS)	31 (62)	37 (76)
Baseline knowledge of subjects (score[b]), mean (SD)	4.38 (1.21)	4.57 (1.22)

[a]English levels were determined according to the Common European Framework of Reference for Languages: Learning, Teaching, Assessment [36]. A2: Basic User, Waystage; B1: Independent User, Threshold; B2: Independent User, Vantage; C1: Proficient User, Effective Operational Proficiency.

[b]Scores ranged from 0 (no knowledge) to 10 (highest level of knowledge).

Main Outcomes

At the end of the experimental period, no significant difference was seen between the two groups in terms of theoretical knowledge gain (intervention group mean score 0.51 [SD 1.19] vs control group mean score 0.49 [SD 1.10]; F_1=0.008, P=.92) (see Table 2). A significant difference was also not seen in the end-of-study total scores (mean score 5.16 [SD 1.30] vs mean score 4.90 [SD 1.24], respectively; t_{92}=-1.019, P=.31). The covariate *POMS-vigor and activity* did not influence the results.

Table 3 shows that the intervention group subjects returned significantly higher scores than the control group subjects for all items assessed postintervention by the IMMS (IMMS_attention: t_{92}=–12.223; IMMS_relevance: t_{92}=–8.315; IMMS_confidence: t_{92}=–7.731; and IMMS_satisfaction: t_{92}=–10.631; P<.001 for all). Their IMMS total motivation scores were also significantly different (mean 136.02 [SD 19.25] vs mean 84.94 [SD 25.37], respectively; t_{92}=–10.963, P<.001).

Table 4 reflects the mood state of the subjects in each group before and after the intervention. ANCOVA revealed a significant difference between the change in confusion and bewilderment for the control and intervention group subjects (mean score 3.67 [SD 8.66] vs mean score –0.50 [SD 6.62], respectively; F_1=6.826, P=.01). A trend toward significance was also seen between the groups in terms of the change in anger and hostility (control group mean score 2.21 [SD 7.97] vs intervention group mean score –1.07 [SD 8.45]; F_1=3.735, P=.05) and total score (control group mean score –1154.17 [SD 3652.10] vs intervention group mean score –17.39 [SD 2767.05]; F_1=2.875, P=.09). No significant differences between groups were seen in terms of the change in tension and anxiety (F_1=1.964, P=.16), depression and melancholy (F_1=0.983, P=.32), vigor and activity (F_1=0.181, P=.67), and fatigue and inertia (F_1=0.233, P=.63). Adjustment for the covariate POMS-vigor and activity in ANCOVA revealed this variable to influence the change in confusion and bewilderment (F_1=7.889, P=.006), anger and hostility (F_1=4.493, P=.03), and total score (F_1=4.603, P=.03). The covariate did not influence the rest of results.

Table 2. Effect of the different learning methods on knowledge gain.

Answers at study time points	Control group (n=48), mean (SD)	Intervention group (n=46), mean (SD)	*P* value[a]
Correct answers			.92
Baseline[b]	8.81 (2.43)	9.30 (2.37)	
Postintervention	9.79 (2.48)	10.33 (2.61)	
Difference	0.98 (2.20)	1.02 (2.37)	
Wrong answers			.92
Baseline	11.19 (2.43)	10.70 (2.38)	
Postintervention	10.21 (2.48)	9.67 (2.61)	
Difference	–0.98 (2.20)	–1.02 (2.37)	
Total score			.92
Baseline	4.41 (1.21)	4.65 (1.19)	
Postintervention	4.90 (1.24)	5.16 (1.30)	
Difference	0.49 (1.10)	0.51 (1.19)	

[a]Repeated-measures analysis of covariance (ANCOVA) was used to examine the differences between groups.

[b]*Baseline* refers to the beginning of the 2-week study period.

Table 3. Learning motivation in the intervention and control groups.

Learning motivation variable[a,b]	Control group (n=48), mean (SD)	Intervention group (n=46), mean (SD)	*P* value[c]
Attention (12-60)	26.06 (9.64)	47.59 (7.20)	<.001
Relevance (9-45)	24.06 (6.58)	34.17 (5.08)	<.001
Confidence (9-45)	22.04 (6.96)	31.83 (5.13)	<.001
Satisfaction (6-30)	12.77 (4.55)	22.44 (4.25)	<.001
Total IMMS[a] score (36-180)	84.94 (25.37)	136.02 (19.25)	<.001

[a]Learning motivation was measured using the Instructional Materials Motivation Survey (IMMS).

[b]Each category is presented with the possible range of its score in parentheses.

[c]The Student *t* test was used to examine the differences between groups. Significance was set at *P*<.05.

Figure 3 shows the results of the global satisfaction survey with the learning method used. The intervention group subjects were more satisfied than the members of the control group in terms of all items evaluated: general satisfaction with the learning method (*Strongly agreed* and *Agreed* in the intervention group were 30% and 65%, respectively, vs 2% and 10% in the control group; *P*<.001), clarity of the instructions (*Strongly agreed* and *Agreed* in the intervention group were 57% and 35%, respectively, vs 27% and 31% in the control group; *P*<.01), clarity with the use of the learning method (*Strongly agreed* and *Agreed* in the intervention group were 30% and 54%, respectively, vs 2% and 29% in the control group; *P*<.001), enough time to complete the proposed exercises (*Strongly agreed* and *Agreed* in the intervention group were 9% and 17%, respectively, vs 8% and 4% in the control group; *P*<.01), and improvement in the capacity to learn content (*Strongly agreed* and *Agreed* in the intervention group were 11% and 57%, respectively, vs 0% and 17% in the control group; *P*<.001). No difference was seen between the groups with respect to satisfaction regarding how the final assessment reflected the course syllabus (*Strongly agreed* and *Agreed* in the intervention group were 11% and 43%, respectively, vs 6% and 31% for the control group; *P*=.06).

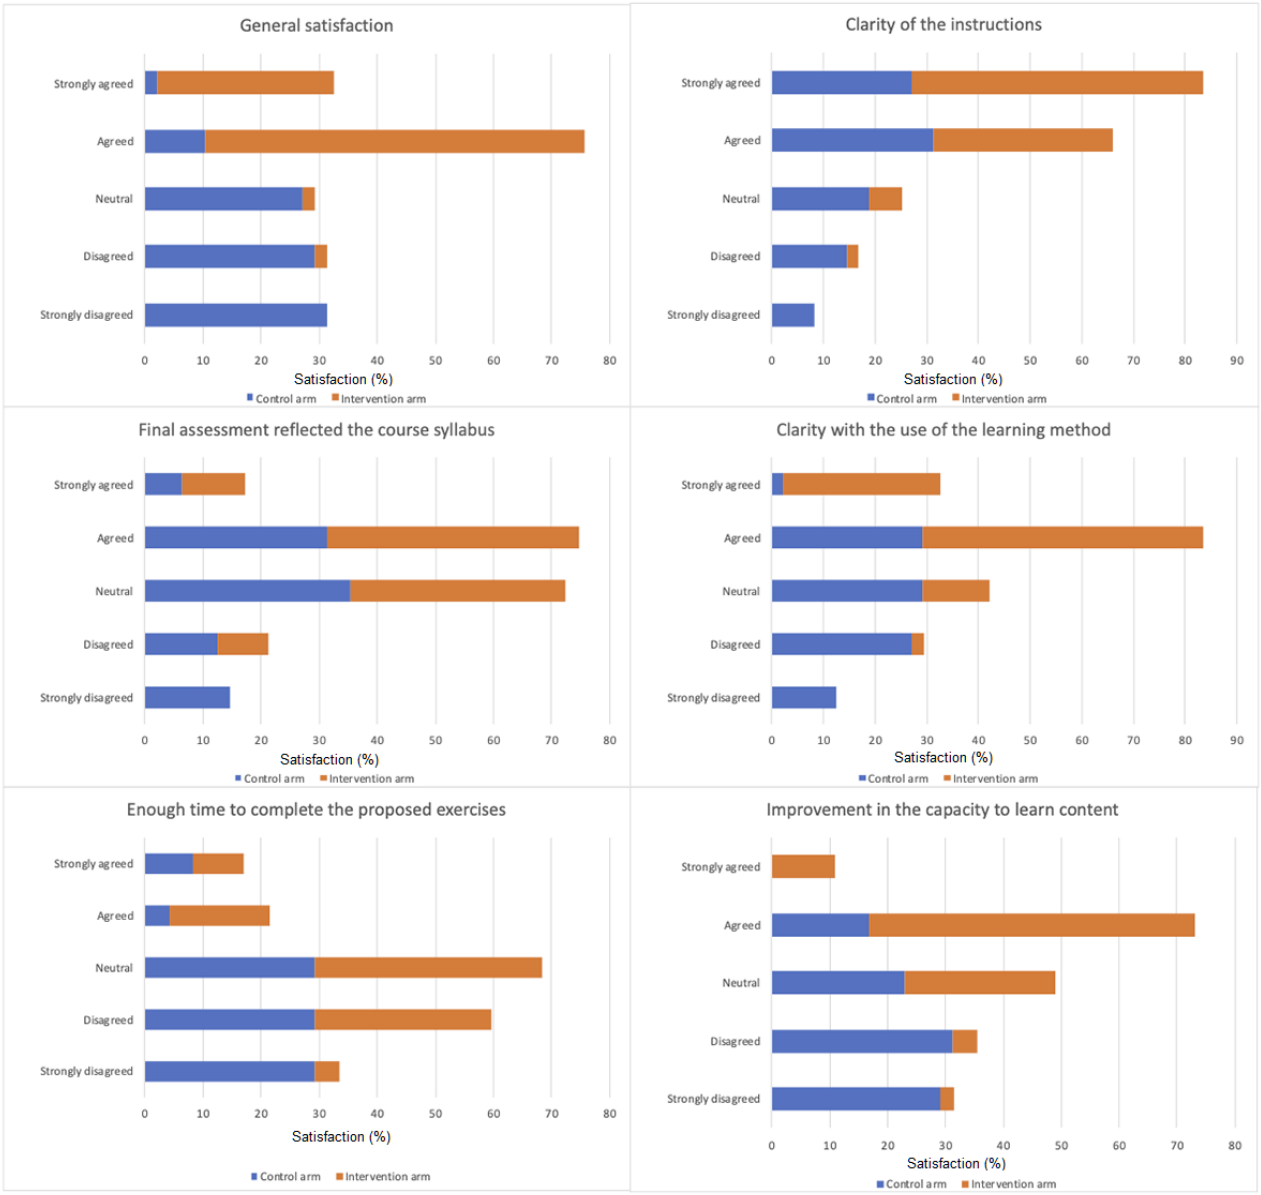
Table 4. Effect of the different learning methods on the Profile of Mood States (POMS) total and subscale scores.

Mood state	Control group (n=48), mean (SD)	Intervention group (n=46), mean (SD)	*P* value[a]
Tension and anxiety			.16
Baseline[b]	45.58 (8.43)	46.78 (9.70)	
Postintervention	46.15 (9.45)	45.00 (10.09)	
Difference	0.56 (8.88)	–1.78 (7.21)	
Depression and melancholy			.32
Baseline	47.38 (5.55)	47.39 (6.82)	
Postintervention	49.21 (7.64)	47.93 (8.64)	
Difference	1.83 (6.55)	0.54 (6.04)	
Anger and hostility			.05
Baseline	51.77 (9.52)	52.67 (8.95)	
Postintervention	53.98 (11.79)	51.61 (10.24)	
Difference	2.21 (7.97)	–1.07 (8.45)	
Vigor and activity			.67
Baseline	54.25 (7.30)	57.43 (6.05)	
Postintervention	51.96 (7.55)	54.67 (6.77)	
Difference	–2.29 (5.80)	–2.76 (4.82)	
Fatigue and inertia			.63
Baseline	47.75 (7.02)	46.59 (6.79)	
Postintervention	48.73 (9.49)	46.80 (7.45)	
Difference	0.98 (9.24)	0.22 (5.51)	
Confusion and bewilderment			.01
Baseline	38.54 (7.38)	39.65 (8.02)	
Postintervention	42.21 (8.43)	39.15 (7.64)	
Difference	3.67 (8.66)	–0.50 (6.62)	
Total score			.09
Baseline	–17677.08 (2899.91)	–17565.22 (3453.13)	
Postintervention	–18831.25 (4052.59)	–17582.61 (4088.16)	
Difference	–1154.17 (3652.10)	–17.39 (2767.05)	

[a]Repeated-measures analysis of covariance (ANCOVA) was used to examine the differences between groups. Significance was set at $P<.05$; a trend toward significance was defined as $.05 \leq P < .10$.

[b]*Baseline* refers to the beginning of the 2-week study period.

Figure 3. Satisfaction among the intervention and control arms.



The intervention group subjects used the app an average of 3.85 (SD 1.51) days per week. The *quiz* option was the most popular, used by 83% (38/46) of the subjects, followed by *word coupling* (29/46, 63%) and *alphabet soup* (20/46, 43%). In further analysis, the median number of days spent using the app per week (median 4 days) was used to categorize students as infrequent (<4 days/week) and frequent users (≥4 days/week). Motivation among the frequent users was significantly higher than among the infrequent users (IMMS_attention: frequent, mean score 50.04 [SD 5.17] vs infrequent, mean score 44.40 [SD 8.29], t_{92}=–2.669, *P*=.01; IMMS_confidence: frequent, mean score 33.77 [SD 4.87] vs infrequent, mean score 29.30 [SD 4.38], t_{92}=–3.222, *P*<.01; IMMS_satisfaction: frequent, mean score 24.00 [SD 3.03] vs infrequent, mean score 20.40 [SD 4.78], t_{92}=–3.114, *P*<.01; and IMMS_total: frequent, mean score 142.85 [SD 15.52] vs infrequent, mean score 127.15 [SD 20.34], t_{92}=–2.971, *P*<.01). No significant difference was detected, however, between the users in the subgroups in terms of IMMS_relevance (frequent, mean score 35.04 [SD 4.24] vs infrequent, mean score 33.05 [SD 5.92], t_{92}=–1.328, *P*=.19). The frequent users also perceived their general linguistic competence in English to have significantly improved through the use of the app (*P*=.03), although this was not reflected when examining specific domains: written expression (*P*=.57), written comprehension (*P*=.18), and vocabulary (*P*=.11).

Discussion

Principal Findings

The blended learning method led to significant improvements in motivation, mood state, and satisfaction compared to traditional teaching. Moreover, frequent users of the app showed stronger motivation and perceived greater gains in their English-language competence than did infrequent users. However, the results suggest the intervention strategy provided no benefit in terms of knowledge absorbed. The latter finding is consistent with the results of two previous randomized controlled studies evaluating online learning methods [22,23].

In contrast, Chuang et al, whose work had a similar design to this investigation (ie, blended learning vs regular lecturing) and was of the same duration (ie, 2 weeks), reported significant differences in favor of blended learning [37]. It has been suggested that the use of audiovisual material, as employed in the latter study, might generate better learning outcomes [38].

Comparison With Prior Work

In this work, motivation was measured by the validated IMMS tool. Higher scores were recorded for all motivation dimensions in the intervention group. Keller defines motivation as an innate characteristic of students, but also indicates that it can be influenced by external factors such as the instructional method used [39]. The innovative design for reviewing classes described in this work may be responsible for the increased motivation among the intervention group subjects. The use of augmented reality among middle school students [26], and of 3D computer environments among undergraduate students [40], have returned similar improvements in motivation. A recent study [41] reports that a mobile augmented reality (mAR) app boosted motivation in 35 students at four vocational education and training institutes over a period of 20 days. Real-time feedback, the degree of success achieved (ie, ranking), time on task (ie, frequent vs infrequent users), and learning outcomes (ie, theoretical tests) were some of the main predictors of improved learning in this latter study. The greatest difference between the subjects in the groups of this study was seen with respect to IMMS_attention (ie, the interest and curiosity of students in the learning process), which was significantly greater among the intervention subjects. The app's attractive interface, enjoyable quizzes, and user-friendliness may be partially responsible for this result.

The intervention group subjects appeared to be more involved in the learning process; they returned a significant change in two of the six mood state components assessed, which was reflected in the total score. Moreover, anger and hostility as well as confusion and bewilderment improved in the intervention group subjects, while these became worse (ie, increased scores) among those in the control group. The use of the app might thus have helped improve negative mood states. Pekrun et al [42] stated that academic achievement is a complex interaction between emotions, engagement, and performance, and this influences student self-appraisal. Flexible and creative learning strategies facilitate positive academic emotions, while more rigid strategies may spur negative emotions [42]. The “flow” concept proposes that an optimal educational experience may exist when students feel that a task is meaningful and, while perhaps challenging, that they are up to the challenge [43]. Other authors [17,44] who tested mAR interventions (ie, 30 minutes and 45 minutes in length), using a variation of the POMS questionnaire to measure change in mood state, only showed intrasubject changes.

Finally, satisfaction was greater among the intervention group subjects. It seems clear that the role of m-learning was perceived as an appropriate complement to traditional lecturing. With the development of advanced technologies, smartphones can be an effective learning tool for students. The possibility of reviewing classes whenever and wherever one likes, with tailored feedback (ie, scores for the games and quizzes), may have promoted the transfer of knowledge into their short-term and even long-term memories [45].

Limitations

This study suffers from the limitation that it lasted only 2 weeks. This short time frame was due to external factors such as a funder-imposed deadline. Further, the iPOT app was created for use as a post-teaching period review tool, not as a study tool in itself. No difference was detected between the amount of knowledge absorbed by the members of the two groups. However, if, as the results show, the use of the app motivates students, a significant difference in what is learned might be expected after a longer period of use. Further work should investigate this.

Conclusions

Students who received instruction via blended learning involving m-learning showed greater motivation, a better mood state, and greater satisfaction than those who received traditional lectures alone, although no difference was seen in terms of the amount of knowledge absorbed. Longer studies are needed to determine whether the improvements in these factors persist and whether they eventually translate into more knowledge being absorbed.

Acknowledgments

We are grateful to Adrian Burton for assistance with the English language. The authors are also grateful to the students who participated in the study. This work was funded by a grant from the Educational Innovation Unit of the University of Granada, Spain (PID 16-54). Additional funding was provided by the University of Granada, Plan Propio de Investigación 2016, Excellence actions: Units of Excellence; Unit of Excellence on Exercise and Health (UCEES).

Abstract

Background: Cybercivility, the practice of what to say and how to say it in online environments, encourages individuals to treat each other with respect. However, the anonymity of online communities may lead some individuals to behave in ways that violate social and cultural norms. These individuals treat others with a lack of regard and even bully others in faceless online confrontations. This practice of cyberincivility can be found across the internet, on commercial sites, and in schools offering online courses. Research on cybercivility and cyberincivility has increased in the United States, where instruments have been developed to measure the impact of cyberincivility in health profession education. However, there is no available instrument that measures nursing students' online behaviors in South Korea.

Objective: The aim of this study was to develop and evaluate a Korean version of the Academic Cyberincivility Assessment Questionnaire developed in the United States.

Methods: Data were collected from 213 nursing students in three South Korean colleges. The Academic Cyberincivility Assessment Questionnaire developed by De Gagne and colleagues was adapted to measure students' knowledge of cybercivility, and their experiences with and acceptability of cyberincivility. Content validity was tested using the content validity index (CVI). Criterion validity was tested using the digital citizenship scale. Reliability was evaluated using Cronbach alpha. The goodness-of-fit of construct validity was determined through exploratory and confirmatory factor analyses.

Results: The CVI was 0.8 or higher for all items. Kuder–Richardson Formula 20, measuring reliability of the knowledge scale, was 0.22 and Cronbach alpha, measuring reliability of the experience scale, was .96. The goodness-of-fit of the model was Chi square=5568.63 (P<.001), the comparative fit index (CFI) was 0.92, and the root mean square error of approximation (RMSEA) was 0.08, which satisfied the criteria. The reliability of the acceptability scale was .96, and the goodness-of-fit indices satisfied the criteria (minimum Chi square/df=2.34, Tucker-Lewis Index =0.92, incremental fit index=0.93, root mean square residual=0.05, CFI=0.93, and RMSEA=0.08).

Conclusions: This study extended and reevaluated the US version of cybercivility scales in a culturally distinct context. The three dimensions of cybercivility include knowledge, experience, and acceptability. Acceptability is well-validated as a dimension, whereas the knowledge dimension requires reexamination for application to Koreans. A revision of the instrument is needed that considers the cultural differences between South Korea and the United States. This paper calls for more attention to be paid to contextualized cybercivility scales among health professions in countries outside the United States.

cybercivility; health professions education; nursing students; social media; web-based learning

Introduction

Background

Internet and mobile devices are essential to everyday life in the digital age. Most individuals use the internet and social media to keep in touch with friends and family, locate goods and services, and educate themselves on a variety of topics, including health [1]. In South Korea, more than 95% of the population uses smartphones, and the country's use of the internet is among the highest in the world [2]. Moreover, South Korea has an advanced health information technology infrastructure [3]. The use of mobile devices as a means for health information dissemination is well documented [2] and makes South Korea a promising market for such interventions in nursing and nursing education.

The expansion of online networks in which information is exchanged through social networking services (SNSs) has increased opportunities for communication, education, and socialization, but has also led to inappropriate online environment activities [4]. Due to the relative anonymity of individuals meeting online, boundaries are skewed and it is difficult to avoid uncivil exchanges [5,6]. Behaviors that cause harm or unpleasantness in online environments are caused by a lack of awareness as to how opinions, memes, and videos might affect others [7]; a lack of civility in communicating and cooperating with others online; or a lack of literacy that causes well-intentioned posts to convey unintended meanings [8,9]. Cybercivility, defined as the practice of respect and responsibility in the online environment [10], makes it possible to exchange new ideas and make new connections, which is especially important in social networking sites and virtual learning environments.

Cyberincivility is an issue that spans across age and professional groups [1,5]. Recently, research on the behavior of nurses and nursing students revealed a substantial lack of cybercivility, including offensive racial and ethnic remarks through a SNS, posting information without evidence as professional knowledge, using profanity, or violating the confidentiality of patients and coworkers [11,12]. Clinicians or practicum students may breach confidentiality due to lack of civility in online communities by posting patient information via SNSs, providing inaccurate medical information, or posting photos that violate professional ethics [13]. Thus, it is important to provide clear guidelines and education for health profession majors, including nursing students. De Gagne et al [14] developed instruments that measure the knowledge, direct/indirect experience, and perception of cybercivility of health profession students. The authors addressed the issue that future health care professionals experience cyberincivility and perceive incivility as a growing problem. Thus, future health care providers need to be educated on ethical and professional standards, including those that apply in online environments. Although a digital citizenship instrument has been developed to measure incivility in South Korea, since this tool concerns political and global issues [15], Cf it is insufficient to examine the cybercivility of nursing students. Therefore, the aim of the present study was to translate the cyberincivility assessment questionnaire developed in the United States [14] from English into Korean and evaluate its psychometric properties.

Objectives

The aim of this study was to develop a Korean version of the Academic Cyberincivility Assessment Questionnaire (ACAQ) [14] and evaluate its reliability and validity among nursing students in South Korea. These findings could be used as the basis of education about cybercivility for students in health profession education.

Methods

Study Design and Participants

We translated the English version of the ACAQ into Korean and tested the psychometrics of the measures with a survey of nursing students from December 2018 to February 2019. The study participants were students at universities in the Busan and Gyeongnam provinces of South Korea. Approximately 14% of Korean nursing departments are located in these two medium-sized cities in urban locations, which are similar with respect to socioeconomic status. Participants were eligible for inclusion in the study if they were: (1) nursing students and (2) aged 18 years and older. Paper questionnaires consisted of a total of 80 items that included 9 questions about demographics, 15 questions about knowledge, and 28 questions each related to experiences and acceptability of cyberincivility. To perform a factor analysis on the data, the sample size needed to be about five times the number of items in the questionnaire [16]. The appropriate sample size needed for a confirmatory factor analysis (CFA) is at least 200 [17]. The sample size for this study was 213, which satisfied the sample size requirement.

Ethical Considerations

After obtaining approval from the Kosin University Institutional Review Board (KU IRB 2018-0095), we advertised the study on campus. The principal investigator and team members provided paper questionnaires to the researchers or research assistants who explained the research purpose and methods to participants in person. Participation was voluntary, and we explained to the participants that they could drop out at any time during the study. As compensation for their efforts, each participant was given a gift worth the equivalent of 3 USD. We collected 222 surveys, 213 of which were included in the final analysis after excluding 9 surveys due to incomplete information. Permission to use the ACAQ was granted from the original developer of the instrument designed for health profession students (ie, medicine, nursing, physician assistant, and physical therapy) in the United States [14]. Permission from

the authors was also obtained for use of the digital citizenship instrument [15] for assessment of criterion validity of the scale.

Measurements

Questionnaire Development

To assess health profession students' knowledge of cybercivility, and their experience with and perceptions of behaviors related to cyberincivility, De Gagne et al [14] developed the ACAQ. The aim of the present survey was also to determine cybercivility learning needs related to interprofessional education (IPE) core competencies in medical, nursing, physician assistant, and physical therapy programs [14]. The ACAQ consists of 75 items in the following 4 sections: (1) demographics, (2) knowledge about cybercivility, (3) experience and perceptions of cyberincivility, and (4) perceived benefits of including cybercivility education as part of the IPE curriculum. Because the present study surveyed only nursing students and IPE pedagogy is not well-understood among Korean nursing students, we excluded section 4 (perceived benefits of including cybercivility in IPE and preferred formats) from our survey.

Demographics

Demographic questions were based on those in the original studies related to cybercivility [9,14]. The items included in the demographics were gender, year in school, clinical practice experience, SNS memberships (multiple responses), time spent on SNS per day, and number of text messages sent per day.

Knowledge of Cybercivility

The original ACAQ contains 15 items to test students' knowledge of uncivil behaviors in online environments [14]. Response choices were "true," "false," and "I don't know," with a score of 1 and 0 assigned for correct and incorrect answers, respectively; a score of 0 was also assigned for a response of "I don't know." The range of calculated scores was 0-15; the higher the score, the higher the knowledge of cybercivility. The original scale of the reliability measured by Kuder-Richardson formula 20 (KR-20) was 0.58. The scores for KR-20 range from 0 to 1, with a score closer to 1 indicating greater reliability of the test. In general, a score above 0.5 is usually considered to be reasonable [18].

Experience With and Acceptability of Cyberincivility

The original ACAQ includes 28 items in two areas (ie, experience and acceptability) that are responded on a 5-point Likert scale [14]. Respondents were asked to rate how often they had experienced or observed uncivil events described in the questionnaire (1=*never*, 2=*rarely*, 3=*occasionally*, 4=*frequently*, 5=*very often*) and how acceptable they perceived each behavior to be (1=*not at all acceptable*, 2=*slightly acceptable*, 3=*moderately acceptable*, 4=*very acceptable*, 5=*extremely acceptable*). Participants were also asked to report how frequently they experienced or observed their peers, instructors, and other individuals demonstrating certain behaviors. Acceptability was measured by asking the participants to rank the acceptability of the behavior based on its actual or potential consequence(s) related to the students' professional or personal development. Cronbach alpha for the original scale on experience and acceptability with cyberincivility was .95 and .94, respectively.

Digital Citizenship

The digital citizenship instrument developed by Choi and Park [15] to determine the concept of citizenship in the digital age was used as the criterion for evaluating the validity of experience and acceptability of the cyberincivility instrument. This instrument is composed of 23 items in the following five areas evaluated on a 7-point Likert scale: (1) internet political participation, (2) technical ability to use the internet, (3) critical perspective, (4) online communication and collaboration, and (5) sensitivity to community and global issues. The digital citizenship scale has good reliability and construct validity that is supported by an expert panel review, exploratory factor analysis (EFA), and CFA [19]. The digital citizenship scale has been used in several previous studies [19,20]. To determine the reliability of a scale, testing/retesting is necessary, and it should be confirmed that the scales are similar after a retest by applying the same surveys to the same participants after a certain period [21]. However, retesting the same participants would have been difficult and there was the possibility of a decrease in the accuracy due to the prior measurement for this survey. Therefore, we did not use a test-retest method but rather evaluated the validity using the correlations with an existing digital citizenship scale. In a pilot study, there was no ceiling or floor effect observed [22]. After receiving permission from the author, we converted the digital citizenship scale to a 5-point scale to facilitate comparison with the survey of cybercivility. A higher score on this scale indicates a higher level of agreement about digital citizenship. The overall Cronbach alpha was .81 in the original study and was .89 in this study.

Procedure

Instrument Translation and Back Translation

Translation of the instrument was conducted based on World Health Organization guidelines [23] in the order of: (1) preliminary translation, (2) expert panel, (3) back translation, (4) preliminary survey, (5) determination of criterion-related validity, and (6) completion. A bilingual nursing professor working at a nursing college in the United States translated the original instrument into Korean. The translation was confirmed by an investigator who is fluent in both Korean and English. Each item on the scale was verified with the original author for accuracy. For example, item 8 in the *knowledge of cybercivility* section ("Americans encounter incivility almost equally offline and online") was revised with consent of the original author because we assumed cultural differences between South Korea and the United States. Thus, the new statement, "People tend to be ruder online than they are in everyday life," was added to maintain the same number of items in the knowledge section. Similarly, item 14 in the *experience with and perceptions of cyberincivility scale*, "Using displays of attitude such as capitalizing or boldfacing words in an argument," was also modified to "Using new words or abbreviations that seem to mock the other person in discussions in cyberspace" as the Korean language does not have capitalization or bold text. In the expert panel review, there was a comment on possible unfamiliarity of the terms and concepts of cybercivility or

sociocultural differences. Therefore, we reflected on these comments as we translated the instrument. Phrases in the translated instrument were verified by a professor of the Korean language to ensure accuracy. The Korean translation of the experience and acceptability items of the ACAQ is presented in Multimedia Appendix 1.

Preliminary Survey

A preliminary survey was given to 24 nursing students from May 2 to 12, 2018 using the newly translated questionnaire. The purpose of the preliminary survey was to determine the clarity of the content, whether the terminology was easily understood, and if the 15 to 20 minutes allotted to complete the survey was reasonable. The students responded that the survey time was sufficient to answer all questions, and that the items were easy to understand.

Statistical Analysis

The data were analyzed using SPSS 20.0 (IBM Corp, Armonk, NY, USA) and AMOS 22 (IBM SPSS AMOS, Version 22.0. 2013, IBM Corp, Armonk, NY, USA) software. Descriptive statistics, including distribution, were calculated for the demographic variables and item scores. The content validity of the experience and acceptability scales was assessed using the content validity index for individual items (I-CVI) and for scales (S-CVI/Ave). To that end, a 5-member expert panel of four nursing professors and one professor of education scored each item on a 4-point scale (1=not relevant, 2=somewhat relevant, 3=quite relevant, 4=highly relevant).

The I-CVI for each item is computed as the number of experts giving a rating of 3 or 4 divided by the number of experts, and the S-CVI/Ave for the scale is calculated as the mean of the I-CVI values of all items on the scale [21]. The criterion validity of the knowledge section was tested by grouping participants according to whether or not they had taken online classes. To take online classes, students need basic knowledge about and the ability to use the internet [24]; therefore, we assumed that there might be a knowledge gap between those who had taken an online class and those who had not.

The internal consistency and reliability were evaluated using the Cronbach alpha reliability coefficient, which normally ranges between 0 and 1; Cronbach alpha of .8 is considered to be a reasonable goal [25]. The Kaiser-Meyer-Olkin (KMO) measure of sampling adequacy and the Bartlett test of sphericity were conducted to determine the appropriateness of the data for EFA. CFA was used to examine the factor structure. The construct validity was then assessed with EFA using maximum-likelihood estimation with oblique promax rotation. The coefficients for the frequency and acceptability of the cyberincivility items were computed along the eigenvalues of the factors. Each factor was interpreted through examination of the item content, patterns of factor structures, and factor pattern coefficients. Following the EFA, a series of maximum-likelihood estimations via CFA were conducted using AMOS 22.0. The fit of the model was verified by the minimum Chi square/degrees of freedom (CMIN/df) value, comparative fit index (CFI), Tucker-Lewis index (TLI), standardized root mean square residual (SRMR), and root mean square error of approximation (RMSEA). To verify the validity of the criteria, the correlation between experience/acceptability of cyberincivility and digital citizenship was analyzed using Pearson correlation coefficient (r), which ranges from –1 to 1; r of –1 indicates a perfect negative relationship, r of +1 indicates a perfect positive relationship, and r of 0 indicates no linear relationship between variables [25]. The strength of the correlation for the absolute value of r was interpreted as very week for r=0.00-.019, weak for r=0.20-0.39, moderate for r=0.40-0.59, strong for r=0.60-0.79, and very strong for r=0.80-1.0 [26].

Results

Descriptive Statistics

The basic characteristic of the participants are summarized in Table 1. The majority of the participants were women in their 20s who were third-year nursing students with clinical practice experience. The most frequent number of SNS memberships was 1-5, and the most frequently accessed SNS was KakaoTalk, which is a free smartphone app for messaging that is used by most Korean smartphone owners, followed by Facebook, Instagram, Naver Band, KakaoStory, and Twitter. The majority of respondents had taken online classes. Most of the respondents (128/213, 88.3%) with online class experience indicated that the greatest advantage of asynchronistic online classes was the convenience of fitting classes into their personal and professional schedules, while the most common disadvantage reported (101/213, 68.7%) was limited interactions with their professors and peers.

Table 1. Descriptive statistics of survey respondents (N=213).

Characteristic	Value
Age (years), mean (SD)	22.58 (0.78)
Gender, n (%)	
Male	26 (12.2)
Female	187 (87.8)
Year in school, n (%)	
2nd	40 (18.8)
3rd	114 (53.5)
4th	59 (27.7)
Clinical practice experience, n (%)	
Yes	173 (81.2)
No	40 (18.8)
Social networking site memberships, n (%)	
1-5	161 (75.6)
6-10	46 (21.6)
11-20	4 (1.9)
≥21	2 (0.9)
Social network sites (repeated response), n (%)	
KakaoTalk	210 (98.6)
Facebook	187 (87.8)
Instagram	170 (79.8)
Naver Band	117 (54.9)

≥10 hours	1 (0.5)
Experience of online course, n (%)	
Yes	147 (69.0)
No	66 (31.0)

Knowledge of Cybercivility

The average score for cybercivility knowledge was 11.30 (SD 1.86) out of a total of 15 points. The minimum and maximum scores were 5 and 15 points, respectively. Six out of the 15 items were answered correctly by 90% or more of respondents. Three items (items 1, 13, and 14) were correctly answered by 50% or less of the respondents (Table 2). Among them, item 1 received the lowest number of correct answers. Two of these items (items 1 and 14) are related to online privacy protection. The scale used to measure knowledge of cybercivility was a binary scale that assumed possible values of 0 or 1, making it inappropriate for factor analysis. The mean experience measured by frequency was 1.96 (SD 0.78) and the mean perception measured by acceptability was 1.84 (SD 0.72).

Table 2. Participants' knowledge of cybercivility, experience with cyberincivility, and acceptability of cyberincivility (N=213).

Content	Correctly answered, n (%)
An organization ensures that all information it collects about users will be kept confidential.	54 (25.4)
Cyberbullying is a form of incivility that occurs in cyberspace where online communication happens.	203 (95.3)
Cyberincivility is a concern among general college populations, but it has nothing to do with students' learning outcomes.	153 (71.8)
Cyberincivility occurs in social media channels, online learning environments, and email.	195 (91.5)
Ethical standards guiding appropriate use of social media and online networking forums in education are already well-established.	134 (62.9)
People say and do things online that they would not say or do in person.	202 (94.8)
Posting unprofessional content online can reflect unfavorably on health profession students, faculty, and institutions.	192 (90.1)
People tend to be ruder online than they are in everyday life. (Original: Americans encounter incivility almost equally offline and online)	206 (96.7)
Unlike traditional bullying, cyberbullying does not require repeated behavior.	184 (86.4)
Cyberincivility is linked to higher stress levels, lower morale, and incidences of physical harm.	199 (93.4)
Using social media inappropriately cannot lead to civil or criminal penalties.	160 (75.1)
Cyberincivility does not occur in the workplace.	184 (86.4)
Humor, anger, and other emotional components of online messages are the same as face-to-face messages.	98 (46.0)
Breaches of confidentiality on social media may lead to mandatory reporting to licensing and credentialing bodies.	113 (53.1)
Despite privacy settings on social media, nothing is private after it is posted on the internet.	129 (60.6)

The I-CVI of cybercivility knowledge was more than 0.80 and the S-CVI/Ave was 0.92. The criterion validity of the knowledge scale was tested using the known-groups technique. The knowledge of cybercivility among those who took at least one online class was 11.38 (SD 1.85) and was 11.26 (SD 1.87) for those who did not take online classes, which did not differ significantly (t_{125}=0.437, P=.96). The reliability of the knowledge scale assessed by KR-20 was 0.22.

Experience With Cyberincivility

Content Validity

The average score for experience with cyberincivility was 1.96 (SD 0.78) out of 5 points. The I-CVI of cybercivility experience was more than 0.80 and S-CVI/Ave was 0.98.

Exploratory Factor Analysis

The KMO measure of sampling adequacy for experience with cyberincivility yielded an index of 0.94. Bartlett test of sphericity was significant (Chi square=5568.63, P<.001), indicating that the data were appropriate for EFA. When the EFA was run using maximum-likelihood estimation with oblique promax rotation, 4 factors with eigenvalues≥1.0 were extracted and accounted for 72.22% of the overall variance. The factor analysis showed that the commonalities of all items were 0.40 or higher and the eigenvalues were 1 or greater, resulting in 4 factors being extracted. The first item was "Blaming technology for failure of communication, assignment completion, or submissions." This was excluded from the EFA because it was not included in any factor. CFA was then performed using the 4 factors extracted in the EFA. We named these four factors F1 (individual behaviors in online environments), F2 (online class attendance attitude), F3 (email manner in online environments), and F4 (online assignment ethics).

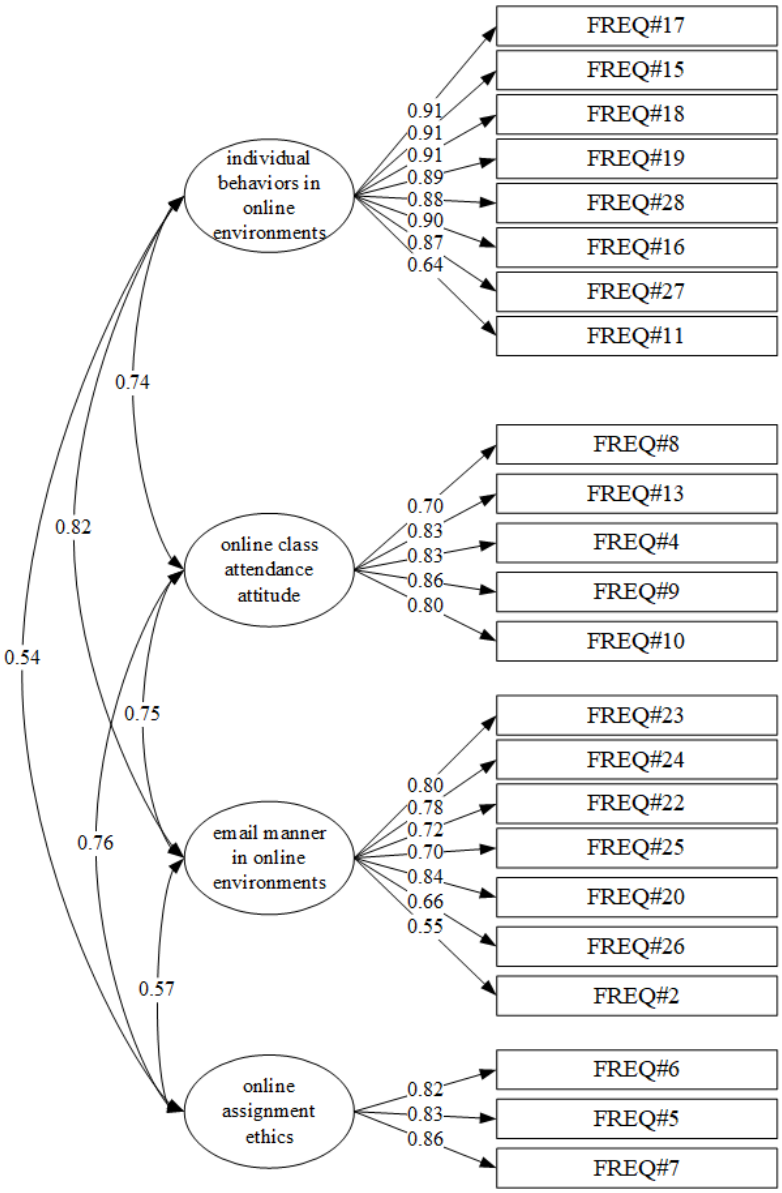
Confirmatory Factor Analysis

A CFA was performed on the 4 subfactor models extracted via the EFA. The path models are shown in Figure 1. The goodness-of-fit indices of the 4-factor structural model were as follows: CMIN/DF=2.724, TLI=0.90, incremental fit index (IFI)=0.92, SRMR=0.06, CFI=0.92, and RMSEA=0.08. The best-fit model criteria were CMIN/df≤3, TLI≥0.90, IFI≥0.90, SRMR≤0.08, CFI≥0.90, and RMSEA≤0.08, which suggests that all of the goodness-of-fit indices of the model satisfied the criteria.

Reliability

Cronbach alpha coefficient of experience with cyberincivility was .96, and the Cronbach alpha coefficients of the 4 subareas were .96 for F1 (individual behaviors in online environments), .90 for F2 (online class attendance attitude), .88 for F3 (email manner in online environments), and .88 for F4 (online assignment ethics).

Figure 1. Confirmatory factor analysis of experience of cyberincivility.



Criterion Validity

The content validity of experience was good, but the criterion validity was low. The experience of cyberincivility [14] was calculated using Pearson correlation coefficient, which was not significant (r=0.085, P=.22).

Acceptability of Cyberincivility

Content Validity

The average score for acceptability of cyberincivility was 1.84 (SD 0.72) out of 5 points. Criterion validity was tested by comparing the means of correlations of the digital citizenship instrument [15].

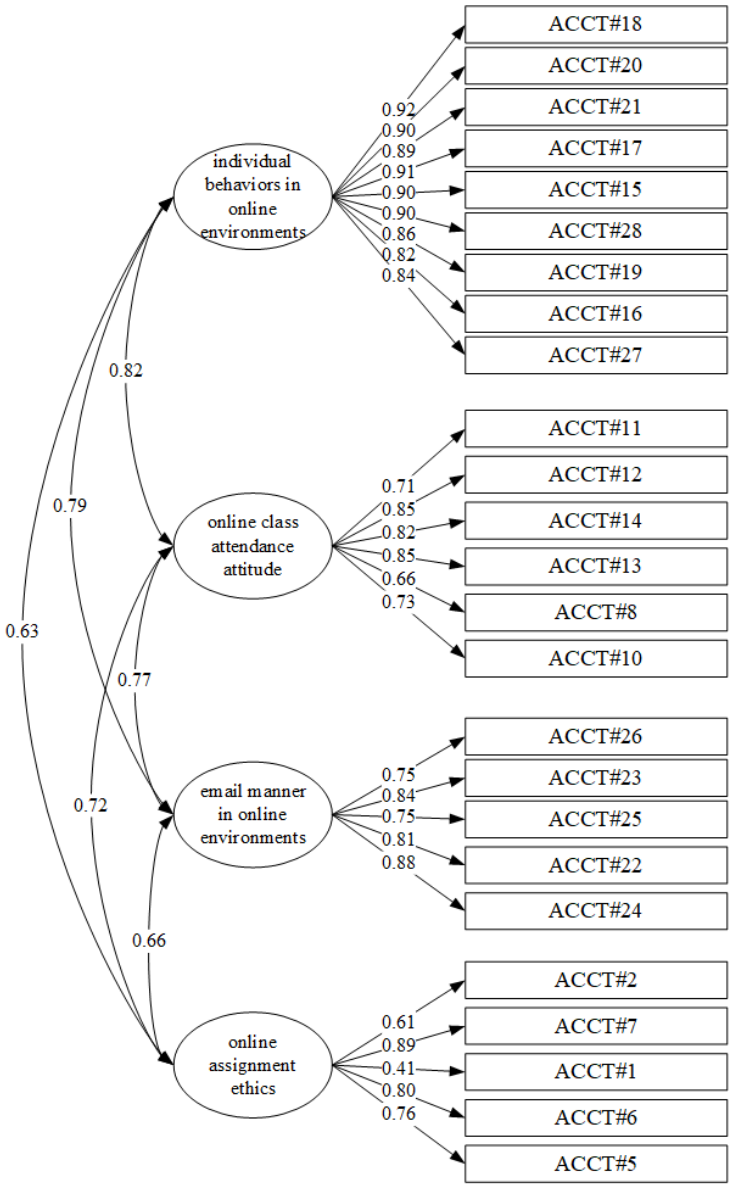
Exploratory Factor Analysis

The KMO measure of sampling adequacy for acceptability of the cyberincivility items yielded an index of 0.94. Bartlett test of sphericity was significant (Chi square=5635.51, P<.001), indicating that the data were appropriate for EFA. When the EFA was run using maximum-likelihood estimation with oblique promax rotation, the commonalities of all items were 0.40 or higher, and the eigenvalues were 1 or greater, resulting in 4 factors being extracted. The overall explanatory power of the analysis was 70.53%, and all values conformed to the goodness-of-fit criteria.

Confirmatory Factor Analysis

A CFA was performed on the 4-factor model based on the 4 subfactors extracted in the EFA; the path model is presented in Figure 2. The goodness-of-fit indices of the 4-factor structural model were as follows: CMIN/df=2.343, TLI=0.92, IFI=0.93, SRMR=0.05, CFI=0.93, and RMSEA=0.08. All of the goodness-of-fit indices of the model satisfied the criteria.

Figure 2. Confirmatory factor analysis of acceptability of cyberincivility.



Reliability

Cronbach alpha coefficient of the acceptability of cyberincivility was .96. Cronbach alpha coefficients of the subcategories were .97 for F1 (individual behaviors in online environments), .89 for F2 (online class attendance attitude), .90 for F3 (email manner in online environments), and .81 for F4 (online assignment ethics).

Criterion Validity

Criterion validity was tested by means of correlations with the digital citizenship instrument [15]. The acceptability of cyberincivility was tested using Pearson correlation coefficient, which was statistically significant (r=0.16, P<.001).

Discussion

Principal Findings

A Korean version of the cyberincivility assessment questionnaire was developed to test knowledge of cybercivility and to explore the experiences and acceptability of uncivil behavior in various cyber domains. The translated questionnaire was then used to measure the knowledge, experiences, and acceptability of nursing students.

Most of the participants of this study were female students who had completed 2 years toward their degrees, a nursing practicum, and at least one online lecture. Since female students make up the majority of nursing students, 80% of the participants were female. In the original study in the United States in which 205 students participated, most of them were also female at 83.4% [14]. Comparing the two studies, 75% of the participants in the current study and 82% of the US participants [14] reported that they were members of 1-5 SNSs.

The content of the Korean scale was deemed to be appropriate to measure the knowledge of cybercivility, experience, and acceptability of cyberincivility as shown in the CVI. Polit et al [21] recommended that for a scale to be judged as having excellent content validity, it should comprise items with I-CVIs of 0.78 or higher for three or more experts and an S-CVI/Ave

of 0.90 or higher. The content validity using I-CVI and S-CVI/Ave of the knowledge, experiences, and acceptability scales satisfied these standards. This might reflect sufficient reviews during the translation by scholars and professors of a Korean expert in second languages.

The average score for cybercivility knowledge was similar to the result of the original study (11.30, SD 1.86 vs 11.53, SD 1.99, respectively) [14]. However, the current study's reliability of cybercivility knowledge was lower than that observed in the original study. The low rate of correct answers may have been due to participants' lack of knowledge or exposure to certain types of cyberactivity. The fact that traditional lectures are more common in South Korea might have been a factor contributing to this difference. In addition, faculty tend to use one-way communication in asynchronistic online classes, such as uploading lectures with voice recordings instead of holding discussions on online portals or conducting virtual online meetings with students in South Korea. Indeed, in a study that examined 2600 courses at one university in South Korea, only 3% of online courses used internet-based discussions and only 8% used online meeting programs to facilitate group work [27]. In addition, the participants of this study were undergraduate students with a mean age of 22.58 (SD 0.78) years, whereas the subjects of the original study were graduate students with a mean age of 29.70 (SD 7.0) years [14]. This age difference might have led to a difference in their experience and knowledge and caused the variation in their responses. It is recommended that future studies consider these results and reconfirm KR-20 with a greater variety of subjects.

The digital citizenship instrument [15] was used to test the criterion-related validity with the translated cyberincivility assessment instrument. The differences between the tests were likely related to their different contexts and populations. That is, the digital citizenship instrument was composed of items designed to address general social relationships on internet use or internet political participation, whereas the cyberincivility assessment questionnaire was developed to address the academic environment from the perspective of students in health-related majors [14]. However, due to differences in communication methods or meanings in different sociocultural environments [28], the definition of cybercivility can vary among individuals and countries. In the case of the United States, it is common to use email for personal and business exchanges and to share opinions in learning management systems during online classes or traditional classes with this online component [29], so that students in a US academic setting are more accustomed to these methods of communication. However, in South Korea, text messaging services using mobile phones are the most frequently used channel of communication among students and faculty [30]. Hence, it is not surprising that differences were found in what constitutes civil or uncivil behavior between these two populations. Furthermore, communication methods and manners in text messaging services are more of a concern than emails or online college communication tools [27].

The significance of the present study lies in the validity of an instrument that can measure the cybercivility knowledge and practices of South Korean nursing students whose professionalism and attitudes are important to their careers and patient care. For future study, to better understand an individual's experience of cyberincivility, there is a need for measuring an individual's direct experiences in addition to observations of others' behaviors in online environments. It is also necessary to modify the knowledge cybercivility assessment questionnaire by considering cultural aspects to obtain a good reliability coefficient. The ways in which individuals communicate and their manners in cyberspace differ between South Korea and the United States, necessitating a revision of the instrument to take into account cultural differences and to provide greater validity for future studies.

Limitations

The experience scale is limited because findings are based on self-reports of students' personal experiences and their observations of others. Although the correlation between experience/acceptability of cyberincivility and the digital citizenship score was significant, care should be exercised in interpreting the results because the instrument might not measure exactly what it was intended to measure due to the low correlation. In addition, owing to cultural differences related to cybercivility, an English instrument rewritten in Korean might have resulted in some words getting lost in translation. The same difficulty would be true for translations into any other languages. Finally, when participants respond to a survey, they tend to give socially favorable responses, which is even more evident for Koreans than Westerners [31].

Conclusions

This study extended and reevaluated the US version of cybercivility scales in a culturally distinct context. The results show that among the three dimensions of cybercivility (knowledge, experience, and acceptability), acceptability is well-validated while the knowledge dimension requires reexamination in the South Korean context. The content validity of experience was good, but the criterion validity was low. This study calls for more attention to contextualized cybercivility scales among health professions in countries outside the United States.

Acknowledgments

This work was supported by a National Research Foundation of Korea grant from the Ministry of Science, ICT and Future Planning of the Korean Government (No. 2018R1C1B5086516).

Authors' Contributions

HM, JCD, SH, KS, and CG were responsible for conceptual development, research design, and drafting of the manuscript; HM, SG, and GC were responsible for collecting data and data interpretation. All authors discussed the results and contributed to the final manuscript.

Abstract

Background: Mental illness affects a significant portion of the worldwide population. Online mental health forums can provide a supportive environment for those afflicted and also generate a large amount of data that can be mined to predict mental health states using machine learning methods.

Objective: This study aimed to benchmark multiple methods of text feature representation for social media posts and compare their downstream use with automated machine learning (AutoML) tools. We tested on datasets that contain posts labeled for perceived suicide risk or moderator attention in the context of self-harm. Specifically, we assessed the ability of the methods to prioritize posts that a moderator would identify for immediate response.

Methods: We used 1588 labeled posts from the Computational Linguistics and Clinical Psychology (CLPsych) 2017 shared task collected from the Reachout.com forum. Posts were represented using lexicon-based tools, including Valence Aware Dictionary and sEntiment Reasoner, Empath, and Linguistic Inquiry and Word Count, and also using pretrained artificial neural network models, including DeepMoji, Universal Sentence Encoder, and Generative Pretrained Transformer-1 (GPT-1). We used Tree-based Optimization Tool and Auto-Sklearn as AutoML tools to generate classifiers to triage the posts.

Results: The top-performing system used features derived from the GPT-1 model, which was fine-tuned on over 150,000 unlabeled posts from Reachout.com. Our top system had a macroaveraged F1 score of 0.572, providing a new state-of-the-art result on the CLPsych 2017 task. This was achieved without additional information from metadata or preceding posts. Error analyses revealed that this top system often misses expressions of hopelessness. In addition, we have presented visualizations that aid in the understanding of the learned classifiers.

Conclusions: In this study, we found that transfer learning is an effective strategy for predicting risk with relatively little labeled data and noted that fine-tuning of pretrained language models provides further gains when large amounts of unlabeled text are available.

Introduction

Mental health disorders are highly prevalent, with epidemiological studies reporting roughly half the population in the United States meeting the criteria for one or more mental disorders in their lifetime and roughly a quarter meeting the criteria in a given year [1]. Available survey evidence suggests that the first onset of mental health disorders is typically in childhood or adolescence and that later-onset disorders are mostly secondary conditions. The severity of mental disorders is highly related to their comorbidity, with complex interactions among disorders [2]. Moreover, severe disorders tend to be preceded by less severe disorders that are often not brought to clinical attention, indicating a need for early detection and intervention strategies [3,4].

Mental disorders are among the strongest predictors for nonsuicidal self-injury and suicidal behaviors; however, little is known about how people transition from suicidal thoughts to attempts [5]. Given the high incidence of mental health disorders and the relatively low incidence of suicide attempts, predicting the risk for suicidal behavior is difficult. In particular, Franklin et al [6] report a lack of progress over the last 50 years on the identification of risk factors that can aid in the prediction of suicidal thoughts and behaviors. However, they also proposed that new methods with a focus on risk algorithms using machine learning present an ideal path forward. These approaches can be integrated into peer support forums to develop repeated and continuous measurements of a user's well-being to inform early interventions.

Peer support forums can be a useful and scalable approach to social therapy for mental health issues [7]. Many individuals are already seeking health information online, and this manner of information access can help those who are reluctant to seek professional help, are concerned about stigma or confidentiality, or face barriers to access [8]. There is limited evidence showing that online peer support without professional moderation is an effective strategy for enhancing users' well-being [7,9]. However, in a systematic review of social networking sites for mental health interventions, Ridout and Campbell [10] identified the use of moderators as a key component of successful interventions on these Web-based platforms. The development of automated triage systems in these contexts can facilitate professional intervention by prioritizing users for specialized care [11,12] or decreasing response time when a risk for self-harm is identified [13]. Although the computational infrastructure of peer support forums is scalable, the effectiveness of human moderation is challenging to grow with community size. If they are accurate, automated systems can address these needs through computational approaches that are fast and scalable.

Previous research suggests that the language of individuals with mental health conditions is characterized by distinct features [14-17], eg, frequent use of first-person singular pronouns has been associated with depression [18]. This has sparked efforts to develop automated systems that, when given social media data, can predict the same level of suicide or self-harm risk that a trained expert would predict.

Such automated systems typically start with a feature extraction step that converts the variable length input text into fixed-length numeric vectors (features). This step is required to apply machine learning classifiers that operate on such vectors. An example is the bag-of-words representation, where each numeric feature represents the count of a specific word that is selected based on frequency or from a lexicon. With such a representation, a classifier may learn that mentions of *hopeless* are more common in text written by depressed individuals. This step of extracting features that best represent the text is a key part of such systems because a significant amount of information loss can occur. For example, in the bag-of-words representation, the order of the words is discarded. In contrast, differences in performance across machine learning classifiers are lower when representations are held constant. For example, good classifiers will have a similar performance on the same representations. Lexicon-based tools are highly dependent on their dictionaries, which require manual curation and validation. However, lexicon- and rule-based approaches are typically more interpretable than more complex neural network–based representations.

Recently, word embeddings have been shown to provide rich representations where words from the same context of a corpus tend to occupy a similar feature space [19]. The use of these embeddings has significantly boosted performance in several natural language processing tasks in recent years [20]. Generating such word embeddings can be done by building a neural network model that predicts a word given its neighboring words or vice versa. These word representations are learned from large corpora. These representations can be reused for other tasks. For example, a pretrained representation of *hopeless* would be similar to *despair*, allowing a classifier to group text that shares these words. This reuse is a type of transfer learning, which allows for the knowledge learned from one domain to be transferred to a task in an adjacent domain [21]. More recently, pretrained word representations have been shown to capture complex contextual word characteristics better than the preceding shallow models [22]. The fine-tuning of large pretrained language models in an unsupervised fashion has pushed forward the applicability of these approaches in cases with small amounts of labeled data [20,23]. Such fine-tuning could alter the learned context of *worries* to account for its placement in the common Australian expression of *no worries* when being transferred from an American to Australian corpus. Given these recent advances in natural language processing, we tested the performance of transfer learning with pretrained language models on risk classification of social media posts.

Reachout.com is an Australian youth-based mental health peer support forum. It is targeted for those aged 14 to 25 years, and the community is maintained by staff and trained volunteer

moderators. Staff and moderators monitor the forums, and they respond, as required, with empathy, support, and referrals to relevant information and available services. The 2017 Computational Linguistics and Clinical Psychology (CLPsych)–shared task organizers provided a corpus of posts from Reachout.com to assess the ability of automated methods to triage forum posts based on the urgency of moderator response [24]. For example, posts that suggest the author might hurt themselves or others are labeled as being high in priority for moderator response (*crisis*). We noted that these labels do not distinguish if the author is contemplating self-harm, nonsuicidal self-injury, or suicide. These constructs have different prevalence and incidence rates [25]. This dataset is small and imbalanced as the majority of posts are labeled as not requiring a moderator response. For example, only 5.2% (82/1588) of the posts are labeled as *crisis*. Given the higher importance of posts requiring moderator response, the organizers of the CLPsych-shared task chose the macroaveraged F1 metric to weight performance equally across the labels that mark the urgency of moderator response. This metric weighs each of those labels for both precision and recall equally. As a result, misclassification of a *crisis* post will be costlier because *crisis* posts occur less frequently. Several advanced methods have been applied to this dataset [24,26], but a systematic evaluation of feature extraction methods has not been performed.

In this paper, we benchmarked multiple feature extraction methods on forum posts from Reachout.com by evaluating their ability to predict the urgency of moderator response. Furthermore, we explored the interpretability through emoji representations and by visualizing word importance in text that mimics themes from suicide notes. We have shown that modern transfer learning approaches that take advantage of large corpora of unlabeled text, in combination with automated machine learning (AutoML) tools, improve performance.

Methods

Data

Reachout.com

Our primary data source was made available for the 2017 CLPsych-shared task and was collected from the Australian mental health peer support forum, Reachout.com [13,24]. The entire dataset consisted of 157,963 posts written between July 2012 and March 2017. Of those, 1188 were labeled and used for training the classification system, and 400 labeled posts were held out for the final evaluation of the systems. Posts were labeled *green* (58.6%, 931/1588), *amber* (25.6%, 390/1588), *red* (11.7%, 185/1588), or *crisis* (5.2%, 82/1588) based on the level of urgency with which moderators should respond. The postannotation task began with the 3 judges (organizers of the shared task) discussing and coming to a shared agreement on the labels for roughly 200 posts, guided by informal annotation and triage criteria provided by Reachout. The annotators ultimately formalized their process in a flowchart to standardize the labeling process and included fine-grained or granular annotations for each of the posts (Summary table of fine-grained labels in Multimedia Appendix 1). They then annotated the remaining posts independently, and the interannotator agreement was measured over these posts (excluding 22 posts labeled ambiguous by at least one judge). The 3 judges achieved a Fleiss kappa of 0.706 and a pairwise Cohen kappa score ranging from 0.674 to 0.761, which is interpreted as substantial agreement by Viera and Garrett [27]. The above mentioned steps, evaluations, and development of this dataset were previously undertaken by Milne et al [13,24].

University of Maryland Reddit Suicidality Dataset

To test the generalizability of the system developed on the Reachout.com data, we used a subset of the data made available from the University of Maryland (UMD) Reddit Suicidality Dataset [28,29]. The collection of this dataset followed an approach where the initial signal for a positive status of suicidality was a user having posted in the subreddit, /r/SuicideWatch, between 2006 and 2015. Annotations were then applied at the user level based on their history of posts. We used the subset that was curated by expert annotators to assess suicide risk. These volunteer experts include a suicide prevention coordinator for the Veteran's Administration; a cochair of the National Suicide Prevention Lifelines Standards, Training, and Practices Subcommittee; a doctoral student with expert training in suicide assessment and treatment whose research is focused on suicidality among minority youths; and a clinician in the Department of Emergency Psychiatry at Boston Children's Hospital. Two sets of annotator instructions (short and long) were used, following an adapted categorization of suicide risk developed by Corbitt-Hall et al [30]: (a) no risk (or *None*): I don't see evidence that this person is at risk for suicide, (b) low risk: There may be some factors here that could suggest risk, but I don't really think this person is at much of a risk of suicide, (c) moderate risk: I see indications that there could be a genuine risk of this person making a suicide attempt, and (d) severe risk: I believe this person is at high risk of attempting suicide in the near future. These categories correspond roughly to the green, amber, red, and crisis categories defined in the Reachout.com data. The longer set of annotation instructions also identified 4 families of risk factors (ie, thoughts, feelings, logistics, and context). A pairwise Krippendorff alpha was used to assess interannotator agreement, with an average alpha of .812 satisfying the recommendation of a reliability cutoff of alpha >.800 [31]. Consensus labels were determined using a model for inferring true labels from multiple noisy annotations [32,33]. The abovementioned steps and development of this dataset were undertaken by Shing and et al [29].

Of the subset with labels by expert annotators, we then selected only data from users who had posted once in /r/SuicideWatch to minimize ambiguity in understanding which of their posts was the cause of the associated label. Predictions were made only on posts from /r/SuicideWatch. In total, there were 179 user posts across the categories (*a*: 32, *b*: 36, *c*: 85, and *d*: 26). The Centre for Addiction and Mental Health Research Ethics Board approved the use of this dataset for this study.

To better gauge our performance on the UMD Reddit Suicidality Dataset posts, we calculated an empirical distribution of random baselines for the macro-F1 metric. This baseline distribution quantifies the performance of random shuffles of the true labels (including the class *a* or *no risk* labels). As expected, across

10,000 of these randomizations, the mean macro-F1 was 0.25. We set a threshold of 0.336, which is 62 of 10,000 random runs to mark Reddit validation performance as better than chance (1/20 × 1/8 × 10000), corresponding to $P<.05$ and a Bonferroni correction for 8 tests (number of feature sets tested).

Composite Quotes

We used 10 composite quotes to share example predictions of our system on text that could be predictive/indicative of self-harming and/or suicidality. These composite quotes were created by Furqan et al [34] and were derived from qualitative research that synthesized primary themes noted in a selection of suicide notes that made explicit mentions of mental illness or mental health care. To assess the role of individual words (or tokens) in the classification of the quote, we iteratively perturbed each token and replaced it with an unknown token outside of the model's vocabulary and reran the prediction.

Data Preprocessing and Feature Extraction

Features were extracted from only the text body of the posts. For all posts, any quotes from previous posts or links to images were removed.

We extracted features using lexicon-based tools such as Valence Aware Dictionary and sEntiment Reasoner (VADER; 4 features) [35], Linguistic Inquiry and Word Count (LIWC; 70 features) [36], and Empath (195 features) [37], which have proven to be useful for characterizing social media text and extracting psychologically relevant signals. Features were also extracted from 3 pretrained artificial neural network models: DeepMoji [38] was used to extract sentiment- and emotion-related features (eg, the use of emoticons in social media text), the Universal Sentence Encoder version 2 (using a deep averaging network encoder) (Google) [39] obtained from Tensorflow Hub that was specifically designed to facilitate transfer learning, and the Generative Pretrained Transformer (GPT) network version 1 (OpenAI) [20]. For DeepMoji, we extracted features that represent the 64 predicted emojis and the neural activations from the preceding attention layer in the network (2304 features, referred to as DeepMoji). We used the Indico Data Solutions implementation to extract features from the default pretrained GPT-1 network and also after fine-tuning on the unlabeled corpus of posts from Reachout.com [40]. All language model fine-tuning was done with 3 epochs over the unlabeled posts, as suggested by the GPT-1 authors.

With Empath and LIWC, sentence splitting was not performed. With the remaining feature encoding (VADER, DeepMoji, Universal Sentence Encoder, and both GPT models) methods, we first preprocessed the text body of each post into sentences using the sentence boundary detection from spaCy version 2.1. Sentence feature vectors were aggregated to the post level by taking their mean, maximum, and minimum for each extracted feature.

Model Optimization and Selection

To train classifiers on the various feature sets, we used 2 AutoML methods that are built upon scikit-learn [41] to optimize and select optimal models. We selected these tools over others because they are open source. Other AutoML tools may have advantages such as ease of use or better performance for different dataset sizes and dimensionality [42]. In both cases, the AutoML methods were customized to maximize the Macro-F1 score (without the *green*-labeled posts). Each model was evaluated with 10-fold stratified cross-validation with five repeats inside of the training set. We trained the classifiers to predict the granular/fine-grained labels while evaluating the final output with the same macro-F1 score of the *amber*, *red*, and *crisis* categories.

We used the Tree-based Optimization Tool (TPOT) [43], which builds and selects machine learning pipelines using genetic programming. TPOT is built to generate pipelines that maximize classification accuracy while penalizing complex pipelines. Similarly, we used Auto-Sklearn to train and build classifiers using Bayesian optimization meta-learning and ensemble construction [44]. Given the high proportion of no risk labels in the datasets tested, we note that Auto-Sklearn contains a *Rebalancer* class for handling imbalanced class distributions. We primarily used default TPOT/Auto-Sklearn parameters with a population size of 200, a maximum evaluation time for a single pipeline of 5 min and total time as a stopping parameter, typically set to 2 days.

Mantel Tests

To compute the matrix of pairwise Euclidean distances between posts for each set of features, we used SciPy's distance matrix function [45]. This test allows quantification of the distances between posts across the various feature spaces. This is done in an unsupervised manner across the training and test posts. We used scikit-bio's mantel function with 999 permutations to perform the Mantel test on these distance matrices.

Emoji Visualization

To better understand the distribution of the 64 emoji features represented across the labeled posts, we aggregated the mean of an emoji feature across sentences in a post. Each of these aggregate features was then normalized to be between 0 and 1 to better compare features against each other. To obtain a measure of feature importance, we permuted each feature column and assessed the decrease in classification performance on the macro-F1 metric while using the best-performing pipeline derived from TPOT. For each emoji feature, we performed this procedure 10,000 times. Images of the emojis were obtained from EmojiOne (currently JoyPixels Inc) and converted to grayscale.

Availability

The CLPsych 2017 and UMD Reddit Suicidality datasets are available upon request from the original sources [28,29]. The code and instructions to fine-tune, train, and test a GPT-1 model on the CLPsych 2017 dataset is available online [46].

Results

Classification

To benchmark the performance of various text derived features for the automated classification of online forum posts, we ran both TPOT and Auto-Sklearn on the features generated from the post bodies. In Table 1, we report the average observed score

across the training folds, the final score on the held-out Reachout.com test set, and the external validation performance on Reddit data of the classifier trained only on Reachout.com data. In Figure 1, we present confusion matrices from 2 separate models trained with Auto-Sklearn to better demonstrate the predictions made across the imbalanced classes. Panel A shows the predictions of the VADER features, which resulted in a macro-F1 of 0.263. Panel B shows the predictions of the top-performing system with fine-tuned GPT features (a macro-F1 of 0.572).

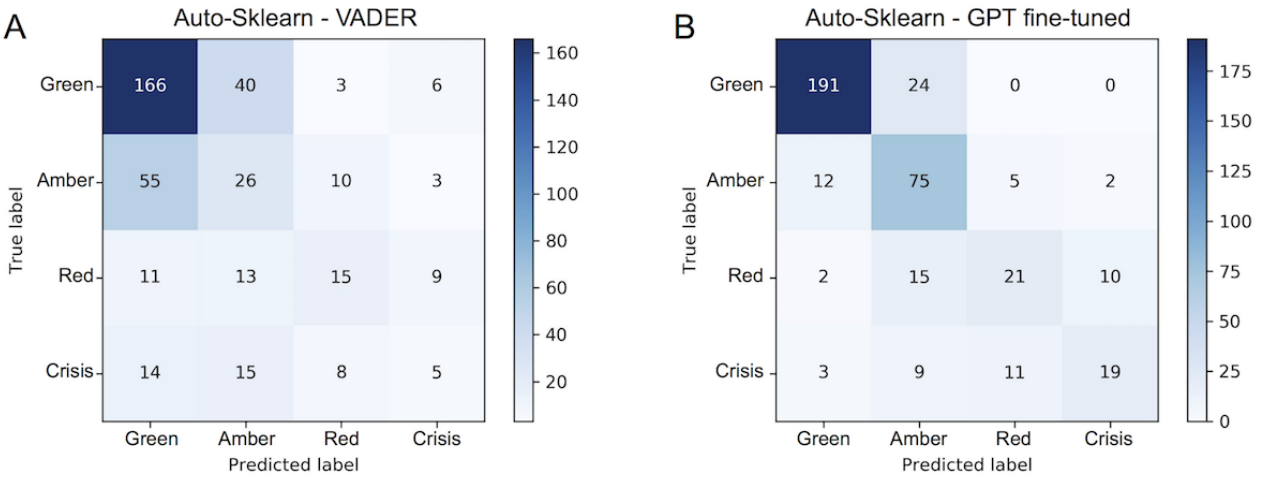
Table 1. Benchmarking by features, automated machine learning methods, and datasets with the macro-F1 metric.

Feature set	Feature count	Tree-based Optimization Tool			Auto-Sklearn		
		Train 10-fold, 5 times	Test	Reddit validation	Train 10-fold, 5 times	Test	Reddit validation
Empath (post)	195	0.280	0.253	0.385[a]	0.292	0.344	0.321
Linguistic Inquiry and Word Count	70	0.434	0.354	0.346[a]	0.433	0.380	0.315
Valence Aware Dictionary and sEntiment Reasoner (sentence)	12	0.363	0.263	0.356[a]	0.340	0.263	0.353[a]
Emoji 64	192	0.425	0.369	0.280	0.424	0.461	0.308
DeepMoji	6912	0.442	0.452	0.345[a]	0.391	0.437	0.351[a]
Universal Sentence Encoder	1536	0.457	0.446	0.300	0.484	0.479	0.236
GPT[b] default	2304	0.373	0.334	0.344[a]	0.396	0.383	0.402[a]
GPT fine-tuned	2304	0.510	0.559	0.320	0.492	0.572	0.324

[a]Reddit validation performance better than chance.

[b]GPT: Generative Pretrained Transformer.

Figure 1. Confusion matrices for 2 models trained with Auto-Sklearn. Each cell in the matrix provides the counts of posts that were labeled in the corresponding row and column axis that represent the predicted and true labels, respectively. Counts are colored from the highest cell (blue) to the lowest (white). The top-left to bottom-right diagonal cells count correctly predicted posts. Panel A trained with Valence Aware Dictionary and sEntiment Reasoner (VADER) features. Panel B trained with features from a fine-tuned Generative Pretrained Transformer (GPT) language model.



We noted that the average macro-F1 obtained during training was a fairly reliable predictor of the score on the held-out test set. Auto-Sklearn performed better on average than TPOT (mean test macro-F1 of 0.414 versus 0.379, respectively). We also observed the trend that features extracted from pretrained models perform better in general (average Auto-Sklearn test macro-F1 of 0.329 versus 0.466). However, the features extracted from the default GPT model (without any additional fine-tuning) were the worst performing of those obtained from neural models, whereas the GPT model that was fine-tuned on the unlabeled posts performed best across all experiments. The Universal Sentence Encoder and fine-tuned GPT features exceeded the highest macro-F1 score reached in the 2017 CLPsych-shared task when a classifier was learned with Auto-Sklearn (0.467; submission by Xianyi Xia and Dexi Liu). Upon inspection, the Auto-Sklearn–generated classifier for the GPT fine-tuned features was a complex ensemble of pipelines with multiple preprocessing steps and random forest classifiers. The TPOT-generated classification pipeline first selects features using the analysis of variance *F* value, then binarizes the values for classification with a K-nearest neighbor classifier (k=21; Euclidean distance). In contrast, the classifiers generated for

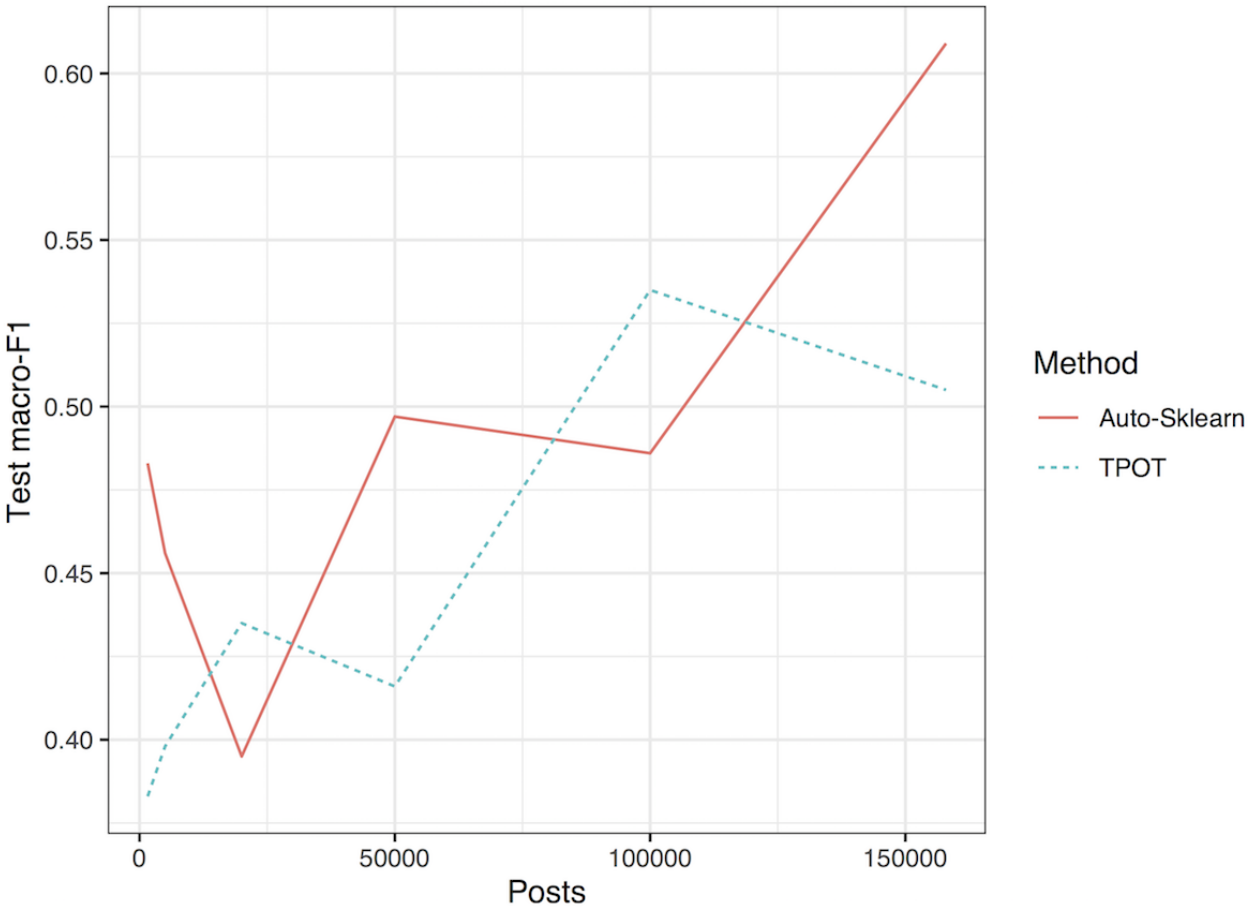
the Universal Sentence Encoder features are a linear support vector machine (TPOT) and ensembles of linear discriminant analysis classifiers (Auto-Sklearn).

To better understand the low Reddit validation scores, we calculated a random baseline. Although it is random, this does use information about the class distributions. We marked Reddit validation performance as better than chance in Table 1 with an [a]. Only classifiers learned from the VADER, DeepMoji, and default GPT features had macro-F1 scores above the threshold for both the TPOT and Auto-Sklearn learned classifiers. Unlike the CLPsych 2017 score that does not include the *green* or no risk labels, we used macro-F1 from all classes in the Reddit validation tests (corresponding to the CLPsych 2019 primary metric). When using the macro-F1 score that excluded the *no risk* class in the Reddit validation, none of the classifiers outperformed random runs at the same threshold. This is because of the classifiers having a good performance on the *no risk* or *green* labels and not the 3 remaining labels.

To better assess the variability of our best-performing system (Auto-Sklearn trained with features generated from the fine-tuned GPT model), we reran the Auto-Sklearn training and testing process 20 times. For each run, Auto-Sklearn was allotted 24 hours of compute time. Across those 20 systems, the average macro-F1 score on the held-out test set was 0.5293 (SD 0.0348). Of those 20 systems, the best- and worst-performing systems had a final test score of 0.6156 and 0.4594, respectively. Importantly, despite the variability and less compute time, the average macro-F1 score of these classifiers performed better than the scores obtained from different feature sets.

To determine the impact of the amount of data used for fine-tuning the GPT model on its effectiveness for feature extraction in the classification task, we fine-tuned models with increasing amounts of unlabeled posts before extracting post-level features to train a classifier (Figure 2). Although there is significant variability, there is a general trend of better performance when using models trained on a larger amount of unlabeled data.

Figure 2. A graph of macro-F1 test scores versus the number of posts used for Generative Pretrained Transformer-1 fine-tuning. Auto-Sklearn methods are marked with continuous red (Auto-Sklearn) and dashed blue (Tree-based Optimization Tool, TPOT) lines.



To compare the different representations or embeddings of the post contents, we used the Mantel test (Table 2). This compares the representations independently of their triage performance and suggests possible combinations for meta-classifiers. This test correlates the pairwise distances between posts in the benchmarked feature spaces, where a high correlation value between compared matrices indicates a significant overlap in the information they contain. Specifically, the Mantel test values range from −1 (perfect negative correlation) to 1 (perfect positive correlation), with zero representing no association between the pairs of posts in the feature spaces. Intriguingly, we observed the highest correlation between the Universal Sentence encoded features with those encoded by GPT. This is despite the comparison of aggregated DeepMoji encoded

features with aggregated 64-dimensional emoji encoding of DeepMoji, which we expected to have the strongest relationship. Similarly, comparisons between the default GPT and the fine-tuned version were slightly lower than correlations with the Universal Sentence Encoder. Although it is unclear, we presumed some of these differences may be due to the aggregation of sentence-level features into a post-level representation. None of the correlations with Empath features were significant, which probably reflects the sparsity of these features.

Table 2. Mantel correlations between the extracted feature sets.

Feature Set	VADER[a]	Empath	LIWC[b]	Universal Sentence	Emoji 64	DeepMoji	GPT[c] default	GPT fine-tuned
VADER	1.000	0.003	0.098	0.453	0.211	0.422	0.430	0.429
Empath	0.003	1.000	0.009	0.006	−0.005	−0.008	0.004	0.001
LIWC	0.098	0.009	1.000	0.148	0.403	0.507	0.267	0.253
Universal Sentence	0.453	0.006	0.148	1.000	0.193	0.509	0.823	0.823
Emoji 64	0.211	−0.005	0.403	0.193	1.000	0.523	0.302	0.335

System Interpretability

In Figure 3, we show the distribution of the mean emoji features for the top 10 most important features when using the mean emoji feature across sentences (64 total features). We noted that the interpretation and even visual representation of these emojis vary greatly, and these emojis were not used in the social media posts but were extracted by DeepMoji [38]. For example, the pistol emoji has been replaced by a ray gun or water gun in most platforms. From these distributions, it is clear that there is considerable variability across posts. This visualization also highlights the difficulty in discriminating the varying levels of risk when compared with the no risk posts. Of these top 10, 2 winking emojis are negatively correlated with risk, marking the importance of a positive sentiment. As expected, the negative emojis are more important, with the pistol, skull, and broken heart emoji ranked in the top 5.

To better understand judgments made by our trained classifier, we present predictions in Figure 4 on a set of composite quotes and their themes from a study of suicide notes [34]. For each quote, we presented the initial prediction (with the granular/fine-grained prediction in parentheses). Across the 10 quotes, 3 were classified as crisis, 4 as red, and 3 as amber. One of the amber classifications is under the "Hopelessness secondary to chronicity of illness and treatment" theme, further suggesting that our system may not recognize expressions of hopelessness.

All words were iteratively masked to indicate their effects on the predicted class (see Methods section). In Figure 4, words that affected predictions are color coded. The colored words are important for indicating severity as removing them makes the quotes appear less severe to our system. Examining these words suggests that negations affected severity (eg, "not," "can't"). In the quotes, negations seemed to indicate a perceived failure or not having done or achieved something the person felt they ought to. Expressions of hopelessness (ie, "no hope left") were also important in classifying quotes as severe by our system. Words reflecting an unwillingness or inability to continue were also important (ie, "I'm done," "I am too tired to") as were words indicating loneliness (ie, "being isolated"). In contrast, replacing a green word with an unknown word shifted the predicted class to a more severe category (eg, from *red* to *crisis*). On examining the nature of the green words (ie, "what," "after"), it was not clear why these words were important for lessening the severity of the quotes.

For 2 of the quotes predicted as red, no words were highlighted, suggesting that, in these instances, many words were key to the prediction. Overall, the quotes would all be flagged as requiring some level of moderator attention, and for the most part, the nature of words that were important in classifying the severity of quotes made conceptual sense.

Figure 3. Violin plot showing the distributions of the 10 most discriminative emoji features across labeled classes. The classes are according to label with crisis in gray. The y-axis is the predicted scores for each emoji that have been scaled to the 0-1 interval. The emojis across the y-axis are marked with their images and their official Unicode text labels. The emojis are ranked from the most to least important feature (left to right).

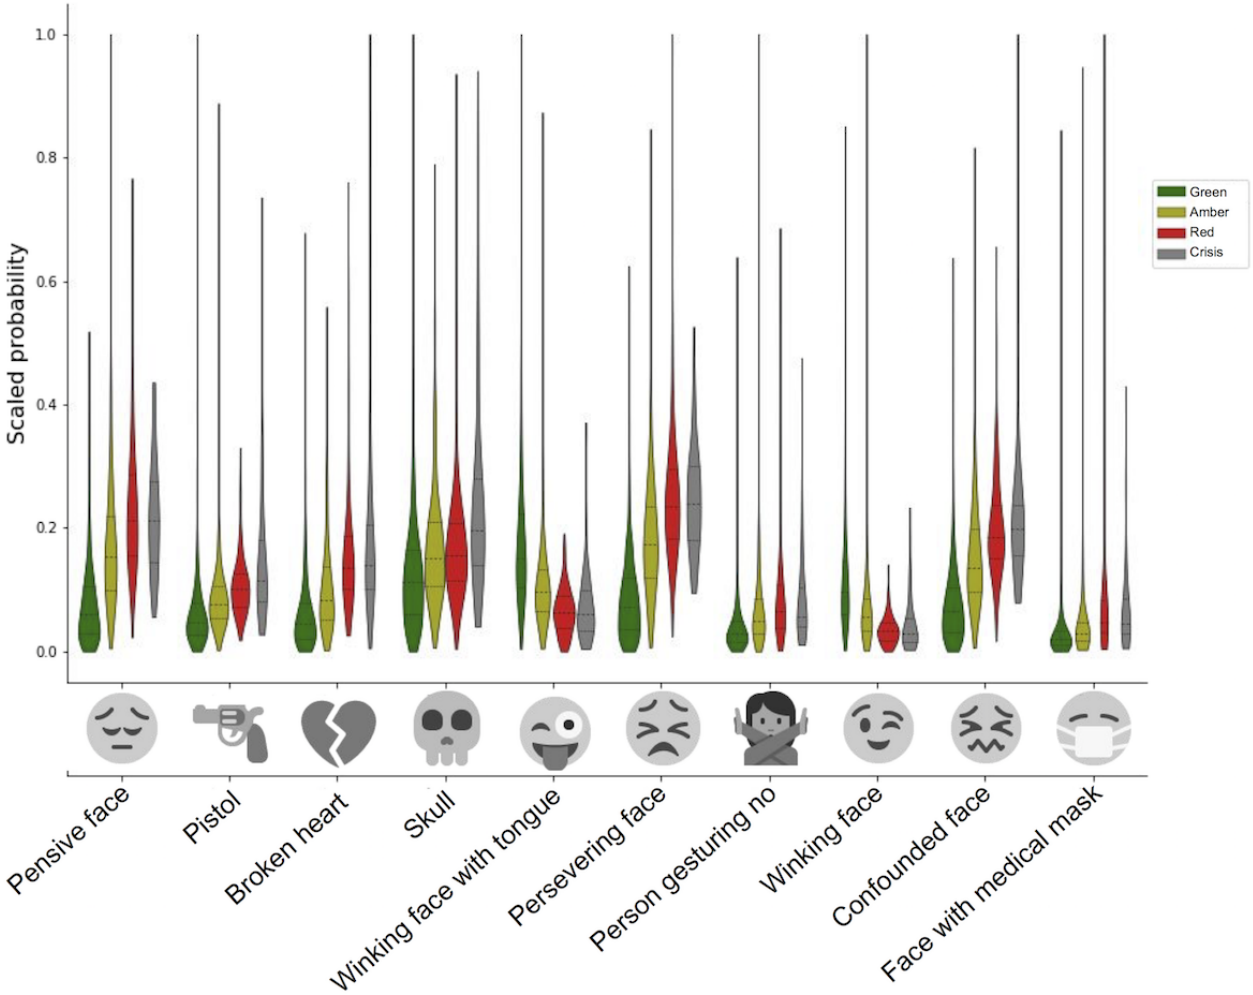

Figure 4. Predictions and highlights of suicide-related composite quotes from Furqan and colleagues. Words that changed predictions are color coded. Replacing a yellow or red word with an unknown word shifts the prediction to a less severe class by 1 or 2 levels, respectively, (ie, replacing a yellow word in text that is classified as crisis would change the prediction to red while a red word would change it to amber). In contrast, replacement of green words will result in more severe predictions.

Theme	Prediction	Composite quote
Suicide as exertion of personal autonomy	Red (currentAcuteDistress)	"I am the person who decides what I m going to do with my life. After being isolated and marginalized, I m done with it all. This is my life and my decision."
Exhaustion	Red (currentAcuteDistress)	"I am exhausted from trying to fix everything. No one understands, not even doctors or my family, and I keep trying to get help. I feel like I m a dead man walking for a long time. I ve been judged by society and have been made to feel ashamed. I m burned out and tired and trying to find some way to rest."
Treatment failure as personal failure	Crisis	"It does n t matter how many treatments I try , there is something so wrong with me. It s not the treatments, it s me."
Treatment failure as personal failure	Crisis	"Medication, therapy, counseling, alcohol I ve tried everything and I ca n t seem to figure out a way out of this, I ca n t crack the code."
Hopelessness secondary to chronicity of illness and treatment	Amber (followupOk)	"After trying multiple treatments , without curing my mental illness, I have realized that a solution other than death just does not exist."
Conflict between Self and Illness	Crisis	"I have fought against my thoughts, depression and alcohol constantly. I am too tired to keep going"
Illness as biological	Amber (followupOk)	"There is a problem in my brain. I think the chemistry is all wrong. No one could have fixed that."
Low levels of perceived agency	Amber (followupOk)	"Forgive me. It s not my fault, it s a disease, I hope you can understand that."
Low levels of perceived agency	Red (followupWorse)	"I sank into a deep depression. It was the depression that ruined my relationship. I want my family to know that."
High levels of perceived agency	Red (currentAcuteDistress)	"I had so much in my life family, friends , career but I let the disease, addiction, and my own personality take over me and it ruined everything in my life. Looking back, there were times that I should have changed the course of my life but I did n t and now there is no hope left."

Discussion

We have shown that there are highly informative signals in the text body alone of posts from the Reachout.com forum. More specifically, we identified a transfer learning approach as particularly useful for extracting features from raw social media text. In combination with the training of classifiers using AutoML methods, we showed that these representations of the post content can improve triage performance without considering the context or metadata of the posts. These methods take advantage of the large amount of unlabeled free text that is often available to diminish the need for labeled examples. We also showed that these methods can generalize to new users on a

support forum, for which there would not be preceding posts to provide context on their mental states. By combining the pretrained language models with AutoML, we were able to achieve state-of-the-art macro-F1 on the CLPsych 2017 shared task. Our content-only approach could be complemented by previous work, which used hand-engineered features to account for contextual information, such as a user's post history or the thread context of posts [26,47]. Future developments could also include multiple types of media (eg, text, photos, videos) that are often present on social media to better assess the subtleties of users' interactions [48].

Our current approach follows methods outlined by Radford et al [20] to fine-tune the language model that was previously pretrained on a large corpus of books. This fine-tuning step allows the model to learn the characteristics of the Reachout.com text. We show that increasing the amounts of in-domain unlabeled data for fine-tuning improves classification performance and has yet to reach a plateau. Further work will be instrumental in defining when and how to fine-tune pretrained language models better [49]. For tasks with limited data availability, the ability to adapt and fine-tune a model on multiple intermediate tasks could be a particularly worthwhile approach, as demonstrated by the Universal Sentence Encoder and others [39,50]. However, it is unclear how these large language models can retain and accumulate knowledge across tasks and datasets. Notably, it has been reported that these large pretrained language models are difficult to fine-tune and that many random restarts may be required to achieve optimal performance [51,52].

We compared the use of AutoML tools, such as Auto-Sklearn and TPOT, to generate classification pipelines with a variety of features extracted from free text. We also identified them as sources of variability in the final scores of our system. When developing our top-performing systems with features extracted from a fine-tuned GPT and using Auto-Sklearn on 20 trials, we obtained macroaverage F1 scores ranging from 0.6156 to 0.4594. In part, this is because of the small size of the dataset and the weighted focus of the macroaverage F1 metric toward the *crisis* class with relatively fewer instances. Further experiments, although computationally intensive, could help distinguish the amount of variability that is inherent in the language model fine-tuning process.

There are a variety of limitations, depending on the use of the approaches we benchmarked. Further experiments would be needed to determine if Reachout.com moderator responsiveness improves when more accurate classifiers are used. The present system performance cannot be extrapolated too far into the future because of changes in the population of users on the forum, shifting topics discussed or variations in language used. Furthermore, it is important to note that any implemented system would require ongoing performance monitoring.

To further understand how our trained models would perform in a new context, we assessed performance on an independently collected dataset and composite quotes that were derived from suicide notes. All composite quotes were flagged as requiring moderator attention. Our classifiers generalize to some degree on the UMD Reddit Suicidality Dataset, which approximates the task outlined for Reachout.com. We noted that the Reddit user base is not specific to Australia, is not targeted explicitly to youth, and may have substantially different topics of discussion than Reachout.com. This performance is primarily driven by good accuracy on the *no risk* or *green* class. We observed that the features derived from the fine-tuned GPT model perform worse than those from the default GPT model, indicating that this model might be specific to unique features of Reachout.com. Future studies could determine whether multiple rounds of fine-tuning on different datasets increase accuracy.

We manually reviewed the errors made by the best-performing system (Auto-Sklearn classifier with the GPT fine-tuned features). The most worrisome prediction errors occur when the classifier mistakes a crisis post for one of lesser importance, which could potentially delay a moderator response. When posts were not classified as crisis posts (but should have been), this was often due to vague language referring to self-harm or suicide (eg, "time's up," "get something/do it," "to end it," "making the pain worse"). Sometimes, forum users deliberately referred to self-harm or suicide with nonstandard variations, such as "SH" or "X" (eg, "attempt X," "do X"). Future work could be instructive in determining whether these words are associated with higher levels of distress/crisis relative to the words they are meant to replace. Alternatively, custom lexicons might be developed to capture instances of self-harm or suicide represented by vague language or nonstandard variations.

In some failure cases (ie, posts that should be classified as being of higher risk than they were), the classifier did not notice expressions of hopelessness, which may cue the imminence of risk. Other prominent failure cases were instances when the classifier did not notice a poster's dissatisfaction with mental health services that provide real-time help (eg, suicide call-back services and crisis helplines, etc). According to the labeling scheme, these posts should be classified as red. However, this dissatisfaction was often conveyed in diverse and highly contextualized ways, likely making it difficult for the system to identify. There were also posts that did not indicate imminent risk but described sensitive topics such as feeling lonely or losing a parent. These were often misclassified as green (when they should have been amber), possibly because they also contained positive language, or the sensitivity of the topic was difficult for the system to grasp.

In some of these failure cases, it may have been useful to take into account the previous post; eg, when the post in question is short or vague, the system may classify the level of risk more accurately if the previous post expresses a high level of concern about the poster or tries to convince the poster to seek immediate help.

Neural networks can build complex representations of their input features, and it can be difficult to interpret how these representations are used in the classification process. In a deeper analysis of DeepMoji features, we identified the most important emoji for classification and found that the emotional features follow a linear arrangement of expression at the class level corresponding to label severity. We also used input masking to iteratively highlight the contributions of individual words to the

final classification. Such highlighting and pictorial/emoji visualizations could speed moderator review of posts. Ultimately, we believe the further development of methods to improve model interpretability will be essential in facilitating the work of mental health professionals in Web-based contexts.

In conclusion, we showed that transfer learning combined with AutoML provides state-of-the-art performance on the CLPsych 2017 triage task. Specifically, we found that an AutoML classifier trained on features from a fine-tuned GPT language model was the most accurate. We suggest this automated transfer learning approach as the first step to those building natural language processing systems for mental health because of the ease of implementation. Although such systems lack interpretability, we showed that emoji-based visualizations and masking can aid explainability.

Acknowledgments

The Centre for Addiction and Mental Health (CAMH) Specialized Computing Cluster, which is funded by the Canada Foundation for Innovation and the CAMH Research Hospital Fund, was used to perform this research. The authors thank the Nvidia Corporation for the Titan Xp GPU that was used for this research. The authors acknowledge the assistance of the American Association of Suicidology in making the University of Maryland Reddit Suicidality Dataset available. The authors also thank the 3 anonymous reviewers for their helpful suggestions and comments. This study was supported by the CAMH Foundation and a National Science and Engineering Research Council of Canada Discovery Grant to LF.

Conflicts of Interest

LF owns shares in Alphabet Inc, which is the parent company of Google, the developer of the freely available Universal Sentence Encoder, which was compared with other methods.

Abstract

Background: An online health community (OHC) is a novel sharing channel through which doctors share professional health care knowledge with patients. While doctors have the authority to protect their patients' privacy in OHCs, we have limited information on how doctors' privacy protection choices affect their professional health care knowledge sharing with patients.

Objective: We examined the relationship between privacy protection and professional health care knowledge sharing in OHCs. Specifically, we examined the effects of privacy protection settings in an OHC on doctors' interactive professional health care knowledge sharing and searching professional health care knowledge sharing (two dimensions of professional health care knowledge sharing). Moreover, we explored how such effects differ across different levels of disease stigma.

Methods: We collected the monthly panel data of 19,456 doctors from Good Doctor, one of the largest OHCs in China, from January 2008 to April 2016. A natural experimental empirical study with difference-in-difference analysis was conducted to test our hypotheses. The time fixed effect and the individual fixed effect were both considered to better identify the effects of a privacy protection setting on professional health care knowledge sharing. Additionally, a cross-sectional analysis was performed for a robust check.

Results: The results indicate that the privacy protection setting has a significant positive effect on interactive professional health care knowledge sharing (β=.123, *P*<.001). However, the privacy protection setting has a significant negative effect on searching professional health care knowledge sharing (β=–.225, *P*=.05). Moreover, we found that high disease stigma positively impacts the effect of privacy protection on interactive professional health care knowledge sharing (coefficients are in the same valence) and negatively impacts the effects of privacy protection on searching professional health care knowledge sharing (coefficients are in the reverse valence).

Conclusions: Privacy protection has a bilateral effect on professional health care knowledge sharing (ie, a positive effect on interactive professional health care knowledge sharing and a negative effect on searching professional health care knowledge sharing). Such bilateral switches of professional health care knowledge sharing call for a balanced state in conjunction with practical implications. This research also identifies a moderate effect of disease stigma on privacy protection settings and professional health care knowledge sharing.

online health community; privacy protection; professional health care knowledge

Introduction

Online Health Communities as Platforms for Sharing Professional Health Care Knowledge

The internet has dynamically invaded, affected, and even changed many traditional industries, such as business (electronic commerce [e-commerce]), finance (internet finance), social (virtual communities), and health care (telemedicine). Compared with the traditional offline mode, the capabilities of the internet (ie, its real-time communication across geographical boundaries, wide and swift spread, easy access, and rapid generation of users) have proven successful in the online mode. Recently, studies in both practice and research have focused on another internet capability: sharing, especially in the sharing economy. For instance, travel apps help in sharing transportation tools (eg, Uber), cloud computing apps help in sharing idle computing capacities (eg, Alibaba Cloud computing), and accommodation apps help in sharing lodgings (eg, Airbnb). In addition, regarding the health care industry, the online health community (OHC) (a kind of telemedicine-providing, doctor-patient means of communication using information and communication technology [1]) provides an online platform for sharing professional health care knowledge.

Similarly, with transportation tools, computing capacities, and lodgings, professional health care knowledge is a scarce and valuable resource. Having abundant and correct professional health care knowledge is conducive to enhancing coping and self-efficacy [2], affecting health-related decisions and the behavior of OHC users and their friends and family [3], enabling better management of chronic health conditions [4], and fueling discussions with health care providers [5]; health care, in general, is thereby maintained. However, most professional health care knowledge networks are owned by a small number of health care professionals. In traditional offline health care activities, professional health care knowledge is mainly shared through face-to-face treatment. In particular, it makes for inefficient sharing in a one-to-one context.

According to the definition of knowledge sharing [6,7], professional health care knowledge sharing is defined as medical professionals (eg, doctors, nurses, and pharmacists) sharing their professional health care knowledge with other health care stakeholders in the form of various activities (eg, treatment, consultations, and published papers) [8]. Fortunately, the OHC provides more possibilities for professional health care knowledge sharing, including the seeking of advice online and by telephone consultation [9,10]; for connecting with other patients with similar experiences [11,12]; and for the understanding of professional diagnoses by reading doctors' published papers. Moreover, the OHC supplies to the public the online interaction records between doctors and patients to help patients with similar ailments [13,14]. From the perspective of doctors, the professional health care knowledge sharing between doctors and patients can be divided into interactive professional health care knowledge sharing and searching professional health care knowledge sharing. Interactive professional health care knowledge sharing refers to the professional health care knowledge sharing process actively carried out by doctors through interaction with patients, such as online consultations and telephone consultations in OHCs. Searching professional health care knowledge sharing, on the other hand, refers to a process where there are no doctor-patient interactions; patients search, learn, and acquire doctors' professional health care knowledge autonomously, such as by searching doctors' published articles and doctor-patient interaction records (in Chinese OHCs, such doctor-patient interaction records, which are anonymously processed, are on display to all visitors by default, like those in the forums). Professional health care knowledge sharing, based on the internet, is being adopted by a growing number of users [15].

Privacy Protection and Professional Health Care Knowledge Sharing in OHCs

Unlike transportation tools, computing capacities, and lodgings, professional health care knowledge sharing is more inclined to be privacy-sensitive. It is more sensitive than other forms of information on online platforms, such as demographic profiles, lifestyle interests, or purchase history information [16]. Just as in an offline context, doctors make a diagnosis according to a patient's conditions; therefore, professionals may ask their patients to provide more personal data in exchange for the utility of the services. To obtain better treatment, manage their conditions, or improve their overall health, patients have to provide their personal information (such as gender, lifestyle, occupation, disease severity, and medical examination results), which may contain more sensitive personal information [17]. Moreover, professionals also post sensitive data about their patients, which is made visible to the public, so that advice on clinical situations or practice management may be shared with other patients or professionals [18,19].

OHCs are opening the door for inappropriate access, misuse, and disclosure of personal privacy [20]. Once such data are handled improperly, patients will be faced with privacy invasion [21], such as negative social stigma, as well as straining of family ties, losing control of medical information, and suffering harassment from commercial advertising [16]. These concerns can even cause individuals to avoid the health care services of OHCs, and thus limit the role of an OHC in professional health care knowledge sharing. Consequently, some OHCs have provided privacy protection mechanisms, such as improving data storage security, building a safe environment, and providing anonymity for patients. In addition, an OHC can enable doctors to activate their patients' privacy protection settings by making the consultation process invisible.

Objectives and Research Questions

Several studies (further previous research can be seen in Multimedia Appendix 1) have investigated professional health care knowledge sharing in OHCs among patients or doctors, such as the patient motivations for health care knowledge sharing on Wikipedia [22] and the development of doctors' knowledge sharing in virtual communities [23,24]. However, a dearth of studies concentrating on professional health care knowledge sharing between doctors and patients remains [25]. Moreover, although studies have explored the positive impact of privacy protection mechanisms on patients' OHC participation intentions and continuous use intentions [16,21],

privacy protection is also a double-edged sword [26] for professional health care knowledge sharing. Doctors' privacy protection settings in OHCs regarding patients' personal health care information will increase patient trust and promote knowledge sharing. However, it also blocks other patients' access to professional health care knowledge in their search for consultation records. Therefore, it is necessary to explore the influence of doctors' choice of privacy protection settings in OHCs on professional health care knowledge sharing between doctors and patients. To fill this research gap, it is essential to understand the nature of professional health care knowledge sharing in OHCs. Hence, we conducted an empirical analysis of a large OHC to explore the effects of privacy protection settings on interactive and searching professional health care knowledge sharing. In further extending our model, we investigated how professional health care knowledge is differentially shared with patients suffering from different levels of disease stigma. For instance, patients with different diseases (eg, influenza versus HIV) may have different professional health care knowledge sharing trajectories from the influence of the associated stigma.

The Enhancing Power of Privacy Protection on Interactive Professional Health Care Knowledge Sharing

In OHCs, interactive forms of professional health care knowledge sharing are mainly conducted through online doctor-patient consultations. In other words, an online consultation thread can be started for a doctor-and-patient pair, and each can interact with the other through text descriptions and the uploading of test and imaging results. Doctors can make judgments and recommendations based on their patients' descriptions of their symptoms to generate professional health care knowledge sharing in their interactions with patients. Without privacy protection, the entire online consultation process described above would be rendered publicly available to all internet users. However, as we mentioned previously, this may be harmful in terms of patients' privacy disclosure. The privacy protection mechanism of an OHC gives doctors the right to set up a transparent consultation process, so as to protect the privacy of their patients.

Previous studies indicated that a privacy policy can improve user trust and loyalty in health care providers, thus influencing health information exchange behaviors in users [27]. In the interactive professional health care knowledge sharing process of an OHC, patients may increase their trust in doctors when they are protected by doctors' privacy protection settings, thus feeling encouraged to share more personal health care information during communication [28]. The feeling of being protected will also increase patients' evaluations of doctors and render them willing to communicate with doctors more frequently, thus increasing the shared professional health care knowledge in the interactive process. Further, doctors' reasonable privacy protection settings will attract more patients to consult online for professional health care knowledge sharing. Hence, by increasing patient interaction intentions, consultation times, and the number of patients, doctors' privacy protection settings can affect the professional health care knowledge sharing frequency of the doctor-patient interaction process.

Thus, we hypothesized the following:

> *H1: Privacy protection settings have a positive impact on a doctor's interactive professional health care knowledge sharing in OHCs.*

Conflicts Between Privacy Protection and Searching Professional Health Care Knowledge Sharing

In addition to interactive professional health care knowledge sharing, searching professional health care knowledge sharing is another approach by which doctors can share knowledge in OHCs. As there are numerous visible consultation records in OHCs that are available to other users, it is easy for a patient to access these consultation records via search engines (eg, Bing, Google, or Yahoo!) [29]. By learning from the professional health care knowledge that doctors share with other patients in their records, patients can internalize such knowledge as their professional health care knowledge.

For doctors, searching professional health care knowledge sharing is a more widely used method of disseminating professional knowledge than interactive professional health care knowledge sharing. Compared with interactive professional health care knowledge sharing in one-to-one communication, searching professional health care knowledge can be extended to any patient who is willing to share such knowledge through the internet under the authorization of doctors. Thus, searching professional health care knowledge sharing provides a more convenient knowledge sharing channel for doctors. According to statistics, among the patients who use the internet to obtain professional health care knowledge, 61% use search engines to access searching professional health care knowledge sharing, which attracts twice the number of users who use social platforms and online communities [3].

Searching professional health care knowledge sharing, which is mainly recorded in doctor-patient interactive history records, often contains patients' specific symptoms, diagnosis results, examination records, and other matters protected by personal privacy. Although these history records will help other patients acquire searching professional health care knowledge sharing more accurately, if such private information is used indiscreetly, it will have adverse effects on those whose privacy has been invaded [16]. Therefore, the OHC provides a function for doctors to protect the privacy of their patients by making the consultation process invisible. It helps to eliminate the privacy exposure of personal health care information and thus fundamentally eliminates privacy invasion. However, while privacy is protected, other patients are not able to access the complete interaction records and, thus, are not able to clearly grasp the details of the shared professional health care knowledge. This negatively affects the searching professional health care knowledge sharing of other patients.

Thus, we hypothesized the following:

> *H2: Privacy protection settings have a negative impact on a doctor's searching professional health care knowledge sharing in OHCs.*

The Moderating Effects of Disease Stigma

Closely related to privacy protection in OHCs is the inherent stigma ascribed to many health conditions [30]. Social stigma refers to negative feelings toward an individual or a group on socially characteristic grounds that distinguish the individual or group from others [31,32].

Compared to offline treatments, online professional health care knowledge sharing provides natural protection, like a veil, for patients with diseases they may feel embarrassed about. Through an OHC, patients with stigma disorders can access professional health care knowledge sharing with doctors without the need for face-to-face interactions. In particular, people living with stigmatized conditions such as mental illness, cancer, or HIV are more likely to seek support and health information online due to the perceived anonymity the internet provides [33-35]. In their study, Zhang et al [16] demonstrated that the internet could support the disclosure of stigmatized illnesses such as HIV by helping the afflicted overcome the aspects of social stigma.

Different types of diseases possess different degrees of stigma. For instance, patients with HIV will be more worried about and feel more ashamed of other people's discrimination than patients with a cold. Berger et al [35] showed that compared to those with nonstigmatized diseases, those with stigmatized illnesses were more likely to be sensitive to privacy disclosure. This is because once a stigmatized patient's privacy is exposed, the disclosure will cause the patient more considerable pain and annoyance than for a nonstigmatized patient. Therefore, when patients with stigmatized diseases use OHCs to interact with doctors to search for professional health care knowledge sharing, they expect their privacy to be fully protected. Patients with stigmatized diseases, who are more sensitive about protecting their privacy, are more likely to trust doctors who devote attention to protecting their patients' privacy. As a consequence, their frequency of searching professional health care knowledge sharing increases.

Thus, we hypothesized the following:

> *H3: The stigma associated with a disease positively moderates the effects of privacy protection settings on interactive and searching professional health care knowledge sharing.*

Methods

Research Settings

One of the biggest OHCs in China, Good Doctor (http://www.haodf.com/), which was launched in September 2006, was chosen for our research context. It provides a virtual online platform for patients and offline registered doctors. Through Good Doctor, patients can engage in professional health care knowledge sharing with doctors through online consultations, telephone consultations, reading articles published by doctors, browsing other patient-doctor consultation records, and so on. These professional health care knowledge sharing processes may be recorded by Good Doctor, and some of them are shown to the public on doctors' profile pages. The professional health care knowledge sharing interaction records include telephone and online consultation records (ie, clinical and academic titles and detailed content of the consultation, from the doctor and patient, during the whole consultation process) with anonymous patients, the number and content of articles published by the doctor (ie, academic papers, summary of medical experience, and related knowledge forwarding), and the total number of patients who have engaged in professional health care knowledge sharing with the doctor. However, if the doctor has set privacy protection on an online consultation, the consultation details are not rendered publicly available. We developed software that crawled doctors' profile pages in Good Doctor every month from January 2008 to April 2016. Finally, we constructed a monthly panel data set for 19,456 doctors.

Variables

Professional health care knowledge sharing was measured by the number of patients who interacted with a doctor or searched the consultation records of that doctor. The number of online consultations between patients and a doctor through which they engage in professional health care knowledge sharing interaction was counted based on the doctor's consultation list and was used to measure our first dependent variable: the doctor's interactive professional health care knowledge sharing (intrctPHKS). The second dependent variable, searching professional health care knowledge sharing (searchPHKS), indicates the number of patients who learned of a doctor's professional health care knowledge through searching that doctor's consultation records without interacting with the doctor. Although this number cannot be collected directly from the website, it can be inferred from the calculation of the number of patients who visit the doctor's profile page minus the number of patients who interact via consultations. Even though the number of patients visiting the profile page may count in "noise" values (such as browsing a doctor's personal information, or repeat visits), in the difference-in-difference model, a random error in the dependent variable will not influence regression estimates of treatment effect. Hence, by ignoring the cases of a patient viewing a doctor's profile page unintentionally, it is assumed that all patients visiting a doctor's page have access to professional health care knowledge sharing with this doctor. In other words, in addition to the number of patients interacting with a doctor through consultations, patients who visit a doctor's page have access to searching professional health care knowledge sharing with that doctor.

Online consultations between doctors and patients can be conducted by means of text and images, and the records of consultations are open to the public unless the doctor changes the privacy protection settings of the records. During a doctor-patient consultation, the doctor has the authority to choose whether to make the consultation records of their patient visible to the public. If an online consultation is set as private, only the patient and the attending doctor can access the entire interaction history. Others who visit this doctor's profile page can view only the topic of a private consultation without seeing the detailed information. We calculated both the total number of a doctor's online consultations with privacy protection settings and the monthly number of privacy protection settings to measure our independent variable: PrivacySetting.

Moreover, patients with different levels of disease stigma may have different attitudes toward privacy sensitivity regarding online professional health care knowledge sharing interactions with doctors. To understand how the stigma of diseases affects the privacy protection setting of consultations on interactive and searching professional health care knowledge sharing, disease stigma (Stigma) was considered as the moderate effect of our model. We used the classification method of De Choudhury et al [8] to measure stigma on a 2-point scale: 1=high stigma and 0=low stigma.

To account for potential confounding effects that influence professional health care knowledge sharing, we included other control variables (ie, the doctor's title, virtual gifts, articles posted online, and thank-you letters). According to the literature, a doctor's offline status and online reputation will also affect their knowledge sharing in OHCs [36]. Therefore, the variables that represent the doctor's offline status and online reputation are treated as our control variables (ie, the title of a doctor [Title], the number of virtual gifts [Gift], the number of thank-you letters [Letter], and the number of published articles [Article]). The official clinical title certified by China's national agency based on uniform standards was used to measure Title. In general, 4 rankings exist for titles: Fellow (4), Associate Fellow (3), Attending (2), Resident (1), and none (0). The variable Gift was used to represent the number of virtual gifts sent by the patients who consulted online. Thank-you letters (Letter) denote the number of thank-you letters submitted by patients who had visited a doctor in both the online and offline contexts. The number of articles the doctor had published online was counted as Article. The defined variables are shown in Table 1.

Descriptive Statistics

Our monthly panel data set included the doctor's identification number, the number of online consultations with and without privacy protection settings, the total number of visits, the number of patients, the number of articles, the number of gifts, the number of follow-up visits, and the title of the doctor. We obtained 631,529 online consultations of 19,456 doctors. More detailed descriptive statistics are shown in Table 2.

The correlation of each indicator using a cross-section is shown in Table 3, which indicates values in the acceptable range. The correlation coefficients between the independent variables are relatively small. In other words, the possibility of variable redundancy is relatively small.

Table 1. Variables defined.

Variable	Operational definition
Dependent	
intrctPHKS[a]	The number of interactive professional health care knowledge sharing
searchPHKS[b]	The number of searching professional health care knowledge sharing
Independent	
PrivacySetting	The number of online consultations with a privacy protection setting
Moderate	
Stigma	The stigma of a disease for which a doctor offers consultations
Control	
Gift	The number of virtual gifts received by a doctor
Letter	The number of thank-you letters
Title	The title of the doctor
Article	The number of articles written by the doctor

Empirical Models

Observing the privacy protection setting of doctors over various periods creates a natural experimental setting that allows a comparison of the effects of differences in privacy protection settings before and after a doctor uses this function. Constructing a panel data set of doctors' monthly online consultations, we estimated the difference-in-difference models, reflected by equations (1) through (4). Difference-in-difference models were used to calculate the effect of a treatment on an outcome by comparing the outcome average change over time from the control group to the treatment group. It helps to remove biases of permanent differences between the treatment and control groups, as well as trend biases caused by the changing of other factors of the outcome over time [37]. Thus, we exploited the effect of privacy protection settings on professional health care knowledge sharing by identifying an exogenous variation of professional health care knowledge sharing that the privacy protection settings are set by different doctors in different months. This identification strategy has been implemented in several extant studies (eg, in Chan and Ghose [38]). Our estimation incorporated doctor-level fixed effects, which allowed us to effectively control for doctor-level unobserved heterogeneity. To control the trend effect of each doctor's professional health care knowledge sharing, we added the time fixed effect in all 4 models. Moreover, we added the individual fixed effect to control the omitted variable bias caused by unobserved heterogeneity. Both the time fixed effect and the individual fixed effect were set as dummy variables. Furthermore, we used a cross-sectional data set to conclude our analyses with a set of robustness checks. Accordingly, our empirical models of doctors' privacy protection settings in OHCs on both their interactive and searching professional health care knowledge sharing are as follows:

$$\text{intrctPHKS}_{it} = \beta_0 + \beta_1 \text{PrivacySetting}_{it} + \beta_2 \text{Stigma}_i + \beta_3 C + A_i + T_t + \varepsilon_{it} \quad (1)$$

$$searchPHKS_{it} = \beta_0 + \beta_1 PrivacySetting_{it} + \beta_2 Stigma_i + \beta_3 C + A_i + T_t + \varepsilon_{it} \quad (2)$$

The moderate effect models are as follows:

$$intrctPHKS_{it} = \beta_0 + \beta_1 PrivacySetting_{it} + \beta_2 Stigma_i + \beta_7 Stigma_{it}*PrivacySetting_{it} + \beta_3 C + A_i + T_t + \varepsilon_{it} \quad (3)$$

$$searchPHKS_{it} = \beta_0 + \beta_1 PrivacySetting_{it} + \beta_2 Stigma_i + \beta_7 Stigma_{it}*PrivacySetting_{it} + \beta_3 C + A_i + T_t + \varepsilon_{it} \quad (4)$$

Where *i* indexes indicate the doctor and *t* indexes indicate time (monthly). A_i is a vector of doctor fixed effects; T_t is a vector of time fixed effects; $PrivacySetting_{it}$ is the binary indicator for the privacy protection setting (that is, $PrivacySetting_{it}$=1 if the doctor has set the privacy in a particular month; zero otherwise); and ε_{it} is an error term. The coefficient β_1 is the difference-in-difference estimate of the effect of a privacy protection setting. If β_1>0, then the privacy protection setting has caused an increase in professional health care knowledge sharing. Control variables are indicated by *C*.

Results

Hypothesis Testing

Stata (StataCorp) was used for our statistical analysis, and the results are shown in Table 4. The adjusted R^2 (0.037, –0.195, 0.037, and –0.223 for models 1, 2, 3, and 4 respectively) and *F* values ($F_{101,143415}$=384.8419, $F_{102,143414}$=381.0676, $F_{101,143376}$=34.43728, and $F_{3,143474}$=5.534647 for models 1, 2, 3, and 4 respectively) were reasonable and significant. The results of the variance inflation factor statistics for the variable indicated no multicollinearity (the variance inflation factor statistic of every variable is not greater than 2.0). The results of models only with our main treatment effect (PrivacySetting) are shown in columns 1 and 3 for interactive professional health care knowledge sharing and searching professional health care knowledge sharing, respectively. The results of models added to the moderate effects of stigma are shown in columns 2 and 4 for interactive professional health care knowledge sharing and searching professional health care knowledge sharing, respectively.

Hypothesis 1 postulated that the privacy protection setting has a significant positive effect on interactive professional health care knowledge sharing. In column 1 of Table 4, this hypothesis is supported as the coefficient of privacy protection setting was seen as positive and statistically significant (β_1=.123, *P*<.001). However, we observed in column 3 a significantly negative effect of the privacy protection setting on doctors' searching professional health care knowledge sharing (β_1=–.225, *P*=.050). Therefore, hypothesis 2, which posits that the privacy protection setting has a negative effect on searching professional health care knowledge sharing online, is also supported. As both the dependent variables of model 1 (intrctPHKS) and model 3 (searchPHKS) represent the amount of a doctor's knowledge sharing, a Wald test [39] was applied to the coefficients for further comparison. In the results for PrivacySetting, the absolute value of the coefficient of searching professional health care knowledge sharing was significantly larger than that of interactive professional health care knowledge sharing (Wald test, $F_{2,175548}$=324.21; *P*<.001).

Hypothesis 3 investigated the moderate impact of disease stigma on the relation between privacy protection settings and professional health care knowledge sharing. Columns 2 and 4 of Table 4 show the stable significant result of the positive moderate effect of disease stigma. In other words, high disease stigma positively impacts the effects of privacy protection settings on interactive professional health care knowledge sharing (coefficients are in the same valence) and negatively impacts the effects of privacy protection settings on searching professional health care knowledge sharing (coefficients are in the reverse valence). Therefore, hypothesis 3 is verified. Specifically, for disease stigma, we found that the stigma has a positive correlation with professional health care knowledge sharing.

Robust Check

To check the robustness of our results, we conducted a cross-sectional rerun of the model. The results presented in Table 5 are consistent with the results of the previous model. The results show that the treatment and the moderate effect have a significant positive effect, which is the same as the main results.

All the control variables have a statistically significant effect on professional health care knowledge sharing. Doctors with higher online and offline reputations will attract more patients [40]. The title reflects a doctor's offline reputation, and higher-level doctors are known to be more professional. Hence, the title has a positive effect on doctors' professional health care knowledge sharing. Moreover, virtual gifts, the number of articles, and thank-you letters can be proxy variables of a doctor's online reputation, which can positively affect professional health care knowledge sharing.

Table 4. Econometric models of the treatment effect and moderate effect. All the control variables and the individual and time fixed effect variables were included in the 4 models. The interaction terms (PrivacySetting*Stigma) represent the moderate effect of stigma.

Discussion

Principal Findings

This study examined the role of a doctor's privacy protection settings in OHCs on professional knowledge sharing. According to the data set from a distinguished OHC in China, both interactive professional health care knowledge sharing (intrctPHKS) and searching professional health care knowledge sharing (searchPHKS) are considered to be representative of a doctor's professional health care knowledge sharing in OHCs. The stigma of diseases is estimated to moderate the association of privacy protection settings and professional health care knowledge sharing.

Our results indicate that our hypotheses on the effect of doctors' privacy protection settings on professional health care

knowledge sharing are significantly supported. The more privacy protection setting a doctor establishes, the more interactive their professional health care knowledge sharing will be. This means that if a doctor sets their interaction records as private, their patients will prefer to make multiple interactions, and more patients will consult this doctor. Thus, a higher performance of interactive professional health care knowledge sharing can be achieved. Similar studies in other privacy-sensitive contexts, such as in financial loans, e-commerce, and so on, have demonstrated that better privacy protection mechanisms increase user trust and, thus, increase user willingness to disclose personal information for better management [41,42].

However, a doctor's privacy protection setting will limit the number of patients searching for professional health care knowledge online. This may lead to patients needing more time to find the right doctor, or they might not learn some useful information on the same health conditions. Therefore, doctors' privacy protection settings restrict their searching for professional health care knowledge sharing with patients. Switching off privacy protection settings properly is good for increasing searching professional health care knowledge sharing. This result is also valid in financial fields, where the appropriate sharing of privacy can overcome the information asymmetry of financial credit [43]. However, it is more acceptable for OHC users to disclosure their online consultation records for searching professional health care knowledge sharing than for borrowers to disclose their financial records for overcoming the information asymmetry. This may be due to the nature of professional health care knowledge sharing, which is reciprocal, and disclosure behaviors can give patients a sense of achievement. However, financial privacy is related to personal property, which a person is usually unwilling to share [44]. The difference has also been confirmed by Xu et al [45] that privacy sensitivity varies across different types of websites (eg, in e-commerce, financial, and health care).

As privacy protection settings positively affect interactive professional health care knowledge sharing and negatively affect searching professional health care knowledge sharing, it presents a bilateral switch of professional health care knowledge sharing, which is positive on one side and must at the same time be negative on the other side. The doctor who prefers to establish privacy protection will enjoy better performance in interactive professional health care knowledge sharing, but this weakens the performance of professional health care knowledge sharing searching. Conversely, a doctor who prefers public records will have better searching professional health care knowledge sharing and relatively weak interactive professional health care knowledge sharing. Figure 1 illustrates the metaphor of the bilateral switch. A doctor's professional health care knowledge sharing is a process of professional health care knowledge flowing from doctors to patients, like blood flowing from one side to the other side in blood vessels. In Figure 1, the privacy protection setting is likened to a bilateral switch that is installed in the blood vessels to regulate blood shunting. When blood (professional health care knowledge sharing) meets the switch (privacy protection settings), a bifurcation moves upward (interactive professional health care knowledge sharing), and the other bifurcation flows downward (searching professional health care knowledge sharing). If a doctor creates a stronger privacy protection setting, the bilateral switch of professional health care knowledge sharing is a downward regulation, thus resulting in more of interactive professional health care knowledge sharing and less of searching professional health care knowledge sharing. However, when the doctor prefers weaker privacy protection settings, there will be more searching professional health care knowledge sharing and less interactive professional health care knowledge sharing, with the switch turning up.

However, as we noted previously, according to the Wald test, the absolute value of β_1 in searching professional health care knowledge sharing is higher than that in interactive professional health care knowledge sharing. Therefore, when the same number of consultations are added that have a privacy protection setting, the loss of searching professional health care knowledge sharing is greater than that of the interactive professional health care knowledge sharing. In other words, the bilateral switch of professional health care knowledge sharing does not form a straight line as shown in Figure 1, but instead shows a thick switch that may cause a loss of professional health care knowledge sharing. We show an example in Figure 2.

In addition, empirical results indicate that the moderating effects of stigma positively affect the relationship between privacy protection settings and interactive professional health care knowledge sharing, and have a negative influence on the relationship between privacy protection settings and searching professional health care knowledge sharing. In other words, for high-stigma diseases, the increase in privacy protection settings is better for interactive professional health care knowledge sharing, while at the same time weakening the reduction of the searching professional health care knowledge sharing. This can be visualized as the stigma adjusting the thickness of the switch, namely professional health care knowledge sharing losses. The higher the stigma, the smaller the thickness of the switch (less loss). Conversely, the lower the stigma, the higher the thickness of the switch (more loss). This is because the virtual interaction mechanism of OHCs appears to be more acceptable by patients with high disease stigma. We show an example in Figure 3. OHCs recognize that they would have more visitors if they provide professional disease treatment support, as patients may disregard the disease stigma.

Theoretical Implications

This study augments OHC-related research with several insights. First, the OHC, as a new application of a sharing economy, provides an efficient sharing platform for scarce professional health care knowledge [46]. Like in other forms of sharing economies, the opportunity for OHCs to share valuable professional health care knowledge is enormous. However, compared with other sharing economy applications, the OHC also faces privacy protection challenges due to the sensitivity and life-threatening nature of medical information. Although previous studies have studied privacy-protection technologies, patient privacy concerns, and intentions, the current OHC privacy protection mechanism is still incomplete. The privacy protection mechanism established by doctors was in an experimental stage in the target website of this study (Good Doctor). Privacy protection settings by doctors have the advantage that doctors can control whether to install privacy protection settings from a professional and objective perspective (compared with patients' subjective perspectives). Therefore, we proposed a research framework that verifies the effect of a doctor's privacy protection mechanism on professional health care knowledge sharing.

Second, we abstracted knowledge sharing in an OHC into interactive professional health care knowledge sharing and searching professional health care knowledge sharing, and empirically proved the significant differences in privacy protection settings between them. A privacy protection setting, like a bilateral switch of professional health care knowledge sharing, positively affects interactive professional health care knowledge sharing and negatively affects searching professional health care knowledge sharing. In addition to the positive effects of privacy protection settings, we uncovered the paradox between privacy protection settings and knowledge diffusion. In other words, the effects of privacy protection settings on knowledge sharing were not seen to be stable and required a balanced state of a bilateral switch. This is another paradox of privacy protection setting in addition to the privacy-personalization paradox [47], which can be denominated as the privacy-knowledge-sharing paradox.

We also examined the moderating effects of disease stigma on the association between privacy protection settings and doctors' online professional health care knowledge sharing. Social stigma has been studied widely in the privacy field but rarely examined in existing studies on knowledge sharing. The empirical studies considered the direct or indirect influences of stigma on an individual's intention to disclose information [21]. However, there is a lack of empirical studies that examine the direct or moderating effect of disease stigma on knowledge sharing. We determined that disease stigma has a positive moderating effect on the relationship of privacy protection settings with online professional health care knowledge sharing. In particular, this result indicates a facilitating effect of privacy protection settings on interactive professional health care knowledge sharing and an inhibiting effect of privacy protection settings on searching professional health care knowledge sharing.

Practical Implications

This study provides several important practical implications for both OHC administrators and doctors. Our results indicate that a doctor's privacy protection settings are the bilateral switch of professional health care knowledge sharing. For OHC managers, protecting patient privacy helps to improve the participation and continuous use intentions of patients. However, it also hinders the extensive spreading of professional health care knowledge, which can help users to realize the social value of the OHC and increase its influence. For doctors, their privacy protection settings help to reduce patient privacy concerns and thus encourage patients to provide more accurate information to provide better advice. In addition, the privacy protection setting renders the doctor's professional health care knowledge more difficult for patients to access in a search, thus reducing the doctor's "exposure" in the OHCs. The fewer patients the doctors have, the less knowledge they are likely to share. Therefore, we postulate that privacy protection settings are a bilateral switch of professional health care knowledge that needs balancing between OHC managers and doctors. The question is how to balance such a bilateral switch, which impacts the performance of both interactive professional health care knowledge sharing and searching professional health care knowledge sharing. Moreover, our empirical results improve the decision making of OHC managers and doctors. Specifically, the privacy protection setting has a cutoff effect on searching professional health care knowledge sharing and a promoting effect on interactive professional health care knowledge sharing. Furthermore, the cutoff effect is weaker than the promoting effect. Therefore, OHC managers and doctors can make their decision (by toggling the bilateral switch of professional health care knowledge sharing) according to whether their target is the OHC or the individual propensity. In addition, the moderating effect of disease stigma positively affects the relation between privacy protection settings and professional health care knowledge sharing. In other words, for a high-stigma disease, the professional health care knowledge sharing process is more friendly toward privacy protection settings. However, a low-stigma disease needs less privacy protection. This will help managers of OHCs and doctors to balance the bilateral switch of professional health care knowledge sharing based on disease stigma.

Limitations and Future Research Directions

Our paper has some limitations that can serve as potential areas for future research. First, our research focuses on the OHC context. The methodologies and insights have the potential to be generalized to other wellness-care contexts, such as mHealth. However, examining the mHealth privacy paradox to compare the relationship and heterogeneity of the impact on patient behavior and outcomes under different health care contexts would be more beneficial and vital for future research.

Second, despite the collection of data from a typical OHC in China and the provision of a unique data set with doctors' privacy protection settings, the general applicability of our conclusions may be limited. Future research could extend this study across different OHCs and cultural settings to enhance the generalizability of our study.

Additionally, although our results effectively explain the privacy protection settings of doctors on professional health care knowledge sharing in OHCs, in-depth interviews or surveys with patients could further investigate perceptions of patients on the relationship between privacy protection settings and professional health care knowledge sharing. Moreover, given the important role of patients in the online professional health care knowledge sharing process, in the future, researchers could also explore how patient-related variables (ie, health status, health conditions, disease severity, participant motivations and reasons) affect doctors' online professional health care knowledge sharing with patients. Although both the difference-in-difference models (in our main analysis) and the cross-sectional models (in the robust check) showed significant verification of our hypotheses, they also indicate that the control variables may have strong explanatory power on doctors' professional health care knowledge sharing (ie, gift 0.49, $P<.001$). These control variables may be the proxy variables for the quality of doctors' treatment. Therefore, future research can deeply explore the effect of online response quality on professional health care knowledge sharing.

Conclusion

The important role of OHCs in sharing health care knowledge has been widely acknowledged by both practitioners and researchers; however, significant gaps remain in our exploration of the privacy protection mechanism in OHCs. This study examined how doctors' privacy protection setting choices affect their professional health care knowledge sharing in a Chinese OHC, a topic that, for the most part, has not been studied from the perspective of knowledge sharing. We used a fresh category of professional health care knowledge sharing; namely, interactive professional health care knowledge sharing and searching professional health care knowledge sharing. Doctors play different roles in these two kinds of professional health care knowledge sharing, both as active and passive actors, where different knowledge sharing processes occur. Using an empirical study on a large OHC, this study identified the bilateral role of privacy protection settings on professional health care knowledge sharing. It is a privacy-knowledge–sharing paradox in which the professional health care knowledge sharing process is not stable and calls for a balanced state. Our findings offer implications for doctors to gain a better understanding of how

to set privacy protection for better professional health care knowledge sharing. Different privacy protection mechanisms can be suggested by OHC executives, which are customized to suit each level of disease stigma. We hope that this study promotes additional research to further enrich our understanding of professional health care knowledge sharing in OHCs.

Abstract

Background: There have been recurring reports of web-based harassment and abuse among adolescents and young adults through anonymous social networks.

Objective: This study aimed to explore discussions on the popular anonymous social network Yik Yak related to social and mental health messaging behaviors among college students, including cyberbullying, to provide insights into mental health behaviors on college campuses.

Methods: From April 6, 2016, to May 7, 2016, we collected anonymous conversations posted on Yik Yak at 19 universities in 4 different states and performed statistical analyses and text classification experiments on a subset of these messages.

Results: We found that prosocial messages were 5.23 times more prevalent than bullying messages. The frequency of cyberbullying messages was positively associated with messages seeking emotional help. We found significant geographic variation in the frequency of messages offering supportive vs bullying messages. Across campuses, bullying and political discussions were positively associated. We also achieved a balanced accuracy of over 0.75 for most messaging behaviors and topics with a support vector machine classifier.

Conclusions: Our results show that messages containing data about students' mental health–related attitudes and behaviors are prevalent on anonymous social networks, suggesting that these data can be mined for real-time analysis. This information can be used in education and health care services to better engage with students, provide insight into conversations that lead to cyberbullying, and reach out to students who need support.

Introduction

Background

The transition from high school to college marks the beginning of an important period of psychosocial development. The academic and social demands of college life are often rigorous and can pose a risk to undergraduate students' health and well-being [1]. One example of the challenges they face is poor sleep [2], which has been linked to a number of adverse consequences, including higher rates of depressive symptoms and stress [3,4], weight gain [5], and poor academic performance [6]. Another concern for undergraduate students that has arisen in recent years is their social media use, as studies show a link between cyberbullying and major health problems such as

substance use, depression, poor sleep, and suicide [7-9]. Given the array of health risks faced by undergraduate students, it is important to be aware of students' health and risk-related behaviors to be able to provide adequate services and support, such as from psychological and medical campus services.

Traditionally, methods for monitoring the health of a population, for example, students on a college campus, have focused on case reports and surveys [10,11]. Although these methods can offer insights into health-related attitudes and behaviors, they can be time- and cost-intensive to implement. However, researchers using social media data can collect and analyze behavior data in real time [10,11], allowing health authorities to address student needs in a flexible and timely manner.

To explore the feasibility of using social media platforms to identify and predict health-related events, Young et al [12] screened geolocated Twitter messages for keywords that suggested HIV risk behaviors. The authors used negative binomial regression analyses to determine the association between tweets about HIV risk behaviors and county-level HIV data in the United States. They ran analyses to determine the association between tweets about HIV risk behaviors and county-level HIV data in the United States. The results showed a strong association between tweets about HIV risk behaviors and actual county HIV data. Additionally, De Choudhury et al [13] successfully used tweets to predict the onset of major depressive disorder with 70% accuracy. They selected tweets based on indicators such as linguistic style, use of terms associated with depression, and social network characteristics.

Yik Yak was an anonymous web-based bulletin board for users within the same geographic area (eg, college campuses) that debuted in 2013 [14]. At the time of this study, it was a popular social network for college students but faced substantial criticism. Critics argued, aided by anecdotal evidence relayed through media reports, that anonymous posting encourages harassment and bullying [14-17]. In a recent content analysis of Yik Yak conversations [18], there was no evidence of a pervasive culture of harassment and abuse. However, contradictory to this analysis, researchers have observed derogatory and incendiary comments, arguably racist and sexist messages, and several likely instances of bullying [18]. Furthermore, other research has shown that harassment is prevalent among users of Yik Yak and other anonymous social networks in Bangladesh [19]. Although Yik Yak is now defunct, the rising popularity of anonymous social networks [20] suggests that its data can still provide useful insights.

Study Overview

In this study, we explored two types of messages students made on Yik Yak. The first type consists of posts exhibiting messaging behaviors that can have an impact on students' health in relation to cyberbullying. This includes cyberbullying itself, which has previously been linked to health problems [7-9]. It also includes prosocial messages, which are messages sent by a user with the intention of benefiting one or more other users [21], or with the intention of seeking such messages. The prosocial messaging behaviors we selected are related to bullying and its effects on health. Two of these are seeking and offering support, as students with high depression or anxiety often turn to social media for social support [22]. The second type consists of messages that discuss one of 4 topics frequently discussed by students on Yik Yak, such as relationships and living on campus, to provide additional context to the messaging behaviors we analyzed in this study. We analyze these messaging behaviors and topics by determining which ones are most frequently discussed and which are the most popular (in terms of votes) and by finding correlations between different messaging behaviors and topics.

Our goal is to provide insights for school administrators, public health researchers, and health care professionals regarding the prevalence of messaging behaviors, such as bullying and social support, and knowledge of general topics discussed in the network. Specifically, the purpose of this study is to show that messaging behaviors that can have an impact on students' health occur frequently on anonymous social networks, demonstrate how they are regarded by other students by analyzing their popularity, describe the prevalence and popularity of topics that are commonly discussed by college students, and explore the intercorrelations between these messaging behaviors and topics. Knowledge of these activities on anonymous social networks can inform interventions that promote healthy and prosocial behaviors among adolescents and young adults.

We also investigated the feasibility of automatic classification of messaging behaviors and topics in this study. This involved training 3 machine learning algorithms with several combinations of hyperparameters to determine the best combination for each messaging behavior and topic. We report the results of these models on test data to demonstrate their effectiveness. An accurate classification model can complement the insights provided by this study by providing administrators, researchers, and health care professionals with a tool to more easily find relevant messages.

Methods

Data

From April 6, 2016, to May 7, 2016, we collected anonymous conversations posted on the Yik Yak social network at 5 randomly selected universities located in each of the 4 most populous US states: California (CA); Florida (FL); New York (NY); and Texas (TX). To protect our analyses from the influence of a university with an exceptionally large number of messages, we calculated the number of messages from each university per capita with respect to the number of students enrolled at that university. We then flagged universities that had a number of messages per enrolled student more than 1.5 SDs above their state's mean. This resulted in the removal of 1 university, the University of Texas at Dallas, leaving a total of 19 universities. Table 1 lists these universities, their status as either a public or a private university, their enrollment, and their ranking according to the 2017 *Wall Street Journal*/Times Higher Education College Rankings [23]. Enrollment and rankings are used as part of our analysis of the interplay between variables. For our analysis, we randomly selected 100 conversation threads from each of the universities (N=16,966 messages), with a mean of 892.95 (SD 128) messages per university. We analyzed the messages with respect to the type

of messaging behavior, content, and popularity of message type and content.

Messaging Behaviors

Within the context of this study, we use the term *messaging behavior* to refer to the intent of a message, that is, what a user is trying to accomplish by posting a message. For each message, we determined if it displayed 1 of the 4 predefined messaging behaviors listed in Table 2. Among these is bullying, which we included in our analysis because of its effects on student health [7-9]. A message was considered to be bullying if it intended harm (ie, if the purpose of the message appeared to be to negatively impact the recipient's mental health), was indicative of a power imbalance (eg, the message was racist or sexist), and if the sender repeatedly sent these messages [25]. We also included seeking help and offering support because of their relation to health and bullying—supportive environments can be seen as more healthy and possibly more likely to prevent or reduce bullying. Humor was included to better understand if users were intentionally bullied or trying to be humorous. A total of 2 undergraduate raters independently coded the selected messages for these 4 messaging behaviors; each message was assigned a messaging behavior only if both raters coded it as such.

Table 3 lists the range, SD, mean, and median for several characteristics of messages with the messaging behaviors defined in Table 2: message length, measured in both characters and words; the number of replies received by any message; the number of replies received by initial posts (ie, the first message in a thread); the post time for messages posted between midnight and noon (AM); and the post time for messages posted between noon and midnight (PM).

Table 2. Definitions of messaging behaviors included in the study.

Messaging behavior	Definition	Examples	Cohen kappa (number of agreements)
Seeking help	Seeking social support (eg, emotional support and help with problems) from other users	• "I like don't know what to do with myself. Literally I have no one to talk to" • "What's the easiest class to fill art requirement? I'm terrible at art"	0.48 (90)
Offering support	Giving social support to other users	• "Hope everything gets resolved OP!" • "You've got this!"	0.56 (86)
Bullying	Intends harm, indicative of a power imbalance, and messages are repeatedly sent [25]	• "You people are disgusting" • "In the words of DJ Khaled 'congratulations you played yourself' it's not hard to portray being a moron. It's quite sad actually"	0.00 (95)
Humor	Intends to be funny without bullying	• "I predict my day based on my morning poo" • "Why get thinner when you can get more dinner?"	0.48 (87)

Message Topics

We applied latent Dirichlet allocation (LDA) to the message corpus to identify themes within the message content. LDA is a common method for categorizing topics and themes [26]. Each topic, in turn, is probabilistically associated with various words. As topics are defined purely in statistical terms, the user chooses its semantic interpretation (ie, its label) based on word probabilities for the topic.

Next, we sought to identify topics in which the LDA message classifications aligned most closely with human judgment. We did this with a subset of 1200 randomly selected messages to which the LDA assigned a topic with a probability greater than 0.7. For each of these messages, a team of 3 raters decided if the LDA topic assignment was correct (ie, does the message discuss topic *X*). On the basis of these results, we selected the 4 topics with the highest classification accuracy: relationships and sex, college living, politics, and school and classes.

In the final step, 2 undergraduate raters independently applied the 4-topic classification scheme to 96 randomly selected messages. We found that their interrater agreement was high (Cohen kappa=0.78), so all remaining messages were coded by 1 of the 2 raters. Table 4 lists Cohen kappa for each individual topic; it is undefined for politics because neither rater coded any of the 96 messages for that topic.

Table 5 lists the range, SD, mean, and median for several characteristics of messages with these topics.

Table 4. Cohen kappa for each topic (n=96).

Statistic	Relationships and sex	College living	Politics	School and classes
Cohen kappa	0.73	1.00	Undefined	0.77
Number of agreements	90	96	96	91

Analysis

Our analysis consisted of 3 parts: frequency of messaging behaviors and topics, popularity of messaging behaviors and topics, and interplay between variables. In the first 2 parts, we used messages that raters uniquely assigned to 1 or none of the 4 predefined messaging behaviors to assess the frequency and popularity of messaging behaviors. Similarly, we used messages that raters uniquely assigned to 1 or none of the 4 LDA-derived topics to assess the frequency and popularity of messaging behaviors. In all statistical analyses, the significance criterion was alpha=.05.

In our analysis of the relative frequencies of messaging behaviors and topics on Yik Yak, Bonferroni-corrected Fisher exact tests determined if differences in the frequencies of these messaging behaviors or topics across states were statistically significant. If we found that the differences for a messaging behavior or topic were significant, we followed this up with Bonferroni-corrected Fisher exact tests for pairwise comparisons between states of the frequency of that messaging behavior or topic.

We determined the popularity of a message by the aggregate score of +1 votes (upvotes) and −1 votes (downvotes) assigned by Yik Yak users before data collection. Notably, if a message on Yik Yak reaches a sum score of −5, it is automatically deleted from the social network. Thus, the lowest possible popularity score for a message in our dataset was −4. To protect our analyses from the influence of a few massively popular messages, we flagged messages with a score greater than 2.5 SDs above the grand mean. We then submitted the individual message scores to state × messaging behavior and state × topic analysis of variance (ANOVA), followed up by Tukey range test to further investigate any significant main effects of each ANOVA.

The third part of our analysis examined the relationship between the frequency of prosocial messages in which users sought help or offered support, the frequency of bullying messages, the popularity of these messaging behaviors, and the frequency of topics. We carried out an analysis at the university level. For each university, we calculated mean messaging behavior frequencies, the corresponding mean popularity scores, and mean topic frequencies. We measured correlations between these variables together with 2 additional variables—the number of students enrolled and school ranking.

Classification

We conducted a series of experiments with 3 text classification algorithms on the messaging behaviors and topics in this study. The first 2 are random forest [27] and linear support vector machine (SVM) [28] classifiers with term frequency-inverse document frequency (TF-IDF) vectors [29], and the third is a convolutional neural network (CNN) text classifier [30] with global vectors for word representation (GloVe) [31].

In each experiment, we selected 1 messaging behavior or topic and regarded each message in the dataset as a tuple (t, c), where t is the message text concatenated with tokens for the university and state the message is from, and c is a class label *positive* (the selected messaging behavior or topic is present in the message) or *negative* (the messaging behavior or topic is not present). We randomly selected 10.00% (1697/16,966) of the dataset to be used as the test dataset. With the remaining training dataset, we used 5-fold cross-validation and measured the balanced accuracy [32] of each classifier to determine the best combination of classifier hyperparameters, which are then used with the full training dataset to build the final classifier model.

Table 6 lists the hyperparameters and their respective values evaluated by our experiments for each classifier. For all classifiers, we preprocess the data by removing stop words and lemmatizing the remaining words with the natural language toolkit [33]. For the random forest and SVM classifiers, we add *balanced* class weights as defined by Scikit-learn [34]. The TF-IDF vectors are also built from the implementation in Scikit-learn [34]. The remaining hyperparameters are set to their default values, as defined by the implementations of these classifiers in Scikit-learn [34]. For the CNN classifier, we perform upsampling such that the positive messages in the training data are as frequent as the negative messages and use 100-dimension GloVe vectors pretrained on Twitter data. All other CNN hyperparameters are set to their default values as defined in the code by Ng [35].

Table 6. Classifier hyperparameter values evaluated in our experiments.

Classifier and hyperparameter	Values
Random forest	
Maximum tree depth	2, 4, 8, 16, 32, 64
Number of trees	10, 100, 1000
SVM[a]	
C[b]	0.001, 0.01, 0.1, 1, 10
Loss function	Hinge, squared hinge
CNN[c]	
Filter window sizes	(2, 3, 4), (3, 4, 5), (4, 5, 6)
Feature maps per filter window size	100, 200, 300, 400, 500, 600

[b]*C*: SVM regularization parameter.

[c]CNN: convolutional neural network.

Results

Frequency of Messaging Behaviors

A total of 11.91% (2021/16,966) of the messages were focused on 1 of the 4 predefined messaging behavior categories: seeking help, offering support, humor, and bullying. Table 7 lists the frequencies of these messaging behaviors by state. We found significant differences in the relative frequency of messages offering support ($P<.001$) and bullying messages ($P<.001$). We found no significant geographic differences for messages seeking help ($P=.20$) or for humorous messages ($P=.40$). Using separate Fisher exact tests, we found that the 2 states with the lowest rates of bullying, CA and FL, differed significantly from the states with the highest rates, NY and TX ($P<.001$ for CA vs TX and FL vs TX, $P=.001$ for CA vs NY, $P=.003$ for FL vs NY).

Table 7. Frequency of messaging behaviors by state.

Messaging behavior	CA[a] (N=4496), n (%)	FL[b] (N=4694), n (%)	NY[c] (N=4273), n (%)	TX[d] (N=3503), n (%)	Total (N=16,966), n (%)	Bonferroni-corrected Fisher exact *P* value
Seeking help	70 (1.56)	94 (2.00)	65 (1.52)	70 (2.00)	299 (1.76)	.20
Offering support	183 (4.07)	381 (8.12)	234 (5.48)	88 (2.51)	886 (5.22)	<.001
Bullying	61 (1.36)	68 (1.45)	98 (2.29)	93 (2.65)	320 (1.96)	<.001
Humor	140 (3.11)	134 (2.85)	144 (3.37)	98 (2.80)	516 (3.15)	.40

[a]CA: California.

[b]FL: Florida.

[c]NY: New York.

[d]TX: Texas.

We also evaluated a sample of messages that were not assigned any of the 4 predefined messaging behavior categories to better understand the nature of messaging behavior outside of these categories. This sample consisted of 100 messages that were the first messages in their respective conversation threads. We found that the majority of these messages (68/100) were commentary, for example, anticipation of future events (“Cant wait for summer!!! #summer16”), reactions to personal experiences (“I hate when people tell me to put on headphones.”), and observations (“So many economics majors on yikyak nowadays”). Other messages (16/100) asked questions that did not seek social support, for example, soliciting opinions (“Do you think all pedophiles should be executed or do you think they deserve a 2nd chance and then should be executed if they relapse?”) and polling (“Quick poll. What's your ethnicity?”). Further messages (12/100) sought people to meet with or talk to for purposes other than social support, for example, for dating (“Any cute girls in the dorms? Drop your snapchat names”) or classes (“Anyone in geology 210 on M for 4:00-5:50?”).

The remaining messages in the sample (4/100) lacked sufficient context to judge their messaging behavior. Although these broadly defined messaging behaviors are not directly related to this study and, thus, not subjected to further analysis, this sample of posts shows that future work focusing on the commentary present on an anonymous social network would likely have substantial coverage of the message content of that network.

Frequency of Topics

Using only messages with 1 or none of the 4 LDA-derived topics (relationships and sex, college living, politics, and school and classes), we excluded 0.69% (117/16,966) of the messages from

the frequency analysis. A total of 26.33% (4437/16,849) of the remaining messages dealt with either relationships and sex (2516/16,849, 14.93%), college living (644/16,849, 3.82%), politics (607/16,849, 3.60%), or school and classes (670/16,849, 3.98%). In Table 8, we break these numbers down further by state. Using separate Fisher exact tests, we found significant regional differences for each topic. NY had the fewest relationship messages and differed significantly from CA (P<.001) and TX (P=.048).

Table 8. Frequency of topics by state.

Topics	CA[a] (N=4443), n (%)	FL[b] (N=4668), n (%)	NY[c] (N=4253), n (%)	TX[d] (N=3485), n (%)	Total (N=16,849), n (%)	Bonferroni-corrected Fisher exact *P* value
Relationships and sex	730 (16.43)	689 (14.76)	532 (13.21)	535 (15.35)	2516 (14.93)	<.001
College living	224 (5.04)	83 (1.78)	157 (3.69)	180 (5.16)	644 (3.82)	<.001
Politics	133 (2.99)	122 (2.61)	317 (7.45)	35 (1.00)	607 (3.60)	<.001
School and classes	208 (4.68)	114 (2.44)	150 (3.53)	198 (5.68)	670 (3.98)	<.001

[a]CA: California.

[b]FL: Florida.

[c]NY: New York.

[d]TX: Texas.

We followed up on these significant effects with Bonferroni-corrected Fisher exact tests for all pairwise comparisons between states for each topic. We found significant differences in the number of college living messages between all states (P<.001), except for CA and TX, the 2 states with the most college living messages (P=.76). Finally, we found significant differences in the frequency of school-related messages between states (P<.001); CA and TX, where school was discussed the most, had the least significant difference (P=.04).

Popularity of Messaging Behaviors

In this and the following section, we report findings on the popularity of the different messaging behaviors and topics, based on the aggregate of +1 votes (upvotes) and −1 votes (downvotes) each message elicited from Yik Yak users. We identified 1.80% (305/16,966) of the messages as popularity outliers and excluded these from further analysis.

Table 9 displays the mean popularity scores for the 4 messaging behaviors (seeking help, offering support, bullying, and humor) at the state level (CA, FL, NY, and TX). We submitted the individual message scores to a state × messaging behavior ANOVA. Both main effects were significant: $F_{3,1940}$=5.11, mean square error (MSE)=4.1, and P=.002 for state and $F_{3,1940}$=25.85, MSE=4.1, and P<.001 for messaging behavior. The interaction between the 2 factors was not significant ($F_{9,1940}$=0.94; MSE=4.1; P=.49).

Table 9. Popularity of messaging behaviors and topics by state.

Messaging behavior	CA[a]		FL[b]		NY[c]		TX[d]		Total	
	Mean[e] (SE)	n	Mean (SE)	n	Mean (SE)	n	Mean (SE)	n	Mean (SE)	n
Seeking help	1.04 (0.26)	68	1.37 (0.21)	92	0.78 (0.30)	63	0.53 (0.27)	70	0.97 (0.13)	293
Offering support	1.00 (0.11)	182	0.98 (0.08)	380	1.22 (0.12)	230	0.77 (0.16)	88	1.03 (0.06)	880
Bullying	0.40 (0.32)	58	0.32 (0.17)	68	0.59 (0.23)	96	0.32 (0.18)	92	0.42 (0.11)	314
Humor	1.50 (0.20)	124	1.71 (0.22)	125	2.14 (0.27)	130	1.27 (0.20)	90	1.69 (0.12)	469

[a]CA: California.

[b]FL: Florida.

[c]NY: New York.

[d]TX: Texas.

[e]Mean: Mean message popularity scores are based on the aggregate number of upvotes (+1) and downvotes (−1) per message.

We used Tukey range test to determine which state exhibited significantly different mean popularity scores. This analysis revealed that, on average, Yik Yak messages received lower popularity scores in TX than in FL (P=.03) and NY (P<.001). Additionally, Tukey test showed that bullying messages were the least popular and differed significantly from messages seeking help (P=.003), messages offering support (P<.001), or humorous messages (P=.001). In contrast, humorous messages were the most popular and scored significantly higher than the other 3 message types (all P<.001).

Popularity of Topics

Table 10 summarizes the mean popularity scores of messages that discussed 1 of the 4 topics identified through LDA: relationships and sex, college living, politics, or school and classes. A state (CA, FL, NY, and TX) × topic ANOVA revealed main effects of $F_{3,4293}$=11.23, MSE=4.9, and P<.001 for state

and $F_{3,4293}$=7.32, MSE=4.9, and P<.001 for the topic as well as a significant state-by-topic interaction of $F_{9,4293}$=2.52, MSE=4.9, and P=.007. We carried out Tukey test to further investigate the significant main effects. We found that TX, the state with the lowest popularity scores overall, differed significantly from CA (P<.001), FL (P=.03), and NY (P<.001). Regarding the popularity of topics, school and classes was a significantly less popular topic than relationships and sex (P=.002), college living (P=.002), and politics (P=.001).

Table 10. Popularity of topics by state.

Topic	CA[a]		FL[b]		NY[c]		TX[d]		Total	
	Mean[e] (SE)	n	Mean (SE)	n	Mean (SE)	n	Mean (SE)	n	Mean (SE)	n
Relationships and sex	1.56 (0.09)	700	1.03 (0.08)	678	1.16 (0.10)	548	0.96 (0.08)	528	1.19 (0.05)	2454
College living	1.31 (0.15)	209	1.56 (0.26)	78	1.70 (0.23)	146	0.78 (0.14)	175	1.28 (0.09)	608
Politics	1.17 (0.21)	129	1.46 (0.24)	119	1.34 (0.14)	314	1.49 (0.43)	35	1.34 (0.10)	597
School and classes	0.84 (0.12)	197	1.09 (0.20)	114	1.08 (0.18)	145	0.43 (0.09)	194	0.82 (0.07)	650

[a]CA: California.

[b]FL: Florida.

[c]NY: New York.

[d]TX: Texas.

[e]Mean: Mean message popularity scores are based on the aggregate number of upvotes (+1) and downvotes (−1) per message.

The significant state-by-topic interaction indicates that states differ with respect to the relative popularity of topics. To identify patterns of topic popularity within each state, we conducted ANOVAs with topic as a single factor, separately for each state. These ANOVAs yielded a significant effect of topic for CA ($F_{3,1231}$=5.36; MSE=5.39; P=.001) and TX ($F_{3,928}$=5.84; MSE=3.17; P<.001) but not for FL ($F_{3,985}$=2.41; MSE=4.91; P=.07) or NY ($F_{3,\ 1149}$=2.34; MSE=5.7; P=.07). We followed up on the significant effects for CA and TX using Tukey test. In CA, school and classes were a less popular topic than relationships and sex (P<.001). In TX, messages about school and classes were less popular than messages about relationships (P=.002) and politics (P<.009).

Interplay Between Variables

We summarize the intercorrelations between the frequency of prosocial messages in which users sought help or offered support, the frequency of bullying messages, the popularity of these messaging behaviors, the frequency of topics, and school enrollment and ranking in Table 11. These correlations are based on 19 schools, except for correlations involving the variable *ranking*, for which n=18.

We found that schools with a greater frequency of help-seeking messages also exhibited a greater frequency of messages offering support (P=.04). Campuses where students posted less about relationships and sex sent more messages offering support (P=.002). Moreover, messages offering support were more frequent at higher-ranking schools (P=.006). Bullying occurred more often on campuses where users posted more about politics (P=.048) and where messages seeking help were popular (P=.02). Messages offering support were more popular at campuses where students posted more about classes (P=.04). Finally, we found that the frequency of messages about college living was positively related to the frequency of messages about classes (P=.04) but negatively related to the number of enrolled students (P=.05). The remaining correlations in Table 9 were not statistically significant.

Table 11. Intercorrelations at the school level.

Classification Results

Tables 12 and 13 summarize the results of our trained classifiers on the test data. As accuracy can be misleadingly high for imbalanced datasets, we also report balanced accuracy. Using this metric, we see that SVM has the best performance on 5 messaging behaviors and topics (offering support, bullying, relationships and sex, politics, and school and classes), with a balanced accuracy of over 0.75 on all but the humor dataset and an average balanced accuracy of 0.7827. CNN was the second-best performer, with the best performance on humor and college living and an average balanced accuracy of 0.7645.

Table 12. Messaging behavior classification results.

Metric and classifier	Seeking help	Offering support	Bullying	Humor
Accuracy				
Random forest	*0.9269* [a]	*0.8120*	*0.9299*	0.6417
SVM[b]	0.6771	0.7501	0.9240	*0.8385*

Discussion

Principal Findings

Owing to the growing popularity of social media across all segments of society, researchers have a plethora of data sources from which they can derive new insights about people's social and health-related attitudes, behaviors, and beliefs. The ability to observe social media users in near real time holds particular promise in the domain of public health and health care, where rapid detection of health-relevant events and timely intervention are essential. This study aimed to explore the prevalence of information pertaining to college students' health and well-being contained in their conversations on an anonymous social network. To this end, we analyzed the frequency and popularity of prosocial messages and bullying messages as well as the frequency and popularity of topics discussed on the web.

In our dataset, prosocial messages (seeking help, offering support, and humor) appeared more frequently than bullying messages (1735/16,966, 10.23% vs 332/16,966, 1.96%), and there were significant regional differences in the frequency of messages associated with support or bullying. Notably, Yik Yak users attending TX colleges sent the fewest supportive messages and the most bullying messages. We should interpret this finding with caution in light of the relatively small number of messages and universities considered for our study. Nevertheless, this finding highlights a potentially problematic pattern of social media use among college students that future research may link to adverse health outcomes. Unsurprisingly, bullying messages were the least popular, and humorous messages were the most popular among Yik Yak users, independent of the state in which they lived.

To identify the topics of Yik Yak messages, we relied on statistical modeling as an alternative to the subjective classification scheme recently used by Black et al [18]. A subsequent analysis of topic prevalence revealed that relationships and sex was the most frequently discussed topic among college students. School and classes turned out to be the least popular topic, as measured by the number of upvotes and downvotes a message received. From an intervention point of view, regional differences in topic frequency and popularity matter because they offer campus representatives and health

professionals clues on how to best engage a student population, both on the web and offline. Although the relative popularity of topics was similar across states, we found greater regional variation in the relative frequency of topics. For example, 7.44% (318/4273) of Yik Yak messages in the state of NY discussed politics compared with only 1.00% (35/3503) in TX, and college living was addressed in 5.60% (252/4496) of messages in CA but in only 2.28% (107/4694) of messages in FL.

With our final correlational analysis, we wanted to learn more about factors that promote prosocial web-based behaviors and prevent cyberbullying at US colleges. Several findings are worth noting. At schools where students often sought help through messages, messages offering support were also more frequent. We speculate that students may offer support in response to requests for help, but the reverse relationship is also conceivable: at schools where support is offered frequently, students may feel encouraged to ask for help. A higher prevalence of supportive messages also appears to be a characteristic of higher-ranking universities. Although the *Wall Street Journal*/Times Higher Education's college rankings [23] do not take into account social support between students, some hidden factors that lead to a higher prevalence of social support may have also been indirectly captured by their methodology. Our observation of a positive relationship between the popularity of messages offering support and the frequency of the school and classes topic may be explained by a positive response, in the form of upvotes, to support offered to students expressing frustrations with coursework and exams. It is more difficult to interpret why messages of support were sent more often at schools where relationships and sex were discussed less frequently. This requires further investigation.

Two results speak directly to the frequency of cyberbullying on college campuses. First, there was a positive relationship between bullying and the popularity of messages seeking help. One interpretation for this finding is that students react prosocially to a higher prevalence of bullying by encouraging help-seeking behavior, although they did not appear to actually offer more support (the correlation between the frequency of supporting and bullying messages was negative and not significant). An alternative hypothesis is that certain prosocial messaging behaviors can trigger cyberbullying. Additionally, students at schools with a higher incidence of bullying frequently discussed politics. This result is unsurprising given the often-heated nature of political discussions.

Of the results regarding the frequency of messages about college living, the positive relationship with the frequency of messages about classes is understandable, given that these 2 topics reflect much of the college experience. However, messages about college living are less frequent at schools with lower enrollment rates. One possible explanation may be that smaller schools have less on-campus housing relative to the number of students, but further study is necessary to make this determination.

Our text classification experiments demonstrate the feasibility of automatic classification of the messaging behaviors and topics in this study. The balanced accuracy of the SVM classifier on the test data was reasonably high for most messaging behaviors and topics. Its worst performance was with the humor dataset, which also had the lowest balanced accuracy with the random forest classifier and the second lowest balanced accuracy with the CNN classifier. This may be because of the complexity of humor—forms of humor such as innuendo, sarcasm, and satire may be difficult for a machine learning algorithm to identify.

Conclusions

This study has strong implications for education, public health, and broader fields of health care. Educators could use similar methods to find topics that may be engaging to students on campus. In particular, campus administrators and health service units could identify topic areas where students could engage in a campus-wide dialogue. This could also be helpful for public health professionals because it would provide insight into campus conversations that lead to bullying or hostility. Educators and clinicians could work together to foster a healthier dialogue around the subject and encourage a campus culture of reaching out to fellow students to offer support. In addition to gaining insights into conversations on college campuses, this study represents a first step in guiding research focused on anonymous social networks. The results of this study can help promote the labeling and mining of social data to help students, parents, administrators, and health care workers identify cyberbullying and design interventions to stop it.

This type of work naturally presents opportunities for computer scientists working in health services as well. Mining data from anonymous social networks can extend beyond the college campus and to the public. Computer scientists can design tools to mine and categorize public social data and help create an even farther-reaching monitoring system for educators and public health professionals [36].

The major limitations of this study include the small number of colleges and universities considered, the lack of ability to generalize as Yik Yak has closed down since this study was conducted, the modest number of Yik Yak messages per school, and the relatively small number of classifier hyperparameters evaluated. We, therefore, caution against generalizing our findings until they can be replicated with larger samples and on other anonymous social networks. The main intention of this study was to understand students' web-based behaviors and interests from their messages on an anonymous social network and, more specifically, to garner initial insight into conditions affecting prosocial and antisocial uses of social media that could be integrated into health services. We believe that the findings reported here can be a stepping stone to further research on this topic as well as differences in health behaviors and risks communicated on anonymous social networks vs nonanonymous social networks.

Authors' Contributions

RR performed text classification experiments, determined statistical characteristics of messaging behaviors and topics, and assisted in writing the manuscript. MS collected and analyzed the data and wrote part of the manuscript. RG worked on the analysis and writing. VH led the technical research. SY led the problem formulation and discussion.

Abstract

Background: With the rapid development of online health communities, increasing numbers of patients and families are seeking health information on the internet.

Objective: This study aimed to discuss how to fully reveal the health information needs expressed by patients with hypertension in their questions in a web-based environment and how to use the internet to help patients with hypertension receive personalized health education.

Methods: This study randomly selected 1000 text records from the question data of patients with hypertension from 2008 to 2018 collected from Good Doctor Online and constructed a classification system through literature research and content analysis. This paper identified the background characteristics and questioning intention of each patient with hypertension based on the patient's question and used co-occurrence network analysis and the k-means clustering method to explore the features of the health information needs of patients with hypertension.

Results: The classification system for the health information needs of patients with hypertension included the following nine dimensions: drugs (355 names), symptoms and signs (395 names), tests and examinations (545 names), demographic data (526 kinds), diseases (80 names), risk factors (37 names), emotions (43 kinds), lifestyles (6 kinds), and questions (49 kinds). There were several characteristics of the explored web-based health information needs of patients with hypertension. First, more than 49% of patients described features, such as drugs, symptoms and signs, tests and examinations, demographic data, and diseases. Second, patients with hypertension were most concerned about treatment (778/1000, 77.80%), followed by diagnosis (323/1000, 32.30%). Third, 65.80% (658/1000) of patients asked physicians several questions at the same time. Moreover, 28.30% (283/1000) of patients were very concerned about how to adjust the medication, and they asked other treatment-related questions at the same time, including drug side effects, whether to take the drugs, how to treat the disease, etc. Furthermore, 17.60% (176/1000) of patients consulted physicians about the causes of clinical findings, including the relationship between the clinical findings and a disease, the treatment of a disease, and medications and examinations. Fourth, by k-means clustering, the questioning intentions of patients with hypertension were classified into the following seven categories: "how to adjust medication," "what to do," "how to treat," "phenomenon explanation," "test and examination," "disease diagnosis," and "disease prognosis."

Conclusions: In a web-based environment, the health information needs expressed by Chinese patients with hypertension to physicians are common and distinct, that is, patients with different background features ask relatively common questions to physicians. The classification system constructed in this study can provide guidance to health information service providers for the construction of web-based health resources, as well as guidance for patient education, which could help solve the problem of information asymmetry in communication between physicians and patients.

Introduction

Background

Hypertension is currently the most common chronic disease and is a major risk factor for the morbidity and mortality of stroke and coronary heart disease in China [1]. According to statistics, the hypertension prevalence in Chinese residents aged 18 years or over is 27.9%, the hypertension awareness rate is 51.6%, and the hypertension control rate is 16.8% [2]. However, the hypertension control rate in the United States is close to 50% [3]. We urgently need to adopt measures to improve public awareness and health management of hypertension. An online health community is a health and medical online community of the *internet plus medical care* model, providing users with better knowledge services in the form of a community [4]. According to a research report, by the end of December 2018, the number of internet users in China had reached 820 million [5], and more than 190 million users had access to medical health information on the internet [6]. An online health community allows users to avoid long waits when seeking health information services, especially those with hypertension who need long-term self-health management at home. The health literacy of patients with hypertension in China is generally low. Owing to the small number of family physicians in the community and the low enthusiasm for signing contracts, the family physician policy has not been effectively promoted throughout the country [7]. After discharge, patients with hypertension cannot be guided or supervised by physicians to help manage the disease properly. When there are issues that may affect compliance, some patients will seek information or help on the internet. Wicks et al [8] showed that an online health community can help users benefit from managing their own disease symptoms, treating side effects, finding fellow patients, and asking for medication advice. We hope that information resource providers will effectively organize and recommend relevant information according to the information needs of each patient with hypertension. In the long term, this will help patients with hypertension reduce information asymmetry with physicians by personalized health education and improve their compliance. The research perspective of this study was to reflect the features of the information needs of patients with hypertension or their families in an internet-based environment according to the textual information disclosed by patients in an online health community when consulting with physicians.

Related Studies

At present, many studies have been carried out on the health information needs of internet users in China and other countries. The investigators mainly used questionnaires [9-11], in-depth interviews [12], and content analysis methods [13,14] to study the types of health information needs of specific populations. The study populations included elderly individuals [9], college students [15], pregnant and parturient women [16], and other populations, and the health problems involved were diabetes [17], hypertension [18], cancer [19], depression [20], and others. Related studies have shown that different populations have different web-based health information needs, which change with the course of the disease [10,12,21]. Patients with different cancers have high needs for information on the likelihood of cure, survival, treatment side effects, and risk [19].

In recent years, with the rapid development of natural language processing research and machine learning algorithms, methods based on topic recognition and text mining have been gradually applied to the analysis of web-based health information needs. Compared with the questionnaire survey method, the web text mining method can fully consider a patient's expression and idioms from a user's perspective. The obtained demand characteristics are more in line with the user's real information needs [22]. Chen used the k-means method to conduct clustering analysis on the text of three online health communities and found that different communities had different hot topics, as well as the same topics, such as patient experience, treatment, drugs, and body management [23]. Lv used the expectation maximization clustering method to perform topic analysis, member role analysis, and sentiment analysis on the MedHelp website and finally defined seven hot topics, including detailed personal introduction, emotional support, symptoms, examinations, complications, medication, and treatment [24]. Patrick et al [25] used a public dataset to predict the intent of the questioner and extracted patients' opinions, emotions, countermeasures, and social support topics from the data of patients with cancer and mental illness. Zhang [26] suggested that the background information of users, such as health status and age at the time of asking questions, should be considered in research on patient information needs. Owing to the professionalism and complexity of medical language and the issues of web users' descriptions, such as miswriting and colloquial words, it is difficult to manage user-generated content, and the machine learning algorithm model that it relies on needs to be trained and validated in an annotated corpus [27,28]. However, a Chinese corpus for patient consultation after current annotation is still lacking.

There are already some studies on the classification of health questions. However, these studies focused on information needs for health care professionals [26,28,29]. Guo et al [30,31]

constructed a Chinese health question classification corpus to study topics on the information needs of patients with hypertension, but these studies did not fully consider the background information of patients with hypertension, such as disease history, symptoms and signs, medication, gender, and age. As a result, they failed to reflect the features of the health information needs of more sophisticated patients with hypertension.

In summary, with the text information actually published in an online community as the research object, the obtained data can better reflect the real situation of the health information needs expressed by patients with hypertension during online consultations. However, nonmanual annotation methods, such as latent Dirichlet allocation (LDA) topic recognition, still have some deficiencies in Chinese medical text applications and cannot effectively reflect the semantic similarities of medical concepts. Although the LDA algorithm can identify the required topics from a large amount of text information, owing to the complexity and professionalism of the medical language, the feature keywords of the topic need to be manually summarized after generating the topic model. The final generated topic tags are medicine dependent, and expert discussions are designed to summarize the expressions of the most typical words [32]. Therefore, in this study, we used manual coding to analyze web text content.

Study Aim

In this study, on the basis of previous studies, we constructed a multidimensional classification system of the health information needs of patients with hypertension according to their consultation records in an online health community and used multidimensional features to reveal the features of the health information needs of patients with hypertension in a web-based environment.

Methods

Data Collection and Preprocessing

Data collection in this study was based on a search engine in the Chinese medical field [33] to filter nonreal, noneffective, and nonauthoritative medical information. Considering that the search engine can aggregate patient consultation data from different websites with disease keywords, it was convenient for us to obtain web-based consultation data for patients with hypertension. In addition, the search engine can mark the consulted physician, the physician's title, and the level of the medical institution. In this study, we searched for relevant records with *hypertension* as the keyword in the search engine and obtained 10,000 related records from 2008 to 2018. Most of the records provided by the search engine were from Good Doctor Online [34]. Good Doctor Online is one of China's leading web-based medical platforms. As of December 2019, it has information on 610,000 physicians from 9917 regular hospitals in China [34]. A survey of Good Doctor Online found that when consulting a physician, patients submit content according to a certain information description framework as follows: consultation title, disease, description of the condition, previous treatment status and effect, and how to get help. Considering that the resources under the same website have similar structures, in this study, we only included 8338 nonduplicate consultation records available on the website. A total of 1000 consultation records were randomly selected for further analysis, and the C# program (developed by YFY within the Key Laboratory of Medical Information Research, Central South University, College of Hunan Province, PR China) was used to extract information about the records of patient questions available on the website.

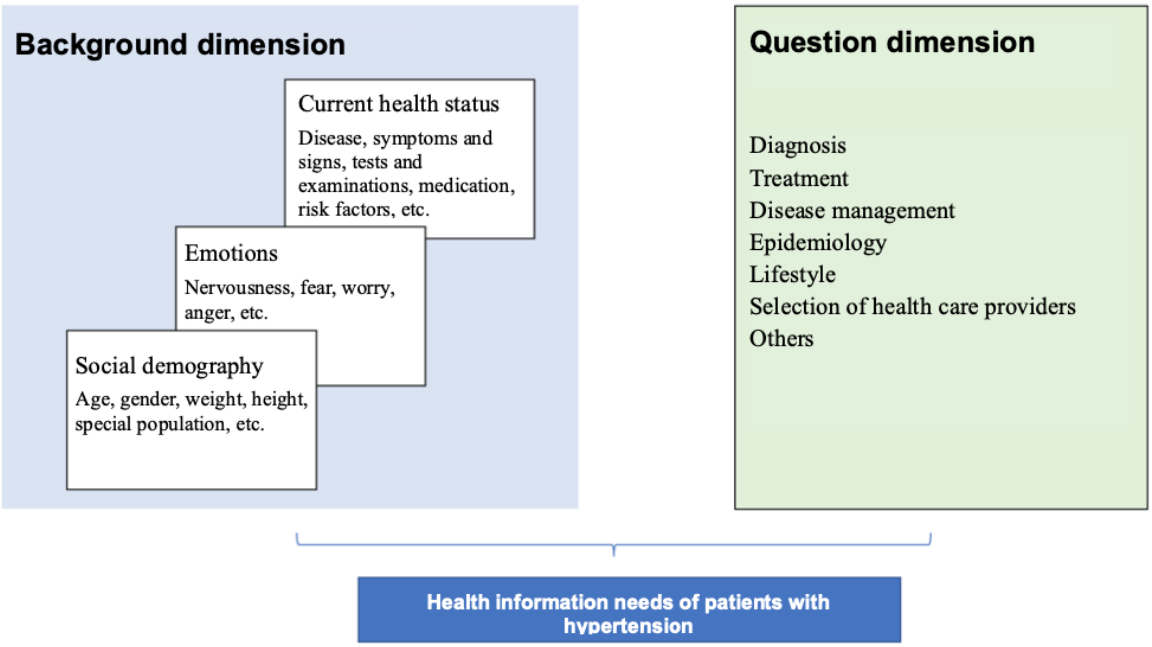
Multidimensional Classification System Construction

We initially summarized the knowledge framework of hypertension from the Guidelines for the Prevention and Treatment of Hypertension in China [35], the 8th Edition of Internal Medicine, and the Health Education Reader Book for Hypertensive Patients. Among them, the Guidelines for the Prevention and Treatment of Hypertension in China is the latest guidance document in China. With reference to the guideline development process of the World Health Organization and the Chinese Medical Association, the compilation team established a set of guidelines for the prevention and intervention, diagnosis and evaluation, classification and stratification, and treatment management of hypertension with Chinese characteristics according to the practice of hypertension prevention and treatment in China.

Based on the knowledge of hypertension, we initially constructed a system involving 12 categories, including epidemiology, etiology and pathogenesis, pathophysiology and pathology, clinical manifestations and complications, laboratory tests, diagnosis and differential diagnosis, prognosis, treatment, hypertension in special populations, risk factors, hazards, and management.

Thereafter, we took into consideration the above-mentioned general clinical question classification system [29], hierarchical model of public health information query scenario, and knowledge elements of hypertension prevention and treatment guidelines; read and summarized the consultation records (Figure 1); and initially constructed a multidimensional classification framework diagram for the health information needs of patients with hypertension. The classification framework mainly included the background dimension system (social demography, emotions, and current health status) and the question dimension system (diagnosis, treatment, disease management, epidemiology, lifestyle, selection of health care providers, and others).

Figure 1. Classification framework diagram for the health information needs of patients with hypertension.

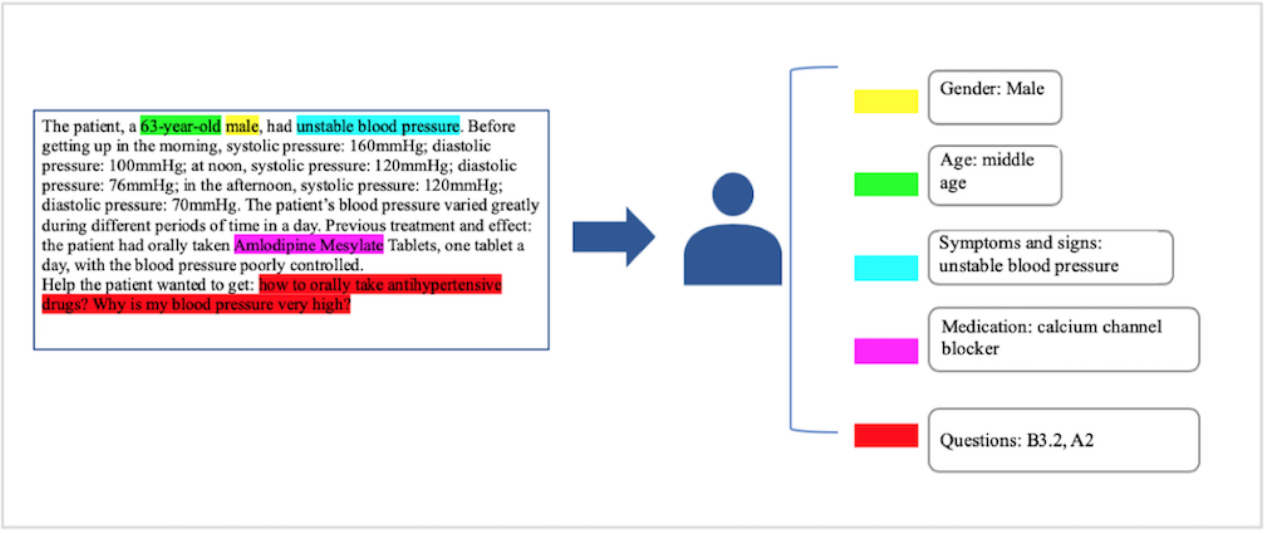


Annotation Process

Initially, two annotators with medical informatics backgrounds independently classified and annotated 100 records randomly selected from the 1000 consultation records mentioned according to the preliminary classification system and the classification example of each category. In the annotation process, each annotator proposed the experience of the annotation process of various entities, made the records, and finally completed the classification table and annotation descriptions for the health information needs of patients with hypertension after reaching a consensus through consultation. Thereafter, the two annotators randomly selected 200 records from the remaining records for repeat annotation, and they discussed inconsistent records (n=23) and reached a consensus after discussion. Finally, the two annotators completed the annotation of the remaining 700 questions and answers independently (ie, 350 questions and answers each). We manually aligned the entities of each type after the annotation was completed. Specifically, the original words were aligned with standard terms. An investigator with a background in medical informatics used this classification system for annotation. The classification system also included a series of annotation rules to improve the usability and accuracy of the classification system.

In particular, we coded each record and aligned the patient description terms with medical phrases under the joint guidance of two medical information professionals and one medical professional. We completed a structured representation of the original question records for patients with hypertension in the sample set. An example is shown in Figure 2.

Figure 2. Structured content coding for the original question record of a patient with hypertension. B3.2 denotes a question about taking medication and A2 denotes a question about symptoms and signs.



Co-Occurrence Analysis and Clustering Analysis

Co-occurrence analysis is one of the content analysis methods in bibliometrics. This method assumes that there is some inherent relationship between multiple keywords that appear in the same document. Co-occurrence frequency refers to the number of occurrences of a group of words in the same document. A larger co-occurrence frequency of two keywords indicates a closer relationship between the two words. Cluster analysis of these words based on co-occurrence frequency can reflect the association between multiple words [36]. Co-occurrence of keywords was considered to be the main approach for identifying research themes and knowledge structure by displaying the relationship between keywords [37]. This study used the co-occurrence analysis and clustering analysis methods to study the relationship between multiple questions from patients with hypertension on the internet. The representative k-means algorithm was selected in the cluster analysis.

This study used the integrated development environments PyCharm and RStudio under Windows, and Python3.6 and R language (developed by ZRX within the Key Laboratory of Medical Information Research, Central South University, College of Hunan Province, PR China) as programming languages for data analysis. In the co-occurrence analysis, the NumPy package was used to calculate the co-occurrence matrix of patient question codes, and the Circlize package was used to visually present the co-occurrence network between question codes. Besides, we used the Sklearn package to implement the k-means clustering algorithm in the cluster analysis.

Results

Feature Mining of the Background Dimension System

The background features of patients with hypertension can be divided into the following eight dimension types: disease, tests and examinations, symptoms and signs, drugs, risk factors, emotions, lifestyles, and demographic data. Among them, risk factors are summarized from the medical knowledge of hypertension, which intersects with other dimensions. The main contents include obesity, high salt and low potassium diet, genetics, diabetes, kidney disease, mental and psychological factors, smoking, drinking, pregnancy, hyperlipidemia, snoring, and others. The feature distribution of background dimensions in 1000 records is shown in Table 1. The drug dimension appeared most frequently in the sample set (814/1000, 81.40%), followed by symptoms and signs (795/1000, 79.50%), tests and examinations (563/1000, 56.30%), demographic data (527/1000, 52.70%), diseases (499/1000, 49.90%), risk factors (352/1000, 35.20%), emotions (119/1000, 11.90%), and lifestyles (114/1000, 11.40%).

Feature mining of the background dimension system can reflect the personalized features of the health information needs of every patient with hypertension on the internet. The personalized features cover 355 names of drugs, 395 names of symptoms and signs, 545 names of tests and examinations, 526 kinds of demographic data, 80 names of diseases, 37 names of risk factors, 43 kinds of emotions, 6 kinds of lifestyles, and 71 kinds of questions. In addition, for the demographic data, we built a system of rules. As shown in Table 2, based on the rules, we effectively mined a total of 385 patient gender records from the text (male: 178, female: 206), with gender unknown in other records. Moreover, we effectively mined a total of 352 age records, including seven underage patients, 177 young patients, 116 middle-aged patients, and 48 elderly patients. It can be seen that basic patient information disclosed on the internet is not complete, although it is important to mine patients' health information needs. To our knowledge, users currently ask physicians to provide sociodemographic information, such as age and gender, when consulting for disease-related issues on Good Doctor Online. However, this part is only visible to physicians and patients. Sociodemographic factors can be obtained by manually labeling the content according to the labeling rules from the public consultation data submitted by patients. However, the multidimensional classification system introduced in this study can make up for the incomplete or missing data of a single dimension through multidimensional mining.

Table 1. Frequency distribution of the background dimension system.

Dimension name	Keywords	Quantity	Records (N=1000), n (%)
Drugs	Calcium channel blocker, angiotensin II receptor antagonist, β blocker, angiotensin-converting enzyme inhibitor, traditional Chinese medicine, antihypertensive drugs, amlodipine besylate, Western medicine, compound antihypertensive drugs, diuretics, and aspirin enteric-coated tablets	355	814 (81.40%)
Symptoms and signs	Dizziness, headache, unstable blood pressure, chest discomfort, discomfort, giddiness, numbness, heart discomfort, pain, rapid heartbeat, movement disorder, palpitation, fatigue, weakness, and head swelling	395	795 (79.50%)
Tests and examinations	Physical examination, electrocardiogram examination, laboratory test, computed tomography examination, color Doppler ultrasound examination, cardiac color Doppler ultrasound examination, B-ultrasound examination, blood lipids, blood glucose, renal function, and routine blood test	545	563 (56.30%)
Demographic data	Gender, age, kinship, medical history, weight, height, fertility, occupation, family history, and others	526	527 (52.70%)
Diseases	Cerebrovascular disease (cerebral infarction, cerebral thrombosis, or cerebral hemorrhage), cardiovascular disease (coronary heart disease or heart disease), digestive system disease (fatty liver), rheumatic disease, other vascular disease, respiratory disease, endocrine disease, urinary tract systemic disease, and pregnancy-induced hypertension	80	499 (49.90%)
Risk factors	Dyslipidemia, diabetes, heredity, kidney disease, nervousness, fertility, drinking, obesity, stress, high blood glucose, smoking, emotional problems, anxiety, and menopause	37	352 (35.20%)
Emotions	Fear, doubt, worry, nervousness, vexation, irritability, anxiety, discomfort, exhaustion, moodiness, stress, bewilderment, depression, and emotional instability	43	119 (11.90%)
Lifestyles	Diet, exercise, sleep, weight loss, drinking, smoking, and others	6	114 (11.40%)

Table 2. Distribution of identified demographic data of the patients with hypertension.

Attribute	Quantity	Records (N=1000), n (%)
Gender		**385 (38.50%)**
Female	206	
Male	178	
Age		**352 (35.20%)**
Underage (<18 years)	7	
Young (18-44 years)	177	
Middle-aged (45-64 years)	116	
Elderly (over 65 years)	48	

Feature Mining of the Question Dimension System

The constructed question classification system for patients with hypertension included 49 items in seven categories, including diagnosis, treatment, disease management, epidemiology, lifestyle, selection of health care providers, and others. Owing to space limitations, only the distributions of the categories in the first and second classes of the classification dimension system are presented (Table 3).

Among 1000 web-based consultation records, 738 (73.80%) had patient questions that were related to treatment (B), mainly drug treatment (B3; quantity: 472), including drug selection, other drug-related questions, drug side effects, medication time, mode, and others. Among them, other drug-related questions were mainly about user consultation on whether medication is needed under the current situation. Regarding questions on medication time, there was a focus on long-term medication or drug discontinuation. Although it is widely known that patients with hypertension must take antihypertensive drugs for the rest of their life, they still asked this question repeatedly with anxiety and worry. Consultation about the side effects of drugs mainly involved drug safety, drug contraindications, and side effects.

Additionally, 32.30% (323/1000) of patients asked questions about the diagnosis of a disease (A), including seeking interpretation of clinical findings and recommendation of test items. Some patients also asked physicians questions about general diagnosis (A0) (eg, whether they contracted a disease). Moreover, 41.00% (410/1000) of patients consulted about not only medication (B1). Furthermore, 20.40% (204/1000) of patients asked questions about epidemiology (D1), such as the etiology of the disease and correlation between the disease and signs and symptoms, and their needs for information were not

limited to the diagnosis and treatment of the disease. Most medical workers paid little attention to answering these questions, and they mainly focused on the process of medical services. In addition, 4.80% (48/1000) of patients consulted about what they should pay attention to in daily life (E0) in order to maintain a good lifestyle, including diet (E4), weight loss (E1), exercise (E2), emotional management (E3), and many other aspects. Some patients realized that hypertension is a chronic disease and that a bad lifestyle could contribute to the progression of hypertension. They wanted to improve their health through a good lifestyle. Further, 10.00% (100/1000) of patients consulted about the selection of health care providers (F0), and they mainly focused on whether they should go to the hospital (F3) or choose hospitalization (F4) according to their physical conditions and other questions. Some patients asked questions about the impact of the disease on fertility (G1) and the reliability of their opinions. A total of 27 patients asked physicians about the reliability of opinions they saw on the internet or were told by others. Seven questions were classified into G0 (others-others) as they could not be classified into other categories.

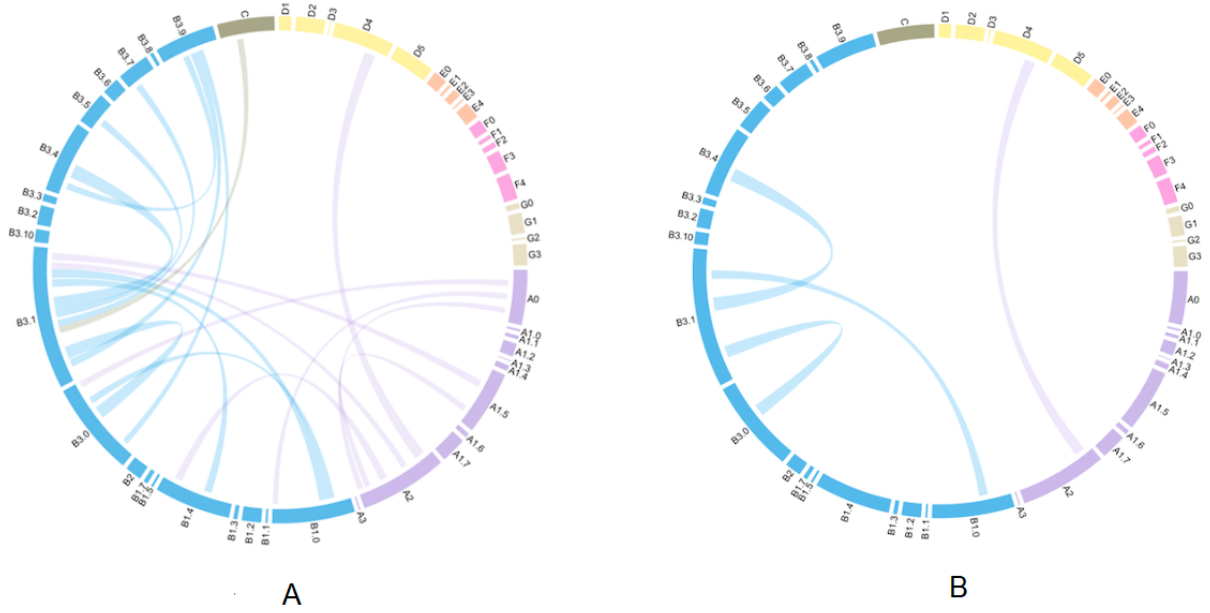
Table 3. Distribution of second-class codes of question features.

First category, second category	Quantity	Records (N=1000), n (%)
A: Diagnosis		**323 (32.30%)**
A0: Other diagnosis-related questions	97	
A1: Tests and examinations	113	
A2: Symptoms and signs	176	
A3: Diagnostic cost	2	
B: Treatment		**778 (77.80%)**
B1: Not only drug treatment	410	
B2: Nondrug treatment	29	
B3: Drug treatment	472	
C: Disease management	128	135 (13.50%)
D: Epidemiology		**204 (20.40%)**
D1: Etiology of a disease	27	
D2: Severity of a disease	41	
D3: Age at which a disease occurs	3	
D4: Others	74	
D5: Prognosis of a disease	75	
E: Lifestyle		**48 (4.80%)**
E0: Other lifestyles	18	
E1: Weight loss	4	
E2: Exercise	11	
E3: Emotion management	3	
E4: Diet	21	
F: Selection of health care providers		**103 (10.30%)**
F0: Other selection of health care provider-related questions	19	
F1: Department selection	7	
F2: Outpatient service	7	
F3: Physician selection	37	
F4: Hospital selection	40	
G: Others		**66 (6.60%)**
G0: Others	7	
G1: Fertility	31	
G2: Medical insurance	2	
G3: Opinion judgment	27	

Feature Mining of Co-Occurrence in the Question Dimension System

Since each patient's online consultation contains multiple questions and involves various information needs, co-occurrence network analysis based on the question type was conducted according to the question features. A total of 658 patients with hypertension asked physicians several questions from one online consulting record. Treatment (B) and diagnosis (A) were the most common issues among patients (Figure 3). Because patients with hypertension need to take drugs for a long time, 283 patients who consulted physicians on the internet were very concerned about drug selection (B3.1). In addition, they asked other treatment-related questions (B), including side effects (B3.4), whether to take the drug (B3.0), how to treat the disease (B1.0), etc. Moreover, among 176 patients who consulted physicians on the internet about the causes of clinical findings (A2), 39 consulted physicians about the relationship between clinical findings and the disease (D4).

Figure 3. Co-occurrence graph for question type. (A) Co-occurrence frequency ≥20%; (B) Co-occurrence frequency ≥30%.



Feature Mining for Patients With Hypertension According to Background and Question Dimensions

We performed k-means clustering on all classification features of the consultation. After many tests, we selected question type as the feature variable, and the elbow method determined that the clustering model was the best when k was 7. Finally, we obtained a schematic diagram of seven types of questions for patients with hypertension. The medical concepts expressed by the main features of each type were clearly defined (Table 4). The seven categories of the population contained background details, such as test and examination items, dizziness symptoms, and calcium channel blocker use.

The first category of the population was "how to adjust medication," which included patients who mainly needed information about drug selection. The background details of their questions mainly involved information on the names of drugs, including calcium channel blockers, angiotensin II receptor antagonists, angiotensin converting enzyme inhibitors, and β-receptor blockers. The second category was "what to do," which included patients who mainly asked physicians to provide information on disease management and prevention. There were more female patients in this group. The third category was "how to treat," which included patients who were mainly seeking information from physicians on disease treatment. Their background descriptions focused on the use of calcium channel blockers and dizziness symptoms. The fourth category was "phenomenon explanation," which included patients who consulted physicians about the causes of clinical findings, the correlation between clinical findings and a certain disease, and the treatment plan of the disease. Their background descriptions mainly included tests and examinations, and dizziness and headache. Most of them were female patients who used calcium channel blockers and angiotensin II receptor antagonists. The fifth category was "test and examination," which included patients who mainly consulted physicians about tests and examinations. Their background data mainly included the description of tests and examinations, and dizziness. Most of them were young male patients who used calcium channel blockers. The sixth category was "disease diagnosis," which included patients who mainly consulted physicians about whether they had a certain disease, whether they needed drugs, the causes of symptoms and signs, and their treatment. Their background data mainly included information of tests and examinations, and dizziness. Most of them were young patients. The seventh category was "disease prognosis," which included patients who mainly asked physicians questions such as "Can the disease be cured?" and "How to treat it?" Their background data mainly included tests and examinations, dizziness, brain disease, and calcium channel blocker use.

Table 4. Classification of the health information needs of patients with hypertension.

Category	Main question, category statistics (N=1000)	Examples of typical questions	Description of main background features (N=1000)	Quantity
1	B3.1 (n=185); B3.0 (71); B3.4 (61)	How to adjust medication or change drugs? Do I need medication? Does the medicine have side effects?	Calcium channel blockers (n=124), angiotensin II receptor antagonists (74), angiotensin-converting enzyme inhibitors (61), dizziness (59), tests and examinations (56), and β-receptor blockers (54)	262
2	C (69)	What to do and how to prevent it?	Tests and examinations (64), female (53), dizziness (47), and calcium channel blockers (45)	205
3	B1.0 (110); B1.4 (68)	How to treat it? How to treat a disease?	Calcium channel blockers (48) and dizziness (46)	184
4	A2 (97); D4 (24); B1.4 (20)	Why do I have such a symptom? What is the relationship between a disease and a symptom? How to treat a disease?	Tests and examinations (36), dizziness (31), female (28), calcium channel blockers (28), headache (24), and angiotensin II receptor antagonists (23)	97
5	A1.5 (53); A1.7 (31)	What examinations are needed? What does the result of the examination mean?	Tests and examinations (66), male (26), dizziness (26), youth (19), and calcium channel blockers (19)	94
6	A0 (85); B3.0 (19); A2 (18); B1.0 (18)	Have I got a disease? Do I need medication? Why do I have such a symptom? How to treat it?	Tests and examinations (32), dizziness (21), and youth (19)	85
7	D5 (73); B1.0 (16); B1.4 (15)	Can this disease be cured? How to treat it? How to treat this disease?	Tests and examinations (29), dizziness (19), brain disease (19), and calcium channel blockers (17)	73

Discussion

Principal Findings

We found some common and distinct features of information needs from the consultation records of patients with hypertension in an online health community. In this study, we constructed a multidimensional *background plus question* classification system for mining various features of health information needs and effectively revealed what Chinese patients with hypertension want to communicate with physicians online. According to our knowledge, no researchers have studied the classification of health information needs in background and question dimensions among patients with hypertension. Our constructed classification system underlines the personal features of the information needs of patients with hypertension, which could help online information service providers and relevant researchers personalize their services. Related online health information resources can be identified according to the classification system of hypertension information needs in this study so as to make online health information resource organization more refined and meet the needs of users.

We found that drug information is quite important to Chinese patients with hypertension on the internet. Additionally, 81.40% (814/1000) of them described their previous medication situation when consulting physicians on the internet, and there are many types of drugs involved. Moreover, 73.80% (738/1000) of them asked their physicians how to treat the disease. This is similar to the findings of Guo et al [30,31,38]. Chinese patients with hypertension mainly asked physicians about drug treatment, including drug selection, drug side effects, medication time, and mode. The results of Zhong et al [39] also showed that the medication literacy of discharged patients with hypertension was poor. More than 70% of patients had no substantial knowledge of the effects and side effects of the medications they were taking. It is worth noting that 16.10% (161/1000) of the questioners with hypertension were concerned about deeper information, including the prognosis, etiology, and progression of the disease.

Most background information described by patients with hypertension when they consulted a physician on the internet involved drug information, followed by symptoms and signs, which accounted for about 80% of patient records. More than 49% of patients mentioned details, such as tests and examinations, diseases, and sociodemographic data. To our knowledge, these values have only been revealed in our study. In this study, we found that patients with hypertension were most concerned about treatment (738/1000, 73.80%) and diagnosis (313/1000, 31.30%). This is similar to the findings of Guo et al [38]. It is worth noting that 16.10% (161/1000) of patients with hypertension were concerned about deeper information, such as the prognosis, etiology, and progression of the disease. In a web-based consultation, Chinese patients with hypertension usually ask physicians many questions without significant priorities, but in an offline consultation, physicians often fail to answer some questions patients are

concerned about owing to the lack of time and the long line of waiting patients.

In this study, we also found common associations when patients asked questions. This is different from the findings of Guo et al [30], and it has not been reported in previous studies. Clustering results based on question features can be explained by medical knowledge. Patients with hypertension can be classified into seven categories, including "how to adjust medication," "what to do," "how to treat," "phenomenon explanation," "test and examination," "disease diagnosis," and "disease prognosis." When new patients with hypertension ask questions, health information service providers can predict which type of population the patients belong to using the clustering model and can recommend other relevant information that the patients may need while recommending the question information. However, owing to the complexity and uniqueness of questioners' background information, we tried to combine the background and question features to conduct clustering research and association rule mining research; however, we did not obtain an interpretable clustering model. This also reflects the personalized differences in the real health information needs of patients with hypertension.

Some patients with hypertension in China still lack an accurate understanding of the risk factors of hypertension and need to acquire more effective knowledge. The risk factors for hypertension were involved in 35.00% (350/1000) of consultations in this study. The risk factors appearing in the research results were presented by the patients when describing the problem, and they may not necessarily recognize the factors as risk factors. Those risk factors were also not question intentions at that time. We hope that when patients consult physicians on the internet, future internet tools will be able to highlight the risk factors of patients with hypertension in a timely manner, as well as promptly remind and push health intervention knowledge of corresponding diseases and their risk factors to patients with hypertension. This is conducive to the provision of targeted information services by information resource providers and to meet the personalized goals of patient education. For example, it can promptly and continuously alert obese patients with hypertension to take measures to control their weight.

The patients with hypertension included underage, young, middle-aged, and elderly people, and thus, hypertension in China can occur in people of all ages. In future health information services, the information that is more in line with the actual health situation and that can improve the health status could be screened from dimensions, such as population and risk factors. In addition, some women were worried about the effects of drugs on pregnancy when they asked about medication. At present, the second-child policy has been widely implemented in China. Medical service personnel need to pay special attention to pregnant women, such as women with hypertension, help them give birth to healthy babies under the support of the existing medical resources, strengthen their accurate understanding of hypertension from the perspective of health information services, and help them relieve their anxiety.

In our study, we found that manual consultation analysis of patient consultation text in Chinese is still needed. Among patient consultation records, medical terms, such as drugs, symptoms and signs, tests and examinations, and diseases, are often not standardized in the patient information description. Owing to typographical errors, omissions, ambiguous words, etc, manual alignment or correction is still needed. This was also noted in the article by Guo et al [30]. The glossary of terms accumulated in this study on summarizing the wording habits of patients in consultations will improve the accuracy of machine learning in feature recognition so as to obtain more accurate predictions of needs categories.

Through this study, we hope to strengthen patient participation with the help of internet technology for improving the personalized characteristics of existing patient education. Patient engagement in their care plays an important role in improving health outcomes [40]. With patient participation, patient education can provide detailed information about drugs, symptoms and signs, tests and examinations, demographic data, diseases, risk factors, emotions, lifestyles, and other information identified in the consultation records for each patient in real time. The cluster analysis method extracts the corresponding population characteristics of patients and further provides the information that the patients need or may need. The process of providing health information to patients through a platform has actually begun to provide health education to the patients, that is, when patients are puzzled about health problems and submit questions on the internet, they can respond to health education services with the help of network technology. Personal questioning data have accumulated on web-based platforms, which have formed the growing consulting big data of users in online health communities. With the help of these big data and the cluster analysis method, it is possible to identify the subdivided hypertension group and obtain the generally needed health knowledge to help the construction and continuous update of patient health education content. We hope that in the future, internet tools will become individual physician assistants for patients under the supervision of professionals. For the information needs of patients, health education can be effectively carried out in real time.

In this study, we used a multidimension approach to identify the features of the health information needs of patients with hypertension in a web-based environment when consulting a physician. Thereafter, according to the classification of these needs, we effectively organized and constructed web-based health information resources and accurately matched the web-based health information resources with the health information needs of each questioner through identification. The unmet information needs will be the focus of future web-based health information resources. In future studies, we will determine how to assess the degree of matching between health information needs and web-based health information resources. In the future, we will also determine how to apply this classification system to clinical consultations in order to reduce information asymmetry between physicians and patients and to help patients and physicians manage diseases together.

Limitations

The classification system may have limitations owing to the insufficient sample size for analysis. In the future, we should continue to expand the sample size and carry out a larger classification of health information needs. The sample data were from a single website, and all information was from the web-based consultation records available on the website. Thus, the target group of the website may affect the results of the construction of the classification system. In the future, we will collect data from several health websites and conduct comparative studies. The information needs of patients with hypertension in this study were the information needs expressed by patients. However, this study did not fully address the feature recognition of patients' unexpressed information needs. Our next goal is to determine how to improve compliance in patients with hypertension.

Conclusions

The classification system of hypertension information needs involving the *background plus question* approach constructed in this study reflects the personalized features of the health information needs expressed by patients with hypertension to physicians in a web-based environment. We believe that multidimensional health information needs should have more refined identifiers, which will enable patients with hypertension to fully express their health information needs during a web-based consultation, thus allowing relevant information service providers of online health communities to organize information resources related to hypertension according to these identifiers. They can use the classification system of hypertension information needs constructed in this study as a classification basis to organize web-based health information resources and provide more accurate information push services to patients when they consult physicians over the internet or wait for physicians to reply in order to reduce information asymmetry in communication between physicians and patients. On the other hand, the Chinese corpus of patients with hypertension based on artificial coding in this study will lay the foundation for future research on the features of automatic identification of health information.

Acknowledgments

We thank the State Key Program of National Social Science of China (grant no. 17AZD037) for assistance in this study. This work was partially supported by the National Natural Science Foundation of China (grant no. 61977062) and the Social Science Foundation in Hunan Province (grant no. 16YBA366). We also appreciate the support of all participants.

Authors' Contributions

AJL conducted the project and designed this research. ZRX drafted the manuscript and programmed with Python and R language. YFY implemented the data collection, preprocessing, and alignment modules. ZQZ, XQP, WZX, WOY, CH, and HYH identified the classification framework. YFY and FL were involved in annotation work. ZQZ and XQP provided their medical expertise. TXW and YC helped analyze the data. All authors reviewed and approved the manuscript for publication.

Abstract

Background: Sleep apnea is a respiratory disorder characterized by an intermittent reduction (hypopnea) or cessation (apnea) of breathing during sleep. Depending on the presence of a breathing effort, sleep apnea is divided into obstructive sleep apnea (OSA) and central sleep apnea (CSA) based on the different pathologies involved. If the majority of apneas in a person are obstructive, they will be diagnosed as OSA or otherwise as CSA. In addition, as it is challenging and highly controversial to divide hypopneas into central or obstructive, the decision about sleep apnea type (OSA vs CSA) is made based on apneas only. Choosing the appropriate treatment relies on distinguishing between obstructive apnea (OA) and central apnea (CA).

Objective: The objective of this study was to develop a noncontact method to distinguish between OAs and CAs.

Methods: Five different computer vision-based algorithms were used to process infrared (IR) video data to track and analyze body movements to differentiate different types of apnea (OA vs CA). In the first two methods, supervised classifiers were trained to process optical flow information. In the remaining three methods, a convolutional neural network (CNN) was designed to extract distinctive features from optical flow and to distinguish OA from CA.

Results: Overnight sleeping data of 42 participants (mean age 53, SD 15 years; mean BMI 30, SD 7 kg/m^2; 27 men and 15 women; mean number of OA 16, SD 30; mean number of CA 3, SD 7; mean apnea-hypopnea index 27, SD 31 events/hour; mean sleep duration 5 hours, SD 1 hour) were collected for this study. The test and train data were recorded in two separate laboratory rooms. The best-performing model (3D-CNN) obtained 95% accuracy and an F_1 score of 89% in differentiating OA vs CA.

Conclusions: In this study, the first vision-based method was developed that differentiates apnea types (OA vs CA). The developed algorithm tracks and analyses chest and abdominal movements captured via an IR video camera. Unlike previously developed approaches, this method does not require any attachment to a user that could potentially alter the sleeping condition.

Introduction

Background

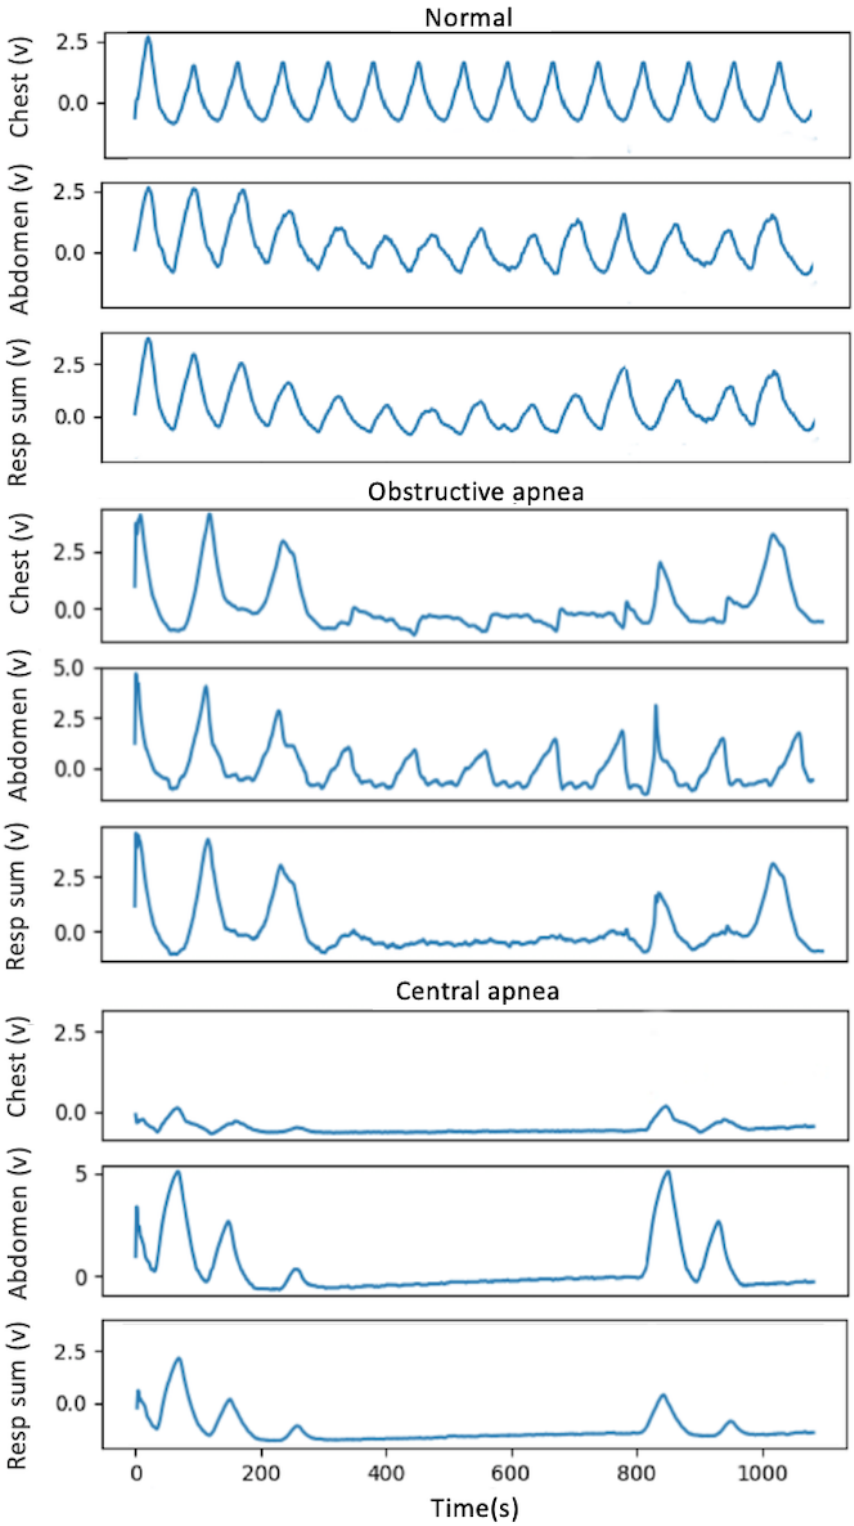
Sleep apnea is a chronic respiratory disorder, caused by intermittent reduction (hypopnea) or cessation (apnea) of respiratory airflow during sleep. About 10% of the population have this disorder [1], and it increases the risk of heart disease by 3-fold, stroke by 4-fold, and car accidents by 7-fold [2-5]. The severity of sleep apnea is commonly measured via the apnea-hypopnea index (AHI), which shows the number of apneas and hypopneas per hour of sleep.

Depending on the presence of breathing effort, sleep apneas can be divided into obstructive sleep apnea (OSA) or central sleep apnea (CSA) by measuring the thoracoabdominal movement and its contributions to the total respiratory volume [6]. The majority of sleep apneas are obstructive [7], which is caused by the full collapse of the pharyngeal airway that blocks the flow of air into the lungs [8]. The rest of sleep apneas are central, which happen due to a reduction in the respiratory drive from the central nervous system [9].

During normal breathing, the chest and abdomen move in phase due to interaction between the diaphragm and parasternal intercostals during inhalation [10]. During obstructive apnea (OA), airway obstruction leads to an out-of-phase motion of the rib cage and the abdomen, causing a reduction in the sum of chest and abdomen's movement [6]. On the other hand, during central apnea (CA), there is no movement in the rib cage or the abdomen due to lack of brain signal for muscle contraction. Figure 1 compares the movements in the chest and the abdomen and the sum of them during OA, CA, and normal breathing. If the majority of events in a person are obstructive, they will be diagnosed as OSA and otherwise as CSA. In addition, as it is challenging and highly controversial to divide hypopneas into central or obstructive, the decision about sleep apnea type (OSA vs CSA) is made based on apneas only.

The treatment of sleep apnea decreases patients' health-related costs by 25% [11]. A highly effective treatment for OSA is continuous positive airway pressure (CPAP) therapy that involves applying positive pressure of air to keep the airway open during sleep. However, CPAP therapy leads to increase mortality in patients with CSA [12]. Therefore, a crucial step for proper treatment of sleep apnea is to differentiate OSA from CSA [13].

Figure 1. Difference between the movements of the chest and abdomen and the sum of the two movements during obstructive apnea (OA), central apnea (CA), and normal breathing. During normal breathing, chest and abdomen movements are in phase. During OA, breathing effort and airway blockage result in the out-of-phase movement of the chest and abdomen, and the sum of the two movement signals (respiratory sum) is close to zero. During CA, there is no movement in the chest or the abdomen. CA: central apnea; OA: obstructive apnea; Resp sum: respiratory sum.



Problem Statement

The gold standard for differentiating OA from CA is the evaluation of swings in esophageal pressure measured via an esophageal catheter [14]. Measurement of esophageal pressure is invasive, uncomfortable, and could disrupt sleep. Therefore, esophageal pressure measurements are only used for physiological research purposes [15,16]. The current clinical approach to distinguish OA from CA based on the different patterns of movement in the chest and abdomen is respiratory inductance plethysmography (RIP). It measures thoracoabdominal movements from two transducer bands over the chest and the abdomen. RIP is a part of polysomnography (PSG), which consists of connecting more than 20 sensors to

patients. PSG is inconvenient during sleep, expensive (>US $400 in Canada), has long waiting time (4-36 months in Canada [17]), and requires a trained technician to manually analyze the recorded signals, including RIP.

A promising approach to distinguish different types of sleep apnea is using computer vision systems. The goal of computer vision is to extract information from images or videos. In this study, a noncontact approach was proposed to identify the types of apneas (OA vs CA) using computer vision techniques. In this approach, the upper body respiratory movements were captured in infrared (IR, *night vision*) video frames and were processed via computer vision algorithms.

Computer vision systems have been previously developed for various applications in sleep monitoring, for example, to monitor the breathing rate and pulse [18-20], to estimate the AHI [21], to screen sleep quality and irregularities [22,23], and to monitor sleep positions [24]. But the use of computer vision to distinguish different types of apnea (OA vs CA) was unexplored and was the main novel contribution of this study.

Methods

Data Collection

Adults aged 18 years or above who were referred to the sleep laboratory of the Toronto Rehabilitations Institute-University Health Network for sleep screening were recruited for this study. The University Health Network Research Ethics Board approved this study (Research Ethics Board approval number 13-7210-DE). Participants signed a written consent form before taking part in the study.

Full overnight PSG was recorded for clinical diagnosis of sleep apnea in two separate rooms. Additionally, an IR camera (Firefly MV, 0.3 MP, FMVU- 03MTM, FLIR Systems) was mounted about 1.4 m above the bed. The rooms were illuminated by IR light (Raytec RM25-F-50). Simultaneous and synchronized with PSG, IR videos were recorded from an overhead view with the aforementioned camera at a resolution of 640×480 at 30 frames per second. The 680×480 resolution captured the upper body part (the head, chest, and abdomen) with sufficient detail.

OA and CA were annotated by 3 trained individuals based on the RIP signal of the chest, the abdomen, the sum of the movement of the chest and the abdomen, nasal pressure, and oxygen saturation, following the American Academy of Sleep Medicine guideline [25,26]. The first 2 experts annotated all data with the agreement of 80%. The third expert annotated the discrepancies.

Data Analysis

Recorded IR videos were down-sampled from 30 Hz to 2 Hz to decrease the computational cost. The breathing rate during sleep is between 12 and 25 breaths per minute, that is, below 0.5 Hz. Therefore, the reduced sampling frequency of 2 Hz still satisfied the Nyquist rate for the respiratory signal by a wide margin. As each apnea lasts a minimum of 10 seconds, the sampling rate of 2 frames per second translates to a minimum of 20 image frames per event.

Frame-to-frame movements were tracked using dense optical flow. FlowNet 2.0 [27], a convolutional neural network (CNN) model, was used for this purpose. Optical flow generates a 2-channel image comprising the *x* (side to side) and the *y* (up and down) movement vector of each pixel from one video frame to the next. A 3D-CNN model was trained to analyze the sequence of optical flow images during each apnea to distinguish between OAs and CAs. This 3D-CNN model processed the optical flow of the entire image without explicit knowledge of where the person was at every frame of the video. For comparison, another CNN architecture was used to analyze the optical flow sequences in only the chest and abdomen regions. This model was trained to distinguish OAs from CAs via a late fusion of two 3D-CNN branches processing chest and abdominal movements. Performance was evaluated when either manually marked or automatically detected chest and abdomen regions were used. The performance of these CNN architectures was compared with three baseline models, including autocorrelation, movement histograms, and 2-dimensional fast Fourier transform (2DFFT)-CNN, which were chosen as commonly used approaches for motion analysis. These models were not applied previously for distinguishing OAs from CAs. The first two baseline models (autocorrelation and movement histograms) operate on the time-series data of optical flow movements, whereas the third baseline model (2DFFT-CNN) first transforms the signal into the frequency domain and then applies a CNN model to the resulting 2DFFT images.

3D Convolutional Neural Network

Sleep apneas last a minimum of 10 seconds [28]. A 3D-CNN model was trained on a sliding window of 10 seconds (20 frames at 2 Hz), starting from 5 seconds before the start of the apnea until 5 seconds after its ending. The size of the input tensor to the 3D-CNN model is 640×480×2×20 (image size 640×480 pixels; number of channels: 2; number of frames: 20). The two channels are outputs of the optical flow image, indicating the changes in the *x* (side to side) and *y* (up and down) directions. Details of the 3D-CNN model are shown in Table 1. RMSProp was used to optimize a class-weighted cross-entropy loss. The Matthews correlation coefficient was used for early stopping. An initial value of 0.001 for the learning rate and 1000 epoch with the batch size of 32 were used. The total number of parameters in this network was 95,649 of which 95,393 were trainable, and 256 were nontrainable.

OAs are more frequent than CAs; therefore, to achieve a more balanced training set, different stride was using for the sliding window in OAs and CAs (stride of 1 second for CA and stride of 5 seconds for OA). In test time, a stride of 1 second was used, and voting (overall strides within an event) determined the estimated label (OA vs CA) for that event.

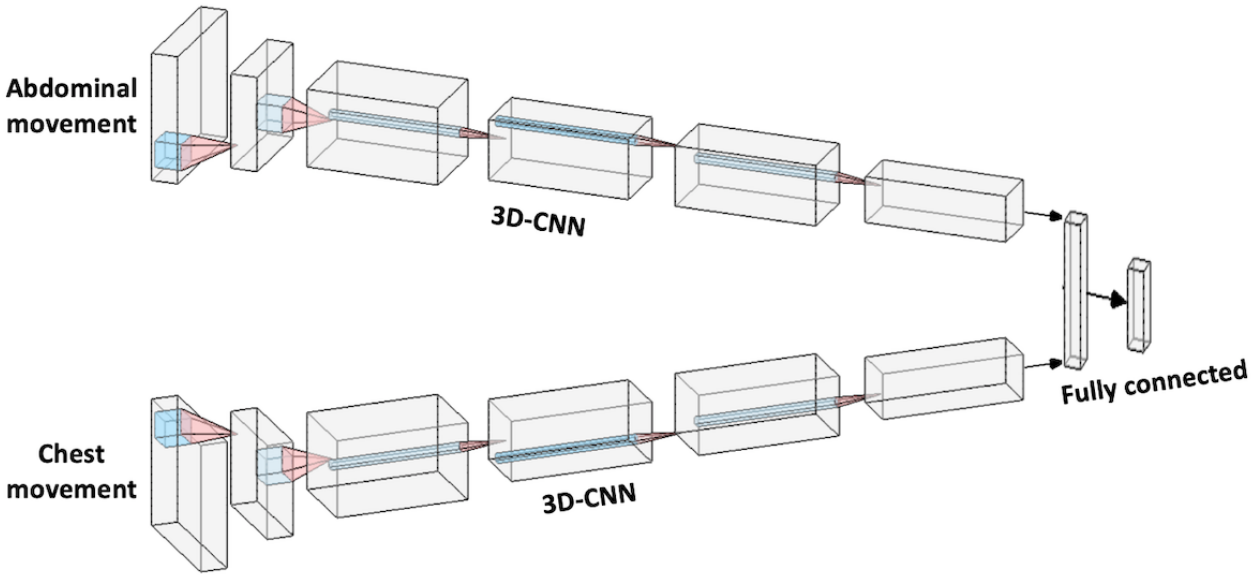
3D Convolutional Neural Network (Chest and Abdomen)

To investigate if knowledge about the location of the chest and abdomen at each image frame improves performance, the frames were manually marked as follows: for each person, at the first video frame of their sleep. After each position shift, a human annotator manually marked the locations of the chest and abdomen via two rectangles on the image. If the participant was covered by a blanket, the annotator used his/her best judgment to mark these locations (based on the current image frame and also by looking at previous and future image frames). Position shifts were automatically detected based on the total amount of movement in the scene, with a low threshold, so even small position shifts were not missed.

As the annotation of the chest and abdomen regions is subjective and time-consuming, we have also developed an algorithm to automatically find the chest and abdomen regions. To develop this model, as the chest and abdomen were often covered by a blanket sheet, it was challenging to train an object-detection CNN to detect them directly. Instead, a CNN model (YOLO v3) [29] was used first to locate the head, and another model was subsequently used to infer the position of the chest and abdomen bounding boxes. Specifically, a random forest regression model was trained based on the estimated head location, BMI, weight, height, head position (supine vs lateral), and body position (supine vs lateral) to estimate the bounding box of the chest and abdomen. The head and body positions were obtained automatically via a CNN-based model that was previously developed and validated [24].

Two 100×100 images were cropped around the estimated center of the chest and abdomen. Dense optical flow was computed in cropped regions of both the chest and abdomen. A 3D-CNN branch processed the sequence of chest movements, and another branch processed the sequence of abdominal movements. Outputs from both branches were concatenated into a fully connected network. The network was trained end to end. The architecture of the entire network is shown in Figure 2. The architecture of the 3D-CNN model in each branch is identical to the one shown in Table 1. The only difference is the first average pooling layer, which has the size and stride of 10 x 10 and 5 x 5, because of the smaller image size.

Figure 2. The Convolutional neural network architecture used to extract and combine information from movements of the chest and the abdomen. 3D-CNN: 3D convolutional neural network; CNN: convolutional neural network.

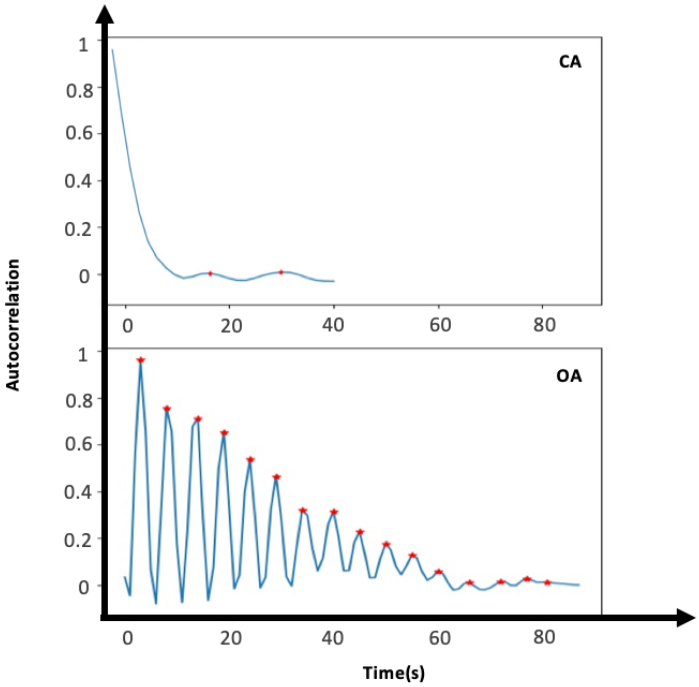


Baseline 1—Autocorrelation

This method uses autocorrelation to separate OAs from CAs based on their periodicity. The magnitude of the movement vector ($d=\sqrt{(x^2+y^2)}$) was calculated from the original 2-channel optical flow image (640×480×2) to form a single-channel movement magnitude image (640×480). Pixels with a large movement magnitude (>0.5 pixel per second), likely caused by large position shifts, were capped, that is, set to 0.5. The average of the movement image was then calculated for each event, leading to a 1-dimensional movement signal $m(t)$. A Butterworth band-pass filter with a lower cutoff frequency of 0.05 Hz and an upper cutoff frequency of 0.5 Hz was applied to the one-dimensional movement signal. Autocorrelation was computed for the filtered signals, and its first 10 peaks (if peaks did not exist, 0 was considered) were used to train three different binary classifiers to distinguish between OA and CA. Classifiers compared were linear support-vector machines, logistic regression, and random forest. Sample autocorrelation signals with their detected peaks are illustrated in Figure 3 for a CA and an OA.

is autocorrelation, where m_t is an event signal, is an average of signal, and is a shifted event with a lag of L. Lag (L) was set equal to the event duration. The summations are over all the values of t.

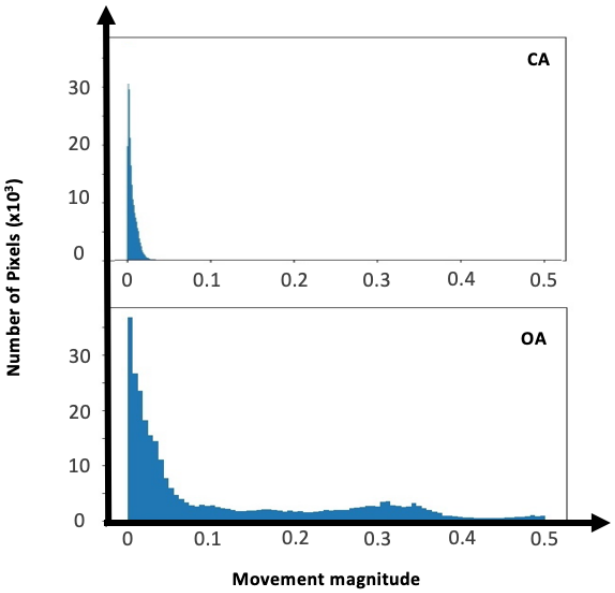
Figure 3. Autocorrelation signal of the movement in an obstructive apnea (OA) and central apnea (CA). OAs are more periodic due to the existence of breathing effort as compared with CAs. Therefore, the OA autocorrelation signal has more peaks, as indicated by red stars. CA: central apnea; OA: obstructive apnea.



Baseline 2—Movement Histograms

This method separates OAs from CAs based on their range of motion. Histogram of the movement magnitude was constructed for movements in the range of 0 to 0.5 pixels/second with a constant number of 1000 bins. Sample histogram signals for OA and CA are shown in Figure 4. The average of each bins (features) of histogram across an event was computed. Principal component analysis (PCA) was subsequently applied to reduce the number of bins. A random forest classifier was trained on the first 100 PCA components to distinguish OA from CA.

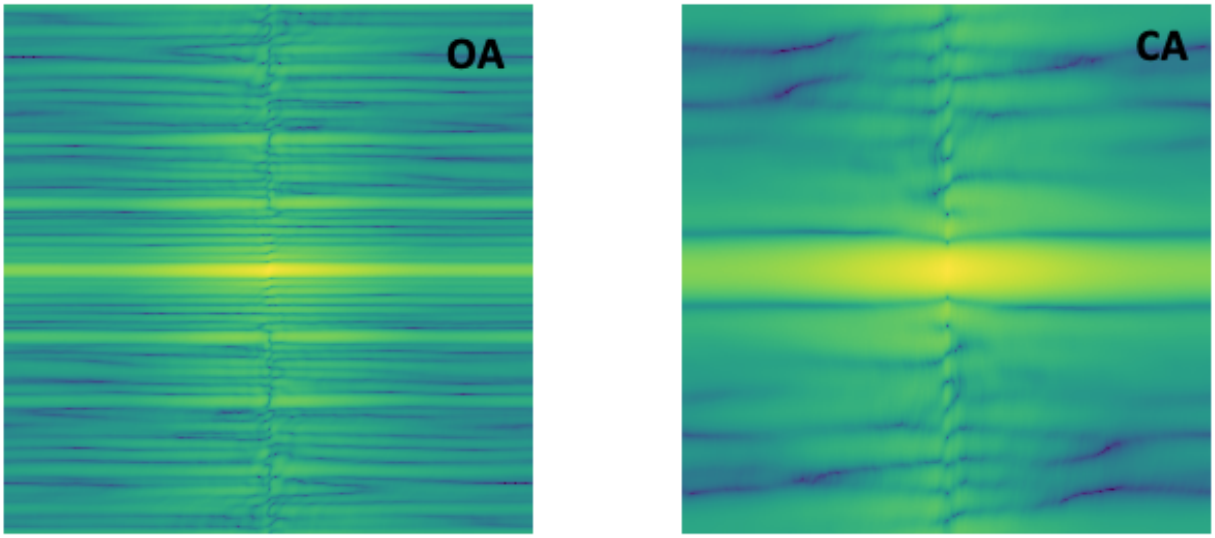
Figure 4. Histogram of movement magnitudes. Obstructive apneas have more range of motion as compared with central apneas because of the breathing effort. CA: central apnea; OA: obstructive apnea.



Baseline 3—2D Fast Fourier Transform-Convolutional Neural Network

This method separates OAs from CAs based on the frequency-domain representation of movement histograms. The movement histograms of each event were concatenated together over time to form an image and then transformed to the frequency domain via 2DFFT with a constant size of 128×128. A sample of 2DFFT signal is shown in Figure 5 for a CA and an OA. A CNN (DarkNet19) [30] was trained on the obtained 2DFFT image to distinguish between OA and CA.

Figure 5. 2D fast Fourier transform (2DFFT) of movement histograms for OA and CA. 2DFFT images of OA have a wider frequency range as compared with CA, as breathing effort during OA causes more fluctuation in the movement signal. 2DFTT: 2D fast Fourier transform; CA: central apnea; OA: obstructive apnea.



Validation

The data were divided into training and validation and test sets by the room in which the study was conducted to ensure the setup camera placement did not affect the algorithm performance. The recorded data of 21 participants (recorded in laboratory room number 1) were used in the training and validation sets. This set included 40 CAs and 313 OAs. The remaining 21 (recorded in laboratory room number 2) comprised the test set, which included 75 CAs and 299 OAs.

For the autocorrelation and movement histogram methods, classifier hyperparameters were tuned via 3-fold cross-validation on the training set. For the 3D-CNN (whole body) and 3D-CNN (chest and abdomen) methods, early stopping was based on performance on the validation set.

Performance of the head, chest, and abdomen bounding box detection was evaluated based on accuracy at the intersection over union values higher than 0.5 between predicted and manually annotated regions.

Results

Data from 42 participants (27 men and 15 women) were collected for this study. Participants' demographic information is shown in Table 2. None of the parameters were significantly different between the groups, except BMI with a *P* value of .04.

Figure 6 shows a sample image frame, as well as the manually marked and automatically detected bounding boxes, for the chest and the abdomen. The performance of the head, chest, and abdomen bounding box detection is quantified in Table 3. The head detection model obtained 92% accuracy, which was higher than the chest and abdomen detection models with accuracies of 83% and 67%, respectively.

Results of distinguishing OAs from CAs are shown in Table 4. Different classifiers obtained similar performance for the movement histograms method. For the sake of space, only results of the random forest classifier are shown in Table 4. The 3D-CNN model obtained the best performance with 95.4% accuracy and an F_1 score of 88.7%.

Discussion

Principal Findings

The proposed 3D-CNN model outperformed all three baseline methods. We hypothesized that localizing the chest and abdomen in the video will increase the signal-to-noise ratio to improve performance. However, as shown in Table 4, applying 3D-CNN on the whole image frame obtained the best performance. Figure 7 illustrates how the use of a blanket may explain these results. The blanket propagates chest and abdominal movements outside of their respective detected (or annotated) regions. As a result, localizing the chest and abdomen locations removed part of the respiratory-related movement signal. In addition, accurate detection of abdomen location is challenging when the body is covered by a blanket; however, increasing the number of data points (>42) could potentially address this challenge. Attention mechanisms could also potentially be used to automatically identify image regions in which chest or abdomen movements are prominent.

Figure 7. Annotated chest and abdomen regions do not capture a large area where most of the respiratory-related movement is visible. Manually annotated chest and abdomen regions are shown with blue boxes. Areas with large movement intensity (magnitude of the optical flow) are highlighted in pink.

Limitations

The methods developed and evaluated in this study are the first to use computer vision to differentiate between OAs and CAs. Although the models were externally validated on data collected in a different room, a limitation of this study was that the same camera model and camera setup was used to collect data in both rooms. Remedying this limitation will involve external validation on a dataset that will be recorded under different conditions, for example, use of another camera model, different viewing angle, or a different camera distance from the bed. This will evaluate how the models trained here generalize to potential variations that might occur in real-life scenarios, for example, in the home. Another limitation of the current system is that it relies on the assumption that apneas were already segmented, for example, using previously developed vision-based methods [21]. Remedying this limitation will involve evaluation of how the combination of such methods with the models developed here will perform.

Comparison With Prior Work

To address the challenges associated with PSG, there have been several investigations to develop convenient sleep apnea screening devices that can also distinguish CA from OA [14,15,28,31,32]. In a study proposed by Argod et al [15], pulse transit time technique was used to measure the delay between the R-wave on the electrocardiogram and a finger. They used the delay to visually classify CA from OA [15]. In another study, Park et al [31] designed an invasive implantable cardiac device to differentiate between CA and OA based on oscillation characteristics of the cardiac electrical activity. Luo et al [14] used the diaphragm electromyogram to track the activity of respiratory muscles to differentiate OA from CA. Thomas et al [28] used a single-lead electrocardiogram to classify OA from CA by measuring the elevated low-frequency coupling of heart rate variability and the fluctuations in the amplitude of the R-wave. These studies either are invasive or need the attachment of sensors to the body, which could be inconvenient and sensitive-to-motion artifacts and disrupt the user's regular sleep pattern. A noncontact method to distinguish CA from OA will address these challenges.

In one attempt, Nandakumar et al [32] tracked body movements via smartphones. They used frequency-modulated continuous-wave transmissions to find the motion changes in body. Although their model counted the number of CAs and OAs, the performance of the model on localizing and distinguishing of apneas was not reported. Moreover, this study did not report cross-validation results.

Conclusions and Future Works

This research project is the first vision-based noncontact method that differentiates sleep apneas by tracking body movements using IR videos. The developed algorithm was validated on 42 participants with various levels of sleep apnea severity. The algorithm performed well in distinguishing the OAs from the CAs. In this study, it was assumed that apneas were given. Future work can apply existing techniques [21] or novel CNN-based methods to identify apneas. Similar approaches can be used for noncontact assessment of respiration and respiratory effort during exercise testing in individuals who are using mechanical ventilators and infants with respiratory problems. Future work also involves collecting more data to perform an external validation of models developed here under varying conditions, as well as to improve chest and abdominal detection accuracy.

Abstract

Background: Phishing is a cybercrime in which the attackers usually impersonate a trusted source. The attackers usually send an email that contains a link that allows them to steal the receiver's personal information. In the United States, phishing is the number one cybercrime by victim count according to the Federal Bureau of Investigation's 2019 internet crime report. Several studies investigated ways to increase awareness and improve employees' resistance to phishing attacks. However, in 2019, successful phishing attacks continued to rise at a high rate

Objective: The objective of this study was to investigate the influence of personality-based antecedents on phishing susceptibility in a health care context.

Methods: Survey data were collected from participants through Amazon Mechanical Turk to test a proposed conceptual model using structural equation modeling.

Results: A total of 200 participants took part. Health concerns, disposition to trust, and risk-taking propensity yielded higher phishing susceptibility. This highlights the important of personality-based factors in phishing attacks. In addition, females had a higher phishing susceptibility than male participants

Conclusions: While previous studies used health concerns as a motivator for contexts such as sharing personal health records with providers, this study shed light on the danger of higher health concerns in enabling the number one cybercrime.

phishing; health concerns; disposition to trust; risk-taking propensity; cybercrime; security, internet; trust; risk-taking; crime victims

Introduction

Background

Phishing refers to an internet cybercrime where a normal computer or mobile phone user is targeted by a cybercriminal through email. This communication is mostly intended to lure the user to provide their sensitive data such as personal health care records, passwords, bank information, and passwords. In a phishing attack, the attacker sends an email that impersonates a legitimate organization or person. The cybercriminal uses social engineering techniques to encourage the receiver to click on a suspicious link. The link can download a malicious app or provide a form that asks the recipient to enter sensitive personal information. Phishing attacks can target individuals, employees, corporations, or governments. Attackers are motivated by many factors such as achieving financial benefits or gaining a reputation in the cybercriminal community. An attacker can sell a stolen personal health care record for thousands of dollars [1].

According to the US Federal Bureau of Investigation's annual Internet Crime Complaint Center report for 2019 [2], there were about US $3.5 billion in financial losses alone due to cases of theft, fraud, and exploitation on the internet. The report states

that the most prevalent type of attack was the category Phishing/Vishing/Smishing/Pharming, various terms that are used to define different means to phish. For example, fraud conducted over the phone is termed *vishing*. *Smishing* refers to attacks conducted using texting. Phishing was ranked first by the number of victims, with more than twice as many victims as the second-ranked type of attacks. Phishing attacks have been increasing significantly in the past few years [3].

A recent IBM Security report ranked the health care industry first in term of the average cost of a data breach [4]. The report stated that phishing was one of the most common methods used in carrying out an attack. In 2018, about 15 million patients' records were breached in the United States. In addition, in the first 6 months of 2019, 25 million patients were compromised with phishing being the main factor behind most breaches [5].

Phishing not only has a negative influence on individuals' monetary assets but also builds doubt every single time they are contacted via phone calls, texts, or emails. For an individual, this shatters the reliability of electronic media to carry out a variety of tasks. This poses a great danger to digitizing traditional paper-based patient records.

According to various recent reports and research, the most common features of phishing emails are that they are astonishingly true, and have a sense of urgency (pushing the recipient to take an action as soon as possible), too many links, unexpected attachments, and an anonymous or unknown sender. Researchers and experts have been developing and testing ways of raising users' awareness so that they can detect phishing attacks.

However, efforts in raising awareness are yet to prove successful. As mentioned above, the success rate of the attacks has increased globally. About 35% of individuals do not even know what phishing is [6]. Many recent studies and current training focus on recommendations that many attackers get around. For example, Jensen et al [7] focused on training and recommendations that help individuals to avoid phishing. One of the main recommendations was to look for "https" in the address bar. Many online materials and articles list similar recommendations, including an unknown sender, generic greetings, and grammatical mistakes. However, according to a 2019 phishing trends and intelligence report, about 50% of phishing attacks use secure socket layer, making them harder to detect [8].

More importantly, attackers have constantly advanced and changed strategies. In fact, 2019 was a year of phishing evolution. Microsoft released a report in December 2019 that talked about evolving methods of phishing and explained the 3 most notable attack techniques of phishing they observed with their Microsoft Threat Protection services in 2019 [9].

Phishing is ultimately a social tactic. According the Verizon data breach investigation report [10], 43% of cyber attacks encompass social tactics, and of those that use social tactics, 93% are phishing attacks. Therefore, constant efforts should be invested in understanding the social and personal characteristics of individuals and victims. Detection, awareness, and training strategies need to be constantly evolving. In addition, one-size-fits-all recommendations and strategies will not benefit most individuals, organizations, or industries.

Literature Review

Research related to phishing can be categorized into two main streams. The first stream of research investigates technical aspects that can automatically detect phishing attacks using various methods such as machine learning and text mining. Jain and Richariya [11] proposed that a Web browser can also be trained to screen emails.

Methods such as text clustering, text mining, topic modelling, and classification have also been used to improve systems that detect and block phishing emails. For example, Basavaraju and Prabhakar [12] used cluster analysis to detect spam emails. Jeeva and Rajsingh [13] applied association rule mining techniques to detect phishing emails that contain malicious links.

Niakanlahiji et al [14] proposed a framework of machine learning to detect phishing webpages. The framework used 15 novel features that can be used on a webpage effectively without relying on search engines or other services. Some researchers have focused on improving text mining and data extraction techniques, which are then used as scripts to extract data from emails in a semiautomatic manner and analyze them to find patterns and other data [15].

However, in 2019, about 30% of phishing emails still bypassed security detection measures [16]. Phishing volume increased by approximately 41% in 2018, and the success rate of attacks has also increased. Although phishing detection technology is advancing, it cannot keep up with the advancement rate of phishing attacks. Therefore, many experts and researchers emphasize the importance of improving user awareness and training in regard to phishing. Most experts agree that the best way to defend against phishing attacks is to train employees and individuals to detect phishing emails in addition to security measures that detect some of the attacks automatically.

Therefore, the second stream of research has focused on the user side of the equation. User awareness of phishing emails stands to be one of the main prevention measures for phishing all around cyberspace. Hence, various awareness campaigns such as public announcements, seminars, and podcasts help to make users aware of these attacks and hence prevent phishing attacks in any form [17]. Miranda [18] suggested that phishing training programs can increase employee resistance to phishing attacks. Various studies proposed a game design framework to prevent many phishing attacks [3,19]. This framework enhances user avoidance behavior through motivation and hence results in preventing these phishing attacks. Other researchers looked at the characteristics of victims such as their email habits, perception of risk, and self-efficacy [20,21].

However, researchers have defined phishing as social engineering where an attacker attempts to fraudulently acquire sensitive information from a victim by impersonating a trustworthy third party. This brings in the scope for understanding normal users and their mentality gaps. Individuals are not always driven by rational thought and knowledge when making a decision or taking an action [22]. People may make

decisions quickly and may be driven by emotions or other factors [23]. For example, Jalali et al [24] found that perceived risk is not associated with click behavior, whereas workload is positively associated with click behavior. The limited number of studies looking at the influence of individuals' characteristics and traits on phishing susceptibility in a health care context creates a gap in the research.

Objective

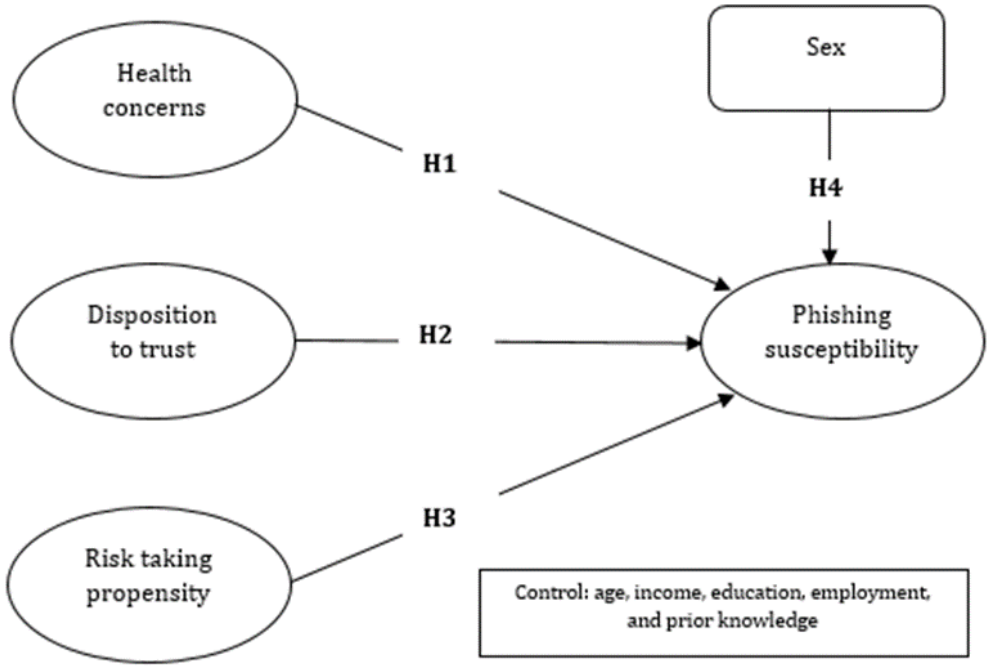
This study, motivated by improving phishing training and prevention measures by understanding individual characteristics, investigated the influence of personality-based factors—health concerns, disposition to trust, and risk taking—on phishing sustainability in health care–related attacks. The antecedents cover three areas of personality related to the context: concerns, risk, and trust. This allowed for identifying risk groups and understanding normal individuals and the mentality loopholes that an attacker uses to execute their tasks. This is one of the few studies that focused on personality-based antecedents as they relate to phishing susceptibility, specifically in the context of health care.

Methods

Conceptual Model

The following subsections argue for the relationships in the conceptual model shown in Figure 1. This is one the first studies that focused on personality-based variables and their influence on phishing susceptibility in the health care context.

Figure 1. Conceptual model.



Health Concerns

Health concerns refers to the degree to which an individual is concerned about their health [25]. Health-related traits have been shown to influence individuals' choices related to behaviors affecting their health directly or indirectly [26]. People who are concerned about their health are anticipated to pursue resources as they participate in behaviors to protect their health [25]. In the context of privacy, health concerns act as a promotor to seek better health outcomes [27]. In addition, the concept of health concerns is linked with a higher likelihood to seek health information online [28]. In general, Brelsford et al [29] found that patients with a high level of health concerns are motivated to take actions related to their health. However, the construct of health concerns has not been investigated in the context of phishing.

The first study hypothesis (H1, Figure 1) was that health concerns is positively associated with phishing susceptibility.

Disposition to Trust

Disposition to trust is a personality construct that refers to individuals' propensity to trust or distrust others [30]. In general, various types of trust have been extensively studied in different disciplines. The perception of trust can be linked with people or systems [31]. For example, the direct relationship between trust beliefs and use of technology has been well established [32-34]. The association between trust and information sharing has also been empirically demonstrated in previous studies [35-37]. These findings suggest that releasing personal information in exchange for e-services requires a great deal of trust. In the context of e-commerce and social media, prior literature has confirmed a positive association between trust in the system and a willingness to use the system [38,39].

The role of disposition to trust as a personality construct has been investigated in internet and website usage in general [30,40]. Bélanger and Carter [32] found that trust has an important role in promoting e-government use. Wang et al [41] investigated the effect of disposition to trust on mobile banking

adoption. In addition, disposition to trust has been linked to a higher likelihood of deception [42].

The second study hypothesis (H2, Figure 1) was that disposition to trust is positively associated with phishing susceptibility.

Risk-Taking Propensity

A key personality aspect that influences decision making is the individual's propensity to take on risks. An individual's risk-taking personality is defined as the behavioral propensity to seek rewards despite the probability of negative consequences [43]. This construct represents an attitude that is independent of any probability of outcome, but is anchored in how individuals value those outcomes [44]. Research has shown the link between different levels of risk-taking propensities and decision making in many contexts. Though the importance of individual differences in decision making has been examined in other fields, little information security research has investigated the impact of individual traits, especially in phishing susceptibility as it relates to health care. Hansen et al [45] found that risk-taking propensity has a direct positive influence on behavioral intention in the context social media use.

The third study hypothesis (H3, Figure 1) was that risk-taking propensity is positively associated with phishing susceptibility.

Role of Sex

Differences between males and females in their online health information sharing behavior is another problem worth investigating. Male-female differences in behavior with regard to phishing has been mostly investigated in general but not specifically in health care–related phishing scenarios. For example, Sun et al [46] found that male students score better than female students in antiphishing behavior. Similarly, Verkijika [47] reported consistent findings in a general phishing context. Results are expected to be consistent in the health care phishing scenario as well.

The fourth study hypothesis (H4, Figure 1) was that males have lower phishing susceptibility than females.

Data Collection

Data were collected online by administering the survey through Amazon Mechanical Turk (Amazon.com, Inc, Seattle, WA, USA), an online survey administration platform that allows for recruiting participants. The participants were redirected to take the survey built in Qualtrics^{XM} experience management software (Qualtrics). Participants had to be 18 years of age or older and reside in the United States. Many studies in the health care information technology context have used online data collection [27,48]. To measure phishing susceptibility (the dependent variable), participants were exposed to a scenario where they had to read an email and then indicate their intention to click on the email. The email was a phishing email in a health care context but participants were not told any information about its validity. The email was adopted from InfoSec [49].

Data Description

Data were cleaned and recoded using SAS version 9.4 (SAS Institute Inc). Responses that included missing data were removed from the final dataset.

Variables in the Model

All latent variables in the survey were borrowed from previous research and adapted to fit this study. Multimedia Appendix 1 shows the items and the source for variables in the model. All latent variable were measured using a Likert scale scored from 1 to 5. Sex was recoded to a binary variable named *Male* where 1 referred to a male participant and 0 referred to a female participant. Control variables were age, income, education, employment, and prior knowledge of the phishing concept.

Measurement Model

After the data were cleaned using SAS version 9.4, IBM SPSS Amos version 25 (IBM Corporation) was used to assess the latent validity and reliability of the latent variables and the overall fit of the measurement model. Confirmatory factor analysis was used to evaluate the overall measurement model.

The validity of the variables was tested using the average variance extracted (AVE). Finally, multicollinearity was assessed using variable inflation factor.

Results

Participant Characteristics

After the data cleaning process, a total of 200 valid response were included in the study. Table 1 shows the descriptive statistics of the participants. For example, 43% of the participants are female and 57% are male.

Table 1. Descriptive statistics of participants (N=200).

Variable, Category	Values, n (%)
Sex	
Female	86 (43.0)
Male	114 (57.0)
Age (years)	
18-25	25 (12.5)
26-35	113 (56.5)
36-45	31 (15.5)
46-55	19 (9.5)
>55	12 (6.0)
Education	
High school or less	23 (11.5)
Technical or community college	26 (13.0)
4-year college degree	105 (52.5)
Master's degree	42 (21.0)
Doctoral degree	2 (1.0)
Other	2 (1.0)
Income (US $)	
<25,000	41 (20.5)
25,000 to <50,000	74 (37.0)
50,000 to <75,000	58 (29.0)
≥75,000	27 (13.5)

Structural Equation Modeling

Structural equation modeling (SEM) was used to test the hypothesized model. Estimates derived from the SEM analysis were used to test the research hypotheses. The model explains 36.9% of the variance in phishing susceptibility. Figure 2 shows the SEM results for the hypothesized model.

Figure 2. Structural equation modeling (SEM) results. CFI: comparative fit index; RMSEA: root mean square error of approximation; TLI: Tucker-Lewis index.

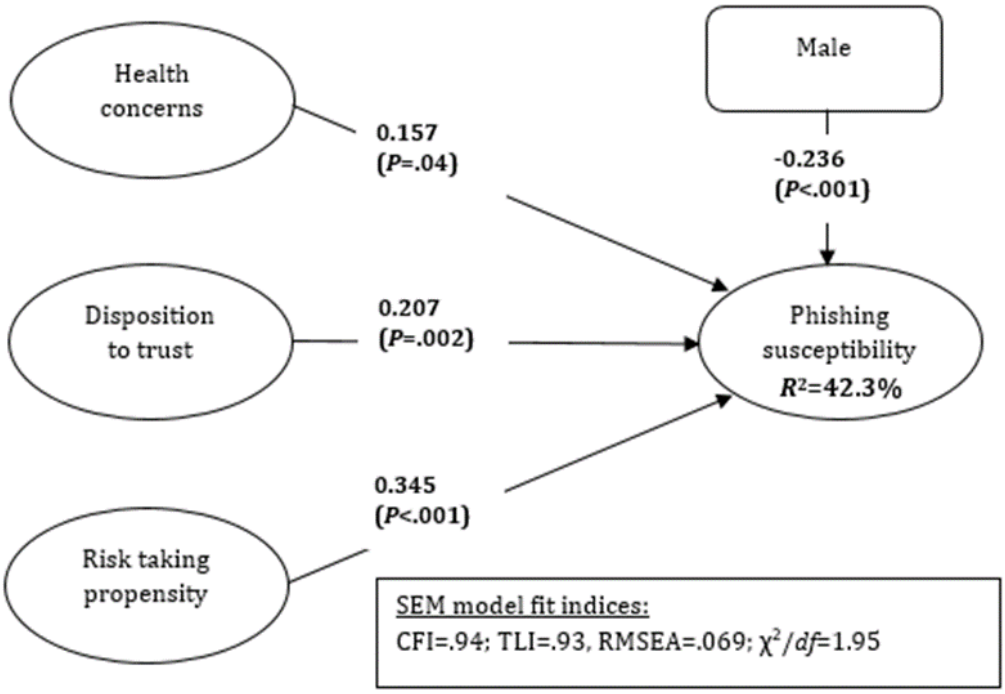


Table 2 show the results of the confirmatory factor analysis. The results show that the model fit well: root mean square error of approximation was .061, comparative fit index was .98, and Tucker-Lewis index was .97 [50]. In addition, all item loadings were high and significant, with scores ranging between .75 and .95.

All scores exceeded .5 AVE, which meets the cutoff for establishing convergent validity [51]. In fact, the smallest AVE score was .62. All AVE scores exceeded the squared construct intercorrelation for the corresponding variable, thus establishing discriminant validity [51]. All variables were reliable, as the construct reliability scores ranged from .83 to .96, exceeding the cutoff score of .7 for establishing reliability of the variable [52] (Table 2).

All variable inflation factor scores were well below the cutoff value of 10 [53]. Thus, there was no evidence to suggest the existence of multicollinearity. In addition, all variables were conceptually distinct.

Hypothesis 1 proposed a positive relationship between health concerns and phishing susceptibility. The SEM results supported this hypothesis. The path coefficient for the health concerns was positive and significant (β=.157, *P*<.04). These results suggested that health concerns lead to higher phishing susceptibility.

Hypothesis 2 suggested that disposition to trust leads to higher phishing susceptibility. The results supported this hypothesis (β=.14, *P*=.04). The path coefficients for disposition to trust were positive and significant, which provides evidence to support hypothesis 2. The finding proposes that individuals who have a propensity to trust others are more susceptible to phishing attacks. In addition, the magnitude of the path coefficient is higher than that of health concerns, indicating a larger influence of disposition to trust than of health concerns on phishing susceptibility.

Hypothesis 3 posited a positive relationship between risk-taking propensity and phishing susceptibility. The results show that the path coefficient was positive and significant (β=.345, *P*<.001), suggesting that risk-taking propensity yields a higher phishing susceptibility, thus supporting hypothesis 3. In addition, the magnitude of the path coefficient is the highest of all antecedents.

Hypothesis 4 argued that males, compared with females, have a lower phishing susceptibility. This hypothesis was supported by the results. The path coefficient for negative and significant (β=–.236, *P*<.001). This result is consistent with previous research [47].

Table 2. Confirmatory factor analysis results.

Discussion

Principal Findings

This study investigated the relationship between personality-based factors and phishing susceptibility as it relates to health care. Personality-based factors have been shown to be associated with action, decision, attitude, and intention in various contexts [27,41,45]. However, limited research has focused on these relationship in a health care phishing context. This study focused on three main personality-based antecedents: health concerns, risk-taking propensity, and disposition to trust. This is one of the few studies that focused on these factors in the phishing context.

The study found that all three factors have in important role in leading to higher phishing susceptibility in a health care scenario. These findings suggest that personality-based factors should be taken into consideration when training individuals on phishing attacks and testing their phishing susceptibility and antiphishing behavior. The influence and effectiveness of training may differ based on personality-based traits. Thus, one-size-fits-all training, simulations, and strategy might not benefit most individuals.

While health concerns were found to be a motivator to engage patients in sharing their personal health information with providers [27], in a phishing scenario health concerns led to higher phishing susceptibility. Thus, health concerns could act as a "double-edged sword." Of all personality-based factors, the results suggested that risk-taking propensity had the highest effect on increasing phishing susceptibility. This implies that future research should study the high risk taker to find optimal methods to reduce phishing susceptibility. The study also confirmed previous findings that females are more susceptible to phishing attacks, but this research confirmed the finding in a health care context.

Limitations and Future Work

This study had several limitations, which can be addressed in future studies. The data were self-reported rather than actual behavior. Real-world behavior is very difficult to capture specifically in the health care context. In future studies, the influence of customized phishing training on individuals with different levels of personality-based factors will be tested.

Conclusions

Phishing remains a problem that continues to increase. While companies, experts, and researchers continue to develop new methods to detect phishing attacks and improve resistance to falling a victim to phishing, attackers are advancing and improving phishing attacks at a higher and a more successful rate. Microsoft named 2019 as a year of phishing evolution as attackers made innovations in both technical and social tactics. The only way to mitigate phishing attacks is get ahead of the attackers. Training and simulation should include a balance of customized material and approaches that fit the characteristics of the receiver.

This study contributes to the phishing literature by investigating personality-based factors and reporting findings that are new and important. In addition, the study contributes to the health care information technology literature by examining health care–related phishing scenarios and factors. There is limited research in the health care context that deals with phishing susceptibility.

Abstract

Background: The public health impact of health and well-being digital interventions is dependent upon sufficient real-world uptake and engagement. Uptake is currently largely dependent on popularity indicators (eg, ranking and user ratings on app stores), which may not correspond with effectiveness, and rapid disengagement is common. Therefore, there is an urgent need to identify factors that influence uptake and engagement with health and well-being apps to inform new approaches that promote the effective use of such tools.

Objective: This review aimed to understand what is known about influences on the uptake of and engagement with health and well-being smartphone apps among adults.

Methods: We conducted a systematic review of quantitative, qualitative, and mixed methods studies. Studies conducted on adults were included if they focused on health and well-being smartphone apps reporting on uptake and engagement behavior. Studies identified through a systematic search in Medical Literature Analysis and Retrieval System Online, or MEDLARS Online (MEDLINE), EMBASE, Cumulative Index to Nursing and Allied Health Literature (CINAHL), PsychINFO, Scopus, Cochrane library databases, DataBase systems and Logic Programming (DBLP), and Association for Computing Machinery (ACM) Digital library were screened, with a proportion screened independently by 2 authors. Data synthesis and interpretation were undertaken using a deductive iterative process. External validity checking was undertaken by an independent researcher. A narrative synthesis of the findings was structured around the components of the capability, opportunity, motivation, behavior change model and the theoretical domains framework (TDF).

Results: Of the 7640 identified studies, 41 were included in the review. Factors related to uptake (U), engagement (E), or both (B) were identified. Under *capability*, the main factors identified were app literacy skills (B), app awareness (U), available user guidance (B), health information (E), statistical information on progress (E), well-designed reminders (E), features to reduce cognitive load (E), and self-monitoring features (E). Availability at low cost (U), positive tone, and personalization (E) were identified as physical *opportunity* factors, whereas recommendations for health and well-being apps (U), embedded health professional support (E), and social networking (E) possibilities were social *opportunity* factors. Finally, the *motivation* factors included positive feedback (E), available rewards (E), goal setting (E), and the perceived utility of the app (E).

Conclusions: Across a wide range of populations and behaviors, 26 factors relating to capability, opportunity, and motivation appear to influence the uptake of and engagement with health and well-being smartphone apps. Our recommendations may help app developers, health app portal developers, and policy makers in the optimization of health and well-being apps.

Introduction

Background

Digital behavior change interventions, such as smartphone apps, can be effective and cost-effective tools to change a range of health-related behaviors [1,2]. For example, there have been promising studies of apps, including (1) delivering health prevention messages for men who have sex with men [3], (2) self-managing diabetes [4] and cardiovascular diseases [5], (3) weight management [6-8], (4) alcohol reduction [9-11], (5) mental health interventions [12], and (6) managing long-term conditions [13]. For certain behaviors such as reduction of alcohol consumption, they could also address the barriers experienced by health professionals when delivering brief interventions in person, such as lack of necessary training [11] and to reduce the stigma associated with alcohol consumption [2]. The public health implications are substantial because of their potential to have a low incremental cost and broad reach.

Despite their promise, effect sizes reported in evaluations of app-based interventions are often small. One potential explanation is the level of uptake and engagement. Uptake refers to the act of downloading and installing a smartphone app. Engagement has been defined as "(1) the extent (e.g. amount, frequency, duration, depth) of usage and (2) a subjective experience characterized by attention, interest and affect" [14]. To date, low uptake and poor engagement are commonly observed with digital interventions, which are often insufficient to sustain behavior change [15,16]. However, there is a lack of evidence regarding the main factors contributing to this problem.

Systematic reviews that focused on one specific behavior or a certain type of health or well-being app suggest that the effectiveness of evidence-based smartphone apps can be improved by targeting the design and engagement features, such as user-friendly design, individualized and culturally tailored content, or health professional support [17-19]. A review based on experiential and behavioral perspectives conceptualized key factors that might affect engagement with digital behavior change interventions: the content (eg, behavior change techniques, social support, and reminders) and how the content is delivered (eg, professional support, personalization, and aesthetic features) [14].

To our knowledge, no systematic review that primarily seeks to identify factors that influence the uptake of and engagement with a wide range of health and well-being smartphone apps has yet been conducted. To narrow the focus of this review, the four public health priority behaviors related to prevention (smoking, alcohol consumption, physical activity, and diet) along with mental health and well-being were targeted.

Theoretical Framework

The capability, opportunity, motivation, behavior (COM-B) model is a comprehensive framework that posits that individuals, to perform or change a behavior, need the capability to undertake it, the opportunity to take part in, and the motivation to engage with that behavior [20]. COM-B is increasingly being applied to inform the development of digital behavior change interventions [21-23]. The theoretical domains framework (TDF) [24] has previously been successfully applied for systematic reviews in other contexts [25,26]. The 14 domains of the TDF, described elsewhere [24], offer a concise coding framework that can be usefully conceptualized as possible targets for behavior change interventions. The TDF, being linked to the COM-B model [24], can be used as subthemes under the components of the COM-B model (see Multimedia Appendix 1).

Objectives

This systematic review aimed to synthesize factors identified in studies that influence the uptake of and engagement with health and well-being smartphone apps among adults targeting public health priority behaviors (smoking, alcohol consumption, physical activity, and diet) and mental health and well-being, and mapped these factors under the components of the COM-B model and constructs of the TDF. This could help inform stakeholders in public health and policy makers, digital behavior change intervention developers, and providers of health and well-being smartphone app portals to better target uptake and engagement.

Methods

Systematic Review

The review was conducted according to the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA; Multimedia Appendix 2) [27], and the protocol was registered on the International Prospective Register of Systematic Reviews (CRD42019120312). The review used a mixed methods approach to generate different but complementary knowledge about users' views from qualitative findings and predictors and patterns of behavior from quantitative findings.

Eligibility Criteria

Eligible studies had to explore factors that influence uptake or engagement with health and well-being smartphone apps among adults. Table 1 summarizes the inclusion and exclusion criteria using the Population, Intervention, Comparison or Context, Outcomes, and Study Type tool.

Table 1. List of inclusion/exclusion criteria.

PICOS[a] component	Inclusion criteria	Exclusion criteria
Participants	• Adults ≥18 years. Studies including individuals ≥16 years were included if at least 70% of the participants were ≥18 years	Apps targeting health professionals
Intervention and context	• Studies investigating digital interventions using smartphone health and well-being behavior change apps on the following behaviors and outcomes: smoking, alcohol consumption, physical activity, diet and mental health, and well-being	Studies where the smartphone was not the primary intervention component
Outcomes	• Qualitative: findings described as facilitators, barriers, determinants of uptake, or engagement with health or well-being apps (either already existing or planned to be developed), including perceptions, beliefs, experiences, and interest of the participants. • Quantitative: uptake, measured as number of downloads, and engagement measured as number of logins, frequency of use, or any other relevant measure that tracks user engagement	Usability and user-testing studies, where functionality and app design were exclusively investigated for specific apps
Study design	• All study designs were included	None

[a]PICOS: Population, Intervention, Comparison or Context, Outcomes, and Study Type.

Search Strategy

Electronic Search

A systematic literature search was developed in consultation with a specialist librarian from the University of East Anglia and a senior information scientist from Public Health England (PHE). An iterative process helped to define the final search terms while ensuring a balance between sensitivity and specificity. A systematic literature search was performed in 8 electronic databases: Medical Literature Analysis and Retrieval System Online, or MEDLARS Online (MEDLINE), EMBASE, Cumulative Index to Nursing and Allied Health Literature (CINAHL), PsycINFO, Scopus, Cochrane library database, DataBase systems and Logic Programming (DBLP), and Association for Computing Machinery (ACM) Digital library. The databases were searched with no data limit, no publication or geographical restriction, but limited to the English language. Synonyms of 3 concepts were searched: (mhealth) AND (behavior change) AND (uptake or engagement; Multimedia Appendix 3 shows the MEDLINE search strategy). The electronic search was initially performed in November 2018 and was updated in August 2019.

Searching for Other Resources

Additionally, the search also included a manual search in key journals, such as *Journal of Medical Internet Research* and *Computers in Human Behavior*, and in *Google Scholar*. Reference lists of all included studies were hand-searched for additional studies. The search for gray literature included dissertations and theses, and unpublished research data and material were sought from government bodies and policy makers during stakeholder communication (PHE, National Health Service [NHS] in England).

Identification of Studies

All records identified by the search strategy were exported to Endnote X9 and deduplicated. To reduce the likelihood of reviewer selection bias and to assess how reliably the study eligibility criteria were applied, a subsample (10%) of records was additionally screened by a second reviewer (FN) during the title and abstract screening. Interrater reliability based on the number of eligible and ineligible studies was tested using Cohen's kappa statistics [28], with the following cut-offs being used: 0.41-0.60 to indicate moderate agreement, 0.61-0.80 substantial agreement, and 0.81-0.99 almost perfect agreement [28]. The full texts of potentially eligible studies were independently screened by DS, with 20% randomly selected and double-screened by FN. The exclusions of the studies were justified and recorded.

Data Extraction

A data extraction proforma was developed by the first author following the existing Cochrane guidelines [29], and the subsequent data were extracted: study characteristics (author, date of publication, sample size and type, location of the study, type of app investigated in the study, aim of the study, methodological characteristics such as design, data collection, and participants), main findings related to the research question of this systematic review (including participants' quotations and authors' interpretations in the qualitative studies and reported results of the quantitative studies), and conclusions of each study. The data extraction was performed by 1 reviewer (DS) and was checked for accuracy by a second reviewer (FN).

Quality Assessment

To assess the quality of the studies, critical appraisal was conducted using the latest version of the mixed methods appraisal tool (MMAT) [30]. MMAT is a unique tool [30] that was developed by pooling together the core relevant methodological criteria found in different well-known and widely used qualitative and quantitative critical appraisal tools [31-33].

The quality of all studies was assessed by the first reviewer (DS) and checked for accuracy by 2 other authors (FN and AJ). The tool is not intended to score the studies or to exclude papers but to offer a guide for interpreting findings [30].

Data Synthesis and Analysis

Integrative synthesis was applied to analyze the data [34,35]. The focus of the synthesis was on interpreting the data using specific concepts of the TDF as a deductive coding framework, which, for ease of interpretation, is summarized under the components of the COM-B model. Using the integrated approach, the data were pooled together by findings viewed as answering the same research questions, rather than by methods (eg, quantitative vs qualitative) [34,35].

Deductive thematic synthesis, a methodology designed to enhance the transparency of synthesizing qualitative data [36], was used to conduct the data synthesis of the findings of the qualitative studies and the qualitative component of the mixed methods studies. Using line-by-line coding, the findings were coded deductively into the domains of the TDF. The coding was conducted by the first author, and a randomly selected 10% of the coding was checked for accuracy by another author (FN). Regular coding meetings were conducted to maintain consistency. The expert opinion of an independent researcher with extensive experience in systematic reviewing was sought for data synthesis. The integrative approach includes interpretation of the quantitative findings by *qualitizing* [35], which refers to the textual interpretation of the findings of the quantitative studies (regardless of the interpretation of the author) so they can be combined narratively with qualitative data [35].

Results

Included Studies

A total of 7633 studies were initially retrieved, with a further 6 identified through manual search and reference check. An additional unpublished research report was received from stakeholders as part of the gray literature search process. No non-English papers were identified. A total of 2138 duplicates were removed. A total of 5429 studies were excluded based on the review of their titles and abstracts. Figure 1 illustrates the inclusion and exclusion of the studies following the guidance of the PRISMA flowchart [27].

During title and abstract screening, *substantial* agreement was achieved between the 2 independent reviewers (κ=0.63) [28]. Two types of disagreements were identified (one reviewer included studies that targeted app used in conjunction with a connected device and purely user-research studies) that limited agreement between the reviewers during the selection process, which were resolved through discussion and consultation with another author (AJ). After disagreements were resolved and the eligibility criteria were updated accordingly, 73 studies were identified as potentially meeting the inclusion criteria. All remaining titles and abstracts of records were assessed by 1 reviewer (DS). Of these, 41 studies were included in the review [37-77], out of which 13 were quantitative [41-44,49,53,55,63-65,68,76,77], 7 were mixed methods [38,47,59,62,73,74,78], and 21 were qualitative studies [37,39,40,45-47,50-52,54,56-58,60,61,66,67,70-72,75].

Description of the Included Studies

The end users of the studies were described as the general public [37,39,42,44,46,47,50-54,56-59,65,71,72,75,76], college students [48], existing app users [38,43,46,49,55,63,67,77,78], male workers in the male-dominated industry [60], lesbian, gay, bisexual, transgender, queer, and other spectrum of sexuality and gender (LGBTQ+) communities [40], rural communities [57], Asian ethnic minorities [41], pregnant women [73], patients in primary care [45,61,74], adult cancer survivors [62], adults with diabetes [57], those infected with HIV [64], those with chronic disease [68], and those with a bipolar disorder [69]. The focus of some studies was very specific and targeted a certain health behavior or condition, including alcohol reduction [38,46,54,58,59,64], smoking cessation [40,58,67,72,77], increasing physical activity [39,45,48,49,53,62,65,68], weight management [47,48,51,53,63,65,66,71,78], depression [52,61], mindfulness [50], diabetes management [57], and health management in pregnancy [73]. Other studies were less specific and targeted a more general mental health app [43,60,70] and a more general health app [37,41,42,44,55,56,74-76]. In all, 15 studies investigated factors influencing one particular app [38,39,43,45,46,49,50,54,55,63,65,67,70,72,77]. The remaining 27 studies examined users' perceptions of a wide range of apps or of a hypothetical app not yet developed.

The studies were published between 2011 and 2019 and were carried out in Australia [37,49,60,61,70], Belgium [69], Canada [40,51,55,67], China [68,73,76], Czech Republic [65], Ireland [45], Italy [39], New Zealand [47], Norway [75], Sweden [52], the United Kingdom [38,46,50,54,58,59,62,66,71,72,74], and the United States [41-44,48,53,56,57,63,64,77]. The study characteristics are summarized in Multimedia Appendix 4.

Quality Assessment of the Studies Included

On the basis of MMAT [30], the majority of the studies employing qualitative methodology were deemed to be of high quality. Concerns related to the sample were identified across many quantitative studies. This included issues around sampling and lack of clarity as to whether the groups were comparable at baseline or whether the sample was representative of the general population. In 4 nonrandomized studies, confounders were not accounted for by the design and analysis. Out of 7 mixed methods studies, 2 were judged to be of low quality, out of which one is an unpublished report (gray literature) and the other one is a published short report. See Multimedia Appendix 5 for details of the quality assessment for each study.

Data Analysis and Thematic Synthesis

Although not all the studies presented data for all aspects of this review, all studies presented some data that could be included in the synthesis. Evidence that was considered weakly explained or was judged to be unclear was not included in the summary of findings. An overview of the identified factors and the level of influence (uptake, engagement, or both) along with a brief description of each factor can be found in Table 2. Examples of supporting evidence are provided in the Textboxes 1-10.

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses flowchart illustrating the inclusion and exclusion of studies.

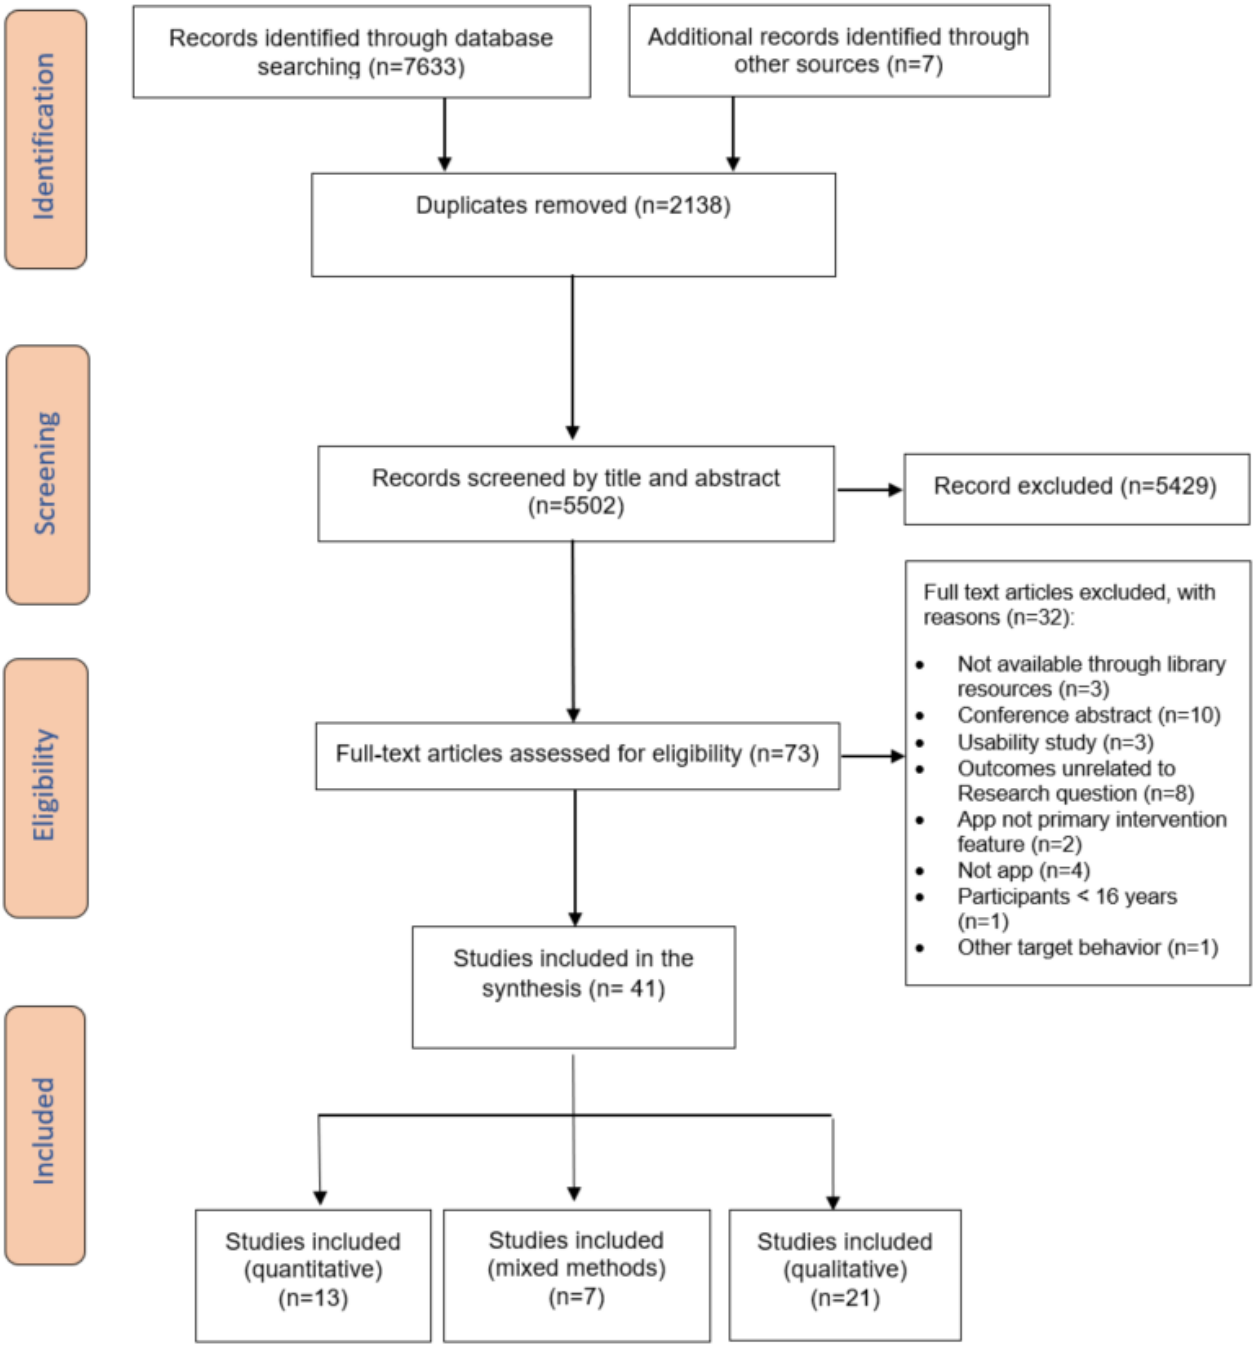

Table 2. Factors identified in the systematic review.

COM-B[a] component, TDF[b] construct, and identified factor (source)[c]	Uptake, engagement, or both	Short description of the factor
Physical capability		
Skills		
App literacy [46,50,57,61,65]	Both	Technological competency
Psychological capability		
Knowledge		
App awareness [54,56,57,61,75]	Uptake	Knowledge of the existence of health and well-being apps
User guidance [37,39,46,50,59,72]	Both	Instructions on how to effectively use the app
Health information [47,51,53,54,56-58,62,69,72,75,78]	Engagement	Educational information related to health and well-being aspects
Statistical information [37-39,46,52,54,57,66,67,71,72,75]	Engagement	A visual or numerical summary of progress
Memory, attention, and decision processes		
Well-designed reminders [37-40,43,46,48,51,52,54,56-58,62,66-69,71,78]	Engagement	The ability to customize reminders
Less cognitive load [37,39,46,48,50,51,54,56-58,60,66,69,71,72,75]	Engagement	The app is not too time consuming, easy to use, and requires minimal input
Coping games [40,60,67,72]	Engagement	Distraction activities within the app
Behavioral regulation		
Self-monitoring [36,38-40,45,48,51,52,55,57,59,60]	Engagement	The ability of the app to help self-regulation of the target behavior
Established routines [38,48,50,54,66]	Engagement	Regularity in using the app
Safety netting [37,61,66,73]	Engagement	Retaining the app for a potential precipitating event in the future
Physical opportunity		
Environmental context and resources		
Availability and accessibility [37,40,45,49,52,57,72,78]	Uptake	The ability to use a smartphone anytime anywhere
Low cost [37,40,47,48,56,68,72,74]	Uptake	The price of the app
Interactive and positive tone [46,51,57-60,69,71,72]	Engagement	Encouraging communication style
Personalization to needs [37,38,40,47,50,52,56,57,60-62,69,71,72,75,78]	Engagement	The possibility to use an app that is tailored to a user's needs
Social opportunity		
Social influences		
Recommendations [56-58,61,74]	Uptake	Suggestions received from other users
Health practitioner support [37,40,51,52,57,59,62,67,69,72,73]	Engagement	Possibility to get in touch with health professionals and practitioners within the app
Community networking [37,39,40,47,56,59,62,66-73,75]	Engagement	Social interaction with users with similar needs within the app or within their community
Social media [39,40,48,54,56,58,61,66,67,71,72,75,78]	Engagement	A choice to connect to social media platforms
Social competition [37,39,48,56,59,66,67]	Engagement	Competitive nature of the app with others or with themselves

COM-B[a] component, TDF[b] construct, and identified factor (source)[c]	Uptake, engagement, or both	Short description of the factor
Personification of the app [39,45,47,48,50,56]	Engagement	Applying human attributes to the app
Automatic motivation		
Reinforcement		
Feedback [37,39,45-48,51,52,54,56,58,62,67,72]	Engagement	Feedback regarding the user's performance
Rewards [37,40,45,46,56-59,66,69,71,75]	Engagement	Tangible and intangible reward in response to the user's effort
Emotions		
Curiosity [38,52,54,61]	Uptake	Desire to acquire knowledge and skills to use a behavior change tool
Reflective motivation		
Goals		
Goal setting [38,39,45,48,51,54,56,58,59,66,71,74]	Engagement	Establishing what the user would like to accomplish
Beliefs about consequences		
Perceived utility of the app [37,46,52,59,61,74]	Engagement	Discrepancy of what the users are looking for and what the app offers

[a]COM-B: capability, opportunity, motivation, behavior model.

[b]TDF: theoretical domains framework.

[c]Studies where the factors were identified.

Physical Capability

Theoretical Domains Framework: Skills

Skills refer to one's ability to perform an action and include constructs such as competencies, interpersonal skills, skill development, and practice (Textbox 1). App literacy [46,50,57,61,65], defined as technological competency to use a smartphone app, was reported by participants as being of high importance for both uptake and engagement. A basic level of app literacy is required to be able to download and initiate engagement with an app (see quote 1, Q1), whereas adequate app literacy skills would enhance users' intentions to engage with an app (Q2) [46,50]. In a cross-sectional study, advanced app literacy was associated with increased use of the social functions of an app, such as networking, but not with the functions that target action planning and goal management [65]. This suggests that app literacy might be an important aspect for successful uptake, but this alone might not be enough to maintain engagement. In contrast, users have reported that lack of app literacy skills could trigger negative emotions toward themselves (eg, self-blame and disappointment of not being able to use an app) [46,50,61] and could contribute to their perceived low self-confidence in using technology [61].

Textbox 1. Illustrative quotes (Q1 and Q2) for factors mapped onto the physical capability subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: skills.

Uptake and engagement

App literacy

- Quote 1: "I'd be happy to do it if I knew how to do it [but] I don't know how to download apps...I need help with technology. Like, I'm 58 and I didn't grow up in a technological age and so do find that I lack confidence with technology." [61]
- Quote 2: "I've never used it [these apps] because I never got it to work the way I wanted it to." [57]

Psychological Capability

Theoretical Domains Framework: Knowledge

Multiple factors were identified under the TDF domain that covers rational, procedural, and other types of knowledge; information; and awareness of the existence of something (Textbox 2). App awareness [54,56,57,61,75], such as information on the existence of health and well-being apps, would positively influence the uptake of health and well-being smartphone apps (Q3). It was suggested that many participants were not aware of the availability of such tools, and some found the disorganized nature of the commercial app stores confusing and represented a barrier for uptake [61].

Textbox 2. Illustrative quotes (Q3-Q13) for factors mapped onto the psychological capability subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: knowledge.

Uptake

App awareness

- Quote 3: "I didn't realize that they had an app." [57]

Engagement

User guidance

- Quote 4: "I want something to tell me 'Do number 1 first, then number 2. When you've done this go here' so I don't have to think too much about it. Once I've got it up and running I'm fine." [46]
- Quote 5: "Just at the beginning of the app, when you've downloaded it and you're using it for the first time, it should tell you what to do. But not every time. You don't need guidance how to use it and where things are, because I think it would just be annoying." [59]

Health information

- Quote 6: "[It is] important and really helps me to learn about bipolar disorder and read about stuff." [67]
- Quote 7: "I... enjoy learning something new. It's quite informative and makes you think about what you're doing. [QG] helps you to understand a bit more about what's going on...what could go wrong by continuing [to smoke]." [72]
- Quote 8: "I personally am scared of getting lymphedema, and still don't know sometimes what exercises are good to prevent it, so I think that maybe educating people about [...] consequences of not exercising from a really good NHS source would be helpful." [62]
- Quote 9: "I think everyone has heard that information many times. It's actually quite patronizing...shallow stuff, not hard-hitting useful facts. It obviously isn't a tailored app to each person, but it gives enough information that each person can relate to it in a tailored way. I find it really engaging, I suppose that's why I stuck with it." [72]

Statistical information

- Quote 10: "I like the numbers. I like to track stuff and have some figures behind it rather than just like, oh, I'll go for a run today. I'll be like, well, I'll go for a run today but what's my time from last time and how can I beat it? And I think that's why this kind of app appeals to me. If I just put the drinks in and it just said you're drinking too much but didn't give any numbers behind it, I'd probably delete it within a few days." [38]
- Quote 11: "It was like a visual of my day of smoking. And every day, you'd look at it, it went down and down and down, like it got better every day. So it was like a motivational thing to just look, like positive reinforcement." [67]
- Quote 12: "I couldn't find any graph that's reflected the mood so therefore I didn't see the point of having to fill that part out and I stopped filling it out." [46]
- Quote 13: "If you're having a bad day or a couple of bad days, seeing it on [the app] as a reflection [of your bad days] just like kicks you in the face even more, you know?" [67]

User guidance [37,39,46,50,59,72], namely, instructions on how to effectively use an app, such as how to create achievable goals, influenced uptake and initial engagement. It was proposed that having a guide on how to use an app could positively affect the users' intention to engage with it, and hence, users might be able to better regulate their behavior (Q4) [46,59]. However, the presence of a guide was reported off-putting and unnecessary for long-term engagement by producing negative emotions (eg, annoyance) once the knowledge regarding app functionality has been gathered (Q5) [59].

Available health information within the app was perceived by users as beneficial and positively influenced their engagement in several studies (Q6 and Q7) [47,51,53,54,56-58,62,69,72,75,78]. Depending on the target behavior, end users wished to (1) access advice on exercise routines [39,56,62,66]; (2) seek nutritional education [39,51,56,57,66,70]; (3) widen their knowledge of health consequences [58,67,72]; (4) find out more about healthy living while living with a medical condition [62,73]; (5) know more about the conditions they are living with [69,73,75]; (6) improve their health literacy [75]; (7) demystify myths [72]; (8) receive health news updates, such as on smoking taxes and bans [72]; and (9) better understand alcohol units in the UK [54].

However, the quality of information was identified as potentially affecting engagement [72]. Some users wanted a credible source, a trustworthy and evidence-based guide with references to the information they receive (Q8) [62,70,73]. Health information that focuses on negative aspects of past behavior that cannot be modified (eg, smoking or alcohol consumption) would trigger negative emotions (eg, regrets) [58]. It was suggested that better quality of information would increase the likelihood of maintaining users' engagement with an app, and consequently, they would better self-monitor their behavior [56,67]. This could be achieved by providing a wide range of information that everyone could relate to rather than facts that are already known (Q9) [72]. For example, 1 qualitative study suggested the use of health quizzes to promote engagement [75]. Health quizzes were also found promising by a large study that evaluated the uptake of a loyalty points–based health app conducted in Canada [55]. One of the intermediate objectives of that study was to

improve the Canadian population's health literacy by using health information related to quizzes. The app usage data included quiz completion rates, and the results showed that 60% of the users were highly engaged with the app by having more than 75% of health quizzes completed. Furthermore, better health literacy might enhance beliefs about consequences (eg, health outcome expectancies) [67,72] and the users' intention to stay engaged with an app and subsequently with the behavior they target to change [72,75]. Mackert et al [53] also found that adequate heath literacy was associated with increased engagement with fitness and nutrition apps.

Users valued available statistical information [37-39,46,52,54,57,66,67,71,72,75], which was a visual or numerical summary of progress or a trend in their behavior. This included features such as step counting [71,75], the number of calories consumed [54,71], number of days spent abstaining from smoking [67], the amount of money saved by quitting smoking [72] or by reducing drinking [54], a trend in their alcohol consumption and how it changes over time [38,46,54], as well as a way to allow analysis of user data [37,75]. Being able to check their progress helped users better monitor their behavior (Q10) [37-39,71,72], and for some individuals, a positive trajectory acted as a behavioral reinforcement (Q11) [46,67]. In 2 studies, participants reported that a lack of visual representation of progress led to disengagement with the alcohol reduction app (Q12) [38,46], and 1 study on smoking cessation reported negative emotions associated with progress viewing during *a few bad days*, suggesting discouragement (Q13) [67].

Theoretical Domains Framework Domain: Memory, Attention, and Decision Processes

This domain focuses on the ability to retain and select information, including aspects of attention, memory, decision making, and cognitive overload (Textbox 3). Reminders [37-40,43,46,48,51,52,54,56-58,62,66,67,69-71] to engage with an app were reported to be useful for people with busy schedules and for those who tend to forget engaging with the app and, therefore, with the target behavior [37,39,43,56,67]. Individuals described being inclined to check their phones when receiving a notification [37,38,40]. Reminders positively affected behavioral regulation by prompting engagement with self-monitoring and the tracking features of the app (Q14) [37,39,40,51,54,62,67,69-71] as well as reinforcing the users by reminding them about their positive progress [40,48,51]. A microrandomized trial found that a push notification that contained a tailored health message resulted in a small increase in the engagement with a health app [43]. A large study conducted on engagement with a weight loss app found that 16% of the most engaged group used reminders, compared with 1% of the least engaged group [64]. However, not all users found reminders useful [37,39,51,56-58,66]. In the case of behaviors that are associated with stigma (eg, alcohol consumption), reminders would threaten the users' social identity when they are received at an inappropriate time or wrong place (Q15) [38,46,54]. Therefore, the timing of when the reminders were sent as well as the language used appeared to be important conditions. If these conditions were not met, users were more likely to turn the notifications off [37,38,69] or ignore them (Q16) [56,66,67].

Textbox 3. Illustrative quotes (Q14-Q20) for factors mapped onto the psychological capability subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: memory, attention, and decision processes.

Engagement

Well-designed reminders

- Quote 14: "I found it was almost like having my girlfriend there, in a good way. So you're like, oh I haven't done this in two days, I didn't even realize, but my phone just reminded me. Better keep it going." [67]
- Quote 15: "I think because they were just pinging... and I was just thinking, I don't really want to read this right now. Obviously, and I don't know whether they do but I guess most people check their phone when something pings in and you can be with your friends and actually maybe you wouldn't want to be saying to your friends, I've just got a notification from Drinkaware." [38]
- Quote 16: "I completely ignored them [notifications]. Actually, I'm pretty sure I had the notifications that were from the app all turned off. It just felt like a pop up, like another thing for me to click close on throughout the day. I completely paid no attention to it." [67]

Less cognitive load

- Quote 17: "I really loved it [Couch to 5K], there was no excessive login, it was really easy you just downloaded and start you have to have your email, no password, no nothing like that, they don't send you a bunch emails that annoy the crap out of me. Nothing." [48]
- Quote 18: "What I'm thinking is, this better be easy, because otherwise I'm probably not going to do it. If there are too many obstacles in the way I won't. Even though I know I need to do this, I probably won't." [46]

Coping games

- Quote 19: "If there was a bunch of games on the app that were there to distract you from smoking, (you could) go play 5 mins of a quick game instead of smoking." [40]
- Quote 20: "Maybe if they had prior to like some type of like a mini game or something in there that would keep the mind occupied rather than telling you, "Don't smoke." [72]

Regarding attention and decision processes, the findings of the studies included in the review proposed that cognitive overload should be avoided to maintain engagement with an app. An app that is less time consuming, requires minimal input, and is easy

to use and log into was preferred (Q17) [37,39,46,48,50,51,54,56-58,60,66,69,71,72,75]. Additional functions that decrease the time spent on a task using an app were highly appreciated [37,39,48,50,54,56,71,72,75]. The automatization of data collection, for example, by linking apps to wearables [37] or by using the camera function to scan the barcodes to input calories [71] was found to be particularly useful in physical activity and weight management apps. An app that is easy to use and does not require extra effort would increase the intention to engage with it [39,46,48,54,56,57,74] and would improve users' self-monitoring and self-management strategies [48,51,66,75]. Conversely, using a difficult and time-consuming app would affect the users' perceived competence in engaging with it (Q18) [50]. Such an app often would be deleted or replaced with another app that is perceived to be easier to use [46,48,56,66,71]. Only 1 study found that users who are highly committed to change behavior (in this case, to reduce alcohol consumption) would be willing to overcome this barrier [54].

Including coping games [40,60,67,72] as distraction activities has been suggested as a helpful way to cope with cravings (smoking) [40,67,72] or with distress [60]. Some users indicated that by using their hands and minds, they expected to be preoccupied, instead of engaging with the undesirable behavior, while keeping them engaged with the app itself (Q19-Q20).

Theoretical Domains Framework Domain: Behavioral Regulation

Behavioral regulation refers to managing, monitoring, or changing actions or behavior (Textbox 4). Self-monitoring, the ability of an app to help monitor and regulate the target behavior [36,38-40,45,48,51,52,55,57,59,60], was found to be important in supporting behavior change. A self-monitoring feature was able to raise awareness about the number of cigarettes smoked [40,58], the amount of alcohol consumed [58], the number of steps taken [45], the mood they have [60], or users calorie intake (Q21) [48,56]. It also enhanced users' intention to engage with an app [51,52,58], provided *self-reinforcement* [52], helped increase self-efficacy (Q22) [56,61,71], and evoked feelings of *control, security, health, empowerment, and autonomy* [54].

An established routine or regularly using an app [38,48,50,54,66] positively affected the intention to engage with an app [50] and to maintain engagement (Q23). Furthermore, safety netting [37,61,66,73], defined as the ability of an app to provide *aftercare* [66] and an option to retain an app for a potential precipitating event in the future and for relapse prevention, was found to be useful to maintain the behavior, even when the target behavior has been achieved (Q24).

Textbox 4. Illustrative quotes (Q21-Q24) for factors mapped onto the psychological capability subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: behavioral regulation.

Engagement

Self-monitoring

- Quote 21: "You get a chance to see what you do on a daily basis, something you're probably not aware of." [56]
- Quote 22: "Because I can see I'm getting better, I use the app now, but I can see myself in the future not having to use it. Kind of like a stepping stone I guess." [71]

Routines

- Quote 23: "Because, I've got a couple of other little apps that I look at on a daily, not all apps, but a little regime of four or five, you know, I check the weather and I look at my drink app, and various things like that, a little routine, so pretty much daily." [38]

Safety netting

- Quote 24: "I think the migraine one's probably outlived its usefulness for me, but the back pain one, I could still go back to that at any time. If I started to need to monitor my pain again in a systematic way, I'd still go back to it." [37]

Physical Opportunity

Theoretical Domains Framework: Environmental Context and Resources

This domain refers to the circumstances of an individual's situation or environment that positively or negatively affects the uptake of or engagement with health and well-being smartphone apps (Textbox 5). The availability and accessibility of a smartphone [37,40,45,49,52,57,72,78] facilitate both uptake and engagement by having a behavior change device in close proximity (Q25). Although smartphones or tablets enhance the portability and accessibility of health apps, the development of an accompanying website was suggested to reduce inequality for those who might not have the opportunity to own a smartphone (Q26) [40]. Furthermore, the results of a digital behavior change intervention study examining engagement and nonusage attrition with a physical activity program suggest that when the app was used together with the accompanying website, a higher engagement rate was observed compared with those who used the app-only or the web-only versions [49].

The low cost of an app was found to be an influential factor for uptake [37,40,47,48,56,68,72,74] so that low-income individuals would be able to afford them (Q27) [47]. In a questionnaire study in China, 1 of the top barriers to using a health app was the extra cost, having a total of 83% of patients reporting that they would not be willing to pay for a health app [68]. Nevertheless, a few participants expressed their willingness to pay a small extra fee (ie, under US $5) if, this way, they could unlock unique features otherwise not available with the free version (Q28) [37,48,56,74].

Textbox 5. Illustrative quotes (Q25-Q34) for factors mapped onto the physical opportunity subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: environmental context and resources.

Uptake

Availability

- Quote 25: "It was real easy you just put it in your pocket and off you go and... you could do it at your own pace." [45]
- Quote 26: "I feel like there would need to be a website equivalent with it (for) people who don't have access to smartphones but do have access to public libraries. A lot of smokers are LGBTQ and a lot of LGBTQ are in poverty and homeless. The people that you want to access might not be able to access the program." [40]

Low cost

- Quote 27: "I wouldn't pay money for an app. I think that's kinda stupid." [48]
- Quote 28: "I'm prepared to pay for applications. As well as being in the software industry, I understand that it's people's livelihoods are attached to this. I use some free applications, but I often will pay for the upgraded or the purchased option." [37]

Engagement

Positive tone

- Quote 29: "I had a chocolate bar today and It would say, this chocolate bar contained this much saturated fat and... I just feel really guilty now." [71]
- Quote 30: "I think I'm more likely to listen to practical advice rather than finger wagging..." [58]
- Quote 31: "I just see it as a way to help me monitor what I'm doing and maybe give me a little kick in the pants every now again to be like, 'By the way, that donut had five hundred calories in it. Maybe make a better choice at dinner'." [51]

Personalization

- Quote 32: "The more I would be able to manipulate the app to be and do what I wanted or needed, for my own circumstances, the more likely I am to use it." [59]
- Quote 33: "It must be very personalized, it's easy to find things on the Internet, but it's mostly for normal people." [75]
- Quote 34: "Assuming that it's customised to LGBTQ (and) it incorporates the kinds of struggles that we've lived through, it wouldn't be any average quit-smoking app. The fact that it's specific to a community... the fact that it's LGBTQ-specific, that would help us more than if it was just a general quit-smoking app." [40]

Numerous studies have found that interactivity and positivity of tone may be efficacious for engagement, especially when attempting to change behaviors associated with self-blame (eg, weight management) (Q29) [46,51,57-60,69,71,72]. In total, 3 studies provided evidence that an encouraging tone rather than a condescending tone was important [46,58,69]. Evidence from 1 study suggested that apps should use praise but avoid shame [51], and another study provided evidence that a relaxed tone may be beneficial and may include jokes [46]. Several studies suggested that demanding or annoying language would be ignored (Q30) [57-59], although a study of nutrition apps reported the occasional need for a tougher attitude to achieve goals (Q31) [51]. Nevertheless, careful selection of the terminology used to understand the app and what it does, such as using simple and clear language, was suggested to make a noteworthy difference in the effectiveness of the content [60,72]. Terminology around certain behaviors might make a difference. For example, it was reported that using a *nonsmoker* label as opposed to an *ex-smoker* label would increase people's self-confidence [72]. It was suggested that unsupportive language would evoke negative emotions (eg, guilt and regret), which would affect the intention to engage with an app [46,59,71].

A personalized app was highly valued for engagement [37,38,40,47,50,52,56,57,60-62,69-72,75]. Users would want to have control over the app (Q32) [59,66,69]. They would like to be able to switch off features they do not use [37], and to use external incentives, such as uploaded photos or quotes [66,67], and to personalize their goal and how to achieve it [40]. Users would also like to choose a level where to start using a particular app. For example, a more experienced user would want to have the possibility to start a mindfulness practice at the intermediate level rather than at the beginner level [50]. Users were seeking to receive more personalized information about their current behavioral habits, demographic characteristics, long-term effects of the current behavior [38,56,60,78], and recommendations based on their tracked data [57]. Personalization can also be extended to their identity (Q33). Participants were looking for an app that is tailored to their cultural and social identities, such as LGBTQ+ people, cancer survivors, or other patients who are predisposed to have other struggles and mental health issues (Q34) [40]. Personalization to users' needs and preferences suggested better engagement [58,59,61], whereas lack of flexibility in content was found to be a reason to stop engagement [52], and in some cases, it created frustration [71]. Furthermore, a large study found that 30% of the most frequently engaged group customized the app more, for example, uploaded pictures, than the least engaged group (2%) [63].

Social Opportunity

Theoretical Domains Framework: Social Influences

Social influences are interpersonal influences (received from other individuals) that could impact an individual's behaviors, decisions, thoughts, and feelings (Textbox 6). In 5 studies, recommendations to use an app [56-58,61,74], received from health care practitioners or trusted providers [57,61,74], friends and families [56,60,74], or by reading user reviews [56,58,74], positively affected the uptake of health and well-being apps (Q35-Q37).

Connections between an app and health practitioner support were highly valued [37,40,51,52,57,59,62,67,69,72,73]. Participants reported that counseling services should be linked to an app [40,67,69], such as an *emergency button* feature [69], whereas others have emphasized the importance of linking an app to their health care provider (Q38-Q40) [37,62]. Health practitioner support could help overcome potential barriers caused by lack of skills, such as app literacy [52]; enhance self-monitoring [52,62]; and act as reinforcement [52], having the potential to enhance intentions to engage with the app (Q40) [52,62,72].

The possibility of community networking within apps with other users or other people with similar needs has been identified in multiple studies [37,39,40,47,56,59,62,66,67,69-73,75]. It was considered an important social support by reinforcing behavior change [47,56,59,62,69,72,73] and by sharing knowledge and experiences [37,69,73,75]. This was found to increase their intention to engage with the app and, subsequently, the behavior (Q41-Q42) [62]. A large study found that the most engaged group had a mean number of 24 friends within the app, as opposed to the least engaged group (1 friend) [64]. Users' potential social roles or group identities and personal preferences should be taken into consideration. For instance, individuals from the LGBTQ+ community [40] and cancer survivors [62] would wish to interact with people who face similar challenges (Q41). In addition, some users would not want to share information with strangers due to fear of social comparison [39,59] or social stigma [54], whereas others were more open to connecting with strangers rather than with friends or family (Q42-Q44) [56].

Evidence for the importance of embedded social media for engagement has been mixed [39,40,48,54,56,58,61,66,67,70-72,75]. It largely depends on the individual's attitude toward these channels and on the target behavior. Some users found this reinforcing (Q46) [40,61,71,75], whereas others did not want to engage with such features due to social stigma (eg, smoking, alcohol consumption, or weight management; Q46-Q47) [39,48,54,56,58,67,72].

Social competition [37,39,48,56,59,66,67] includes the possibility for individuals to compete with themselves (ie, their previous achievements or breaking their own records) or with other app users (Q48-Q49). A total of 5 studies suggest that the reinforcing nature of social competitions might increase the intention to engage with an app [37,48,56,59,66]. The increased engagement was anticipated when the competition is based on support by receiving encouragement from others [39,67], rather than on defeating each other, which might prompt discouragement to use the app (Q50) [67].

Several studies described that some participants felt that apps can impersonate a little person [39,45,47,48,50,56], which increased the intention to use the app (Q51-52) [45,48,50]. It was also suggested that if the app is too impersonal, it would not offer the social support the users' need [47]. In contrast, in 2 studies, the participants were concerned about having a machine telling them what to do (Q53) [47,56].

Moreover, personal experience related to noncommunicable diseases might increase the chances of the uptake of apps. One study conducted on Latino and Asian subgroups in the United States found that the odds of downloading a health app was twice as high for those who had a family history of heart attack (odds ratio 2.02, 95% CI 1.16-3.51), compared with those who did not [41].

Automatic Motivation

Theoretical Domains Framework: Reinforcement

Reinforcement is a process or action of encouraging a pattern of behavior (Textbox 7). Users reported better engagement when positive feedback was received (Q54) [37,39,45-48,51,52,54,56,58,62,67,72]. Visual feedback of progress made users aware of their advancement in reaching their goal (Q55) [37,45,46], whereas auditory feedback was seen as encouraging during physical activity (eg, running) [37,48]. For some, instant feedback on their progress, even if it is of a positive nature, was perceived to cause pressure and potential disappointment if they were not able to reach their goal (Q56) [45,56].

Offering rewards [37,40,45,46,56-59,66,69,71,75] was found to be a useful way to increase engagement. Participants suggested including gamification elements in apps to enhance engagement [37,56,69,71,75]. Some users found intangible rewards (eg, badges) motivating (Q57) [46,56,58,59,66,71], whereas others would want to receive tangible rewards instead (eg, free t-shirt, gift cards, cash, reduction in health insurance, or vouchers provided by hospitals or doctor's office; Q58-Q59) [40,56,58,66]. This has been partly supported by 2 quantitative studies. In 1 study, having a health insurance was associated with uptake of, but not with engagement with, health apps [42]. Another study found that when offering loyalty points, engagement increased for at least three months [55].

Textbox 6. Illustrative quotes (Q35-Q53) for factors mapped onto the social opportunity subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: social influences.

Uptake

Recommendations

- Quote 35: “I’d rather ask a counselor or a doctor what they would recommend.” [61]
- Quote 36: “Most of mine [my apps] are friend recommendations, people with similar activities.” [56]
- Quote 37: “...if an app has a good rating, despite the one or two people who are not satisfied, I think it would mean that it works for the majority of people.” [58]

Engagement

Health practitioner support

- Quote 38: “It would help in times of crisis to be able to be in touch with a professional, or if I needed to ask health questions related to alcoholism.” [59]
- Quote 39: “I want to let others know when I’m not well, the app would help me.” [69]
- Quote 40: “The therapist helped me to find my motivation every now and then, and then I was on top of it for about a week or so, and eventually the application sort of became a part of my everyday life. Then it was pretty obvious that I would use it and then I didn't even think about whether it was hard to use it, I just did it.” [52]

Community networking

- Quote 41: “It is so important to get in touch with people who went through the same thing as you have. [...] I think that if an app for cancer survivors had a forum on it as a part of the application to motivate each other, that would be amazing.” [62]
- Quote 42: “I don't think I would share on the social media, but within the app community I think it is important to like inspire and be motivated by others.” [66]
- Quote 43: “So having some sort of platform where everyone can just say, ‘This is how I stopped’ or ‘This is how I'm trying to stop’ and then other people giving feedback saying, ‘This is good’ or, ‘This is not’.” [72]
- Quote 44: “Being able to exchange feedback with strangers with the same goal could be supportive but non-judgemental as you will probably not know the other users.” [59]

Embedded social media

- Quote 45: “Integrating it with the social media is definitely a great thing to do because they can always fall back to Facebook, Twitter, etc. And through this, people can get to share their experiences and keep an update and tell whatever experiences they may have to share. So it’s like ongoing support.” [40]
- Quote 46: “Yeah you can share on Facebook and stuff, but I hate that. I hate when apps sync to like every form of social media. I’m like really weird about social media, so, no I don’t want to share it.” [48]
- Quote 47: “Don't want to share progress on social media in case you fail.” [72]

Social competition

- Quote 48: “Whenever we do a weekend challenge, you always have a look at what the other person's doing and [their] competitive side. I just want to beat the other people I see on there, so [using the app] is quite a good motivator.” [37]
- Quote 49: “It made me want to exercise more just, as like, kinda like, a competition to see how many calories because it takes your calories off whenever you exercise so I’m like let’s see how many I can get off this time.” [48]
- Quote 50: “Someone whose successful and quit smoking isn’t any better than someone that’s struggling with it. Like, no, I didn’t-I don’t like that aspect...it just makes someone feel bad.” [67]

Impersonated app

- Quote 51: “It’s like a ‘little boss in my pocket’... that’s sort of saying ‘you know you need to get out and do this’.” [45]
- Quote 52: “It’s like your own little motivator, in a way. And it definitely, it’s like, okay it’s like a little person, but it doesn’t talk, but it’s like, you shouldn’t eat that, or it’s like you should. So I don’t know it’s, I like it—I mean, I think it’s cool. It’s like my own little motivation.” [48]
- Quote 53: “I don’t want an electronic device telling me what to do.” [56]

Textbox 7. Illustrative quotes (Q54-Q59) for factors mapped onto automatic motivation subcomponents of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: reinforcement and emotions.

Engagement

Feedback

- Quote 54: "I liked how it gave notifications, like every day I've got a notification saying; You're on day four of your smoking quitting history. You could do this, don't give up. Stay loyal and stuff like that. That was quite impressive." [72]
- Quote 55: "The big green continue at the bottom and when it moves on to the next thing I feel great, I've achieved something, I've filled something in correctly. I like that. And a nice little noise which made me think, Oh, I'm not an idiot." [46]
- Quote 56: "The progress I didn't make—it shows [and thus is demotivating]." [56]

Rewards

- Quote 57: "Earning badges [was] important when I was doing it...We learned as a kid, to consider [it] as [an] accomplishment." [56]
- Quote 58: "Each time you try, you get the points. And if these points can be converted to something else. Because you know, you're not really working for the badge but if the virtual badge can turn into something tangible, I would want that." [57]
- Quote 59: "Well, both of them are a kind of 'well done for doing this', they're both a reward, they both make you feel a bit better. But a badge, it's a cool fact, but it's not the same as having vouchers, where you can go and treat yourself to something you want." [59]

Theoretical Domains Framework Domain: Emotions

Emotions, based on previous experiences and behavior, are a complex reaction by which people tend to respond to a personally important event or matter (Textbox 8). Curiosity [38,52,54,61] positively influences the uptake of health and well-being smartphone apps (Q60). However, in 2 studies, both targeting alcohol consumption reduction, this factor was only relevant for a specific user type: for those who were characterized as *low-risk* drinkers [38] and *noncommitters* (ie, users who did not commit to engage with the app and, thus, did not gain any benefit from it) of the app [54].

Textbox 8. Illustrative quote (Q60) for factors mapped onto the automatic motivation subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: emotion.

Uptake

Curiosity

- Quote 60: "It was more like seeing an ad and just, okay I should try this — and then I found it on the internet and signed up. It was more like a fun thing. We'll see if it works. More like that." [52]

Reflective Motivation

Theoretical Domains Framework: Goals

Goals are outcomes that an individual would like to achieve to change a certain behavior (Textbox 9). Goal setting [38,39,45,48,51,54,56,58,59,66,71,74] was related to sustained engagement with health and well-being apps (Q61). Some users chose to set a goal, and mostly, this was only 1 goal at a time, so their focus would remain on 1 single aspect of change of the behavior (Q62), whereas others were more reluctant to use this feature because of fears of not being able to achieve their set goal and to avoid disappointing themselves (Q63) [38]. In general, the studies suggest that users were more determined to engage in behavior change when they had set goals [45] and believed they had successfully achieved or could achieve their goals with the help of an app by increasing their intention to use the app and by better monitoring the target behavior (Q64-Q65) [48,54,56,58,59].

Textbox 9. Illustrative quotes (Q61-Q65) for factors mapped onto the reflective motivation subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: goals.

Engagement

Goal setting

- Quote 61: "I'm not good at self-discipline and exercise, so maybe this [goal setting in the app] can help me get to my goal." [56]
- Quote 62: "I only set one goal because I was very keen to kind of remain focused on one thing. I didn't want to come and get lost in the app using it like a game. You know, I wanted to use it for one very specific thing... I think I set it to drink probably within guidelines." [38]
- Quote 63: "No, it didn't appeal - probably because I thought if I put some goals in I'm probably not going to stick to it, which probably makes me sound a bit naughty." [38]
- Quote 64: "If you set those manageable goals, so you could achieve it, if you feel like you're actually progressing, getting something, then you're more likely to go back." [58]
- Quote 65: "It would encourage me to open the app on a daily basis." [59]

Theoretical Domains Framework Domain: Beliefs About Consequences

This domain includes aspects related to outcome expectancies (Textbox 10). Perceived utility of the app [37,46,52,59,61,74] refers to where there is a discrepancy between what the users are looking for and what an app actually offers. It was suggested that the unmet expectations of an app would lead to disengagement and frustration with the app (Q66-Q68).

Textbox 10. Illustrative quotes (Q66-Q68) for factors mapped onto the reflective motivation subcomponent of the capability, opportunity, motivation, behavior model and coded under the theoretical domains framework: beliefs about consequences.

Engagement

Perceived utility of the app

- Quote 66: "I do have some apps I don't use often, mainly because they've kind of bored me in a way. I'll just do an example: one fitness app shows you how to lose weight, but the way it's describing it, it's not what I'm after. It's one of those free apps I bought that—I thought [the fitness app] would be great, but when you actually use it, it's not the same." [37]
- Quote 67: "I think that's where it let itself down for me. Once I'd played with it, once I tried the game, done the identity and whatnot, there wasn't much else there for me." [46]
- Quote 68: "It [mindfulness app] didn't add anything...I guess it didn't detract, it didn't make anything worse, but it didn't add anything to my armoury, I guess, my tool kit, as keeping myself sane, I suppose, it didn't add." [61]

Other Factors

There were a number of sociodemographic factors that did not fit clearly under the components of the COM-B model.

Sociodemographic Factors

Apps were more frequently downloaded by women than men, with the percentage ranging from 59% to 74% [38,41,49,53,55,63], although 1 study found that being male was associated with using an app to manage alcohol consumption [65]. Being younger than 44 years was associated with a higher level of uptake and engagement [38,41,42,44,49,53,55,63,64] than older adults. Living in an urban area [42,44,55]; having a better education level, such as having high school education or higher [41,42,44,64] and college degree or higher [41,53]; and having a higher income [44] were also associated with better engagement with health and well-being apps.

Discussion

Principal Findings

This is the first systematic review to conduct a theoretical analysis using the COM-B model of factors influencing the uptake of and engagement with health and well-being apps. The findings from this review suggest that there are 26 key factors across the constructs of capability, opportunity, and motivation that influence the uptake of and engagement with these types of apps, which were found to be important for a wide range of populations and behaviors.

Our review replicates previous findings in the wider literature on digital behavior change interventions. The core findings of our review suggest that attention should be perhaps shifted mainly to the support and guidance offered to new and existing users of health and well-being apps. We found that support and guidance of uptake can be targeted by increasing their awareness of health apps through, for example, recommendations received from health practitioners. In line with the findings of previous reviews, help with initial engagement could be achieved by improving the users' app literacy skills and by providing knowledge [14,17]. We present knowledge in a novel way by breaking it down to instructions on how to use it (ie, user guidance), advice related to the target behavior or condition (ie, health information), and information on their progress or data (ie, statistical information). This suggests that allowing access to users to different information that serves different purposes (eg, health benefits vs progress data) would enhance their engagement through different channels, such as guidance, support, and education.

Potentially, one of the most important factors for engagement identified in this review is health practitioner support. In line with the emerging evidence from the human-computer interaction (HCI) literature, we found that an app coupled with human support [14,17] was likely to be more effective by increasing the intervention effectiveness and engagement [78,79]. Alternatively, human support can be impersonated by embedded artificial intelligence (AI) features. A recent experimental study found that a supportive AI-powered chatbot doubled the engagement with a smoking cessation app and increased its effectiveness [80]. This suggests that embedded human support or features that mimic human support might lead to greater engagement with digital behavior change tools.

Behavior change techniques, widely reported by others previously [14,17-19], were also identified as important factors to sustain engagement, including self-monitoring, feedback, goal setting, reminders, rewards, and social support. However, we found that not all of these have a positive effect. Reminders and social support factors (embedded social media and social competition) are not universally useful and might cause disengagement or even harm by triggering negative emotions. One plausible explanation is that the participants of the studies included may or may not have real-life experience with health and well-being apps. Some of the included studies examined participants' perceptions about a hypothetical app or an app that was planned to be developed. These studies relied on the participants' opinion of what they think would be important for them in terms of uptake of and engagement with health and well-being apps, rather than sharing their lived experiences with such tools. For example, reminders were found useful in all the

studies targeting a hypothetical app, as opposed to those that were researching engagement with an app that had been used by the participants, where opinions about reminders were mixed, with some users finding them annoying. Another explanation is that the importance of these factors might be dependent on the target behavior. For example, people using apps that target mental health might not want to engage with social competition features or to share their progress or experiences on social media. This suggests that some of the identified factors in this review might be behavior dependent.

Another interesting finding, not identified in previous literature, is the safety netting characteristic of an app. This characteristic could promote long-term engagement rather than short goal-oriented engagement. The user could disengage at any time and reengage at a later stage when needed. This feature might be particularly useful for addiction research targeting relapse prevention strategies.

No factors were coded directly under 4 out of the 14 TDF domains (optimism, social identity, beliefs about capabilities, and intentions). However, 2 of these were highlighted in this review. We described how several factors coded under different domains affect intentions (eg, having adequate app literacy skills or user guidance provided to the user), in a manner similar to how emotions, other than curiosity, affect engagement with an app (eg, lack of app literacy skills triggers negative emotions, some found reminders annoying, or some fear of social comparison related to sharing on social media). We also found that aspects of the factor *personalization to needs* also include social identity aspects. Some communities (LGBTQ+ and cancer patients) prefer an app that is personalized to their social identity. Although social identity, in this case, was judged to be a weak factor to list it independently. In terms of the other two absent domains, factors under beliefs in their capabilities and optimism might be less relevant for uptake and engagement with health apps, or the studies may have missed them out, or, potentially, we failed to identify them from the included studies.

The importance of promoting equality and embracing cultural diversity has been partially identified previously [18]. Several studies in this review reported that apps should be provided at a low cost to users. It was suggested that multiculturalism should be embraced, and regional languages should be added. The concern of inequality for those who do not own a smartphone was also raised in this review [40]. An accompanying website was suggested as an alternative for homeless people who would not have access to a smartphone but may have access to the internet through nonprofit organizations, charities, or community libraries.

Strengths and Limitations

One major strength of this paper is that it adhered to the best practice processes for undertaking reviews by following the PRISMA guidance and Cochrane handbook [27,29]. By including all study designs, we were able to pool together and triangulate evidence and provide a novel and powerful synthesis of different study designs.

The use of theoretical frameworks is another strength. Other theoretical models were considered for this review, including the technology acceptance model [81] and the HCI models and theories [82]. However, the COM-B and TDF present advantages owing to their dynamic nature and by explaining the influences between components as they were developed from, and to represent, all theoretical components in behavior change–related models and theories. COM-B was explicitly developed to inform behavior change interventions through its connection to the Behavior Change Wheel [83], a tool that provides guidance on designing behavior change interventions. The factors identified under the components of the COM-B model allow easy identification of the intervention functions to target increased uptake of and engagement with health and well-being smartphone apps.

This review has several limitations. The review focused on 4 major behaviors related to prevention (smoking, alcohol consumption, physical activity, and diet) and mental health and well-being and could not capture other prevention type behaviors (eg, fall prevention). Factors relating to the uptake and engagement of apps focusing on other behaviors or conditions may differ from those found in this review and warrant further investigation.

Although we captured a wide range of populations, most of the included studies were carried out in high-income countries. Therefore, the findings might not be transferable to low- and middle-income countries or to other cultures. The quality of the studies was mixed. In some qualitative studies, the authors provided interpretations of their findings without an explicit quotation to support them. These interpretations were handled with care and were often ignored when no further explanation was provided about a concept. This might have led to losing some potentially important factors, not identified otherwise.

Policy and Practice: Recommendations and Implications

The findings of this review can inform app developers and researchers on how to develop health and well-being smartphone apps to better support behavior change and manage and monitor different physical and mental health conditions in adults.

This review may also have implications for policies that target prevention using digital technologies. Apps are an easy way to provide health-promoting behaviors and may play an important role in prevention strategies. For example, the UK government has recently published a Green Paper entitled *Advancing our health: prevention in the 2020s*, which shifted their focus from *cure to prevention*, committing to encourage the population to live a healthier life [84]. Additionally, the *Long Term Plan* policy document of the NHS in the United Kingdom dedicates an entire chapter to prevention programs and includes plans on digitally delivered methods to improve access to information, education, and intervention [85].

As part of prevention and health management strategies, the NHS and partners have created a pool of health and well-being apps for the individuals to access (NHS Apps Library). This research could help people access effective apps that people will remain engaged with, although the extent to which the population is open to use these portals for uptake is yet unknown and something worth investigating in the future.

A number of important themes are described in the projects and policy documents mentioned above. Some relate to digital health, for example, with an aim to reduce health inequalities [84] or to improve population health with personalized content and tailored lifestyle advice [85]. Our review suggests that app literacy skills are important for uptake. Enhancing app literacy skills for the elderly (eg, drop-in sessions in community settings) might be a feasible way to reduce health inequalities. Furthermore, some of the engagement-related factors might suggest the use of tailored lifestyle advice to address health behaviors, for example, by receiving personalized content within the app and web-based or offline help or advice from health practitioners as well as receiving recommendations for use of health apps from their health care professionals and general practitioner practices.

Therefore, our findings could inform stakeholders in public health, policy makers, and providers of health and well-being smartphone app portals to provide additional support for the uptake of and engagement with these digital interventions for adults.

Recommendations for stakeholders in public health, policy makers, and health and well-being app developers derived from the findings of this review can be found in Table 3.

Table 3. Recommendations for stakeholders in public health, policy, industry, health care, and health and well-being app development.

Component	Policy makers/industry/health care providers might want to consider	App developers might want to consider
Capability	• Improving app literacy skills • Increasing awareness of effective health and well-being apps, by advertising offline (eg, general practitioner practices) and web-based (eg, social media)	• Promoting less cognitive load by enabling automatization of data collection • Including user guidance that can be deactivated once the functionality of the app has been achieved (eg, help button) • Including content that targets education, health prevention, and health consequences related to the behavior that is targeted to change • Including statistical information (eg, graphs, percentages, and numbers) about the user's progress • Including well-designed reminders where the user can choose the time and frequency of receiving it • Including the self-monitoring feature that enables users to create routines • Including a *safety netting* feature that allows users to fall back on, even when the target behavior has been achieved
Opportunity	• Providing web-based or offline health practitioner support • Providing recommendations for health and well-being apps by health care professionals • Offering apps for free or at a low cost	• Allowing the provision of health professional support within the app • Allowing community networking within the app with other users • Organizing competition and challenges for users to opt in to • Avoiding automatic synching with the embedded social media (when applicable) • Personification of the app, by designing human-type attributes • Offering apps for free or at a low cost • Offering personalization of the app according to their demographics and individual and cultural needs
Motivation	• Offering tangible rewards, such as points that could be used as a discount in pharmacies or at other health- and well-being–related domains or health insurance providers • Providing a meaningful title and clear description of what the app does and what can offer, and how can help the user	• Providing positive, nonjudgmental, constructive, and informative feedback • Include gamification elements and offering rewards • Including goal-setting features (when applicable) • Providing a meaningful title and clear description of what the app does and what can offer, and how can help the user

Future Research

Although some of the factors identified and presented in the Results section appear to have a positive influence on uptake and engagement, there are mixed findings that might benefit from further investigation, such as reminders, embedded social media, and social competition. In the studies included in the review, descriptions of notification-type messages, such as reminders, feedback, push notifications, and other notifications, were used interchangeably, and it was not always clear which notifications were being referred to. Consistent terminology would help eliminate doubt around these concepts in the future. Issues around equality and diversity were highlighted in a few studies as something future research should address. Further

work is also needed to aid our understanding of how to avoid digital health widening inequalities through the exclusion of individuals who face a financial barrier to owning a smartphone or to purchasing an app, or who do not possess the skills to use one.

Conclusions

This is the first systematic review to investigate factors that influence the uptake of and engagement with health and well-being smartphone apps. We identified 26 factors that are relevant to a wide range of populations and different behaviors. These have clear implications for improving population health and targeting health inequalities. We provide a list of recommendations built on the identified factors to guide app developers, health app portal developers, and policy makers when commissioning, developing, and optimizing health and well-being smartphone apps. These can help address the issues of suboptimal uptake and engagement, which currently constrain the public health benefit of apps.

Acknowledgments

The authors would like to thank Mathew Smith, Academic Librarian for the Faculty of Medicine and Health Sciences at the University of East Anglia, and Nicola Pearce-Smith, senior information scientist from PHE, for their thoughts on the systematic search strategy. Furthermore, the authors are grateful to Dr Katherine Deane and to the University College London Tobacco and Alcohol Research Group for their expert opinion on this research. DS was funded through a Doctor of Philosophy studentship, provided jointly by PHE and the University of East Anglia.

Authors' Contributions

The initial concept was developed by DS, TC, and FN. DS wrote the study protocol with contributions from FN, AJ, TC, and JB. DS undertook data collection (literature search, screening, data extraction, and quality appraisal), data analysis, interpretation, and report writing. FN double checked the study selection, data extraction, and data coding. FN and AJ double assessed the quality of the included studies. DS prepared the paper. All authors read, commented, and contributed to the final paper.

Conflicts of Interest

None declared.

Abstract

Background: Evidence was found for the effectiveness of virtual reality-based cognitive behavioral therapy (VR-CBT) for treating paranoia in psychosis, but health-economic evaluations are lacking.

Objective: This study aimed to determine the short-term cost-effectiveness of VR-CBT.

Methods: The health-economic evaluation was embedded in a randomized controlled trial evaluating VR-CBT in 116 patients with a psychotic disorder suffering from paranoid ideation. The control group (n=58) received treatment as usual (TAU) for psychotic disorders in accordance with the clinical guidelines. The experimental group (n=58) received TAU complemented with add-on VR-CBT to reduce paranoid ideation and social avoidance. Data were collected at baseline and at 3 and 6 months postbaseline. Treatment response was defined as a pre-post improvement of symptoms of at least 20% in social participation measures. Change in quality-adjusted life years (QALYs) was estimated by using Sanderson et al's conversion factor to map a change in the standardized mean difference of Green's Paranoid Thoughts Scale score on a corresponding change in utility. The incremental cost-effectiveness ratios were calculated using 5000 bootstraps of seemingly unrelated regression equations of costs and effects. The cost-effectiveness acceptability curves were graphed for the costs per treatment responder gained and per QALY gained.

Results: The average mean incremental costs for a treatment responder on social participation ranged between €8079 and €19,525, with 90.74%-99.74% showing improvement. The average incremental cost per QALY was €48,868 over the 6 months of follow-up, with 99.98% showing improved QALYs. Sensitivity analyses show costs to be lower when relevant baseline differences were included in the analysis. Average costs per treatment responder now ranged between €6800 and €16,597, while the average cost per QALY gained was €42,030.

Conclusions: This study demonstrates that offering VR-CBT to patients with paranoid delusions is an economically viable approach toward improving patients' health in a cost-effective manner. Long-term effects need further research.

KEYWORDS

psychosis; virtual reality; cognitive behavioral therapy; cost-effectiveness

Introduction

Psychotic disorders impose a large disease burden—morbidity plus mortality—on the population, and in its wake, substantial economic costs occur for society and health care systems. The main drivers of societal costs of schizophrenia are health care costs and productivity losses, but patients and their families also incur substantial costs [1]. Low participation rates of individuals with psychosis in the labor market are an important cause of productivity losses, while the main contributor to health care costs are in-patient psychiatric admissions [2]. All in all, treatment costs of psychotic disorders consume a significant part of health care budgets in European countries [3].

Paranoid ideation is a common delusion in individuals with a psychotic disorder. Even when medicinal treatment is successful, paranoid thoughts and anxiety often remain because of conditioned avoidance and other acquired safety behaviors in social situations [4]. Social avoidance hinders recovery in social participation for patients and keeps unemployment rates as high as 70%-85% [5,6]. A poor social network contributes to stigma and a lack of empowerment, resulting in more depressive symptoms and lower quality of life [7]. A smaller social network size is associated with more severe overall psychiatric and negative symptoms [8]. Virtual reality-based cognitive behavioral therapy (VR-CBT) was found to be an effective treatment for paranoid ideation in individuals with a psychotic disorder [9,10]. The use of virtual reality (VR) treatment in clinical practice is expected to become more widespread as VR technology becomes more readily available [11]. Therefore, information on the cost-effectiveness of this kind of treatment is required. This study was designed to evaluate whether adding VR-CBT to treatment as usual (TAU) would be effective in treating paranoid ideation in a cost-effective way with respect to improving social participation. A trial-based cost-effectiveness analysis (CEA) was conducted using data collected in seven outpatient mental health care services in the Netherlands, comparing add-on VR-CBT with TAU alone. This paper aims to determine the short-term (ie, 6-month) cost-effectiveness of VR-CBT from a societal perspective.

Methods

Research Design

The health-economic evaluation was embedded in a randomized controlled trial evaluating VR-CBT in 116 patients with a psychotic disorder suffering from paranoid ideation [10]. The VR-CBT study was a randomized, controlled, single-blind multicenter trial in two parallel groups, comparing add-on VR-CBT to TAU alone over a period of 6 months [10]. This study was approved by the Vrije Universiteit (VU University) Medical Ethics Committee for mental health service research and was registered retrospectively at the ISRCTN (International Standard Randomised Controlled Trial Number) registry (ISRCTN12929657). The trial protocol is provided elsewhere [12]. Four virtual social environments—a street, bus, café, and supermarket—were created with Vizard software (WorldViz). Within the environment, participants could move by operating a Logitech F310 Gamepad. They used a Sony HMZ-T1/T2/T3 head-mounted display with a high-definition resolution of 1280 × 720 per eye, a 51.6 diagonal field of view, and a 3DOF (3 degrees of freedom) tracker for head rotation. VR-CBT therapists were psychologists with at least basic cognitive behavioral therapy (CBT) training. They received 2 days of training in VR-CBT. The VR-CBT manual described a structured treatment plan for all 16 sessions. Therapists were supervised in a group for 4 hours every month by two VR-CBT specialists.

Recruitment

Participants were recruited at seven treatment centers in the Netherlands between April 1, 2014, and December 31, 2015. To be included, participants had to meet the following criteria: (1) 18-65 years of age; (2) DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition) diagnosis of schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, or psychotic disorder not otherwise specified; (3) suffering from at least mild paranoia, as assessed by Green's Paranoid Thoughts Scale (GPTS) (score of >40); and (4) self-report of avoiding at least one social situation. Exclusion criteria were as follows: (1) insufficient competency of Dutch language; (2) IQ below 70; and (3) a concurrent diagnosis of epilepsy. Assessments were performed at baseline and at 3 and 6 months postbaseline.

Interventions

All participants continued to receive TAU (ie, antipsychotic medication, regular contact with a psychiatrist to manage symptoms, and regular contact with a psychiatric nurse). Participants in the experimental condition also received therapist-led VR-CBT. VR-CBT treatment consisted of 16 biweekly sessions of 60 minutes each, using 40 minutes for exposure and behavioral exercises in virtual social environments. The therapist used an individual case formulation to help patients falsify their harm expectancies. No homework exercises were given between VR-CBT sessions. The treatment protocol, in Dutch, is available from the corresponding author.

Outcome Measures

Overview

We conducted both a CEA with three measures of improved social participation as outcome and a cost-utility analysis (CUA) with quality-adjusted life years (QALYs) gained as outcome. The outcome measures are described in more detail below.

Social Participation

The outcome of interest in the CEA was social participation. Social participation was operationalized in three ways: (1) objective social participation as the amount of time spent with others, (2) subjective social participation as momentary anxiety, and (3) subjective social participation as momentary paranoia. *Momentary* in this context meant that it was measured in real

life during social company. All three outcomes were assessed in real time using the ecological sampling method (ESM). ESM is a structured diary method in which individuals are asked in daily life to report their thoughts, feelings, and symptoms, as well as the appraisal of the present social context. To that end, all participants carried an electronic device (PsyMate) for the ESM assessments. The device beeped at semirandom moments 10 times a day over 6 days. At each beep, the device collected self-assessments on a 7-point Likert scale ranging from 1 (not at all) to 7 (very). A positive treatment response on each of the three outcome measures was defined as an improvement of at least 20% at 6 months follow-up relative to the patient's baseline score.

Quality-Adjusted Life Year

The outcome in the CUA was the QALY derived from the GPTS [13]. The GPTS is an established broad measure of paranoid-delusional functioning that has long been used as an outcome measure. This instrument was chosen to be able to compare results with earlier CUA research on the subject. Mean GPTS scores at each measurement were first converted into the standard mean difference (SMD) by dividing the raw mean change scores by the SD of the GPTS at baseline in the control condition. In a next step, we used Sanderson et al's conversion factor [14] of 0.1835 (ie, the average of 0.209 using a rating scale and 0.158 using time trade-off), such that a change of 1 standard unit (ie, SMD) on the GPTS is equal to a corresponding change of 0.18 utility. The utility is a quality of life valuation and is needed to compute QALY gains in the VR-CBT condition relative to the TAU condition over the full 6 months between baseline and follow-up.

Resource Use and Costing

Societal costs were computed by adding (1) the direct medical costs of health care services use including the costs of antipsychotic medication and, in the experimental condition, the additional costs of adjunctive VR-CBT treatment; (2) direct nonmedical costs of travel; and (3) indirect costs stemming from lower productivity. For each participant, cost data over the last 3 months were collected at each of three measurement points. Resource use data, for costing, were collected using the Trimbos Institute and Institute of Medical Technology Assessment Questionnaire for Costs Associated with Psychiatric Illness (TiC-P) [15]. The TiC-P is the most widely used health service interview in the Netherlands. It consists of questions on the number of contacts by type of health care provider and questions on productivity losses. A health service questionnaire is a valid and reliable method for quantifying costs in trial-based economic evaluations in health care [16]. A cross-validation sample comparing TiC-P self-report to electronic patient files showed all data to be reliable, except for the number of reported sessions with a psychologist (data available upon request from first author). Not all patients had understood that they needed to incorporate the 16 VR-CBT sessions into their TiC-P self-report. This information was, therefore, 100% cross-checked using electronic patient files. The main cost driver was admission to psychiatric hospitals, so the number of days admitted to a psychiatric hospital was also 100% cross-checked against electronic patient files and corrected where needed.

Direct medical costs were calculated by multiplying health service units (eg, sessions, visits, and hospital days) with their standard economic cost price (see Multimedia Appendix 1). We also added the medication costs, consisting of antipsychotic and antidepressant medication. Corresponding costs were calculated as the cost price per standard daily dose, as reported in the Dutch Pharmaceutical Compass [17], multiplied by the number of prescription days, plus the pharmacist's dispensing costs of €6 per monthly prescription or €12 for a first-time prescription [18].

Virtual Reality Costs

For VR therapy hardware, software and training costs were calculated. Total yearly costs for one VR system was €23,995, according to CleVR BV, a company who builds VR sets. Yearly costs for training and supervision of the psychologists was €13,400. Per-patient costs per 16 VR-CBT treatment sessions was €373.95.

Travel Costs

Travel costs arose when participants had to make return trips for receiving health care at health services. Travel costs were computed as the average distance to a health service (7 km) multiplied by the costs per km (€0.21) [18].

Productivity Costs

Research assistants monitored changes in the participants' work status at baseline and at 3 and 6 months postbaseline using the TiC-P. Productivity losses in paid work were calculated according to the human capital approach [19], reflecting changes in the contractual number of hours worked per week and adjusting these for work-loss days arising from sick leave over the full period of 6 months using gender-specific hourly productivity costs [18]. Costs were originally expressed in Euros for the reference year 2014, but indexed to 2015 using the consumer price index as reported by Statistics Netherlands. In the reference year 2015, 1 Euro in the Netherlands equaled 1.235 US$.

Statistical Analysis

Imputation

Following the CONSORT (Consolidated Standards of Reporting Trials) and CHEERS (Consolidated Health Economic Evaluation Reporting Standards) guidelines, all our analyses adhered to the intention-to-treat principle. To that end, missing values were imputed using multiply imputed chained equations (MICE) for nonparametric data with M of 100 bootstraps for each incomplete variable. Baseline variables predictive of effects (ie, QALYs and treatment response) were used for imputation, such as baseline data of the variable with missing values, treatment condition, ethnicity, education, sex, age, and safety behaviors at baseline. Safety behaviors, such as avoiding eye contact or escaping from social situations, were measured using the Safety Behaviour Questionnaire-Persecutory Delusions (SBQ-PD) [20]. *Time spent with others* showed a large difference at baseline despite randomization and was added as covariate in the CEA where *time spent with others* was used as the treatment response outcome of interest.

Main Analysis

Both the CUA and CEA were conducted from the societal perspective. In each of these analyses, the incremental cost-effectiveness ratios (ICERs) were calculated as the between-group cost difference divided by the between-group effect difference. The ICER is interpreted as the additional costs per additional unit effect (ie, per additional treatment responder; per QALY gained). Cost and effect differences were obtained from seemingly unrelated regression equations of costs and effects, thus allowing for correlated residuals in the equations. The seemingly unrelated regression equations (SURE) models were bootstrapped 5000 times. In each bootstrap step, the mean cost differences and the mean outcome differences were computed and these were plotted on the cost-effectiveness plane. Finally, cost-effectiveness acceptability curves (CEACs) were graphed. CEACs inform decision makers about the likelihood that an intervention is deemed cost-effective, given a range of willingness-to-pay ceilings for gaining 1 QALY and gaining 1 treatment responder. All analyses were conducted in Stata, version 13.1 (StataCorp).

Sensitivity Analyses

The following sensitivity analyses were carried out. First, a sensitivity analysis was done including safety behavior at baseline as a covariate because despite randomization there was a significant difference at baseline, and it was found to be the main mediator in reducing paranoid ideation [10]. Second, a sensitivity analysis was done including psychiatric admission costs at baseline as a covariate because there was a large difference between groups at baseline. Third, a sensitivity analysis was done including both safety behavior at baseline and psychiatric admission costs at baseline as covariates in the model.

Results

Overview

After providing informed consent, 116 participants agreed to participate: 58 (50.0%) in the control condition and 58 (50.0%) in the experimental condition (see Figure 1).

Baseline characteristics of the sample can be found in Table 1. Results of costs and outcomes can be found in Table 2. A small group of participants was responsible for a large portion of the baseline costs, largely related to hospital admissions. The total days of psychiatric admissions were 233 days at baseline, 101 days posttreatment, and zero days at follow-up for the VR-CBT group. The total days of psychiatric admissions were 138 days at baseline, 20 days posttreatment, and 68 days at follow-up for the TAU group.

Figure 1. Trial flow diagram. *Specification of participants lost to posttreatment: 6 declined further participation and 2 were lost due to clerical errors by therapist. ‡Specification of participants lost to follow-up: 9 declined further participation, 1 died of unrelated causes, and 2 were lost due to clerical errors by therapist. First published in Lancet Psychiatry (Pot-Kolder et al, 2018). VR-CBT: virtual reality-based cognitive behavioral therapy.

[a]VR-CBT: virtual reality-based cognitive behavioral therapy.

[b]TAU: treatment as usual.

[c]GPTS: Green's Paranoid Thoughts Scale.

[d]Scores are on a 7-point Likert scale ranging from 1 (not at all) to 7 (very).

Incremental Effects

Time Spent With Others

The treatment response rate regarding the time spent with others was 13 patients out of 58 (22%) in the control group and 24 patients out of 58 (41%) in the experimental group. The baseline-adjusted between-group difference between the response rates (ie, the incremental effect) was 0.23, which was statistically significant (SE=0.076, t_{113}=3.07, 95% CI 0.08-0.38, *P*=.003).

Momentary Anxiety

The treatment response rate with regard to momentary anxiety was 17 patients out of 58 (29%) in the control group and 24 patients out of 58 (41%) in the experimental group. The between-group difference between the treatment response rates (ie, incremental effect) was 0.12, but this difference was not statistically significant (SE=0.089, t_{114}=1.36, 95% CI –0.055 to 0.290, *P*=.18).

Momentary Paranoia

The treatment response rate in momentary GPTS paranoia was 11 patients out of 58 (19%) in the control group and 28 patients out of 58 (48%) in the experimental group. The between-group difference in the response rates was 0.29 and was statistically significant (SE=0.0841, t_{114}=3.48, 95% CI 0.126-0.460, *P*=.001).

Quality-Adjusted Life Years

The SMD of GPTS paranoia was 0.523, which was statistically significant (SE=0.120, t_{114}=4.37, 95% CI 0.285-0.760, *P*<.001). Using Sanderson et al's conversion factor [14] of 0.1835 and taking into account a follow-up period of half a year, this became a QALY gain of 0.048 (0.523 × 0.1835 × 0.5) favoring the VR-CBT condition and this was statistically significant (SE=0.011, t_{114}=4.37, 95% CI 0.026-0.069, *P*<.001).

Incremental Costs

Incremental Health Care Costs

As can be seen in Table 2, the average per-patient health care costs in the TAU group was €1396 at baseline, €648 at posttreatment, and €1039 at follow-up. The average per-patient health care costs in the VR-CBT group was €1918 at baseline, €3031 at posttreatment, and €887 at follow-up. This includes €373.95 per patient for VR-related costs included in the posttreatment costs.

The cumulative costs per patient between baseline and follow-up, including the costs of VR-CBT, were €1686 and €3917 in the TAU and VR-CBT conditions, respectively. The between-group difference was €2231 (€3917–€1686) and was statistically significant (SE=663, t_{114}=3.36, *P*=.001) when not adjusted for the initial cost difference between the conditions at baseline. After adjustment for baseline costs, the incremental health care costs became slightly less at €2170 and retained statistical significance (SE=661, t_{113}=3.28, *P*=.001).

Incremental Costs Stemming From Productivity Losses

A total of 11.2% (13/116) of the participants had paid work. The average costs stemming from productivity losses per person for the TAU group was €224 at baseline, €214 at posttreatment, and €104 at follow-up. The average costs stemming from productivity losses per person for the VR-CBT group was €553 at baseline, €359 posttreatment and €28 at follow-up. The cumulative costs per patient between baseline and follow-up were €317 and €387 in the TAU and VR-CBT conditions, respectively. The between-group difference was €70 (€387–€317) and was not statistically significant (SE=274, t_{114}=–0.26, *P*=.80).

Travel Costs

The average costs stemming from travel per person for the TAU group was €29 at baseline, €23 at posttreatment, and €24 at follow-up. The average travel costs per person for the VR-CBT group was €31 at baseline, €60 at posttreatment, and €28 at follow-up. The cumulative travel costs per patient between baseline and follow-up were €47 and €88 in the TAU and VR-CBT conditions, respectively. The between-group difference was €41 (€88–€47) and was statistically significant (SE=6, t_{114}=–6.73, *P*<.001).

Incremental Costs From the Societal Perspective

The cumulative societal costs per patient between baseline and follow-up were €2050 and €4393 in the TAU and VR-CBT conditions, respectively. The between-group difference was €2343 (€4293–€2050) and was statistically significant (SE=747, t_{114}=–3.14, *P*=.002).

Incremental Cost-Effectiveness Ratios From the Societal Perspective

The mean incremental costs for a positive treatment responder was as follows:

1. Time spent with others: €2343/0.23=€10,069.
2. Momentary anxiety: €2343/0.12=€19,525.
3. Momentary paranoia: €2343/0.29=€8079.
4. The mean incremental cost per QALY: €2343/0.048=€48,868.

Figures 2 to 4 depict the distribution of the 5000 bootstrapped ICERs over the cost-effectiveness plane for each of the social participation measures. Figure 2 depicts time spent with others, the plane illustrates 99.70% of the ICERs fall in the northeast quadrant, indicating that more QALYs are gained for higher costs. Figure 3 depicts momentary anxiety, the plane illustrates 90.74% of the ICERs fall in the northeast quadrant, indicating that more QALYs are gained for higher costs. Figure 4 depicts momentary paranoia, the plane illustrates 99.74% of the ICERs fall in the northeast quadrant, indicating that more QALYs are gained for higher costs.

Figure 5 depicts the distribution of the bootstrapped ICERs over the cost-effectiveness plane, with the vast majority of the ICERs in the northeast quadrant, indicating that more QALYs are gained but for higher costs, while 0.02% of the simulated ICERs fall in the southeast quadrant (ie, QALY gains for lower costs) for the VR-CBT group compared with the TAU group.

Figure 2. Cost-effectiveness plane and willingness to pay (WTP) acceptability curve for time spent with others.

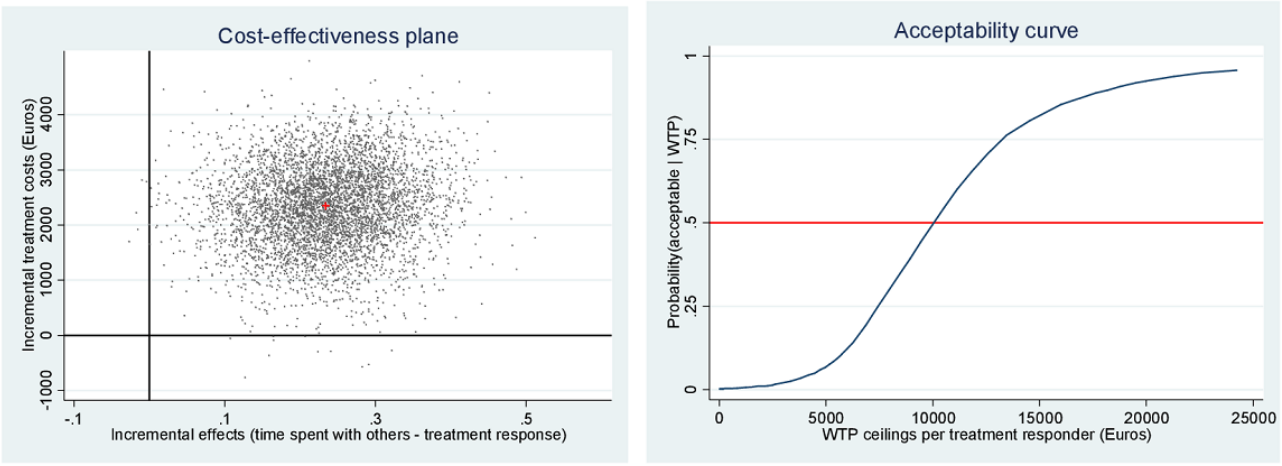

Figure 3. Cost-effectiveness plane and willingness to pay (WTP) acceptability curve for momentary anxiety.

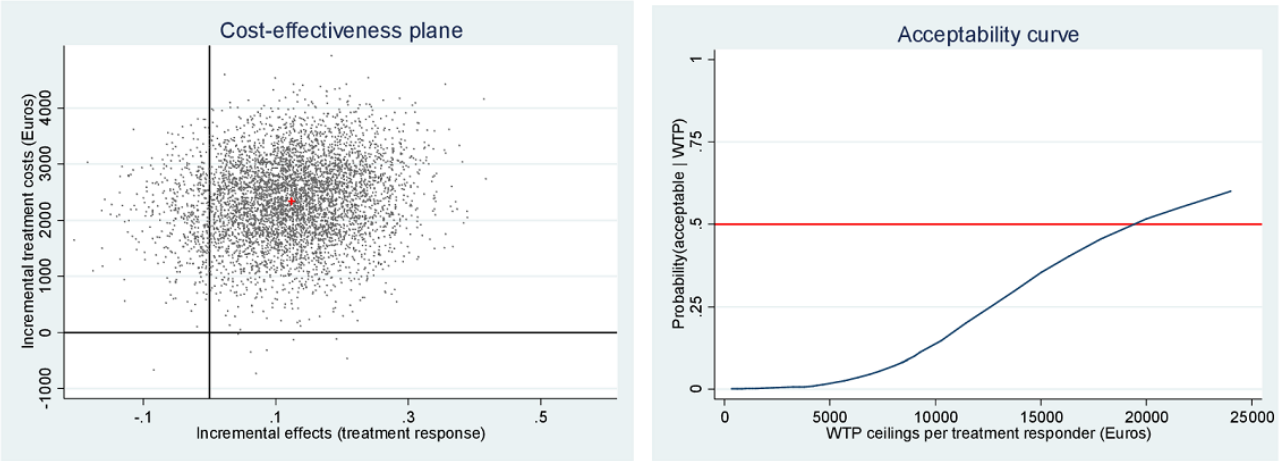

Figure 4. Cost-effectiveness plane and willingness to pay (WTP) acceptability curve for momentary paranoia.

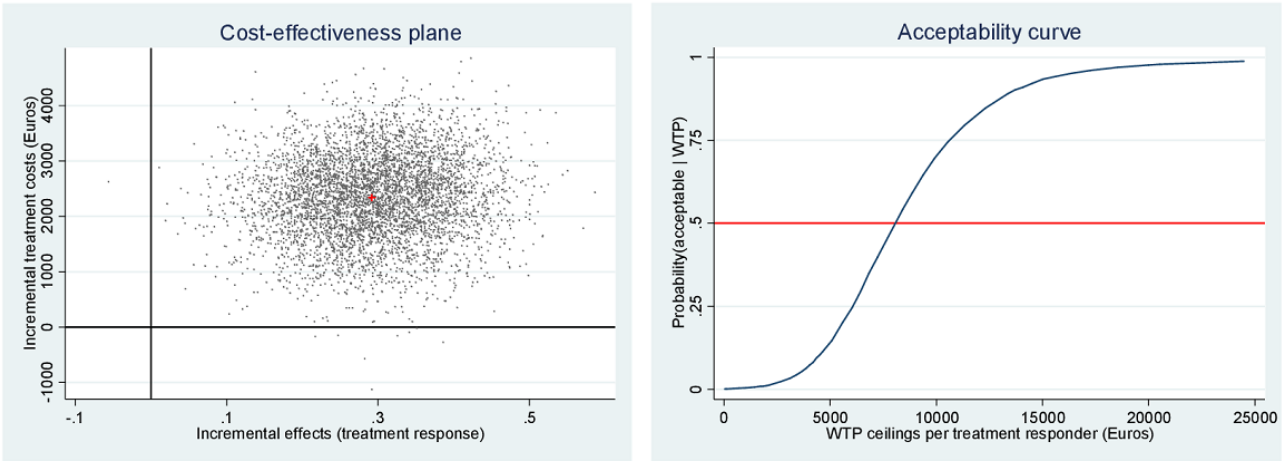

Figure 5. Cost-effectiveness plane and willingness to pay (WTP) acceptability curve for quality-adjusted life year (QALY) gain (costs per QALY gained) after 6 months.

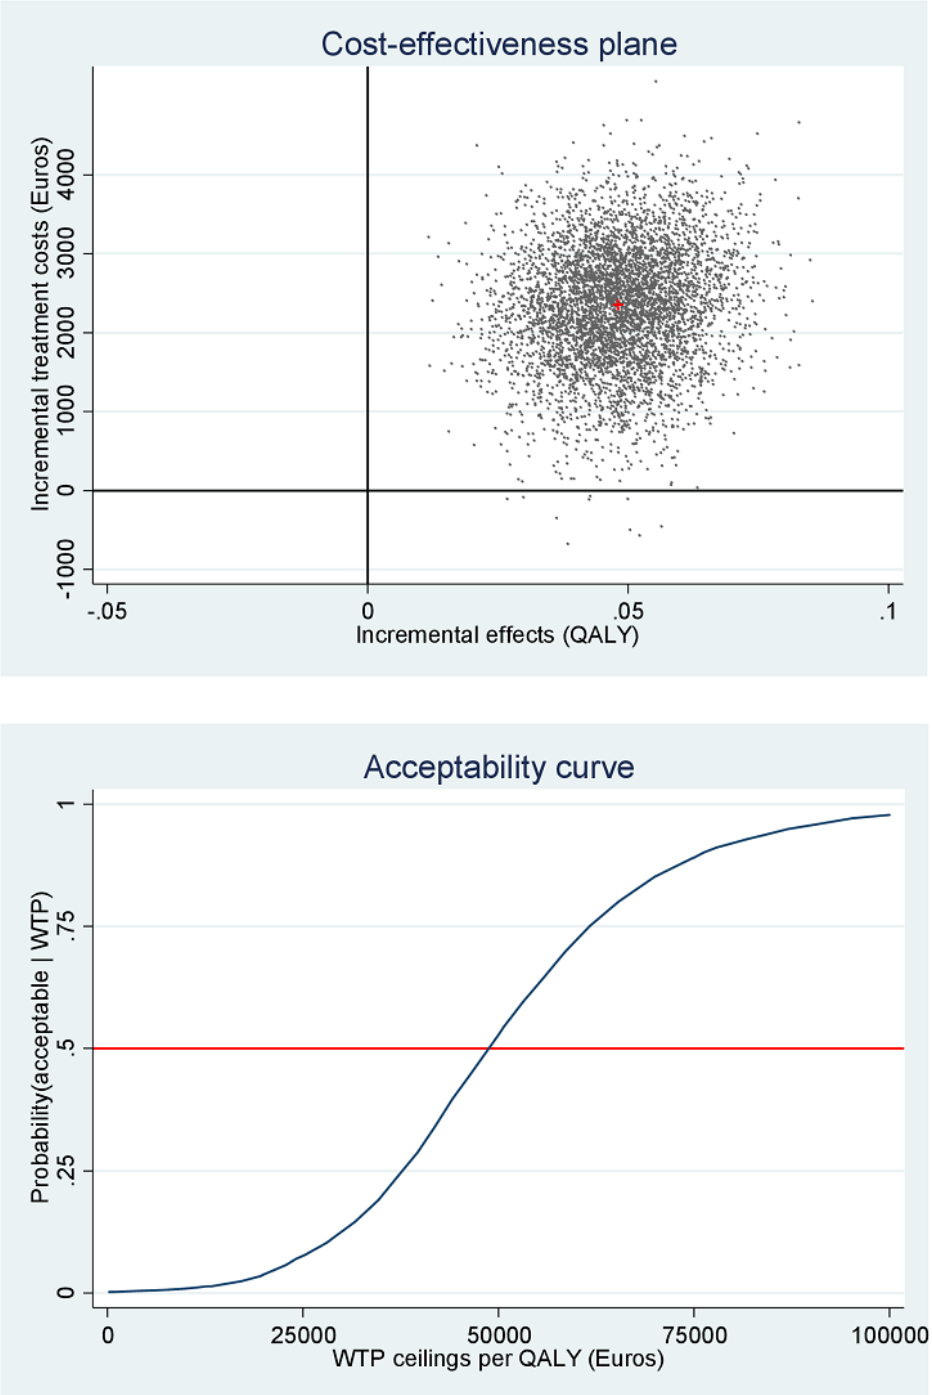

Acceptability

The mean incremental cost per QALY was €48,868. When looking at the acceptability curve in Figure 5, a higher probability that the VR-CBT intervention is deemed cost-effective can also be calculated. For an 80% certainty of cost-effectiveness, the incremental cost for gaining 1 QALY is €66,161, which falls well below the willingness-to-pay ceiling of €80,000 in the Netherlands for a severely disabling condition, such as schizophrenia characterized by paranoid delusions [21].

Looking at the three treatment responses, at 50% probability of being cost-effective, the costs are as mentioned: *time spent with others*, €10,069; *momentary anxiety*, €19,525; and *momentary paranoia*, €8079. Supposing that a decision maker needs an 80% certainty, *time spent with others* will have to be valued at €14,293 per treatment responder; *momentary anxiety* at €50,000; and *momentary paranoia* at €11,342.

Sensitivity Analysis

When including safety behavior at baseline as a covariate, the incremental costs per treatment responder on *time spent with others* became €9136; *momentary anxiety* became €17,535; and *momentary paranoia* became €7219. When including safety behavior at baseline as a covariate, the incremental costs per

QALY gained became €44,597. Overall, incremental costs were somewhat lower when the baseline difference of safety behaviors was included in the analysis.

When including psychiatric admission costs at baseline as a covariate, the incremental costs per treatment responder on *time spent with others* became €9729; *momentary anxiety* became €18,879; and *momentary paranoia* became €7750. When including psychiatric admission at baseline as a covariate, the incremental costs per QALY gained became €47,308. Overall, incremental costs were somewhat lower when the baseline difference of psychiatric admission costs was included in the analysis.

When including both psychiatric admission costs at baseline and safety behavior at baseline as covariates, the incremental costs per treatment responder on *time spent with others* became €8592; *momentary anxiety* became €16,597; and *momentary paranoia* became €6800. When including both psychiatric admission costs and safety behavior at baseline as covariates, the incremental costs per QALY gained became €42,030. Overall, incremental costs were lower when the baseline differences of both safety behaviors and psychiatric admission costs were included in the analysis.

Discussion

Principal Findings

This study aimed to get an impression of short-term cost-effectiveness of VR-CBT for patients with paranoid delusions in comparison to TAU from a societal perspective. Data were collected 6 months after baseline at follow-up. Costs per treatment responder gained were estimated to be between €8079 and €19,525 for different aspects of social participation, with between 90.74% and 99.74% showing improvement. Cost per QALY gained at follow-up was estimated to be €48,868 with 99.98% showing improved QALYs. Sensitivity analyses showed costs to be lower when baseline differences in both safety behavior and psychiatric admission costs were included in the analysis. Costs per treatment responder gained were then estimated to be between €6800 and €16,597, with cost per QALY gained at €42,030.

Results in Context

How much a society values solidarity with people burdened by disease will determine if guidelines are translated to actual treatment of patients. While the VR-CBT treatment condition is more expensive than TAU only, that was to be expected, as the aim was to add to existing treatment. Results show that this addition improves social participation for people with a psychotic disorder suffering from paranoid ideation. We see this improvement for time spent with others, momentary paranoia, momentary anxiety, and paranoid ideation, via the GPTS.

Engaging in psychological therapy is challenging for many patients suffering from paranoid ideation and treatment results vary. There are several aspects that favor VR treatment. Person-specific behavioral exposure is an important part of increasing treatment effect [22], which is exactly what the interactive VR social environments offer. Patients themselves also prefer VR over in vivo exposure treatment [23] and VR improves treatment motivation for patients [24].

Interestingly, during the follow-up we see that the VR-CBT group resulted in decreased health care costs and decreased costs due to productivity loss compared to the TAU-only group. There were no psychiatric admission days at follow-up for the VR-CBT group. To determine whether this was a coincidence or a trend, a much longer follow-up period is needed. Short-term societal costs were between €8079 and €19,525 for a positive treatment response. A disability weight of zero represents no loss of health and a weight of 1 represents health loss equivalent to death [25]. In the Netherlands, the willingness to pay for gaining a QALY ranges between €20,000 and €80,000 but differs per disease [26]. For a severely disabling disease such as schizophrenia, which according to the Global Burden of Disease study 2010 has a disability weight of 0.76, the willingness to pay is €80,000 [21,26]. In this context, the VR-CBT treatment that has an ICER of €48,868 per QALY gained can be regarded as acceptable from the cost-effectiveness point of view.

Limitations

The study has several limitations. First, data were collected only 6 months postbaseline. Any longer-term effects and costs are unknown. There are indications that cost-effectiveness for treatment of psychotic symptoms improves with time [27] as health benefits continue. Second, minimal treatment response was set at a 20% symptom reduction. A 20% symptom reduction after just 8 weeks of therapy is clinically relevant in a patient group with an average duration of illness of 14 years with persistently high problematic isolation. Third, VR-CBT was compared to TAU only. The next step would be to compare VR-CBT directly to CBT, which is the current gold standard, as CBT without VR also results in additional costs to TAU. There are, however, also indications that VR-CBT could have positive results in fewer sessions compared to CBT [9]. Comparing VR-CBT directly to CBT also allows for the study of presumed benefits of VR therapy, such as better engagement and the ecological validity of VR on outcome effects. Such a study comparing VR-CBT and CBT on *time to response* and *costs* is currently ongoing (Netherlands Trial Register number NL7758). A final limitation was that QALYs were not measured directly. As the EQ-5D (European Quality of Life Five Dimension Scale) was not administered, QALYs were calculated using Sanderson et al's conversion factor [14]. Future research needs to include the EQ-5D for direct measurement.

Conclusions

This study found VR-CBT to be cost-effective in the short term from a societal perspective. However, the effect of additional VR-CBT sessions and long-term effects need to be determined while using direct measurement of QALYs.

Abstract

Background: Basic life support (BLS) is crucial in the emergency response system, as sudden cardiac arrest is still a major cause of death worldwide. Unfortunately, only a minority of victims receive cardiopulmonary resuscitation (CPR) from bystanders. In this context, training could be helpful to save more lives, and technology-enhanced BLS simulation is one possible solution.

Objective: The aim of this study is to assess the feasibility and acceptability of our augmented reality (AR) prototype as a tool for BLS training.

Methods: Holo-BLSD is an AR self-instruction training system, in which a standard CPR manikin is "augmented" with an interactive virtual environment that reproduces realistic scenarios. Learners can use natural gestures, body movements, and spoken commands to perform their tasks, with virtual 3D objects anchored to the manikin and the environment. During the experience, users were trained to use the device while being guided through an emergency simulation and, at the end, were asked to complete a survey to assess the feasibility and acceptability of the proposed tool (5-point Likert scale; 1=Strongly Disagree, 5=Strongly Agree).

Results: The system was rated easy to use (mean 4.00, SD 0.94), and the trainees stated that most people would learn to use it very quickly (mean 4.00, SD 0.89). Voice (mean 4.48, SD 0.87), gaze (mean 4.12, SD 0.97), and gesture interaction (mean 3.84, SD 1.14) were judged positively, although some hand gesture recognition errors reduced the feeling of having the right level of control over the system (mean 3.40, SD 1.04).

Conclusions: We found the Holo-BLSD system to be a feasible and acceptable tool for AR BLS training.

augmented reality; cardiopulmonary resuscitation; automated external defibrillators

Introduction

Sudden cardiac arrest is a major cause of death in adults in developed countries [1]. As such, basic life support (BLS) is a fundamental aspect of the emergency response system. Survival rates are higher when bystanders are able to deliver early cardiopulmonary resuscitation (CPR) and defibrillation [2]. Unfortunately, although laypeople and health care providers are increasingly trained, only a minority of cardiac arrest survivors receive bystander CPR. Therefore, despite major gaps that still exist in the delivery of optimal care [3], training plays a pivotal role in saving lives [4].

The standard approach to BLS training of laypeople involves classroom-based courses consisting of skill demonstrations, hands-on practice, and lectures given by a certified trainer [5]. Simulation with manikins allows trainees to acquire and practice skills without the risk of harming the patient [6]. Debriefing provides an important learning moment in simulation sessions, as it gives participants the opportunity to critically reflect on decisions and actions performed and to learn from mistakes [7]. Although it is still a matter of debate how simulation realism influences learning outcomes [4], the importance of elements of stress and cognitive load in education has been proven, and they should be factored into the instructional design [8]. Self-directed learning systems are an effective alternative to the standard approach, which, according to multiple studies reported by the American Heart Association guidelines, show no statistical difference in learning outcomes compared with instructor-led courses [5].

In the context of self-instruction approaches, emerging technologies allow people to build new cognitive structures [7], and technology-enhanced simulation offers new models for training, which are associated with better knowledge, improved skills acquisition, and a moderate effect on patient outcomes [9]. One such emerging technology is augmented reality (AR), which enhances the user's perception by overlaying virtual objects (or "holograms") on the real-world environment [10]. AR is being applied across various disciplines in health care education including anatomy classes and surgical training [11-13]. In their integrative review, Zhu et al [14] reported that AR could improve health care education by reducing failure rates and improving accuracy.

In this study, we investigated the use of AR as an innovative technology for BLS training. The aim of this study is to assess feasibility and acceptability of Holo-BLSD, our AR prototype tool for CPR training.

Methods

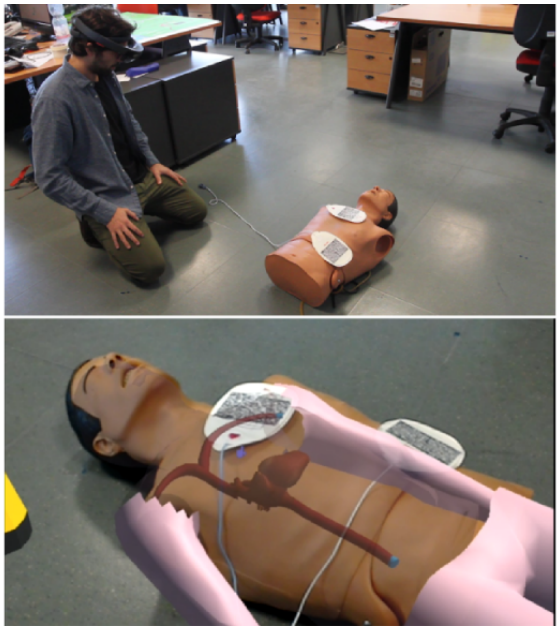
Development

Holo-BLSD was developed jointly by the SIMNOVA simulation center (Novara, Italy) and the Department of Computer Engineering of Politecnico di Torino, in collaboration with Logosnet's e-REAL Immersive Simulation Labs in Lugano, Switzerland. The app uses Microsoft's HoloLens device, a wearable headset for AR experiences, and meets the recent American Heart Association guidelines [2]. Holo-BLSD can be used in different real environments, and its contents can be adapted to where the system is being used: virtual elements can be placed and anchored in the desired position.

Since the majority of potential users are likely to have little or no experience with AR apps or the HoloLens, Holo-BLSD provides a specific training session to help users get acquainted with the system. During interaction training, all interaction types are introduced individually with detailed instructions that include vocal and visual clues.

After the interaction training, users can begin the BLS training. Holo-BLSD guides users step-by-step through the resuscitation procedure of an adult experiencing cardiac arrest. The simulated activities include the following: scene safety, in which any potential hazard should be removed; responsiveness check, performed by shaking and calling the victim; activation of local emergency medical services by using a public phone booth and interacting with a simulated operator; automated external defibrillator (AED) retrieval by asking a witness to find an AED; CPR, using a real manikin torso and superimposing a person's full body using AR (Figure 1); use of AED, once available, by directing pad placement and delivery of shock, if recommended. All generated data are logged, and a feedback sheet can be generated, allowing trainees and instructors to intuitively identify errors and strengths of the performance, thus supporting debriefing sessions and enabling the creation of a library of training events.

Figure 1. A trainee using the HoloLens device (above) and AR displayed in the trainee's field of view (below).



Participants were recruited on a voluntary basis during a national simulation-based training event for medical residents [15]. The selection of subjects represents a convenience sample, and medical background was not a required inclusion criterion. Experiments took place at the SIMNOVA Simulation Center in Novara, Italy.

The experience was divided into three phases, in which volunteers (1) learned how to use the device through the interaction training session, (2) performed a BLS simulation using the Holo-BLSD app and a standard torso manikin, and (3) filled out the evaluation questionnaire.

Software Evaluation

Participants completed a survey of 61 questions divided across six categories (user input, system output, system usability, fidelity of simulation, immersivity, likeability), and graded on a scale from 1 (strongly disagree) to 5 (strongly agree). The complete questionnaire can be found in Multimedia Appendix 1.

The results are presented with relative percentages for each of the five possible grades and summarized as mean and standard deviation. Given the explorative nature of the study, we did not plan any statistical inference tests.

Feasibility

Feasibility was assessed using the user input scale (interaction with gaze and gestures); the system output scale (quality of the display and sound); and the system usability scale [16], which is a standardized tool to evaluate interfaces based on the ISO 9241-400 guidance on ergonomic factors.

Acceptability

The remaining scales of the survey (fidelity, immersion, and likeability) were designed to assess acceptability.

Ethics and Statistical Analysis

Written informed consent was obtained from all participants, and the study results were presented in aggregate with no identifiers. The study was conducted in accordance with the principles of the Declaration of Helsinki. Descriptive statistics were calculated using Microsoft Excel (Version 2003, Microsoft Corporation).

Results

This study involved 26 participants whose characteristics are summarized in Table 1.

Feasibility

Responses to the feasibility scale are shown in Multimedia Appendices 2 and 3 and aggregated data for the system usability scale are presented in Table 2. The cognitive load required to operate the HoloLens was minimal (mean 1.77, SD 0.86) and no high physical effort was required (mean 1.19, SD 0.40). Users felt confident using the software (mean 3.62, SD 1.06). Voice (mean 4.48, SD 0.87), gaze (mean 4.12, SD 0.97), and gesture interaction (mean 3.84, SD 1.14) were evaluated positively. Words and symbols (mean 4.70, SD 0.56) and audio instructions (mean 4.43, SD 0.79) were easy to understand. Users were most critical of the quality of the display (mean 2.45, SD 1.47), although they rated it as appropriate for the function (mean 3.62, SD 1.17). Finally, users rated the system as easy to use (mean 4.00, SD 0.94).

Acceptability

Responses to the acceptability scale are summarized in Multimedia Appendices 4-6. The sensorial information provided by the AR gave participants the impression of physically being in the scenario (mean 3.52, SD 0.95). Users reported that the experience was pleasant (mean 4.13, SD 0.81) and enjoyable (mean 4.65, SD 0.57) and that the virtual contents were realistic (mean 3.74, SD 1.05). Users judged the system as capable of providing real benefit as a training tool (mean 4.22, SD 0.67).

Table 1. Respondents' demographics and characteristics[a].

Characteristic	Participants, n (%)
Gender

Table 2. Aggregated data for the system usability scale.

Question	Strongly Disagree (%)	Disagree (%)	Neither (%)	Agree (%)	Strongly Agree (%)	Mean (SD)
System Usability Scale (SUS)						
I think that I would like to use this system frequently	0.0	11.5	23.1	38.5	26.9	3.81 (0.98)
I found the system unnecessarily complex	48.0	36.0	12.0	4.0	0.0	1.72 (0.84)
I thought the system was easy to use	0.0	7.7	19.2	38.5	34.6	4.00 (0.94)
I think that I would need the support of a technical person to be able to use this system	15.4	19.2	30.8	23.1	11.5	2.96 (1.25)
I found the various functions in this system were well integrated	0.0	3.8	30.8	42.3	23.1	3.85 (0.83)
I thought there was too much inconsistency in this system	26.9	34.6	23.1	11.5	3.8	2.31 (1.12)
I would imagine that most people would learn to use this system very quickly	0.0	3.8	26.9	34.6	34.6	4.00 (0.89)
I found the system very cumbersome to use	32.0	24.0	28.0	8.0	8.0	2.36 (1.25)
I felt very confident using the system	0.0	23.1	11.5	46.2	19.2	3.62 (1.06)
I needed to learn a lot of things before I could get going with this system	57.7	26.9	11.5	0.0	3.8	1.65 (0.98)
ISO 9241-400						
The HoloLens device is too bulky or too heavy	19.2	42.3	3.8	26.9	7.7	2.62 (1.30)
The mental effort (concentration) required to operate the device was very high	46.2	34.6	15.4	3.8	0.0	1.77 (0.86)
The physical effort required to operate the device was very high	80.8	19.2	0.0	0.0	0.0	1.19 (0.40)
Arm and hands/fingers fatigue was very high	76.9	19.2	3.8	0.0	0.0	1.27 (0.53)
Eye fatigue was very high	42.3	23.1	19.2	7.7	7.7	2.15 (1.29)
Head fatigue was very high	38.5	38.5	15.4	0.0	7.7	2.00 (1.13)
I would be comfortable using the device for long time	15.4	15.4	30.8	34.6	3.8	2.96 (1.15)

Discussion

Principal Findings

Experts are paying increased attention to the realism and scenario design of CPR training. The physical features of manikins and simulators by themselves are insufficient in suspending learners' disbelief and positively influencing learning outcomes [4]. Despite ongoing advances in resuscitation science, cardiac arrest survival rates remain suboptimal and the educational efficiency of caregivers is still critical, as highlighted in 2003 [17] and 2018 [3]. Education facilitated through technology has been identified as a strategy to improve the effectiveness of BLS training. We developed the Holo-BLSD app using Microsoft's HoloLens technology as an AR self-instruction learning environment for training and assessment of CPR and AED use, by using high definition holograms to immerge trainees in realistic scenarios, and a standard low-cost torso manikin to deliver tactile feedback. In this pilot study, we measured the feasibility and acceptability of our first prototype of the training app.

An excessive cognitive load may impair participants' perceptions and performance, decreasing attention and problem-solving skills [6], and physical effort and fatigue may reduce user enjoyment of the experience. Despite these conditions, users rated the system as easy to use and they judged the learning experience as pleasant and enjoyable. Volunteers reported that the mental effort required to operate the device was minimal. Similarly, users indicated that the head-mounted display was comfortable. Unlike other head-mounted displays, such as the Google Glass used in Chaballout's study [6], no delay between the real and virtual environment was experienced.

Some users noted that ambient light affected the quality of the holograms and made visual instructions difficult to interpret. Users judged the lack of peripheral view, which is known to increase cognitive load [18], as a major limitation. The assembled environment was considered complex enough to be of use, allowing users to focus on the tasks without leaving them disoriented. It is worth noting that trainees found the virtual contents realistic, stating that the system could provide a real benefit as a training tool and help practitioners be more effective.

In this study, we presented preliminary evidence that validated the Holo-BLSD app as a BLS training tool. Additional studies comparing traditional instructor-led training with low and high-fidelity simulation or other models will be useful.

Limitations

The limitations of the study are the small number of participants, which makes it difficult to draw clear conclusions about the benefit of the proposed technology on learning outcomes. Nevertheless, this study was intended to provide a proof of concept and to measure the feasibility and acceptability of AR technology in a life support simulation. To this end, positive user responses indicate that future studies are warranted.

Conclusions

AR is in the early stages of application within health care education, but it has enormous potential. In this study, we presented Holo-BLSD, an AR system for BLS training that offers realistic haptic feedback through a manikin and a virtual scenario that can be easily reconfigured to generate different situations, including extreme and dangerous ones. We found the proposed application to be feasible and acceptable as a tool for self-instruction training. The positive outcomes of this preliminary study make this prototype worthy of future testing.

Abstract

Background: The language gap between health consumers and health professionals has been long recognized as the main hindrance to effective health information comprehension. Although providing health information access in consumer health language (CHL) is widely accepted as the solution to the problem, health consumers are found to have varying health language preferences and proficiencies. To simplify health documents for heterogeneous consumer groups, it is important to quantify how CHLs are different in terms of complexity among various consumer groups.

Objective: This study aimed to propose an informatics framework (consumer health language complexity [CHELC]) to assess the complexity differences of CHL using syntax-level, text-level, term-level, and semantic-level complexity metrics. Specifically, we identified 8 language complexity metrics validated in previous literature and combined them into a 4-faceted framework. Through a rank-based algorithm, we developed unifying scores (CHELC scores [CHELCS]) to quantify syntax-level, text-level, term-level, semantic-level, and overall CHL complexity. We applied CHELCS to compare posts of each individual on online health forums designed for (1) the general public, (2) deaf and hearing-impaired people, and (3) people with autism spectrum disorder (ASD).

Methods: We examined posts with more than 4 sentences of each user from 3 health forums to understand CHL complexity differences among these groups: 12,560 posts from 3756 users in Yahoo! Answers, 25,545 posts from 1623 users in AllDeaf, and 26,484 posts from 2751 users in Wrong Planet. We calculated CHELCS for each user and compared the scores of 3 user groups (ie, deaf and hearing-impaired people, people with ASD, and the public) through 2-sample Kolmogorov-Smirnov tests and analysis of covariance tests.

Results: The results suggest that users in the public forum used more complex CHL, particularly more diverse semantics and more complex health terms compared with users in the ASD and deaf and hearing-impaired user forums. However, between the latter 2 groups, people with ASD used more complex words, and deaf and hearing-impaired users used more complex syntax.

Conclusions: Our results show that the users in 3 online forums had significantly different CHL complexities in different facets. The proposed framework and detailed measurements help to quantify these CHL complexity differences comprehensively. The results emphasize the importance of tailoring health-related content for different consumer groups with varying CHL complexities.

consumer health informatics; readability; digital divide; health literacy

Introduction

Background

The language gap between laypersons (health consumers) and health care professionals has been long recognized as the main hindrance to effective health communication and health information comprehension [1-3]. When interpreting health documents written mainly in professional language, consumers often depend on their own language to *fill in* the comprehension gap (eg, *depression* vs *depressive disorder*), which might lead to misinterpretation. Accordingly, it has also been widely agreed that health consumers should be given access to resources in their own languages [3-6]. To improve the readability of health-related content for average health consumers, there has been increasing interest in examining consumer health vocabularies [2,7], health readability measurement [8-10], and automated health text simplification approaches [11-14]. Studies on consumer health vocabularies have largely focused on extracting and building a terminology system of lay health terms used by average health consumers [2,7]. Health readability assessments have focused on developing linguistic metrics to quantify the text complexity of health content generated by health experts and professionals [9,13,15,16]. On the basis of the findings in both areas, automated health text simplification usually focuses on simplifying difficult texts with respect to 1 or 2 aspects (eg, medical jargon, long sentences) [1,11,12,14,18,19].

However, without a comprehensive understanding of the complexity difference between professional health language and consumer health language (CHL), current automated simplification approaches are inadequate to accurately determine what needs to be simplified and to what extent they should be simplified. Also, current simplification approaches assume that consumers share the same CHL preferences and that simplifying text to its lowest complexity can satisfy all users. For example, in synonym replacement tasks, researchers typically identify difficult medical words and then replace them with easier synonyms [12,19]. These one-size-fits-all automated simplification approaches ignore the diverse simplification needs of different health customers. Research suggests that consumers with varying health literacy levels have different CHL preferences [20-22]. In addition, contextual and sociocultural factors are found to affect the language preferences of different consumer groups to think, express, and communicate health-related topics [3]. For example, compared with average health consumers, cancer patients would be more familiar with cancer-related professional health terms (eg, genetic predisposition). Another drawback of this one-size-fits-all approach is that simplifying health content by replacing terms with lay alternatives with the lowest complexity may affect information accuracy and may inadvertently increase the length of the text [23]. In other words, an adaptive simplification approach that can balance simplicity, accuracy, and sentence length for user groups with various CHL preferences is ideal.

In this paper, CHL has been defined as a system of vocabularies, expressions, and grammar that is commonly used by a group of health consumers in thinking, expressing, and communicating their health-related topics. CHL complexity is defined as a combined measure of varying linguistic metrics, each of which quantifies the complexity of one linguistic feature of a CHL (eg, semantics, syntax, term). The goal of adaptive health text simplification is to simplify the professional health language used in Web-based health content to match the CHL complexities of targeted consumer groups. To quantify the CHL complexity differences for simplification purposes, the linguistic complexities of CHLs used by various health consumer groups should be investigated. The increasing availability of user-generated Web-based health communications (eg, blogs, online communities, social question and answer [Q&A] websites), provides us with ample opportunities to assess CHL complexity through automated text analysis [2,7,24].

Studies focused on health readability assessment typically quantify the complexity of Web-based health content written by health professionals for health consumers [25-27]. Researchers have developed complexity metrics that utilize a combination of various extracted linguistic features to assess the complexity of Web-based health content [9,13,16]. The metrics utilized in previous literature can be categorized into 4 groups, namely, text-level complexity (eg, syllables per word) [16,28], syntax-level complexity (eg, distributions of parts of speech [POS]) [16,29], term-level complexity (eg, density of professional medical terms) [15,16], and semantic-level complexity (eg, diversity of semantics) [15]. Examining how these linguistic features differ among various CHLs can help us gain a more accurate and comprehensive understanding of CHL complexity.

Objectives

In this proof-of-concept study, we developed an informatics framework (consumer health language complexity [CHELC]) to assess CHL complexity based on existing health text readability metrics and apply this framework to explore complexity differences in CHL in 3 online forums designed for the general public, deaf and hearing-impaired people, and people with autism spectrum disorder (ASD). In previous studies, the latter 2 groups have been found to have relatively low health literacy [30-33], different language use behaviors [34,35], and limited access to adaptive health information services [36]. People with ASD were found to be repetitive and expressive by composing long sentences and words on the Web [35,37,38]. Pollard and Barnett [39] found that even highly educated deaf adults showed significant difficulty in understanding health vocabularies used in the Rapid Estimate of Adult Literacy in Medicine test. In addition, compared with the general population, deaf and hearing-impaired people exhibit significantly lower levels of health literacy and health knowledge [32]. Accordingly, ASD and deaf and hearing-impaired user groups might use less complex CHL, especially less complex health terms in their expressions. Motivated by these observations, in this study, we explore the use of different measures to assess CHL complexity and provide insights for the development of adaptive health text simplification tools to address the needs of various consumer groups.

We formulated 2 research questions (RQs) in this study:

- RQ1: What is the feasibility of using CHELC, which combines text-level, syntax-level, term-level, and semantic-level measures for examining CHL complexity among users in 3 distinct online forums designed for the general public, people with ASD, and deaf and hearing-impaired people?
- RQ2: How do the CHLs of users in online forums designed for the general public, people with ASD, and deaf and hearing-impaired people differ in complexity on the text level, syntax level, term level, and semantic level?

Methods

Consumer Health Language Complexity Measurement Framework

We built CHELC to incorporate a comprehensive array of linguistic complexity metrics developed in previous research. In this framework, we incorporated metrics of text-level, syntax-level, term-level, and semantic-level CHELC scores (CHELCS) to compare various CHLs through a rank-based algorithm. The overall complexity of CHL ($CHELCS_{overall}$) was defined as the average value of 4 complexity scores.

We systematically reviewed the metrics that have been utilized in health readability and complexity assessment studies and comprehensively included credible metrics from all facets of linguistic measures. We performed the search on PubMed using the search terms of *health readability* to retrieve relevant articles and abstracts, which returned 3605 full-text articles to be screened. After excluding duplicates, non-English articles, and articles not about health readability evaluation or assessment, 9 studies with different assessment metrics were identified (Table 1).

Considering the overlap between lay and professional health terms, we proposed to use the ratio of core professional term coverage, which is the percentage of health terms that are in the Systematized Nomenclature of Medicine-Clinical Terms (SNOMED-CT) but not in consumer health vocabulary (CHV). In total, we included 8 metrics for text-level, syntax-level, term-level, and semantic-level complexity measurements in the proposed framework CHELC (Figure 1).

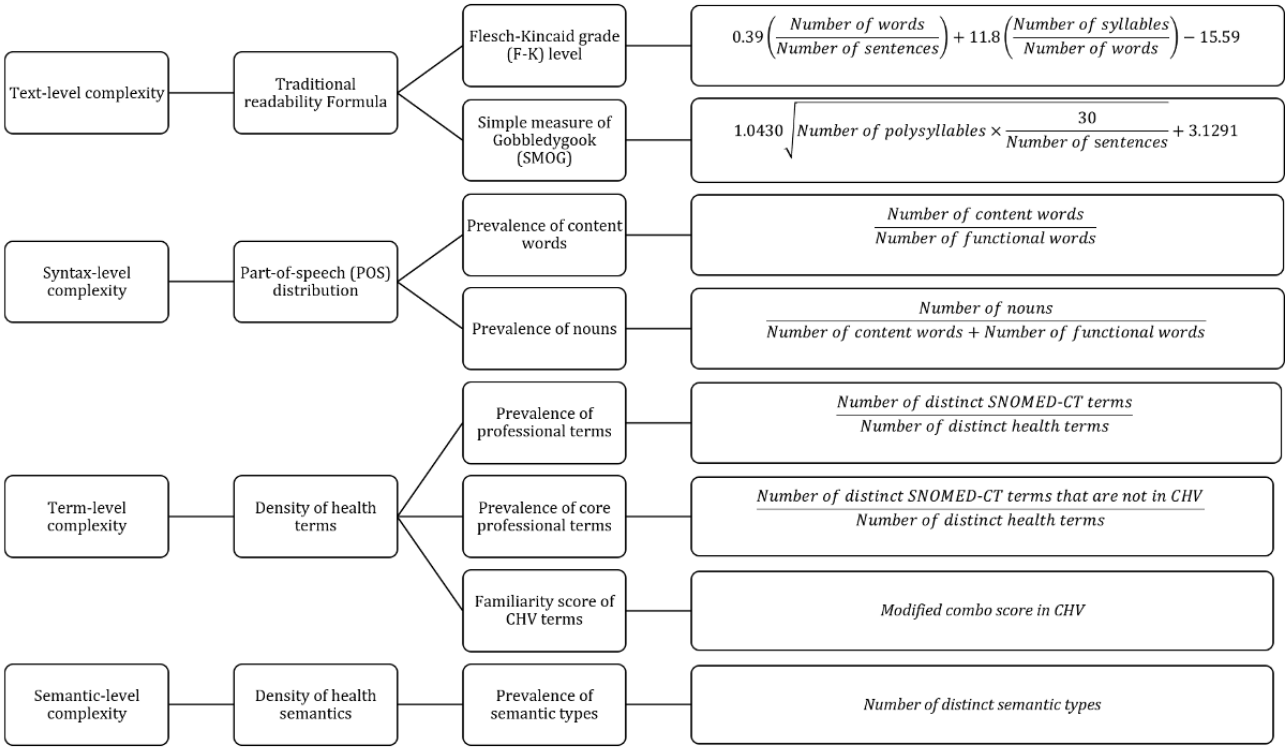
Table 1. Existing metrics for assessing health text complexity.

Health readability measure	Measure specification	Inclusion	Inclusion or exclusion rationale
Text level			
Word length or syllable length [16,28]	Average number of characters (eg, syllables) in a given lexical item	No	Already measured in traditional readability metrics
Sentence length [16,28]	Average number of words in a sentence	No	Already measured in traditional readability metrics
Paragraph length [16,28]	Average number of sentences in a paragraph	No	Not applicable for CHL[a] complexity measure
Traditional readability metrics [10,25,26,40,41]	Flesch-Kincaid grade level, Simple Measure of Gobbledygook, and Gunning fog	Yes	(1) Well-established formulas that are widely utilized in the literature; (2) Combining word, syllable and sentence length; and (3) Flesch-Kincaid grade and Simple Measure of Gobbledygook are the most used readability metrics
Syntax level			
Ratio of content word [15,42]	Ratio of content words (ie, noun, adjective, verb, and adverb) to functional words (ie, pronoun, determiner, preposition, qualifier, conjunction, interjection)	Yes	Indicator for syntax-level complexity measure; validated in previous literature
Ratio of nouns [16,42]	Ratio of nouns to all types of parts of speech	Yes	Indicator for syntax-level complexity measure; validated in previous literature
Term level			
Average familiarity score of CHV[b] [17,28]	Frequency use of each CHV term to the lay people	Yes	Indicator to tell how lay health terms are used in CHL
Coverage in CHV [15]	Ratio of CHV terms of all terms	No	We used the ratio of professional health terms
Coverage in basic medical dictionary [16]	Health terms that are in basic medical dictionaries	No	Not applicable for CHL complexity measure
Coverage in the Unified Medical Language System [15,16]	Ratio of Unified Medical Language System terms	Yes	We utilized the Systematized Nomenclature of Medicine-Clinical Terms as the source of professional health terms
Term overlap ratio [17]	A higher overlap indicates a more cohesive and easier to read text; overlapped terms/all terms in the document	No	Not applicable for CHL complexity measure
Vocabulary size [16]	Distinct word counts in the corpus	No	Not applicable for CHL complexity measure
Style level			
Semantic level			
Diversity of health topics [15]	Ratio of semantic types indicated in the Unified Medical Language System	Yes	Indicator for semantic-level complexity measure; validated in previous literature

[a]CHL: consumer health language.

[b]CHV: consumer health vocabulary.

Figure 1. Consumer health language complexity measurement framework (CHELC).



Text-Level Complexity

Text-level complexity utilizes the length of lexical units (eg, words, sentences, paragraphs) to indicate the lexical complexity of health texts. The unit may change depending on whether the length is applied to words (average number of syllables/characters per word) [16], sentences (average words per sentence) [28], or paragraphs (average sentences per paragraph) [16]. As a commonly used metric, it assumes that longer lexical units require more cognitive loads, thereby making the text more complex. Most studies have utilized one or more readability formulas (eg, the Flesch-Kincaid grade level [F-K] and Simple Measure of Gobbledygook [SMOG]) to assess text-level complexity, in which word length or sentence length are considered in the grade level ranking or level of difficulty of the health texts [10].

For text-level complexity, we applied F-K [43] and SMOG [44] to quantify the text-level complexity of CHL. The F-K formula assigned a grade level to indicate the minimum schooling (grade) readers should have to understand the text. The formula assumes that the higher the average number of syllables and words per sentence there are, the more complex the text is [43]. A grade lower than 5.0 indicates that the text is very easy to comprehend. A grade higher than 12.0 indicates greater difficulty and reading level that requires a college degree or above. Similarly, the SMOG formula considers the number of polysyllabic words [44]. Essentially, the more polysyllabic words, the higher the SMOG score, and the more difficult the texts are.

Syntax-Level Complexity

Syntax-level complexity utilizes POS distribution to evaluate the complexity of health texts [29]. In general, there are 10 commonly used POS types in English, which can be categorized into content words (ie, noun, adjective, verb, adverb) and functional words (ie, pronoun, determiner, preposition, qualifier, conjunction, interjection). Every word in the health text can be assigned a POS tag. A higher proportion of noun words or content words indicates more complex health texts [16]. Accordingly, we calculated the ratio of (1) noun words to all POS words and (2) content words to functional words used by each user. We assume that the higher the ratio is, the more complex the CHL is.

Term-Level Complexity

Term-level complexity focuses on the complexity related to the density of professional or lay terms (eg, *myocardial infarction* vs *heart attack*). According to health readability research, the more professional terms and fewer lay terms there are, the more complex are the health texts [16]. By mapping terms to existing controlled vocabularies, previous studies have typically measured the term-level complexity with the prevalence of professional terms or lay terms [6,15,16]. Other studies have also utilized the familiarity scores of consumer health terms (provided in CHV) and term cohesiveness (ie, distinct word count or overlapped term ratio) to measure the term-level complexity [16,28,].

To assess the term-level complexity of the health text, we first used the text processing and entity recognition tool MetaMap [45] to extract health terms that belong to 84 out of 127 semantic types in the Unified Medical Language System (UMLS, a compendium of over 190 medical controlled vocabularies) that are relevant to biomedicine, health, and nutrition [46,47]. Then we evaluated the density of professional terms and lay terms by mapping our extracted health terms to 2 controlled vocabularies in the UMLS: CHV and SNOMED-CT. CHV contains a collection of lay health concepts and expressions

commonly used by health consumers in their everyday communications [3]. We used the 2015AA version, which includes the latest version of CHV with over 116,324 terms [3]. SNOMED-CT is the world's largest standardized vocabulary of clinical and medical terms mostly used in health information systems such as electronic health records [48-50]. In this study, CHV was used to evaluate the usage of lay health terms, whereas SNOMED-CT terms were referred to as professional terms. We developed the following 3 measures to evaluate term-level complexity:

- Prevalence of professional terms: we used the ratio of professional terms (number of distinct SNOMED-CT terms) to all health-related terms (number of distinct health terms) to measure the density of professional terms used by each user in a health corpus. We assumed that the higher the ratio is, the more complex is the CHL.
- Prevalence of core professional terms: we first excluded CHV terms from SNOMED-CT terms to obtain the core professional terms (professional health terms that are not commonly used by laypersons), and used the ratio of core professional terms to all health-related terms to measure the density of core professional terms used by each user in a health corpus. We assumed that the higher the ratio is, the more complex is the CHL.
- Familiarity score of CHV terms: it refers to the familiarity of each CHV term to laypersons [17]. It is also referred to as the combo score in CHV, which combines frequency score (term difficulty based on its frequency in several large text corpora), context score (term difficulty based on its context), and Concept Unique Identifier score (term difficulty derived from how it is close to well-known easy and difficult concepts in the UMLS). We used a modified combo score that ignores easy words from the Dale-Chall list [17,51]. The higher the score is, the easier the term is. We calculated the average familiarity score of terms written by each user. We assumed that users using more complex CHL have a relatively low average familiarity score for the CHV terms.

Semantic-Level Complexity

Semantic-level complexity refers to the complexity of the diversity of the semantics of health texts. Previous studies have found that if the health text includes more diverse health topics, it is more complex [10]. Operationally, the coverage of semantic types in the UMLS was accounted for semantic-level complexity [47].

We extracted the health terms using MetaMap and counted the average distinct semantic types of the terms used in CHL. We assume that if a user mentioned more distinct semantic types, his or her CHL is more complex.

Consumer Health Language Complexity Scores

We regarded CHL complexity as a 4-faceted variable, which includes metrics related to text-level, syntax-level, term-level, and semantic-level complexity. Each corpus was represented by a vector of 8 metrics for complexity computation. The values of all 8 metrics were generated for every user in the health corpus.

For each metric, the values for users in all health corpora were ranked [52,53] using the same mechanism of Wu et al [16]. In other words, the ranking value for each metric for users was indicated as the complexity differences among users [54,55]. Except for the familiarity score of CHV terms, the higher the metric value is, the more complex the user's health language is. It should be noted that we ranked the familiarity score of CHV terms in reverse order. All the missing values of metrics were replaced by the mean of the corresponding metric.

In this proof-of-concept study, each metric in a facet was regarded to contribute equally to the complexity score of that facet. As there is no agreed-upon definition of health text complexity, each facet has equal weight when calculating the overall complexity score ($CHELCS_{overall}$). The idea of aggregating the metrics is that described by Wu et al [16]. We aggregated the ranks of metrics for each facet using standard aggregate functions with the same weights [56]. Other researchers can use different weights for each metric or facet based on their definitions of CHL complexity.

Let f_{ij} be the j^{th} observed metric value of the i^{th} facet and f'_{ij} be the j^{th} observed metric value of the specific user whose complexity is calculated in the i^{th} facet.

The formula of $CHELCS_{overall}$ for every user in the health corpora was as follows:

We defined r_{ij}, the rank of the j^{th} metric of the i^{th} facet, as the number of users whose f_{ij} is not greater (not smaller for metric *familiarity score of CHV terms*) than $f'_{ij.}$ Note that m represents the number of facets, n_i represents the number of metrics in the i^{th} facet, and N is the total number of users.

We calculated the aggregated rank of the metrics for all facets of CHL complexity. We defined r_{ij}/N as the normalized rank ranging from 0 to 1. Then the aggregated complexity score of the i^{th} facet is calculated as  . The overall complexity score of all facets is calculated as  , which is used to represent the overall CHL complexity of every user. All CHELCS range from 0 to 1, and the higher score means the responding user has more complex CHL complexity in all health corpora.

Data Collection

We utilized CHELC, a complexity measure framework that combines text-level ($CHELCS_{text}$), syntax-level ($CHELCS_{syntax}$), term-level ($CHELCS_{term}$), semantic-level ($CHELCS_{semantic}$), and overall ($CHELCS_{overall}$) complexity scores, to compare the CHLs used in online forums targeting 3 user groups: general public, people with ASD, and deaf and hearing-impaired people. We collected data from various online discussion boards and social media to represent the CHL use of our groups of interest. All 3 data sources in this study were chosen because of their popularity in our interest groups and the convenience of data collection.

We chose AllDeaf [57], a leading online community for deaf and hearing-impaired people who can communicate in English. As of June 2017, AllDeaf had 63,566 members and 114,801 threads. This community has 22 forums in which people can communicate different aspects of everyday life concerns related to deafness, such as sign language, assistive technologies, and health. The majority of the health-related issues are discussed in the forum *Lifestyle, Health, Fitness & Food*. After manually removing the threads that were unrelated to health (eg, food recipes), we retained 1639 threads and 31,006 posts from that forum, which includes health discussions from 2005 to 2016.

Another data source was Wrong Planet [58], which is the main English-language online community developed for people with ASD to discuss everyday life topics. It has 37,350 members and 290,067 threads. Similar to AllDeaf, Wrong Planet has 29 forums. Their users mainly discuss health-related topics in the forum *Health, Fitness & Sports*. After manually removing unrelated threads in that forum, we obtained 2816 threads and 31,194 posts, covering health discussions from 2004 to 2017.

To represent the use of health language by general health consumers, we selected general health discussions in Yahoo! Answers, which is one of the most popular social Q&A sites used by people to discuss health and other life topics. To make the sample size comparable to those collected from AllDeaf and Wrong Planet, we generated a random sample of 8000 questions and their respective answers in the health category, resulting in 34,048 posts from 2009 to 2014.

Data Processing and Analysis

We extracted health-related posts in the 3 forums and calculated CHELCS for each user using text-level ($CHELCS_{text}$), syntax-level ($CHELCS_{syntax}$), term-level ($CHELCS_{term}$), semantic-level ($CHELCS_{semantic}$), and overall ($CHELCS_{overall}$) complexity. As it is not feasible to analyze behavioral patterns for users contributing to few discussions, we only analyzed posts from users who contributed more than 4 sentences per post on average. For the term-level analysis, we only included users who used more than 20 distinct health terms per post. For text- and syntax-level metrics, we generated the scores for each post through a Web-based readability measurement tool [59] and then calculated the complexity score for each user in the 3 corpora using a rank-based algorithm. For the term coverage and semantic analysis, we analyzed the data in MySQL (Oracle Corporation) and Microsoft Excel. We visualized the distributions using $CHELCS_{text}$, $CHELCS_{syntax}$, $CHELCS_{term}$, $CHELCS_{semantic}$, and $CHELCS_{overall}$ for users in each group in Microsoft Excel. Then we employed a 2-sample Kolmogorov-Smirnov test (K-S test) to determine if the CHELCS of the various groups were significantly different. We conducted an analysis of covariance (ANCOVA) to control for possible impacts of sentence number per post on CHELCS when comparing CHL complexity scores of the 3 groups. More detailed comparison results of 3 groups in 8 metrics were presented in Multimedia Appendix 1, and correlations of CHELCS scores were analyzed in Multimedia Appendix 2. K-S test and ANCOVA were performed in R software (The R Foundation for Statistical Computing).

Results

Basic Characteristics of the Corpora

As seen in Table 2, although we extracted similar numbers of posts from the 3 corpora regardless of the number of sentences, the numbers of posts with more than 4 sentences were different among the 3 groups. Compared with the other online forums, Yahoo! Answers had the fewest number of posts, the most threads, and involved the most users, but had the least number of distinct health terms contributed by the average user. This might be because of the differences between specialized online forums that are closed communities and general social Q&A sites that are open to the public [60]. However, the 3 corpora did not have major differences in the number of sentences, sentence lengths, and word lengths, implying that platform differences would not significantly impact the overall CHL used in each community. The 3 user groups shared 68 out of 84 health semantic types in the UMLS.

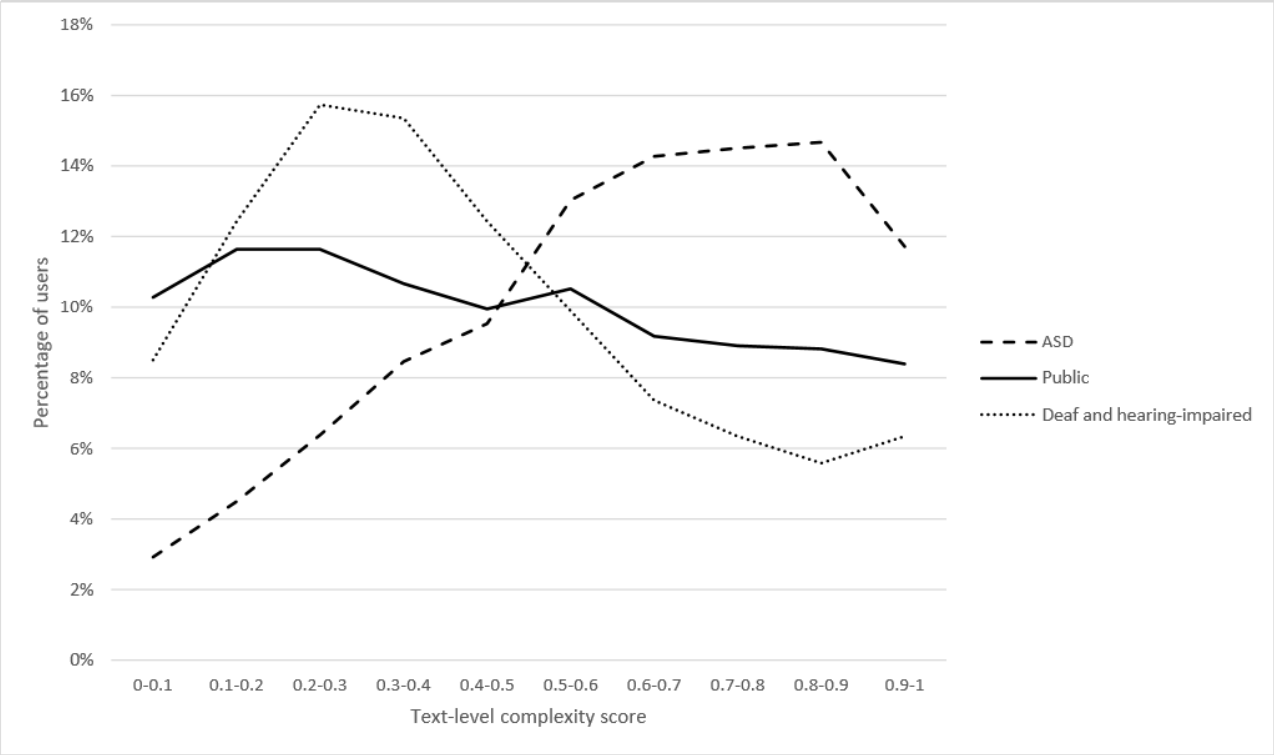
Table 2. Basic textual characteristics of the 3 health corpora.

Basic textual characters	Health corpora		
	AllDeaf (deaf and hearing-impaired people), n	Wrong Planet (people with ASD), n	Yahoo! Answers (general public), n
Number of posts	27,545	26,484	12,560
Number of threads	1623	2751	3756
Number of involved users	788	2978	9544
Average number of sentences per post per user	9.21	9.15	9.63
Average number of words per sentence per user	12.14	13.99	13.09
Average number of syllables per word per user	1.37	1.41	1.35
Average number of letters per word per user	4.14	4.23	4.11
Distinct health terms per user	199.87	91.63	39.09
Mentioned semantics number	71	71	72

Text-Level Complexity

The $CHELCS_{text}$, which ranges from 0 to 1, indicates the text-level complexity ranking of the individual user among all users in the 3 online forums. Figure 2 shows the distribution of text-level complexity scores of users in 3 corpora.

Figure 2. Text-level complexity comparison for users in the 3 health corpora. ASD: autism spectrum disorder.



The 2-sample K-S test results indicate $CHELCS_{text}$ scores of people with ASD, deaf and hearing-impaired people, and the general public were significantly different ($D_{d\text{-}a}$=0.332, $P_{d\text{-}a}$<.001; $D_{d\text{-}p}$=0.108, $P_{d\text{-}p}$<.001; $D_{a\text{-}p}$=0.228, $P_{a\text{-}p}$<.001 [d-a refers to score comparison between *$CHELCS_{text}$ of deaf and hearing-impaired users* and *$CHELCS_{text}$ of users with ASD*; d-p refers to score comparison between *$CHELCS_{text}$ of the deaf and hearing-impaired users* and *$CHELCS_{text}$ of the general public*; a-p refers to score comparison between *$CHELCS_{text}$ of userswith ASD* and *$CHELCS_{text}$ of the general public*]). As seen in Figure 2, most deaf and hearing-impaired users wrote texts with lower complexity, whereas users with ASD used more complex texts in their posts. General public users did not significantly differ in their use of polysyllabic words.

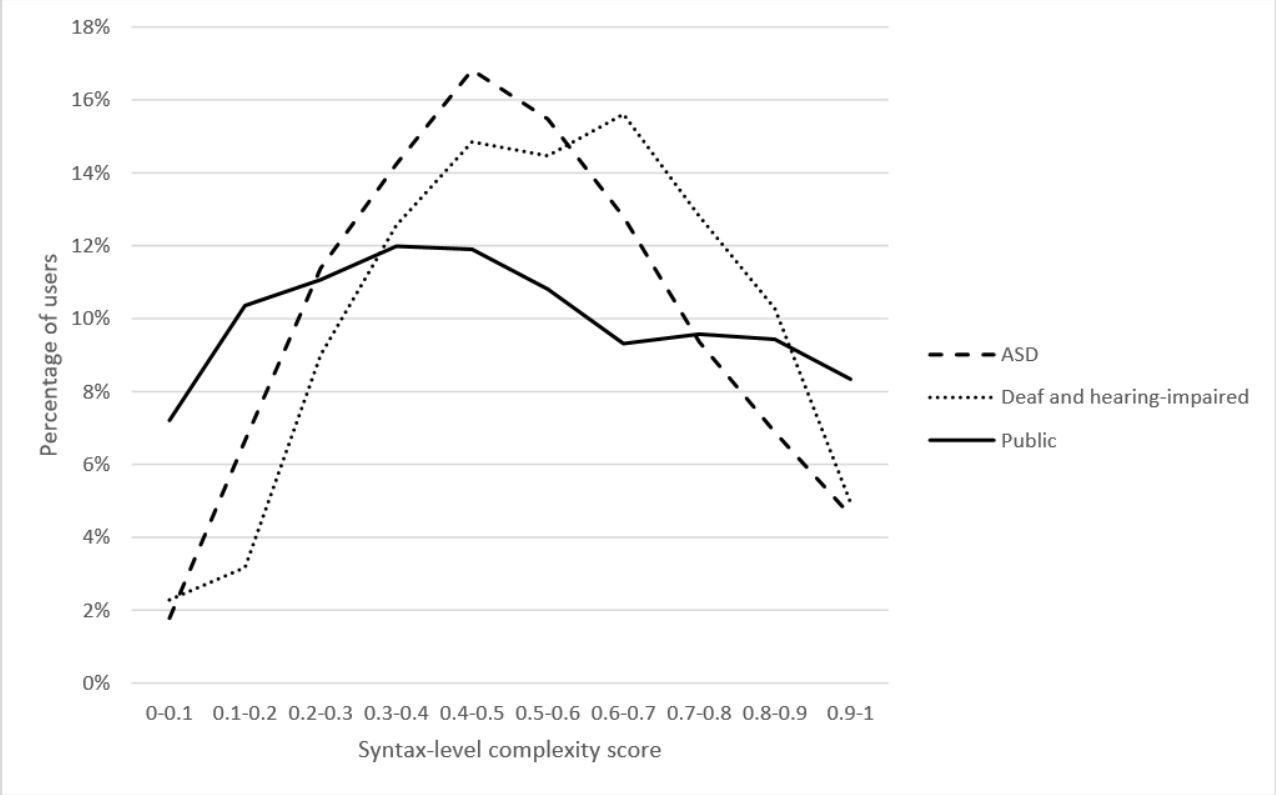
After controlling for the number of sentences per post, the ANCOVA results (F_2=304.5; P<.001) show that users with ASD (mean 0.606) used significantly more complex texts than the other 2 groups (P<.001) and the general public used significantly more complex texts (mean 0.473) than those in the deaf and hearing-impaired group (mean 0.431; P<.001).

Syntax-Level Complexity

The $CHELCS_{syntax}$ indicates complexity ranking related to the prevalence of content words, especially nouns. As seen in Figure 3, the peak $CHELCS_{syntax}$ scores for deaf and hearing-impaired users ranged from 0.6 to 0.7, whereas the peak $CHELCS_{syntax}$ scores for users with ASD ranged from 0.4 to 0.5. Regarding general public users, they did not show a clear syntax complexity preference. The two-sample K-S tests indicate that $CHELCS_{syntax}$ scores were significantly different ($D_{d\text{-}a}$=0.108, $P_{d\text{-}a}$<.001; $D_{d\text{-}p}$=0.153, $P_{d\text{-}p}$<.001; $D_{a\text{-}p}$=0.098, $P_{a\text{-}p}$<.001).

After controlling for the number of sentences per post, the results (F_2=19.206; P<.001) show that deaf and hearing-impaired users used (mean 0.551) significantly more complex syntax than those in the other 2 groups (P<.001), whereas usage of complex syntax was not significantly different between users with ASD (mean 0.506) and the general public (mean 0.494; P=.07).

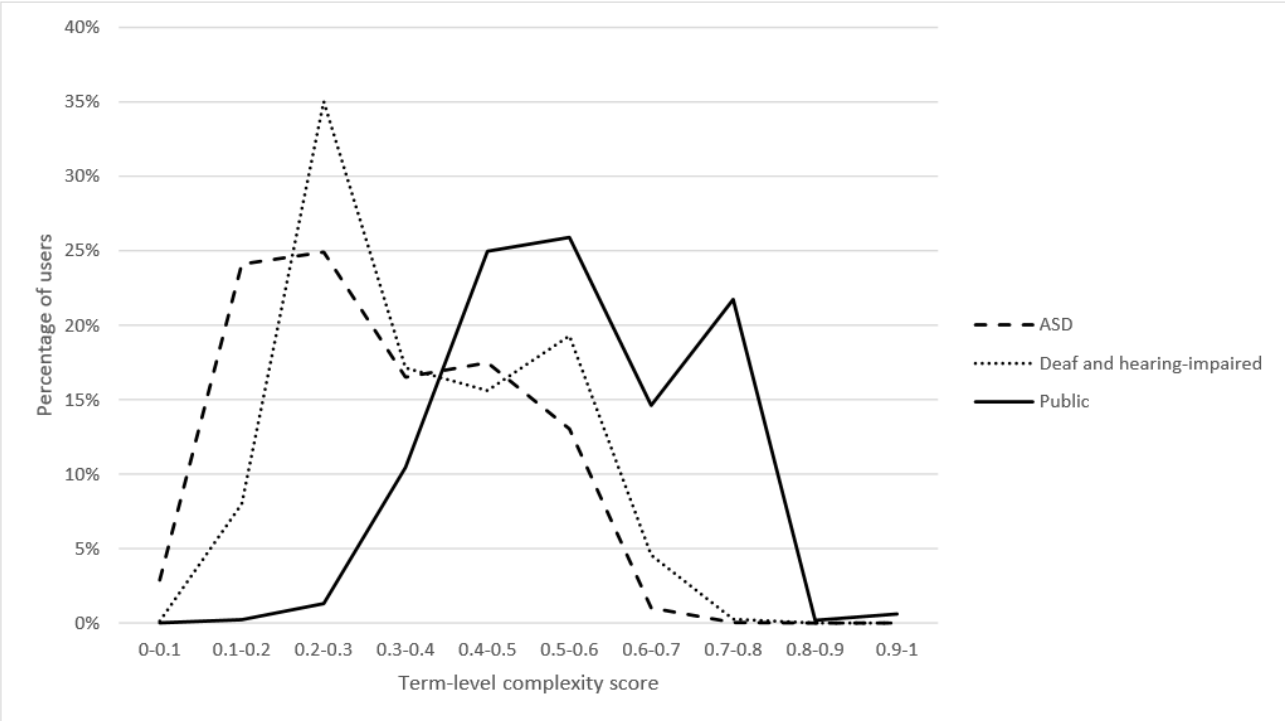
Figure 3. Syntax-level complexity comparison for users in the 3 health corpora. ASD: autism spectrum disorder.



Term-Level Complexity

The $CHELCS_{term}$ focuses on the complexity of the health terms used in each forum. As seen in Figure 4, bimodal distributions were observed in all 3 corpora. Most general public users had relatively higher $CHELCS_{term}$ ranging from 0.2 to 0.9, whereas most users in the other 2 groups had complexity scores lower than 0.7. The two-sample K-S test results indicate that the $CHELCS_{term}$ scores of users with ASD, deaf and hearing-impaired, and general public users were significantly different in the prevalence of professional terms ($D_{d\text{-}a}$=0.208, $P_{d\text{-}a}$=.009; $D_{d\text{-}p}$=0.523, $P_{d\text{-}p}$<.001; $D_{a\text{-}p}$=0.590, $P_{a\text{-}p}$<.001).

Figure 4. Term-level complexity comparison for users in the 3 health corpora. ASD: autism spectrum disorder.

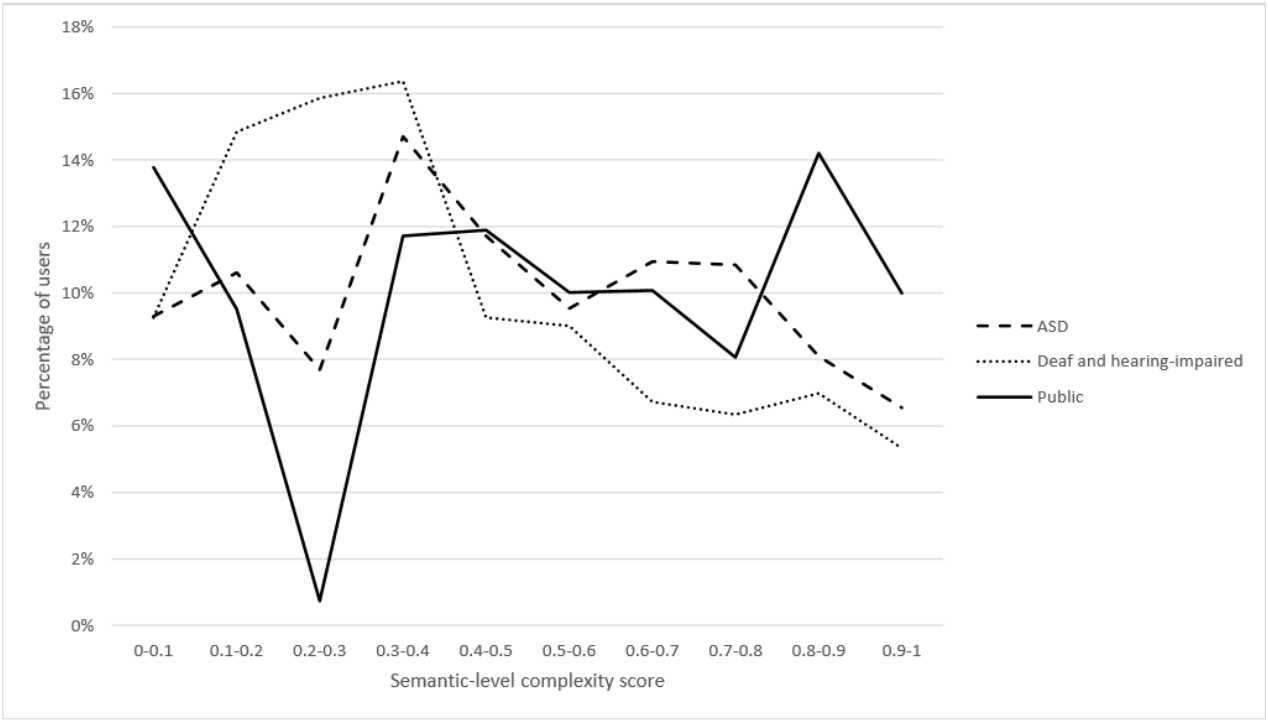


After controlling for the number of sentences per post, the ANCOVA results (F_2=3822.320; P<.001) show that the general public users (mean 0.568) used significantly more complex health terms than those in the other 2 groups (P<.001), and deaf and hearing-impaired users (mean 0.370) used more complex terms than users with ASD (mean 0.316; P<.001).

Semantic-Level Complexity

The $CHELCS_{semantic}$ indicates the diversity of semantic types. Figure 5 shows the distribution of the semantic-level complexity scores in the 3 groups. The two-sample K-S test results indicate that the $CHELCS_{semantic}$ scores for the 3 groups were significantly different ($D_{d\text{-}a}$=0.141, $P_{d\text{-}a}$<.001; $D_{d\text{-}p}$=0.215, $P_{d\text{-}p}$<.001; $D_{a\text{-}p}$=0.116, $P_{a\text{-}p}$<.001). As all health corpora were from social media platforms, the semantics that people utilized might be more influenced by the context than personal health literacy.

Figure 5. Semantic-level complexity comparison for users in the 3 health corpora. ASD: autism spectrum disorder.



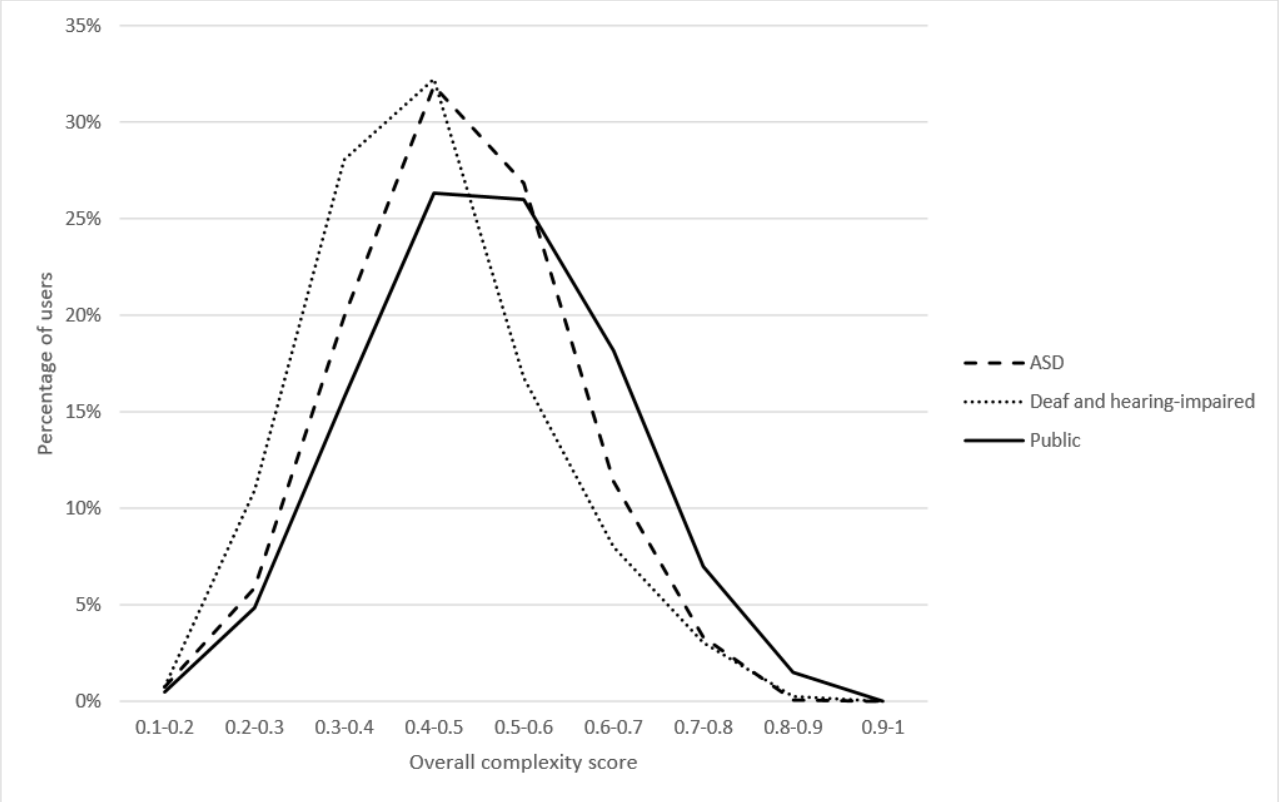
By controlling the number of sentences per post, results (F_2=53.082; P<.001) show that, on average, general public users (mean 0.514) used more semantic types than those in the other 2 groups (P<.001). Users with ASD (mean 0.478) included more semantic types than deaf and hearing-impaired users (mean 0.416; P<.001). In essence, general public users mentioned more diverse health topics than users with ASD and deaf and hearing-impaired users.

Overall Complexity

Figure 6 shows the $CHELCS_{overall}$ for users in the 3 forums. The two-sample K-S test results indicate that the overall CHL complexity scores for users in the 3 corpora were significantly different ($D_{d\text{-}a}$=0.171, $P_{d\text{-}a}$<.001; $D_{d\text{-}p}$=0.250, $P_{d\text{-}p}$<.001; $D_{a\text{-}p}$=0.129, $P_{a\text{-}p}$<.001).

After controlling the number of sentences for each participant, the ANCOVA result (F_2=167.748; P<.001) shows that, on average, general public users (mean 0.512) had more complex CHL than the other 2 groups (P<.001). Users with ASD (mean 0.476) had more complex CHL than deaf and hearing-impaired users (mean 0.442; P<.001).

Figure 6. Overall complexity comparison for users in the 3 health corpora. ASD: autism spectrum disorder.



Discussion

Principal Findings

As health information on the Web often contains medical jargon and complex sentences, general health consumers often find it hard to search for and understand Web-based health information [17]. We argue that health text complexity measurements need to measure the complexity of various CHLs to inform content providers to tailor health information on the Web for health consumers with varying CHL preferences [20,36]. To this end, we developed CHELCS to quantify CHL complexity differences. We applied this measurement to examine CHL complexity differences of health-related posts in 3 online forums targeting the general public, people with ASD, and deaf and hearing-impaired people. In particular, we collected user-generated discussions from 3 online health communities: Yahoo! Answers, Wrong Planet, and AllDeaf. We calculated 8 health readability metrics for each post in the 3 online forums, and calculated text-level ($CHELCS_{text}$), syntax-level ($CHELCS_{syntax}$), term-level ($CHELCS_{term}$), semantic-level ($CHELCS_{semantic}$), and overall ($CHELCS_{overall}$) complexity scores. We then compared the CHL complexity differences for the 3 user groups based on these 5 complexity scores (CHELCS).

The results supported that CHLs of the 3 user groups were significantly different. General public users used more complex health terms and more diverse semantics compared with users with ASD and deaf and hearing-impaired users. Consistent with previous findings, users with ASD used words with more syllables, fewer content or noun words, and less complex health terms [35,38]. Deaf and hearing-impaired users used more content words or nouns, fewer complex words, and less diverse semantics [34,36]. CHELCS results indicated that overall, general public users used more complex CHL than those in the other 2 groups. Overall, the findings from CHELCS measurement were consistent with previous findings of CHL differences among people with ASD, deaf and hearing-impaired people, and public groups.

On the basis of our results, when developing algorithms to simplify health content for different user groups, we need to use more lay health terms for deaf and hearing-impaired users and for users with ASD, less complex words for deaf and hearing-impaired users, and more functional words for users with ASD. For example, as the average F-K grade of MedlinePlus articles is around 8 to 10 [15,16], deaf and hearing-impaired users may need more textual simplifications than the other 2 groups.

To the best of our knowledge, this is the first framework that harnesses consumer-generated textual data to assess the complexity of language that they are comfortable using in their health communications. An understanding of the various CHL complexities of different user groups can provide better insights for the development of adaptive readability assessment tools and adaptive text simplification services.

Limitations

Some limitations should be noted. We could not filter out all the users who are not deaf and hearing impaired or users with ASD, which might affect our findings of the 3 user groups to a certain extent. The data were collected from 3 nontopic–specific health forums. The impact of health topics on text complexity

was not controlled in this exploratory study. For example, CHLs by patients with chronic conditions may be more complex than the average healthy consumers. As the average user contributed little text content in the forums, the findings might not fully depict the language complexity preference of each user. More datasets, such as patient blogs and social media, need to be explored in future studies.

In this proof-of-concept study, the framework CHELC was developed with 8 metrics validated in previous health readability studies to compare CHL complexity differences. Although these metrics have been validated in previous studies, to the best of our knowledge, they have not been used to compare CHLs of different consumer groups. With a lack of research in this field, there is no agreed-upon definition of CHL complexity with respect to different aspects. Therefore, we cannot find a ground truth dataset or standard to validate CHELCS when estimating CHL complexity differences. In this exploratory study, the evaluation of CHELCS was based on previous research findings of the 3 groups in terms of their language complexity preferences. Although our results were consistent with previous findings, this framework and complexity scores are more informative than conclusive. For example, the scores will be different if more metrics are included in this framework, or if the weights of different metrics are defined differently. Also, to more accurately estimate adaptive simplification efforts, it is critical that future studies further assess the CHELCS difference between Web-based consumer health information sources and various CHLs.

Conclusions

The results of this study demonstrate that differences exist among health consumers with respect to the complexity of their language use when discussing health-related topics. A complexity measurement framework (CHELC) and its accompanying scores (CHELCS) were developed to quantify CHL complexity differences among different user groups. Future studies could further apply CHELCS to other datasets from different user groups. Specifically, there is a clear need for the research on understanding CHL complexity differences that translates to adaptive simplification services for different user groups.

Abstract

Background: Many children and adolescents are surrounded by smartphones, tablets, and computers and know how to search the internet for almost any information. However, very few of them know how to select proper information from reliable sources. This can become a problem when health issues are concerned, where it is vital to identify incorrect or misleading information. The competence to critically evaluate digital information on health issues is of increasing importance for adolescents.

Objective: The aim of this study was to assess how children and adolescents rate their internet-based health literacy and how their actual literacy differs from their ratings. In addition, there was a question on how their search performance is related to their self-efficacy. To evaluate these questions, a criteria-based analysis of the quality of the websites they visited was performed. Finally, the possibility to increase their internet-based health literacy in a 3-day workshop was explored.

Methods: A workshop with a focus on health literacy was attended by 14 children and adolescents in an Austrian secondary school. After prior assessments (Culture Fair Intelligence Test, revised German version; Reading Speed and Reading Comprehension Test for Grades 6 to 12, German; electronic health literacy scale [eHEALS]; and General Self-Efficacy Scale, Reversed Version, German), the students were asked to perform an internet-based search on a health-related issue. Browser histories and screenshots of all internet searches were gathered, clustered, and analyzed. After the workshop, the health literacy of the students was assessed again by using the eHEALS.

Results: The 14 students opened a total of 85 homepages, but only eight of these homepages were rated as good or fair by two experts (independent rating) based on specific criteria. The analysis showed that the students judged their own internet-based health literacy much higher than the actual value, and students who had rated themselves better did not visit websites of high quality. Internet-based health literacy correlated significantly with the self-efficacy of the students (r_s=0.794, *P*=.002).

Conclusions: Our study showed that it is possible to draw the attention of students to critical aspects of internet search and to slightly improve their search competence in a workshop. Targeted improvement of health literacy is urgently required, and students need special instruction for this purpose. Further investigations in this area with larger sets of data, which could be feasible with the help of a computer program, are urgently needed.

KEYWORDS

internet-based health information–seeking behavior; eHealth literacy; children and adolescents; mixed methods study

Introduction

At present, a huge amount of information is accessible on the internet at almost any time and any place. In the United Kingdom, in 2015, 82.8% of adolescents (mean age 13.67 years) used the internet between 1 and 4 hours a day [1]. In the United States, in 2015, 92% of teenagers (aged 13-17 years) used the internet daily, with only 8% of them using the internet once a week or less [2]. In Austria, in 2019, 94% of Austrian youth (aged 11-14 years) had access to the internet at home and spent on average 94 minutes a day using the internet, and 62% of them searched for information using the internet [3]. This is consistent with the finding that 64% of all young people (aged 16-29 years) in the European Union searched for information using the internet in 2015 [4].

The information seeking process usually starts with a need for information [5], which is often satisfied by using search engines (eg, Google) on the internet [6]. Search engines usually require the user to express an information need by formulating a search query. Search queries submitted to a search engine can be quite different, ranging from keywords to whole questions. A recent study showed that children and young adolescents (aged 11-13 years) mainly formulate phrase- and question-like queries rather than keywords when searching for information regarding a particular task [7]. Moreover, young students were more likely to use questions, and the use of keyword queries increased with an increase in the grade level [7]. In this context, a previous study showed that using question-like queries can be advantageous, at least for unexperienced users like young children who have great difficulties in formulating precise and comprehensive keyword queries [8].

Another challenge for children and adolescents who use search engines is the ranking of search results by search engines, with the placement of paid advertisements first, rather than more reliable sources. Children and young adolescents tend to open the top-ranked results, dismissing lower-ranked results [9,10]. In addition, after opening one of the top results, they frequently continue their search only if they are not satisfied with the obtained information. If the first page clicked provides an answer to their question, they complete their internet-based search without evaluating the source [6,11]. However, evaluating the source can help readers assess the reliability and quality of the provided information [12,13]. Knowledge about the person or organization publishing the information can help to recognize the intention of publication (whether it is professional or for sales or marketing). The publication date or the last time a webpage was updated can help to estimate if the information provided is still relevant or is outdated [14,15]. Therefore, readers should evaluate information from authors or webpages they identify as being appropriate [12,14,16].

Children and adolescents in primary and secondary schools usually do not evaluate the sources and information they read on the internet [14,17-19]. They often only evaluate the length of text or the design of a webpage [20]. When middle school students (aged 10-15 years) are asked to evaluate an internet source, it is usually very difficult for them to determine which person or organization authored the information and to assess the actual expertise of the author [11]. Although ninth grade students have a basic idea of the concept of evaluation criteria, they often have difficulties in applying them to information on the internet [19].

Query formulation and source evaluation skills are especially important in health-related searches, because the majority of internet users have searched for health information on the internet at least once [21-23]. Besides health professionals (eg, doctors and nurses) and family or friends, the internet is among the first three choices for most people who have health-related questions [22]. In the European Union, the proportion of people aged 16 to 74 years seeking health-related information on the internet increased from 24% to 51% between 2007 and 2017 [24]. A survey in 2016 showed that 84% of teenagers in the United States (aged 13-18 years) had obtained health information on the internet previously, with 38% searching the internet for health information once a year and 24% searching at least monthly or more frequently [25]. Search engines (eg, Google) are usually used to search for health information on the internet, whereas health portals are rarely used [6,25].

Although the internet can be a very powerful source of health-related information, many experts criticize its trustworthiness. The quality of internet-based health information is consistently rated as problematic [26-29]. Commercial sites, discussion lists, online support groups, and newsgroups frequently provide poor quality or even false health information. In many cases, this information does not meet safety and quality standards. It rather promotes nonevidence-based treatments, provides advice to generally avoid drug intake, or omits possible drug interactions. Furthermore, the content of such webpages is seldom updated [27].

Children and adolescents are rarely aware of these shortcomings of health information on the internet and are especially easily influenced by false or biased information [14,17-19]. Despite the obvious need for educational interventions in schools targeting competence regarding internet-based health information and systematic source evaluation, the respective skills are not part of the national curriculum in most education systems [20,30]. However, in several countries, including Austria, health education is part of the core curriculum [31,32]. In the last decade, the perception of what health education should contain has slowly changed, drawing the attention of policy makers to the concept of health literacy as a complement to health promotion and disease prevention.

Health literacy is defined by the US Department of Health and Human Services as follows: “The degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.” [33]. Health literacy means the knowledge and competence of finding and understanding health-related information, as well as dealing with that information. For appropriate handling of health-related internet-based information, a high level of health literacy is essential. Health information–seeking skills (finding information) and source evaluation skills (appraising information to make appropriate decisions) can be considered strongly related to health literacy. In addition to information seeking skills and source evaluation

skills, reading literacy (understanding information) and self-efficacy are important influencing factors for health literacy [11]. The concept of self-efficacy was discovered and described by the sociocognitive action theorist Albert Bandura [34-36] and means "own trust in one's own ability." Self-efficacy regarding information seeking and understanding is considered important to start the information seeking process in the first place [11] and supports a person's inclination to make health-related decisions.

Despite an increased awareness of the importance of health literacy in general and the teaching of health literacy–relevant skills, evidence-based intervention programs to improve health literacy in children and adolescents are rare. Often teachers are not familiar with this concept or do not know how to address health literacy in their lessons. One of the main reasons is the lack of valid data regarding the current internet health information–seeking behavior of children and adolescents, especially in Europe (no data available in Austria).

Therefore, the aim of this mixed methods study was to assess the internet-based health information–seeking behavior of secondary school students (aged 12-14 years) in Austria and focus on the quality of information sources used by this age group. The first goal was to find out how competent children and adolescents are when dealing with health-related information on the internet. Additionally, the strategies they used when searching the internet were observed. Finally, we aimed to find out if a 3-day training on interned-based research competence and reading strategies could enhance the students' health literacy. The following research questions were addressed: (1) How did the students rate their internet-based health literacy? (2) Which websites did they visit to access health-related information and what was the quality of the visited websites (before the students received any training)? (3) How does the students' perceived internet-based health literacy relate to the actual quality of their internet search and the selected sources and how accurate is their assumption of their own health literacy? (4) Is there a relationship between the change process of the students' internet-based health literacy (during a workshop that aimed at improving internet health information–seeking behavior and source evaluation) and their general self-efficacy?
