Abstract

Background: Telehealth is increasingly being used in home care and could be one measure to support the needs of home-based patients receiving palliative care. However, no previous scoping review has mapped existing studies on the use of telehealth for patients in palliative home care.

Objective: The aim of this study was to map and assess published studies on the use of telehealth for patients in palliative home care.

Methods: A scoping review was conducted using the methodological framework of Arksey and O'Malley. Reporting was guided by Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews. A systematic and comprehensive search of Medical Literature Analysis and Retrieval System Online, EMBASE, PsycINFO, and Cumulative Index to Nursing and Allied Health was performed for studies published between January 2000 and October 2018. Two authors independently assessed eligibility and extracted data.

Results: The review included 22 papers from 19 studies. Four thematic groupings were identified among the included papers: easy and effortless use of telehealth regardless of the current health condition, visual features that enhance communication and care via telehealth, symptom management and self-management promotion by telehealth, and perceptions of improved palliative care at home.

Conclusions: The use of telehealth in palliative home care seems to be feasible, improving access to health care professionals at home and enhancing feelings of security and safety. The visual features of telehealth seem to allow a genuine relationship with health care professionals. However, there are contradicting results on whether the use of telehealth improves burdensome symptoms and quality of life. Future research should investigate the experiences of using telehealth among patients with life-limiting illness other than cancer and patients aged 85 years or older. More research is needed to increase the body of knowledge regarding the effectiveness of telehealth on symptoms and quality of life.

KEYWORDS

health care technology; review; palliative care; telemedicine

Introduction

The preferred place of care for most patients in need of palliative care is their own home, and many of them are able to spend time at home and receive the needed care [1,2]. Patients want, as usual, to feel meaning and to maintain governance of their lives; thus, they prefer independent access to health care professionals when needed. Moreover, patients in need of palliative care express preferences for continuity of care and for health care professionals to provide coordinated care [2,3], which may be challenging in home care. Patients who receive care at home report unmet palliative care needs, such as the lack of regular communication with nurses and physicians and between primary and secondary health care professionals [4]. Furthermore, patients may feel uncertain about the urgency of their problems, whom they should contact in times of need, what the response may be, and the legitimacy of their needs, in addition to perceptions of poor continuity in home follow-up and coordination of services [4-6]. Physicians, nurses, physiotherapists, and social workers are often involved in the care and follow-up of patients in need of palliative care at home [7].

Telehealth is increasingly being used in home care [8] and could be one measure to meet the reported challenges and support the needs of home-based patients receiving palliative care. Telehealth is defined as "the provision of healthcare remotely by means of a variety of telecommunication tools" [8]. Telehealth can be delivered in an interactive mode, which invites an exchange of information or messages between patients and health care professionals, or in a passive mode, which is a form of communication that does not require an immediate response by the recipient [9].

Telehealth may be useful for conditions that require close monitoring, clinical assessment, and early intervention to prevent adverse events, such as unwanted emergency hospitalization [10]. The potential benefits of telehealth could include increased quality of life by improving independence and self-management with increased choice, improved access to community palliative care services for those wishing to die at home, and reduction in unnecessary hospital admissions [11]. Moreover, telehealth could be used to reduce patient travel burdens and provide access to services after regular clinic hours [12]. The use of telehealth appears to be promising as a help to meet patients' expectations and needs related to maintenance of their care at home. However, challenges also exist. Head et al [13] claimed that palliative care has been characterized as high touch rather than high tech, which could limit the interest of health care professionals in applying technological advancements when developing and honing interventions [14].

Several systematic reviews have examined home-based telehealth in palliative care settings. One systematic review examined the evidence for home-based telehealth in pediatric care by including studies identified in two databases, focusing on children, adults, and health care professionals [14]. Other systematic reviews have examined patient outcomes [13] and caregiver outcomes [14,15] on telehealth interventions. Head et al [13] found heterogeneity regarding patient population and technology use. The outcome measures showed that all the included studies, except one, reported improvement in quality of life or symptom management. Another systematic literature review assessed the effectiveness of electronic health interventions for patients in palliative care or stakeholders such as health care professionals or caregivers [16]. Some of the included studies indicated positive results regarding quality of care, communication, and cost development. However, no randomized controlled trials (RCTs) were found.

Other literature reviews have been limited to geographical areas and have explored the use of telehealth in palliative care in the United Kingdom [17,18] and the development and use of mobile devices in palliative care services in sub-Saharan Africa [19]. In addition, the review by Johnston [17] was limited to older people. Kidd et al [18] found that telehealth was used by patients, relatives, and health care professionals in several contexts related to palliative care: oncology settings, specialist palliative care, primary care, and nursing homes. Telehealth applications including videoconferencing; consultations; symptom assessments; and advice for patients, relatives, and health care professionals were deemed usable and acceptable for patients and health care professionals.

Telehealth is increasingly being used in patients' homes [8], and new technologies are being developed and implemented rapidly. Furthermore, as previously mentioned, some of the previous literature reviews are older and limited by geographical areas and to older patients. Consequently, there is a need to conduct an updated and broader literature review to develop an overview of the body of knowledge within this field and to identify gaps in knowledge for evidence-based practice. To our knowledge, no scoping review has mapped existing studies on the use of telehealth for patients in palliative home care. Consequently, this scoping review aimed to map and assess published studies on the use of telehealth for patients in palliative home care. The specific research question was as follows: What is known from the existing research literature about patients' experiences of the use of telehealth in palliative home care?

Methods

Design

This scoping review used the framework of Arksey and O'Malley [20], which comprises five stages: identifying the research question; identifying relevant studies; study selection; charting the data; and collating, summarizing, and reporting the results. The reporting of the scoping review was guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) checklist [21]. The protocol for this scoping review has not been registered or published.

Identifying Relevant Studies

A systematic broad search was performed in October 2018 using the databases Medical Literature Analysis and Retrieval System Online (MEDLINE), PsycINFO, EMBASE, and Cumulative Index to Nursing and Allied Health (CINAHL) for studies published between January 1, 2000, and October 16, 2018. The

search strategy was built in MEDLINE by 4 of the authors (SS, AAGN, AW, and AK) and a librarian using Medical Subjects Headings and text words. The search was adopted for each subsequent database. The search strategy is described in Multimedia Appendix 1. In addition, a hand search was performed to screen the reference lists of the included papers.

Study Selection

On the basis of the inclusion and exclusion criteria (see Table 1), pairs of authors independently screened titles, abstracts, and full-text papers for inclusion in the study. When there was disagreement, an independent assessment of whether or not a publication met the inclusion criteria was conducted by a third author.

Table 1. Inclusion and exclusion criteria.

Criterion	Inclusion	Exclusion
Types of studies	Qualitative, quantitative, and mixed method studies on the phenomenon published in peer-reviewed journals	Letters, comments, conference abstracts, editorials, doctoral thesis, or any type of review
Period	January 1, 2000, until October 16, 2018	Before January 1, 2000, and after October 16, 2018
Language	English, Portuguese, Spanish, or Scandinavian	All other languages
Type of participants	Patients in a palliative care trajectory regardless of diagnosis, aged 18 years or older, and living at home	Patients who are not in a palliative care trajectory; patients aged 17 years or younger; and patients who use telehealth in a hospital, nursing home, or hospice setting
Phenomenon of interest	Patients' experiences of using telehealth at home with follow-up from health care professionals	Patients' experiences of using telehealth at home without follow-up from health care professionals or experiences of using telehealth in a hospital, nursing home, or hospice setting
Type of outcomes	Patients reported subjective and objective outcomes	Proxy-reported (next of kin or health care professional) outcomes

Charting the Data

Pairs of authors extracted data from the included publications, using a standardized data-charting form and maintaining the wording and terminology from the papers. The form included the following information: authors, year of publication, country of origin, aim, population and sample size, telehealth application, delivered mode, design and method, and results (see Multimedia Appendix 2). Any disagreements were resolved by a third author.

Collating, Summarizing, and Reporting the Results

An inductive approach was used to thematically organize and summarize the results from the included papers to answer the research question [20]. The extracted results from each paper were read several times to identify frequent patterns, similarities, and differences in patients' experiences of using telehealth, regardless of the type of technology. The identified emerging patterns were organized in four thematic groupings. The first, second, and last author discussed the results and agreed upon the final groupings of the results. A frequency table illustrating which articles were included in which grouping was made (see Table 2).

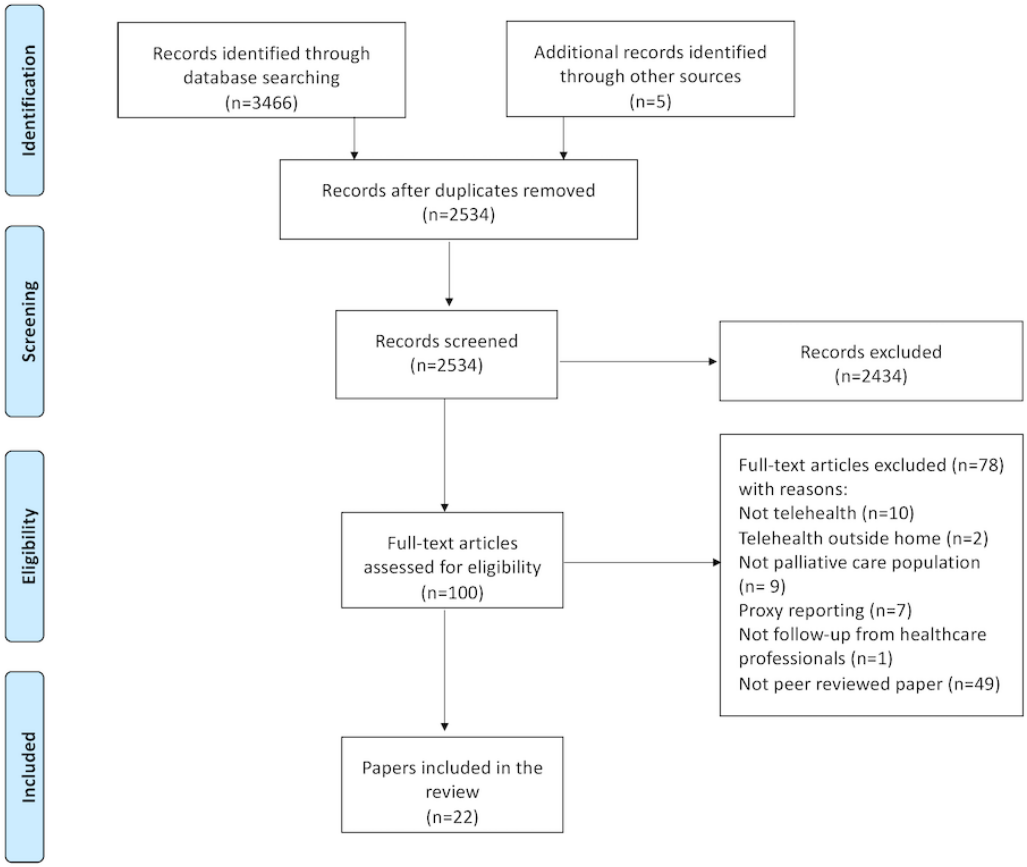
Table 2. Articles included in thematic groupings.

Theme	Study	Number of articles
Easy and effortless use regardless of the current health condition	Aoki et al [22], Hochstenbach et al [23], McCall et al [24], Pinto et al [25], Whitten et al [26], Besse et al [27], Lind and Karlsson [28], Passik et al [29], Tieman et al [30], Reinke et al [31], Lind [32], Lind et al [33], Stern et al [34], Hennemann-Krause et al [35], van Gurp et al [36]	15
Visual features enhance communication and care via telehealth	Hebert et al [37], Miyazaki et al [38], Whitten et al [39], Whitten et al [26], Passik et al [29], Wilkinson et al [40], Reinke et al [31], Stern et al [34], Hennemann-Krause et al [35], van Gurp [36]	10
Symptom management and self-management promotion by telehealth	Bonsignore et al [41], Hebert et al [37], Hochstenbach et al [23], McCall et al [24], Miyazaki et al [38], Pinto et al [25], Whitten et al 30], Besse et al [27], Hoek et al [42], Lind and Karlsson [28], Wilkinson et al [40], Lind [32], Lind et al [33], Hennemann-Krause et al [35]	14
Perceptions of improved palliative care at home	Aoki et al [22], Bonsignore et al [41], Hochstenbach et al [23], McCall et al [24], Pinto et al [25], Whitten et al [39], Whitten et al [26], Lind and Karlsson [28], Wilkinson et al [40], Lind [32], Lind et al [33], Stern et al [34], van Gurp et al [43], van Gurp et al [36]	14

Results

The database and hand searches yielded 3471 publications. After 937 duplicates were removed, titles and abstracts for 2532 publications were screened. On the basis of the inclusion and exclusion criteria, full text of 100 publications were read; 78 publications were excluded and 22 publications from 19 studies were included in the review (see Figure 1).

Figure 1. Summary of the selection of studies.



Description of Included Studies

A total of 22 papers from 19 studies were included. The included studies were conducted in Australia (n=1), Brazil (n=1), Canada (n=2), Japan (n=1), the Netherlands (n=4), Portugal (n=1), Sweden (n=1), United Kingdom (n=3), and United States (n=5). The sample size of the included studies ranged from 2 to 187 participants, and in 6 papers, the samples consisted of 11 participants or fewer. Papers included patients with cancer (n=13); chronic obstructive pulmonary disease (COPD; n=1); cystic fibrosis (n=1); and a mix of different life-limiting illnesses such as cancer, COPD, multiple sclerosis, and amyotrophic lateral sclerosis (n=4). Three papers did not report diagnoses. Six papers included patients aged 85 years and above (oldest-old patients). Nine papers used mixed method or multimethod design, combining qualitative and quantitative methods [22-26]; 7 papers used quantitative design [27-31]; 3 papers used case study design [32-34]; 1 paper used case series design [35]; and 2 papers used qualitative design [36,43]. Three papers included an RCT [37,40,42]. The characteristics of the included studies are shown in Multimedia Appendix 2.

In 15 papers, telehealth was delivered using an interactive mode, whereas the passive mode was used in 7 papers (see Multimedia Appendix 2).

Video-based technology (n=14) was the most frequently used telehealth application in palliative home care. In 10 papers, teleconsultation with patients, relatives, and health care professionals was used to discuss patients' needs, concerns, symptoms, and other problems and to give patients advice [22,26,30,35,36,39-42]. When possible, patients' general practitioners participated from patients' homes [36,42,43]. In four papers, videotelephone was used for individual contact between patients and health care professionals for support, symptom management [34,37,38], and dignity psychotherapy [29]. Webinar technology without video was used to enhance patients' knowledge and skills about end-of-life issues and conversations [31].

Mobile devices such as mobile phones [27]; PDAs [24]; apps on smartphones, tablets, or PCs [23,25,41]; and digital pens and diaries [28,32] were used for pain education and the monitoring and management of pain and other symptoms.

Two studies described a theoretical framework for telehealth intervention: self-monitoring [23] and dignity psychotherapy [29].

To answer the research question regarding what is known about patients' experiences of the use of telehealth in palliative home care, the results of this scoping review are presented in four thematic groupings: easy and effortless use of telehealth regardless of the current health condition, visual features that enhance communication and care via telehealth, symptom management and self-management promotion by telehealth, and perceptions of improved palliative care at home (see Table 2).

Easy and Effortless Use of Telehealth Regardless of the Current Health Condition

Fifteen papers reported patients' experiences of using the telehealth apps. In 10 papers, patients were able to use telehealth despite declining or poor health conditions. The apps were perceived as simple, clear, easy, effortless, and not too time consuming to use. Patients felt comfortable using the technology [23,25,27-34]. Although it was easy to use a digital pen and diary, because of the amount of information the patients received about the equipment, the diary, assessment, and the reporting of symptoms, the app was perceived as confusing [32,33]. App simplicity was seen as a prerequisite, especially for older people, in using the technology [22].

In four papers, patients were unable to use the apps because of their poor health condition, physical limitations, or unfamiliarity with the telehealth equipment, and they required assistance from their family [24,25,34,35]. Patients experienced challenges related to the design of the equipment, such as small font size on smartphones, the small size of videophones, or the lack of equipment portability [25,26,34,36]. The required use of a desktop device prevented teleconsultations for bedbound patients and reminded some of approaching death, which was not the case when the desktop device was replaced with a tablet device [36].

Visual Features that Enhance Communication and Care via Telehealth

Patients experienced that telehealth including video was useful for communication and interaction with health care professionals [26,29,34-36,38-40]. Across these studies, patients noted that the visual features allowed them to see the health care professionals they were interacting with, which provided assurance and comfort as well as enhanced care and nursing assessments. The use of video enabled nonverbal communication, such as body language, facial expressions of happiness or suffering, and other emotions, in addition to the situational context [35,36]. According to van Gurp et al [36], this allowed patients and health care professionals to be immersed in a digital connectedness. Communication via video helped health care professionals to discern how patients felt, even when they tried to maintain a facade and pretend that everything was fine [36,39]. Moreover, a physically distant professional listener provided the freedom and privacy that patients needed to talk about difficult issues; thereafter, they continued as usual [36].

In 1 study in which patients were coached on end-of-life communication using webinars, patients reported that this format lacked interpersonal dynamics such as social presence as well as aural and visual communication cues that were considered important because of the sensitive nature of the topic. Nevertheless, patients stated that having the live video of the discussion facilitator and the ability to see other participants could have made it easier to follow the discussions [31]. In another study, although patients indicated a higher level of readiness to use video technology than home care nurses, patients preferred fewer visits overall and preferred to see the home care nurses in person [37].

Symptom Management and Self-Management Promoted by Telehealth

There were equivocal results of whether the use of telehealth improved burdensome symptoms and quality of life. A study testing the feasibility of SMS and interactive voice response found a significant reduction in mean pain score using the European Organization for Research and Treatment of Cancer Quality Questionnaire, but the study found no change while using the Numeric Rating Scale for pain. Furthermore, there was no change in overall quality of life [27]. Another study, using TapCloud for remote monitoring of symptoms, found improved symptom management for moderate to severe dyspnea, moderate to severe depression, and poor well-being [41]. Two RCTs using teleconsultation found no significant differences between the telehealth group and the control group regarding symptom management and quality of life [37,40]. In contrast, an RCT investigating whether weekly teleconsultations from a hospital-based specialist palliative care team improved patients' symptom burden found significantly higher symptom burden in the intervention group than the control group after 12 weeks [42].

Patients perceived that use of telehealth improved quality of care, enhanced self-management of pain, and contributed to more sincere pain reporting [23,26,28,32,38]. Patients who tended to forget which medication they had taken regarded the medication overview on the app as supportive, and those who took their analgesics based on the clock found the visual and sound reminders useful [23]. Patients perceived that the symptoms included in the app were too general [24], and they wanted the possibility to elaborate on their answers that were primarily related to pain, such as multiple localizations, type of pain, and why or how pain changed [24,33]. Furthermore, patients did not agree on how often the app for symptom monitoring should be used [25]. In 1 study, patients assessed symptoms using the Edmonton Symptom Assessment System, both at the hospital and at home via teleconferencing with a multidisciplinary team [35]. This study suggested that teleconferencing allowed improved symptom control.

Perceptions of Improved Palliative Care at Home

Patients felt that the use of telehealth increased and improved their access to health care professionals at home [22-24,26,28,33,34,36,39,43] and perceived that they had increased access to health care professionals in case of emergency, during the night, or on an as-needed basis [26,39].

Furthermore, patients noted that contact with nurses was the most valuable component of the app [23].

It was important for the patients to know that health care professionals were available for them, were looking after them, and were monitoring them by means of telehealth. This contributed to feelings of being cared for at home, connectedness, relief, tranquility, and enhanced security [24,25,33,36,40]. Symptom monitoring at home facilitated communication of symptoms to hospital-based health care professionals [24,28,33], and remote home follow-up was perceived as less intrusive than a phone call [33,40]. During teleconsultations with their palliative care team and general practitioner, patients experienced concentrated responsiveness and possibilities for direct agreement on the division of responsibilities for future actions. However, patients felt insecure and needed to act as mediators when there was disagreement among health care professionals [43].

Discussion

Principal Findings

This scoping review mapped and assessed published studies on patients' experiences of using telehealth in palliative home care. The results showed that telehealth apps seemed to be feasible for use in palliative care, increased and improved access to health care professionals at home, and enhanced feelings of security and safety. The visual features of telehealth allowed a close connectedness with health care professionals, although there were contradicting results on whether the use of telehealth improved burdensome symptoms and quality of life.

Telehealth apps seem to be feasible for use in palliative care and do not seem to add further burden to most patients. The prerequisites for patients' willingness to use telehealth seem to be app simplicity and telehealth services being perceived as valuable to the patients [44]. However, the results indicate that the design issues of the apps had negative consequences of usability and user friendliness for some patients. Design issues may increase the dependency on help from others or act as a reminder of declining health and approaching death. Moreover, experiences of usability and other concerns related to telehealth may differ among patients with different illnesses [45]. To design and deliver apps and telehealth services that are even more closely aligned with patient needs, participation of users in the design process of technical solutions is crucial [46].

The results indicate that the use of telehealth improved access to health care professionals, although patients remained at their own homes. The use of telehealth seems to support the patient's choice of living at home for as long as possible, which is important for many patients [2]. Patients may feel more comfortable, in control, and in a safer place at home compared with being in hospitals. In addition, the home environment seems more conducive to engaging in meaningful activities and relationships [2,36,47]. Patient choice and autonomy are essential in palliative care [48]. Promoting patients' choice about *where* and *how* health care is provided may contribute to patients retaining stewardship over their lives, which is often compromised by illness [49].

The use of telehealth apps may strengthen the relationship between patients and health care professionals [50]. Our results suggest that in using telehealth, patients experienced a genuine relationship with health care professionals who looked after them and provided care according to their needs. This promoted feelings of being cared for and feeling secure. Trust is an important element of the health care professional-patient relationship, and it has been described as "a belief that good will be taken care of, or an attitude bound to time and space in which one relies with confidence on someone or something, and as willingness to engage in oneself in a relationship with acceptance of that vulnerability may arise" [51]. Trust may be regarded as something health care professionals must earn and work hard to attain. Availability and access to health care professionals and feeling physically and emotionally safe are described as important in this scoping review, in addition to respectful communication. These are some of the prerequisites for trust in the health care professional-patient relationship [51]. Patient awareness and the trust in the fact that health care professionals are watching over them may reduce feelings of loneliness with their health condition [52,53]. However, palliative care nurses have expressed concerns that technical issues with telehealth apps could jeopardize the relationship of trust with patients [54].

The finding that the use of video-based technology enhances communication and care is supported by previous reviews [55,56]. In line with a meta-ethnography on the experience of telehealth in patients with COPD [57], visual features using video images contributed to experiences of closeness, despite the remote contact. Although patients seem to highly value the use of telehealth, many simultaneously underline the importance and value of the physical presence of health care professionals at their home [58,59]. This may be especially important for those with limited social networks or poor social relations [2,57,59]. In addition, it may be more challenging to create a trusting relationship remotely than in person [8], and a caring touch, which patients in need of palliative care may appreciate [2], is impossible with remote contact. Some found that it may not be appropriate to discuss serious diagnoses or end-of-life issues via video because of the lack of physical closeness [60,61], whereas others found that the lack of physical closeness helped them address difficult issues with health care professionals. Consequently, health care professionals need to distinguish the appropriateness of using telehealth for communication and, in turn, individually tailor patient care [56,57].

Contradicting results were found on whether the use of telehealth improved burdensome symptoms and quality of life. Two one-group pre-post studies reported some improvements, whereas two of the RCTs found no significant differences between the groups. This is in line with a previous systematic review [13]. RCTs are considered the gold standard for investigating the effectiveness of interventions, as the design minimizes the risk of bias [62]. However, RCTs in palliative care research are often limited by poor recruitment, small sample size, and attrition, and consequently, quasi-experimental and observational design may be justified when randomization is considered inappropriate [63,64]. In the last RCT [42] included

in this scoping review, a significantly higher symptom burden was reported in the experimental group compared with the controls. The patients in the experimental group may have had a higher awareness of symptoms leading to worsening symptom experience, or their symptoms may have been more precisely registered compared with controls, because of weekly teleconsultations [42]. Another explanation could be the increase in patients' honesty in reporting their symptoms when using telehealth [32]. Nevertheless, this may also suggest that improving the symptom burden in these patients is complex.

A theoretical framework for understanding the mechanism of an intervention is recommended when conducting palliative care research on complex interventions [63]. Therefore, it was surprising that none of the studies that investigated whether the use of telehealth improved symptoms or quality of life applied such a framework. The use of theory in the development phase of the intervention is imperative to be able to explain eventual achieved effects [65]. The use of theory seems to be associated with positive results and large effect sizes [66].

Patients' experiences of using telehealth in palliative home care have mostly been studied in populations comprising patients with cancer. Although the origins and the development of palliative care are closely linked to oncology, early integration of palliative care is increasingly emphasized [67,68]. Patients with life-limiting illnesses other than cancer also experience various problems and care needs early in the illness trajectories [69,70]. However, these patients may have a more unpredictable illness progression than patients with cancer, which presents a challenge in identifying the optimal time for introducing palliative care [71,72] and telehealth. However, patients with a life-limiting illness other than cancer may have been included in other studies, without the interventions being classified as palliative home care interventions.

Notably, few studies included the oldest-old patients, although this population increases continuously and also lives longer with life-limiting illness because of improvement in treatments [61,73]. There may be challenges to including the oldest-old patients in telehealth research. The oldest-old patients may not perceive telehealth as an appealing form of interaction with health care professionals, or health care professionals may inadvertently act as gatekeepers believing that old age and rapidly deteriorating health conditions make participation in telehealth research unfeasible [73].

This scoping review indicates that patients' experiences of telehealth in palliative home care has mostly been studied in populations comprising patients with cancer, and few papers included the oldest-old patients. Mixed method is most frequently used for study design, whereas a limited number of papers used an RCT design. Furthermore, none of the papers that investigated whether the use of telehealth improved symptoms or quality of life applied a theoretical framework for their intervention.

A strength of this review was that we used an acknowledged framework for conducting scoping reviews, in addition to the PRISMA-ScR for guiding the reporting of the review. We performed a broad comprehensive and systematic search to identify published studies. Furthermore, the study selection process and data extraction were conducted independently by pairs of authors.

Considering the limitations of this review, different terms and synonyms are used for telehealth and palliative care in the literature [11,74]. There may be terms that we have not been able to identify and include in our search strategy. Patients with life-limiting illnesses other than cancer may have been included in studies without the intervention being classified as a palliative care intervention. Finally, our search strategy had language restrictions as we only included studies in English, Nordic, Spanish, and Portuguese. Owing to these choices, the results may be affected by information bias. Furthermore, only 6 of the 22 included papers were recent papers. Potential sources for heterogeneity in our scoping review are different study populations, diverse use of technologies, and different study designs across the included papers. Consequently, the results related to the patients' experiences of telehealth should be interpreted with caution.

Conclusions

The use of telehealth in palliative home care does not seem to add further burden to most patients. Telehealth increased and improved access to health care professionals at home, and it enhanced the feelings of security and safety. Furthermore, the visual features of telehealth allowed a close connectedness with health care professionals, which seemed to be highly valued. There were contradicting results on whether the use of telehealth improved burdensome symptoms and quality of life. The results further suggest that telehealth apps may be a positive addition to palliative home care, and patients' reports thereof are in favor. However, health care professionals need to individually tailor the telehealth app to enhance usability and user friendliness for patients. Technology including video was preferable to patients.

To make solid inferences and suggest recommendations for practice and policy, more systematic reviews and studies highlighting the negative aspects of telehealth should be conducted. Future studies also need to address the experiences of using telehealth among patients with life-limiting illnesses other than cancer and the oldest-old patients. It is important to investigate whether other populations have different experiences of usability or other concerns regarding telehealth, as compared with patients with cancer and younger patients. Furthermore, studies including RCTs, when appropriate, are required to increase the body of knowledge regarding the effectiveness of telehealth on symptoms and quality of life. The involvement of users in the development of apps and studies is imperative. Using theoretical frameworks to better understand the mechanisms of interventions is important for future knowledge translation and application.

Abstract

Background: Owing to increasing access to Web-based pornography and concerns about its impact on viewers, many researchers have attempted to systematically analyze the content of pornography.

Objective: We aimed to systematically review the results of quantitative content analyses of video-based pornography and identify the degree to which the following behaviors are depicted: (1) sexual behaviors and themes, (2) condom use during sexual behaviors, and (3) aggression and violence.

Methods: Inclusion criteria for article eligibility were (1) peer-reviewed publications, (2) articles in the English language, (3) articles describing a quantitative content analysis of video pornography, and (4) articles quantitatively examining at least one variable of interest.

Results: A total of 23 studies met the eligibility criteria. Studies varied in scope and definitions of behavioral variables. Condom use was rare, although more commonly depicted in gay male pornography (36%-64% videos) compared with heterosexual pornography (2%-3% videos). Normative sexual behaviors were most frequently depicted in pornography samples (eg, vaginal intercourse in 48%-90% and fellatio in 52%-90% of heterosexual videos; fellatio in 66%-100% and anal intercourse in 70%-80% of gay male videos). Extreme acts of violence (1%-3% videos) and rape (0%-6% videos) were relatively rare. However, more subtle forms of aggression, such as spanking (5%-75% videos), were more common, and unequal sexual relations (eg, domination) were also common. Although estimates varied by study, dominating and violent behaviors were nearly always directed toward women.

Conclusions: Condom nonuse and gender inequalities are common in pornography, which has implications for the development of healthy sexual relationships among pornography viewers. Higher quality research, including study replication and consistent methodological choices, is needed.

KEYWORDS

pornography; content analysis; sexual media; sexual violence; sexual behavior

Introduction

Background

Pornography, in various forms, has existed throughout human history. Different concerns about the content of pornography have periodically emerged over history as social and sexual norms shift. For example, some earlier concerns related to the controversy of depicting nudity and sexual acts in an uncensored manner, whereas more recently concerns in some areas have shifted to “extreme” or “hard-core” violence and its impact on the viewer. These concerns have driven studies of pornographic content and informed their analytical framework.

In the internet age, pornography use is more popular and accessible than ever before; for example, in one survey of young people aged 15 to 29 years, 100% of young men and 81% of young women had ever viewed pornography [1]. With consideration of its nearly ubiquitous nature, pornography is argued to influence the sexual socialization of its viewers, impacting upon beliefs of what is normal and desirable in sexual contexts [2]. Young people have reported that viewing pornography can allow exploration and education around sexuality via exposure to new and appealing behaviors [3,4]. Regardless, it is most likely that pornography's effect on the viewer, be it positive or negative, are at least partially impacted by the types of behaviors that they are viewing [2].

Research has found links between pornography use and potential harms. For example, a large body of research indicates that pornography use is associated with greater unsafe sexual practices and more sexual partners [5,6], and condomless sex among men who have sex with men [7]. Around half of men who have sex with men have reported perceptions that pornography has contributed to their engagement in "riskier" sexual behaviors, while over 90% have fantasized about engaging in similar acts to those seen in pornography [7]. Young people have reported a perception that pornography impacts their sexual relationships, including influencing their understandings of what is normal and desirable, leading to pressure from partners to perform certain acts (eg, young women have reported feeling pressured to engage in anal intercourse with their male partners [8]).

Many individuals have expressed concerns that with the rise of the internet, pornography is becoming more extreme as well as more accessible. Estimates indicate that while 18% of adolescents have been exposed to affection-themed pornography, 18% have been exposed to pornography with themes of dominance, and 10% have been exposed to violent pornography, with exposure to more extreme genres increasing with age [9]. With consideration of the abundance of free pornography currently available, pornography producers have described a competitive climate in which films must show increasingly extreme or niche acts across multiple mediums in order to stand out from other pornography films and appeal to as many sexual desires as possible [10]. In qualitative research, young people have described acts that some people would describe as degrading or violent as being common and normalized in pornography, such as ejaculating on women's faces and apparently nonconsensual bondage, dominance, and sadomasochism (BDSM) [11,12]. Frequency of pornography use and the number of pornography genres viewed have both been associated with higher sexual preferences for types of sexual practices presented in pornography [6]. Of particular concern, a recent meta-analysis has found that using pornography is associated with increased sexual aggression for both men and women, with stronger associations for verbal than physical aggression [13]. The relationship between sexual aggression perpetration and intentional exposure to pornographic material appear to be stronger for violent pornography compared with nonviolent pornography [14]. Pornography use has also been associated with stronger attitudes supporting violence against women [15].

In response to these arguments, several studies have attempted to quantify what pornography depicts in order to determine the messages viewers may be internalizing. These content analyses, which aim to be systematic and replicable analyses of media [16], have ranged in scope, methodology, and complexity. This means that there are various results which can inform policy, but also risk being misinterpreted. For example, one content analytic study [17] reported that 88% of pornographic scenes depicted physical aggression in their analysis; this statistic is frequently used in articles and opinion pieces arguing that pornography is violent and harmful [18,19]. However, other studies have found much smaller estimates of physical violence, such as 13% of internet videos [20] or 1% of video and DVD scenes [21]. This relates to differences in sampling methodology (eg, sampling "popular" pornography, subgenres, or different mediums) and issues with behavioral definitions (eg, only coding aggressive acts that researchers interpret as being nonconsensual [22]). Therefore, there is a need to systematically synthesize content analyses of pornography to provide more accurate estimates of behaviors depicted in pornography.

Objectives

This systematic review aimed to review and synthesize the results of content analysis study designs that quantitatively analyzed content of video-based pornography. The outcomes measured were the frequency with which the following types of behaviors are depicted: (1) sexual behaviors and themes, (2) condom use, and (3) aggression and violence.

Methods

Study Design

This systematic review was conducted in accordance with Cochrane methodologies [23]. Methods and results are presented in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses statement [24]. A protocol was developed by the authors prior to the study to guide the search and data extraction; this protocol has not been published.

Eligibility Criteria

Inclusion criteria for article eligibility were (1) peer-reviewed publication in an academic journal; (2) English language; (3) described a quantitative content analysis of video pornography, and (4) quantitatively examined at least one variable of interest (Table 1). A quantitative content analysis was understood to be an analysis "which involves the creation and use of pre-determined categories for the purpose of understanding and describing media messages in a way that can be counted and quantified" [25]. Quantitative content analyses were chosen over qualitative or narrative approaches as they are the most common type of content analysis and the use of systematic categories allows relatively easy comparison [25]. Video pornography is understood here as video-based material containing the explicit display of sexual organs or activity, intended to stimulate sexual excitement, thereby eliminating solely still image, written or audio erotica from the review.

Table 1. Variables included in the systematic review.

Category, variables, and subvariables	Example description[a]
Sexual behaviors	
Kissing	Kissing between actors on mouth
Oral sex	
Fellatio	Oral-penile contact between actors
Cunnilingus	Oral-vulva or oral-vaginal contact between actors
Anilingus	Oral-anal contact (a.k.a. rimming) between actors
Intercourse	
Vaginal intercourse	Penetration of one actor's vagina by another's penis
Anal intercourse	Penetration of one actor's anus by another's penis
ATM	"Ass-to-mouth"; where an actor inserts their penis into the mouth of another actor after engaging in anal intercourse
Bondage, domination, and sadomasochism (BDSM)	
BDSM (any)	Group category–sexual interaction between two or more people involving domination (one person clearly leading the sexual activity with another person clearly following or submitting) and bondage (physical confinement) of one or more actors
Domination and submission	Depiction of dominating or submissive behaviors (without specifying the presence of bondage)
Bondage	Depiction of bondage behaviors (without specifying the presence of domination or submission)
Group sex	
Group sex (any)	Sexual contact between three or more actors, including threesomes or orgies
Vaginal-anal double penetration (vaginal-anal DP)	Simultaneous penetration of one actor's vagina and anus with two actors' penises
Anal double penetration (anal DP)	Simultaneous penetration of one actor's anus with two actors' penises
Paraphilias	
Bestiality	Sexual interaction between an actor and an animal
Incest	Sexual interaction between actors explicitly described or depicted as relatives
Pedophilia	Sexual interaction involving children
Condom use	Any depiction of condom use by actors, by type of sexual behavior
Orgasms	
Any orgasm	Presence of visible ejaculate or other indicators of orgasm, by gender of actor (eg, shuddering and verbal statements communicating orgasm)
Ejaculation location	Ejaculation by one actor onto another (eg, on face or in mouth)
Aggression and violence	
Verbal aggression	
Name calling or insulting	One actor calling another names or slurs, or otherwise insulting verbally
Physical aggression	
Hair pulling	One actor pulling or tugging another's hair
Spanking	One actor slapping another on buttocks (open-handed)
Slapping	One actor open-handed slapping another on other location on body (not buttocks)
Gagging	One actor inserting their penis very far into another actor's mouth; may or may not stimulate gag reflex
Choking	One actor places hands around another actor's neck; may or may not squeeze
Punching	One actor strikes another with closed fist
Kicking	One actor strikes another with foot or feet
Torture	Infliction of severe or excruciating physical pain by one actor to another

Category, variables, and subvariables	Example description[a]
Murder	Killing of an actor by another
Rape	One actor forces another to engage in sexual intercourse in the absence of consent

[a]These are example definitions; definitions were not always provided within studies, or sometimes differed slightly between studies. Author discretion was used when comparing categories across studies based on definitions. Behaviors included within each variable may be real or simulated by actors.

Variables included in this systematic review are described in Table 1. Variables were chosen using first a deductive approach, focusing on sexual behaviors, condom use and various indicators of aggression and violence. These variables were identified a priori in accordance with public health concerns relating to the prevalence of certain sexual scripts and violence against women [26]. After immersion in the literature, further sexual behavior variables (including those relating to domination of one person over another) and behaviors often conceptualized as illegal, deviant, or socially unacceptable (eg, bestiality, pedophilia, and incest) were chosen. The authors of 3 studies were contacted to provide additional data, which was able to be provided by the authors of one study [27].

Search Procedure and Data Sources

A systematic search of 7 databases, covering all years until the search date, was conducted over a one-week period in March 2016. The search was applied to MEDLINE, PsycINFO, Scopus, EMBASE, CINAHL Plus, Communication and Mass Media Complete, and Cochrane Library databases. Past research has identified challenges searching for content analyses as not all studies use the term "content analysis" [25]. To increase the likelihood of finding articles, additional terms were included. Search terms were developed by all 3 authors and included a combination of a term for pornography and a term indicative of a content analysis [25]. For example, the Medline search was *(porn* or "sexually explicit" or erotic*) OR Erotica/ AND (content ADJ2 analy* OR content ADJ2 review*OR "descriptive study" OR descri* ADJ2 content OR evaluat* ADJ2 content OR map* ADJ2 content)*. The search was repeated in September 2017, to identify any newly published articles.

Data Collection Process

Inclusion of articles was determined in three stages. At each stage, if the authors did not agree on the inclusion of an article, it was discussed and the senior author (ML) was consulted if necessary. First, two authors (EC and AD) each screened all titles for eligibility according to inclusion and exclusion criteria. Abstracts for titles deemed relevant were then screened by the two authors. Finally, articles were subjected to full-text review by either EC or AD to confirm eligibility. Finally, the reference lists of studies in the full-text review were screened by EC and AD to identify potential articles that were not found during the database search, using a similar process. Ambiguities were discussed between authors.

Data Extraction and Risk of Bias

Data extracted included: date of publication, pornography medium (ie, video home system [VHS], DVD, or internet-based video), sampling methods, sample size (eg, number of videos in sample), unit of analysis (eg, scene), variables analyzed, and results.

No best-practice tools are available for assessing bias in systematic reviews of content analyses that are known to the authors. A customized risk of bias tool was created by the authors, based on the Johanna Briggs Institute Critical Appraisal Checklist [28] with reference to content analysis best practice recommendations [29-31]. The 16 checklist items included the reporting of clear inclusion and exclusion criteria, appropriate sampling strategies, development of coding procedures, characteristics of coders, use of appropriate measures of interrater reliability, and measurement of outcomes. At least two authors completed the checklist for each article, with results discussed to reach a conclusion. Risk of bias was deemed "low" if "yes" was selected for 13 to 16 items, "medium" if 9 to 12 items, and "high" if 0 to 8 items (ie, less than half of the criteria were met). A copy of this checklist is available from the corresponding author upon request.

Synthesis of Results

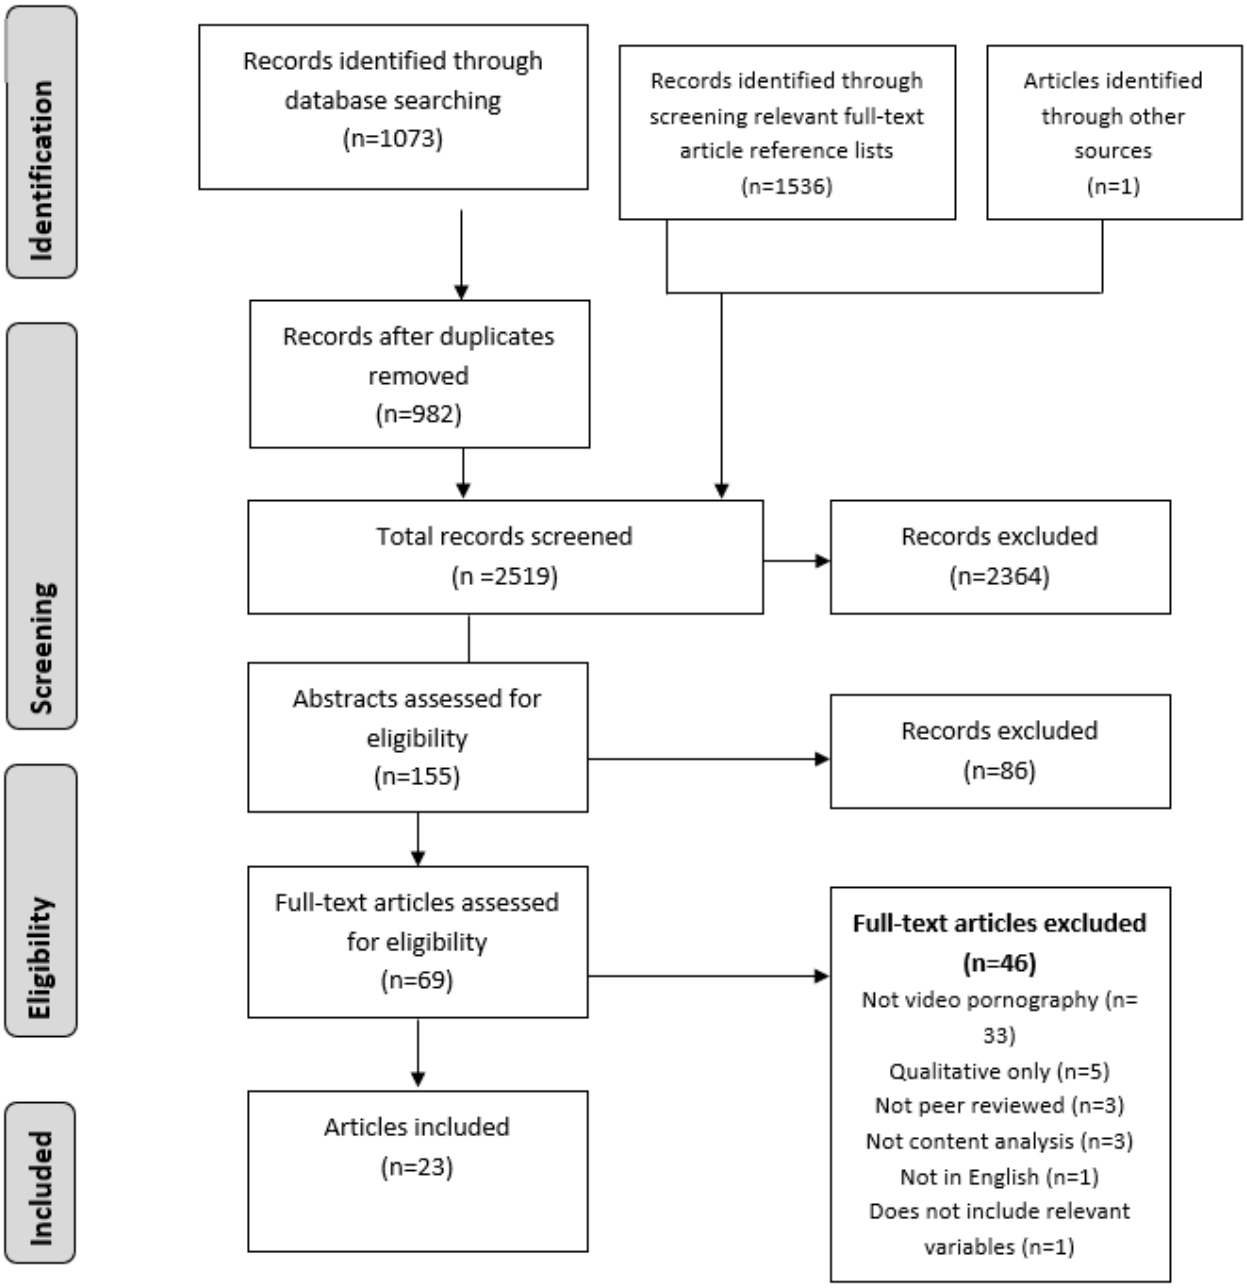
No meta-analyses were conducted due to the heterogeneity of designs, samples, definitions, analyses, and outcome measures. Performing a meta-analysis for such heterogeneous data increases the risk of making erroneous conclusions [32]. Instead, a narrative approach was taken to describe the results [33]. Results were grouped and presented based on the behaviors studied within the sample (eg, sexual behaviors), with consideration of the year of the study, the medium of the pornography (eg, DVD) and the genre (eg, heterosexual). To simplify the presentation of data, frequencies are rounded to the nearest integer, unless less than 1% or greater than 99%. Means are presented rounded to one decimal point. Results are only discussed if providing a specific descriptive statistic for relevant variables (eg, results are not included if the authors described behaviors as simply "rare" or "frequent").

Results

Study Selection

The study selection procedure is illustrated in in Figure 1. The initial database search was conducted in March 2016, producing 1035 articles, and repeated in September 2017, identifying 38 new citations. After removal of duplicates, 982 articles remained. A total of 155 articles were included in the abstract review and 69 articles for the full-text review. In all, 17 studies met the inclusion criteria through database searching. Reference lists of full-text articles were screened, with 1536 articles identified, and 5 articles included. One additional article [34] was located which was not identified through these searches, presumably due to the recent nature of its publication. A total of 23 articles thereby met all the inclusion criteria across both searches.

Figure 1. Screening process and article exclusion.



Sample Characteristics

Table 2 provides a summary of study characteristics. Dates of publication ranged from 1986 to 2017, with the oldest film extracted from 1961 [35] and the most recent in 2015 [34]. Studies varied with regards to the medium of pornography studied, and how data were summarized. Most studies described data using frequencies or percentages (eg, percentage of scenes depicting an act), while some provided means (eg, mean number of acts per video). Studies which provided data by time (eg, amount of time in videos dedicated to an act) are not included in the synthesis due to difficulty comparing with other studies. As seen in Table 2, the most common medium was VHS, followed by internet videos, and DVDs. Most studies were appraised as having a medium risk of bias (11/23, 47.8%), while 8 studies (37.8%) had a low risk of bias and 4 studies had a high risk of bias (17.4%).

Table 2. Characteristics of content analyses identified in the review, by year of publication.

Sr. No.	Year of publication	First author	Content type	Genre (author defined)	Sampling	Unit of analysis	Data type	Behaviors studied relevant to review	Risk of bias
1	1986	Palys [35]	VHS (XXX-rated and "adult" videos)	Unspecified, but intentionally included an "extreme" violent subset	Two videos randomly selected from various video home systems (VHS) rental stores until 125 titles chosen. A further 25 violent videos chosen based on a list of videos that had been charged based on obscenity.	Scenes with either sex or aggression (n=2102)	Frequencies	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, incest, bondage, punching, kicking, torture, rape, murder, domination	Medium
2	1988	Cowan [36]	VHS	Unspecified but predominantly heterosexual ("none seemed targeted at a homosexual population")	Purposive selection 45 "widely available" videos from 7 VHS rental stores.	Sex scenes (n=443)	Frequencies	Ejaculation, incest, name calling, bondage, rape, domination	Low
3	1991	Garcia [37]	VHS	Unspecified	Students in a human sexuality class selected the first video they saw in a VHS rental store.	Videos (n=20)	Means	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, group sex	High
4	1990	Prince [38]	VHS	"Classic" "Popular" films	Purposive selection of popular or well-known feature films produced between 1972 and 1985.	Sex scenes (n=248), actors (n=325), violent acts (n=44)	Frequencies	Ejaculation, orgasms, bestiality, incest, murder	High
5	1990	Yang [39]	VHS (X-rated and XXX-rated)	Unspecified	Randomly selected 30 X- and 30 XXX-rated videos from a VHS rental catalogue.	1639 behavioral sequences (n=984 in X rated, n=655 in XXX rated)	Frequencies	Incest, rape	Medium
6	1991	Duncan [40]	VHS	Unspecified	Randomly selected 50 videos (10% of total available) in a local VHS rental store.	Scenes (n=822)	Frequencies	Incest, bondage, rape	Medium
7	1993	Brosius [41]	VHS	Unspecified but "predominantly heterosexual"	Randomly selected 50 videos from archives of a German copyright firm.	Sex scenes (n=436)	Frequencies	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, group sex, orgasms, domination	Low
8	1994	Cowan [36]	VHS	"Interracial"	Purposive selection of 54 videos in a VHS rental store based on the presence of interracial themes.	Actors (n=476)	Frequencies	Kissing, fellatio, intercourse, cunnilingus, ejaculation, name calling, rape, submission	Medium
9	1999	Monk-Turner [42]	VHS (X and XXX-rated)	Heterosexual	Randomly selected 40 videos from a list of all videos available from a national chain. Only analyzed videos around 2 hours in length and excluded videos with all male or all female actors.	Vignettes (n=209)	Frequencies	Ejaculation, bestiality, name calling, torture, rape, murder	High
10	2000	Barron [43]	VHS	Unspecified	Randomly selected 10 videos in each of 5 stores.	Scene (n=364)	Frequencies	Choking, bondage, punching, kicking, torture, murder, domination	Medium

Sr. No.	Year of publication	First author	Content type	Genre (author defined)	Sampling	Unit of analysis	Data type	Behaviors studied relevant to review	Risk of bias
11	2005	McKee [21]	DVDs and VHS	"Mainstream"	Selected 50 most popular videos across two large video or DVD mail-order companies.	Sex scenes (n=642)	Frequencies, length of scene	Name calling, spanking, slapping, bondage, rape, dominance	Low
12	2008	Sun [44]	DVDs	Unspecified	Sampled 44 videos from a list of most frequently rented VHS and DVDs from a leading trade journal, including 11 female-directed films and 33 male-directed films. Random sample of 61 male-directed scenes selected to match the 61 scenes directed by women.	Scenes (n=61 male directed, n=61 female directed)	Frequencies	Kissing, fellatio, cunnilingus, vaginal intercourse, anal intercourse, double penetration (DP), ass-to-mouth (ATM), group sex, ejaculation, condom use, name calling, spanking, slapping, hair pulling, choking, gagging, bondage, punching, kicking, torture.	Low
13	2009	Grudzen [45]	DVDs	Heterosexual and gay male	Randomly selected DVDs from the largest US distributor of pornographic films, then randomly selected one sex scene from each film.	Sex scenes (n=50 heterosexual, n=50 gay male)	Frequencies	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, anilingus, ATM, group sex, ejaculation, condom use.	Low
14	2010	Bridges [17]	DVD	Unspecified "popular"	Randomly selected 50 videos from the best-selling and most rented lists.	Scenes (n=304), aggression-level acts (n=3375)	Frequencies	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, DP, ATM, group sex, ejaculation, bestiality, condom use, name calling or insulting, spanking, slapping, choking, gagging, bondage, punching, kicking, torture, murder	Low
15	2010	Gorman [20]	Internet videos	Popular free videos (professional and amateur)	Searched Google.com for free pornographic websites, randomly sampled every 5th video from the first five websites per search term.	Videos (n=45)	Frequencies	Kissing, fellatio, cunnilingus, vaginal intercourse, anal intercourse, group sex, ejaculation, condom use, name calling, dominance	Medium
16	2012	Salmon [46]	DVDs	Heterosexual and homosexual best-selling DVDs	30 heterosexual and 30 homosexual DVDs selected from bestselling or top rental lists available through an Web-based adult DVD rental service.	DVD films (n=30 heterosexual, n=30 homosexual)	Means	Fellatio, cunnilingus, vaginal intercourse, anal intercourse, ejaculation, coercion	High
17	2014	Downing [47]	Internet videos	Gay male (amateur and professional) from highly trafficked websites	Selected most recently watched or uploaded video from gay male section of five purposely chosen websites at various times.	Videos (n=302)	Frequencies	Kissing, fellatio, anal intercourse, anilingus, group sex, ejaculation, condom use, spanking, bondage	Low

Sr. No.	Year of publication	First author	Content type	Genre (author defined)	Sampling	Unit of analysis	Data type	Behaviors studied relevant to review	Risk of bias
18	2014	Peters [48]	Internet videos	Popular teen	Identified three popular pornographic websites through Google.com and Alexa.com. Randomly selected 50 videos from "teen" section of each website. Excluded amateur, animated, non-English videos.	Videos (n=150)	Frequencies	Kissing, fellatio, cunnilingus, vaginal intercourse, anal intercourse, anilingus, spanking, bondage, rape	Medium
19	2014	Vannier [49]	Internet videos	Teen compared with mother(s) I'd like to fuck (MILF)	Using Google.com search, identified pornographic websites and excluded those requiring payment, were interactive, or did not have teen and MILF categories. Selected five MILF and five teen videos randomly from each website over a 2-month period.	Videos (total n=100; MILF=50, teen=50).	Frequencies	Kissing, fellatio, cunnilingus, vaginal intercourse, anal intercourse, anilingus, ejaculation, condom use, spanking, domination	Medium
20	2015	Klaassen [27]	Internet videos	"Popular," "mainstream" heterosexual	Selected most 100 viewed videos on four popular pornographic websites and coded first scene of each video. Excluded cartoons, nonsexual videos.	First sex scenes (n=400)	Frequencies	Fellatio, cunnilingus, orgasms, spanking, slapping, pulling hair, choking, gagging, bondage, punching, kicking, torture, rape, murder, domination	Low
21	2016	Zhou [50]	Internet videos	"Asian women" videos compared with other popular categories (eg, teen, MILF, blonde, big tits)	Selected videos from top 10 categories (including "Asian women" category) on xvideos.com, a popular pornographic website. Used systematic, stratified sampling method.	Scenes (n=3132 total, including 172 "Asian women" scenes)	Frequencies	Kissing, fellatio, cunnilingus, anilingus, vaginal intercourse, anal intercourse, ATM	Medium
22	2017	Fritz [51]	Internet videos	"Feminist," "for women" and "mainstream" pornography	Randomly selected videos from Lust Cinema, a website nominated for the Feminist Porn Awards. Also selected content from CrashPad Series, a "queer" feminist site, to diversify selection. Randomly selected videos from "For Women" category on PornHub. Also, randomly selected videos from five largest categories on PornHub to form "mainstream" sample (from categories "teen," "big tits," "brunette," "amateur," "blonde").	Scenes (n=300 total –100 feminist, 100 "for women," 100 "mainstream").	Frequencies	Vaginal intercourse, ejaculation, orgasm, bondage, dominance, and sadomasochism (BDSM), domination	Medium
23	2017	Séguin [34]	Internet videos	Popular	Selected 50 most viewed videos of all time from pornhub.com across all categories.	Videos (n=50) and instances of orgasms (39 male, 20 female).	Frequencies	Orgasms	Medium

Content of interest varied across studies. Types of pornography studied, when specified, were typically heterosexual or "general" or "popular" or "mainstream" videos. Some studies did not specify a genre but noted that their data collected was predominantly aimed at a heterosexual audience. For the purpose of data synthesis, studies are grouped as either "heterosexual" or "gay male." Other analyses specifically studied pornography labeled as interracial [36], "Asian women" [50], feminist/ "for women" [51], teen or youth [48,49], and MILF ("mother(s) I'd like to fuck") [49]. As these genres were likely to be predominantly aimed at a heterosexual audience, these categories were also included in the "heterosexual" group for the purpose of discussion. The authors of this study recognize this is a limitation collapsing broad genres into an overall category and urge readers to seek individual studies for more detailed discussions of their findings. Older studies typically analyzed pornography on a scene by scene basis, whereas internet studies typically analyzed by video, presumably because most internet pornography videos typically involve only one sex scene compared with a feature film or movie interspersed with sex scenes [27].

Sexual Behaviors and Themes

Most studies examined at least one sexual behavior variable. Data for key variables of interest are summarized in Figures 2 and 3 by genre and medium. Where a study presented results by different types or genres of pornography (eg, teen vs MILF [49]), estimates are presented separately here.

Kissing

In all, 7 studies examined kissing. Among heterosexual genre videos, the proportion of scenes depicting kissing ranged from 8% to 50%. Only 1 study specifically examined gay male pornography [47], finding that 34% of Web-based videos included kissing.

Oral Sex

A total of 10 studies specifically examined female to male (F-M) fellatio. The oldest study, an analysis of VHS sex scenes [41], found 54% depicted F-M fellatio. A study of DVDs found that 93% of male-directed scenes involved F-M fellatio, compared with 67% of female-directed scenes [44]. In other pornographic DVD studies, estimates ranged from 84% [45] to 90% [17] of sex scenes, or a mean of 7.0 instances per film [46]. Among 5 studies examining internet videos, F-M fellatio was depicted in 52% to 90% of videos [20,27,48,50].

In all, 2 studies examined male to male (M-M) fellatio in gay male DVDs, with 1 study finding a mean of 11.3 instances per film [46] and another finding 100% of films depicting M-M fellatio [45]. Another study found 66% of gay male internet videos depicted M-M fellatio [47]. Meanwhile, 2 studies examined M-M fellatio in heterosexual or general pornography, with estimates ranging from 0% to 2% of DVD sex scenes [17,44].

Cunnilingus was coded similarly, with estimates differing based on whether the study provided a general overview of cunnilingus or broke behavior down by the gender of actors. The 7 studies that provided a general "cunnilingus" category are presented first. Among VHS studies, cunnilingus was found in 40% to 72% of sex scenes [35,41], or a mean of 4.8 incidents per video [37]. In a DVD study, Salmon and Diamond [46] found a mean of 6.5 instances per heterosexual film, and a mean of zero acts in gay male films. Internet studies found cunnilingus in 41% to 48% of videos [27,48,49].

Some studies broke cunnilingus down by gender. In 2 DVD studies, M-F cunnilingus was found in 43% to 56% of scenes [17,44]. The same 2 studies found that F-F cunnilingus was depicted less frequently [17,44]. Only one study has examined gendered cunnilingus in internet pornography, finding M-F cunnilingus in 18% of scenes and F-F cunnilingus in 6% of scenes [50].

In all, 3 studies specifically examined anilingus, all using internet samples, and 2 studies examined general or heterosexual pornography; 1 study found that 14% of internet videos depicted anilingus [49] while another study found M-F anilingus in 5% scenes and F-F anilingus in 1% scenes [50]. Another study [47] examined internet gay male pornography, finding that 17% of Web-based videos include anilingus.

Figure 2. Percentage of general/heterosexual samples depicting key sexual behaviors, by medium of pornography (VHS, DVD, or internet-based video). Notes: Results are only presented in this graph if the study presented results by percentage of scenes or videos (ie, studies that presented results by time, mean, character excluded from graph). Paraphilias not presented due to sparse data. BDSM and group sex–related behaviors not presented due to variance in definitions and categories between studies. Ejaculation variable is presented in accordance with any estimate of ejaculation; if reporting multiple positions, the highest estimation is provided in this graph. VHS: video home system; MILF: mother(s) I'd like to fuck; BDSM: bondage, dominance, and sadomasochism.

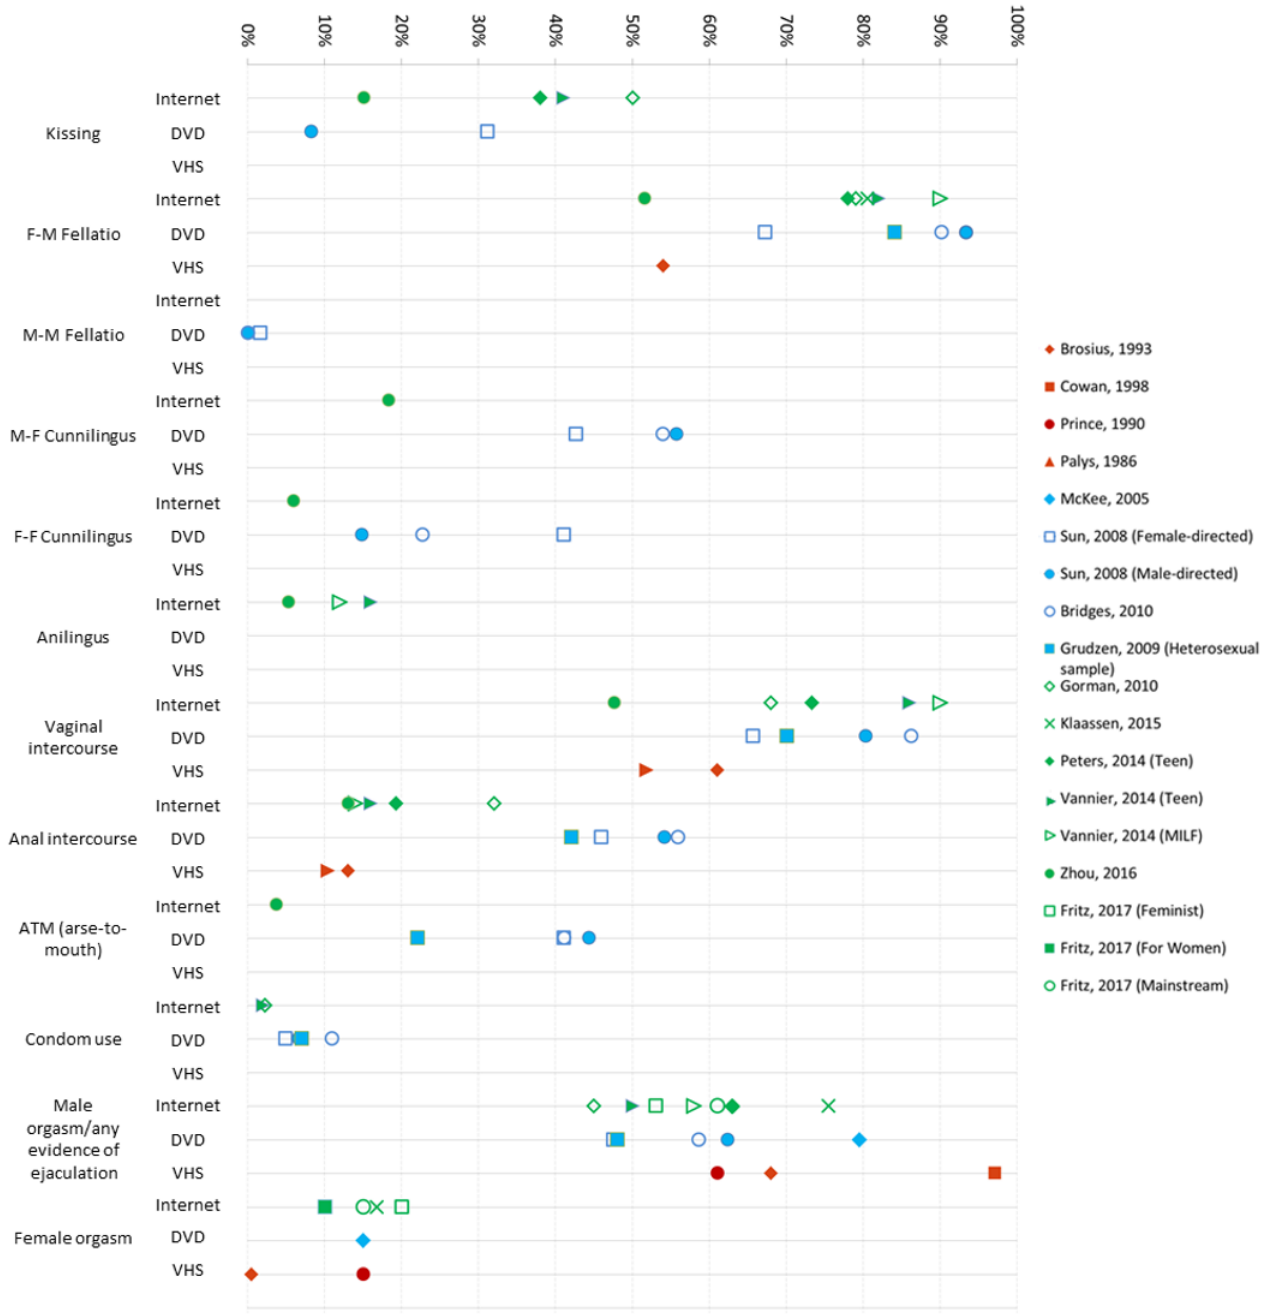


Figure 3. Percentage of gay male/queer samples depicting key sexual behaviors, by medium of pornography (DVD, VHS, or internet-based video), for behaviors studied in these samples. Notes: Results are only presented in this graph if the study presented results by percentage of scenes or videos (ie, studies that presented results by time, mean, character excluded from graph). Paraphilias not presented due to sparse data. Bondage, dominance, and sadomasochism and group sex–related behaviors not presented due to variance in definitions and categories between studies. Ejaculation variable is presented in accordance with any estimate of ejaculation; if reporting multiple positions, the highest estimation is provided in this graph. VHS: video home system.

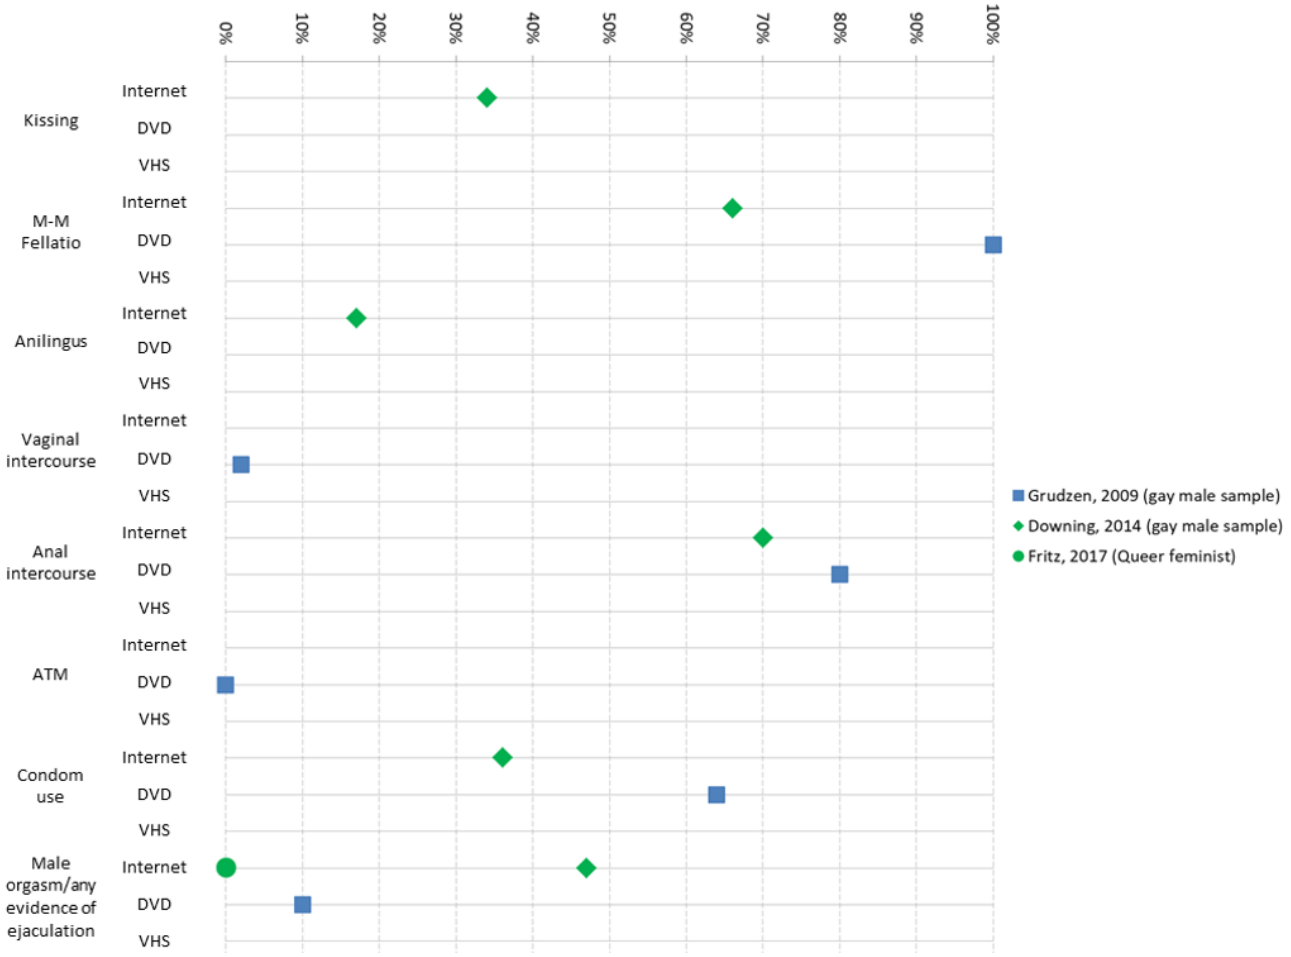


Vaginal Intercourse

Vaginal intercourse was examined by eleven studies, predominantly in general or heterosexual samples. One VHS study [37] finding a mean of 4.2, 2.4 and 4.2 acts for positions "male above," "female above," and "rear entry" respectively per film. Another found that 31.7% of characters began sexual activity with intercourse but did not provide an overall estimate of its prevalence [36]. One study found vaginal intercourse in 61% of scenes, or 81% of scenes that involved at least one male and one female actor [35,41], while another study found it in 52% [35] of videos. DVD specific studies found vaginal intercourse in 66% to 86% [17,44,45] of sex scenes, while Salmon and Diamond [46] found a mean of 8.5 instances per DVD film. Studies of internet videos have found that vaginal intercourse appears in 48% to 90% [20,48-50] of videos.

Anal Intercourse

A total of 12 studies examined anal intercourse. In all, 11 studies examined anal intercourse in heterosexual pornography. One VHS study [37] reported a mean of 1.2 instances in pornographic videos; meanwhile, other VHS studies reported anal intercourse in 10% [35], 13% [41], and 53% [36] of videos. DVD studies found that 42% to 56% [17,44,45] of sex scenes in DVD films included anal intercourse, while another DVD study [46] found a mean of 1.9 acts per film. Internet studies found estimates of 13% to 32% [20,48-50] of videos [20,48-50].

There were 3 studies that examined anal intercourse within gay male pornography. In DVD pornography, anal intercourse was depicted in 80% of sex scenes in one study [45] and 6.8 instances per film in another [46]. Downing et al found that 70% of internet gay male videos depicted anal intercourse [47].

Meanwhile, 4 studies examined ass-to-mouth (ATM). In their study of DVDs, Sun et al [44] found ATM in 44% of male-directed DVD scenes and 41% of female-directed scenes. Specific DVD studies found 22% [45] to 41% [17] of heterosexual scenes depicting ATM, compared with 0% [45] of gay male scenes. One study found ATM in 4% internet video scenes [50].

Group Sexual Activity

Overall, 8 studies examined group sex behaviors. Garcia and Milano [37] found a mean of 1.2 multimale and single female acts, 1.3 multifemale and single male acts, and 0.4 multimale and multifemale acts per VHS film. Brosius et al found 13% of sex scenes featured a man with 2 women, 6% involved 2 men

and 1 woman, and 5% had more than 2 persons of each gender [41]. DVD studies found group sex in 0% to 15% of scenes [17,44]. One study examined gay male pornography, finding 20% of Web-based videos [47] involved 3 or more performers. Brosius et al [41] found a mean of 2.3 actors per VHS sex scene, while other studies found a mean of 1.2 men and 1.2 women actors for general or heterosexual DVDs [45], and 2.5 actors for general or heterosexual internet videos [20]. Gay male studies found a mean of 2.7 men and 0.04 women for DVDs [45], and a mean of 2.4 actors (gender unspecified) for internet videos [47].

Three studies specifically examined a specific group sexual act, double penetration (DP). In their study of DVDs, Sun et al [44] found the highest prevalence of vaginal-anal DP (20% of male-directed scenes, 10% female-directed), while 3% of male-directed scenes and 0% female-directed scenes involved anal DP. In their DVD study, Bridges et al [17] found vaginal-anal DP in 18% of scenes and anal DP in 2% of scenes. Only one internet study [51] examined this act, finding DP in 22% feminist videos, 8% queer feminist videos, 21% "for women" videos, and 17% of mainstream videos.

Bondage and Domination

Bondage, domination, and sadomasochism (BDSM) behaviors were examined by 13 studies. Two studies found BDSM in 10% of gay male internet videos [47], 18% queer feminist scenes [51], and 3% mainstream scenes [51].

Domination was specifically examined by 6 studies. Cowan et al [36] found a general dominance theme occurred in 28% of VHS scenes, and noted that among the scenes characterized by themes of dominance, 78% involved the man in a dominant role and 22% involved women in this role (of these, 37% were women dominating women). Another VHS study found dominance in 14% of sex scenes, with men and women in the dominant role about equally as often (43% depicted dominant men, 45% dominant women, 12% depicted both men and women jointly dominating others) [35]. Another VHS study found 19% of scenes involved dominance, of which 74% had a man in the dominant position while 33% had a woman in this position [43]. A final VHS study found that in 39% of vignettes, a male actor ordered a female actor to perform in a certain way [42]. No studies examined dominance in DVD samples.

In all, 3 studies examined dominance in internet videos, with Klaassen et al [27] finding that 56% of scenes involved a dominant individual, with 39% involving a dominant man and 13% involving a dominant woman. Vannier et al [49] found that in 24% of videos, the male actor had control of the pace and direction of the sexual encounter, while 10% had the woman in control and 66% had shared control. Gorman et al [20] found a male dominance theme in 33% of internet videos (dominance by a woman was not presented in the article). Finally, Fritz and Paul [51] found that male actors instructed the action or behavior of a partner in 25% feminist videos, 19% "for women" videos, and 46% mainstream videos. Comparatively, female actors instructed or directed others in 18% feminist videos, 26% "for women" videos and 33% mainstream videos.

Overall, 5 studies specifically examined submissive behaviors. Palys [35] found that in VHS sex scenes depicting domination, 38% depicted men were in the submissive role, 58% depicted submissive women, and 5% involved men and women jointly dominated by others. Cowan et al [36] found submission in 14% of VHS sex scenes. Another study [49] found that when videos depicted nonegalitarian relations (19% total scenes), 27% involved a man in the submissive position while 78% depicted a woman in this position. An internet study [27] found that 43% of videos involved a submissive female actor, compared with 10% depicting a submissive male actor, while another found that in 47% of videos when at least 2 actors were present, a woman was in a submissive role (results were not provided for prevalence of male submission) [20].

Bondage was examined by 8 studies. Studies of videocassettes indicated bondage was infrequent, present in 2% to 3% [36,40,43] of VHS sex scenes, or 38% of sexually aggressive scenes [35]. Cowan et al [36] also found that only 4 out of 14 bondage scenes depicted a bound man (29%); noting that when men were bound, the tone was typically playful and reciprocal, whereas when women were bound the tone was generally aggressive. In a study of VHS and DVDs, McKee [21] found no instances of bondage, although this was only coded if nonconsensual. Sun et al [44] found that in a sample of DVDs, bondage was seen in 5% of male-directed versus 15% of female-directed scenes, while another DVD study found bondage in 7% of scenes [17]. One internet study [48] found 3% of videos depicted bondage, while another [27] found 0% of internet scenes had men being bound or confined while 1% depicted women in this situation.

Paraphilias

Paraphilias of bestiality, incest, and child pornography were examined, although no studies specifically examined these genres. In all, 3 studies examined bestiality, finding no instances in their samples of video cassettes [38] and DVDs [17,42]. One DVD study reported no instances of pedophilic acts in their sample [17,42]. A total of 4 studies examined incest, prevalent in 0% to 3% of scenes [35,36,39,40].

Orgasms

Several studies provided information about male orgasms or ejaculation, although the focus differed by study. A study of VHS found visible ejaculation in 61% [38] of sex scenes. Vannier et al [49] found that 55% to 58% of Web-based heterosexual videos depicted visible ejaculation, whereas Downing et al [47] found that 47% of Web-based gay male videos depicted any ejaculation.

Some studies specifically identified ejaculation on the face or in the mouth. One DVD study [41] found that in 30% DVD sex scenes, men ejaculated onto a woman's face *or* into her mouth. In all, 5 studies specified ejaculation onto the face of a partner. Studies of general or heterosexual DVDs found estimates ranging from 0% to 5% scenes [17,44], a mean of 4.3 instances per DVD film [46]. Gorman et al [20] found that 45% of Web-based videos depicted ejaculation on the face of a woman by a man. Meanwhile, studies of gay male pornography found a mean of <1% instances of ejaculation on the face of a partner in DVD films [46], or 9% of internet videos [47]. Overall, 3

studies specifically examined ejaculation on or in the mouth of a partner. Studies of general or heterosexual DVDs and videos found this in 48% to 62% of sex scenes [17,44]; meanwhile, Downing et al [47] found this in 8% of gay male internet videos.

A total of 5 studies provided details on female orgasms. Brosius et al [41] noted that less than 1% of women clearly experienced an orgasm in VHS pornography. Prince [38] found that 15% of scenes featured a female orgasm, compared with 61% featuring visible male ejaculation. In video and DVD, a male actor had an orgasm 80% of scenes, compared with 15% for female actors [21]. Similarly, in internet pornography, Klaassen and Peter [27] found that 76% of sex scenes depicted a man having an orgasm, compared with 17% of sex scenes depicting female orgasms. Fritz and Paul [51] found female orgasms in 20% feminist videos, 10% "for women" videos and 15% mainstream videos. Comparatively, they found male orgasms in 53% feminist videos, 63% "for women" videos and 61% mainstream videos.

Condom Use

In all, 6 studies explicitly examined condom use in pornography. For heterosexual pornography, condom use was typically rare. Studies of DVDs found condom use in of 5% to 11% [17,44,45] of sex scenes. In internet samples, 2 studies found condom use in 2% of videos [20,49].

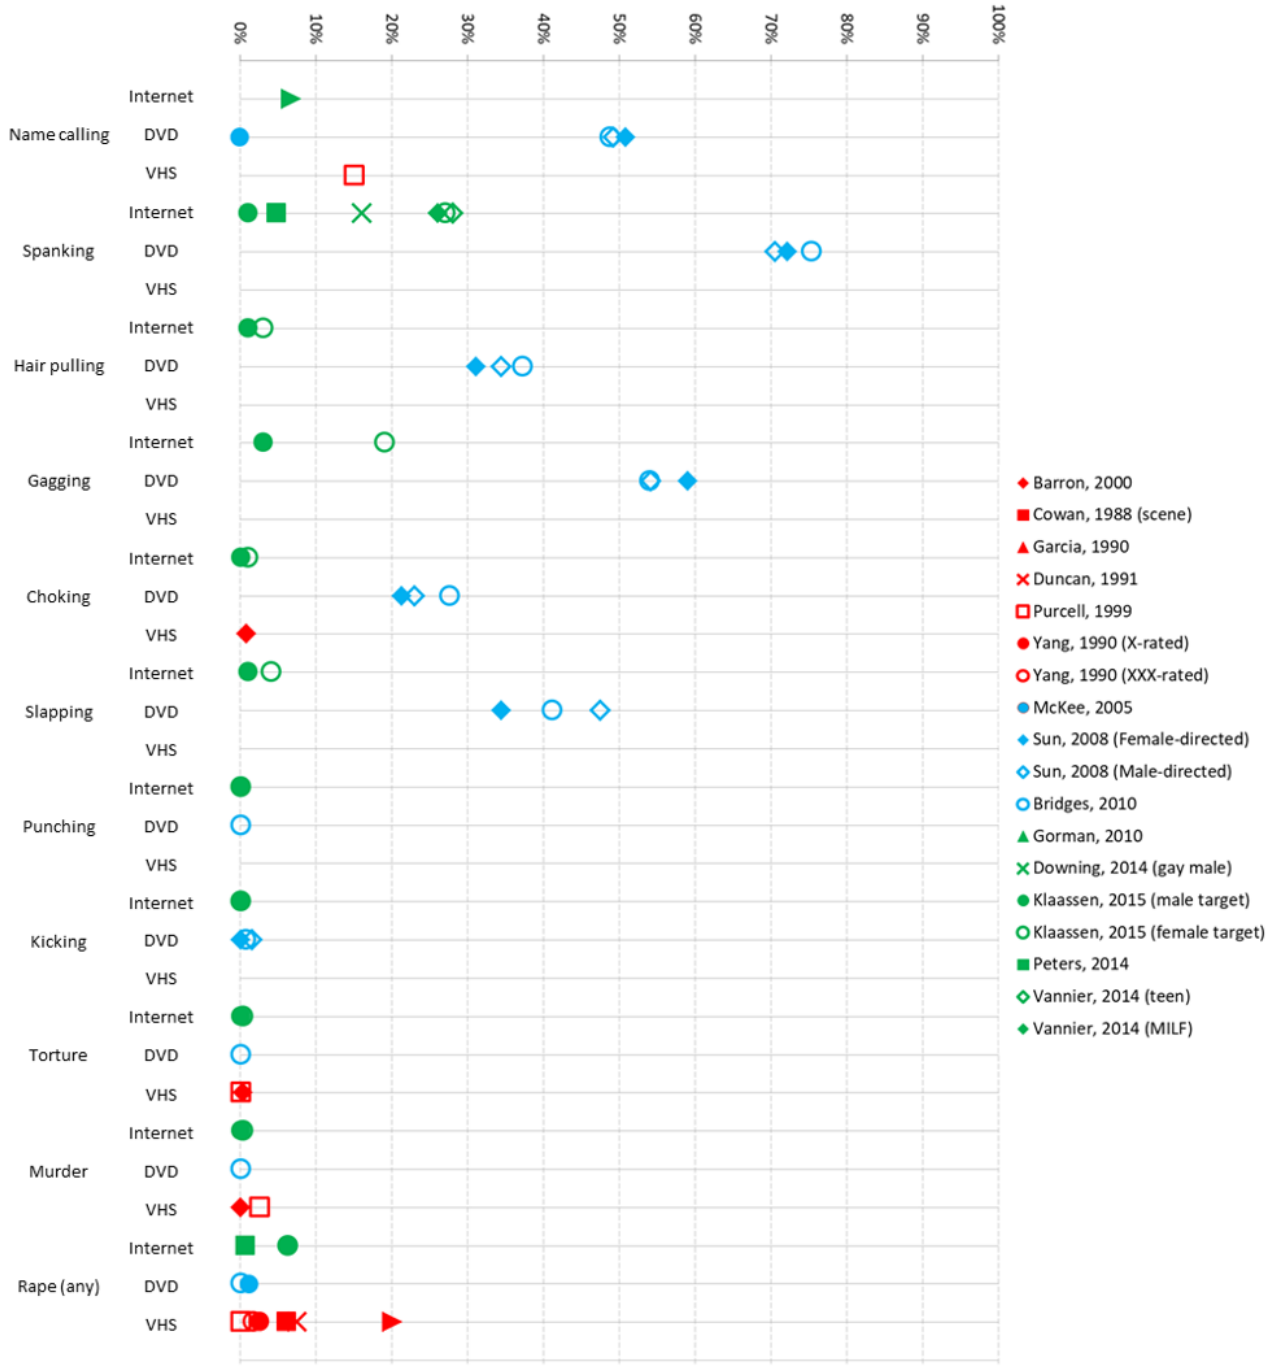
Studies specifically studying gay male pornography had higher rate of condom use than heterosexual pornography. For anal intercourse, condom use was found in 78% of DVD sex scenes [45], while another study found anal intercourse with a condom in 34% of Web-based videos [47]. Only 1 study [47] examined condom use during oral sex between men, finding that nearly 100% was unprotected.

Aggression and Violence

Several studies examined aggression and violence. Of note, only 1 study [35] intentionally included a subsample of violent pornography to form their total sample.

Although many studies present summary variables of both verbal and physical violence, for the purpose of data synthesis, violence is broken down by types of behavior and gender of perpetrator and recipient, when presented. This aims to avoid problems associated with heterogeneity of definitions and behaviors included in these summary statistics. For example, some studies specifically exclude aggressive behaviors which appear to be consensual [21], whereas others purposefully included behaviors regardless of the presence of consent (eg, Garcia and Milano [37]). Most did not specify whether consent was included in their definition. Violent behaviors identified by Monk-Turner and Purcell [42] and Yang and Linz [39] are not presented here as these studies only presented summary statistics. Data are presented graphically in Figure 4.

Figure 4. Percentage of samples depicting key violent behaviors, by medium of pornography (VHS, DVD, or internet-based video). Notes: Results are only presented in this graph if the study presented results by percentage of scenes or videos (ie, studies that presented results by time, mean, character excluded from graph). Only results for specific acts are presented, not for summary variables, due to heterogeneity of these categories. Downing et al's study is presented here as no other gay male/queer studies examined violent behaviors. Palys's (1986) study is not presented here as it purposefully oversampled violent pornography, skewing data. VHS: video home system.



Name Calling and Insulting

A total of 6 studies examined name calling and insulting. Name calling was demonstrated by 6% to 9% of actors [36] and presented toward women in 15% [42] of vignettes in VHS studies. McKee's [21] VHS and DVD study identified no instances of nonconsensual name calling. DVD studies found name calling in 49% to 51% of scenes [17,44]. Name calling was found in 7% of internet videos [20].

Hair Pulling

In all, 4 studies examined hair pulling. In VHS, Cowan and Campbell [36] found that 3% of actors engaged in hair pulling. Two studies examined DVDs; with hair pulling depicted in 31% to 37% of scenes [17,44]. The only internet study [27] found

that 1% of sex scenes involved men having their hair pulled, while 3% involved this for women.

Spanking, Hitting, and Kicking

Spanking was specifically examined by 7 studies. One VHS study found that spanking occurred in 33% of sexually aggressive scenes [35]. McKee's [21] VHS and DVD study identified no instances of nonconsensual spanking. DVD studies found spanking in 71% to 75% scenes [17,44]. Studies of internet pornography had more heterogeneous results. Estimates within general or heterosexual pornography ranged from 5% to 28% [48,49] of videos, while one study found that 27% of sex scenes had women being spanked compared with 1% having men being spanked [27]. Downing et al [47] found spanking in 16% of gay male videos.

In all, 4 studies examined open-handed slapping. McKee's [21] VHS and DVD study identified no instances of nonconsensual slapping. DVD studies found slapping in 34% to 48% of scenes [17,44]. Klaassen and Peter [27] indicated that, in internet videos, 1% of videos involved men being slapped and 4% of videos involved women being slapped.

Punching and kicking were also examined. Overall, 2 studies combined punching and kicking into one variable, with Barron and Kimmel [43] finding this occurred in <1% of VHS scenes, and Palys [35] finding punching or kicking in 24% of aggressive VHS scenes. The 2 studies that specifically examined punching did not find any occurrences in either sample (DVD or internet) [17,27]. In all, 3 studies specifically examined kicking; findings for videos and DVDs ranged from 0% to 2% of scenes [17,44] and, for internet pornography, 0% of videos [27].

Choking and Gagging

A total of 3 studies examined gagging. Of these studies, 2 examined DVDs, finding gagging in 54% to 59% of scenes [17,44]. The remaining study examined internet videos, finding gagging of women occurred in 19% of sex scenes, while gagging of men occurred in 3% of scenes [27].

In all, 4 studies examined choking. Within a VHS sample, Barron and Kimmel [43] found choking occurred in <1% of scenes. Two studies examined DVDs, finding gagging in 21% to 28% of scenes [17,44]. Klaassen and Peter [27] found that, for internet videos, 0% of scenes involved men being choked while 1% involved women being choked.

Torture and Murder

Among 4 studies which examined torture, the oldest study found torture in 2% of aggression scenes [35], and other studies found torture in 0% to 1% of their sample [17,27,42,43]. A total of 5 studies examined attempted or actual murder. For VHS, frequencies ranged from 0% to 3% of scenes [42,43], to 5% [38] of violent acts and 16% of aggression scenes [35]. Other estimates include 0% of DVD scenes [17] and 0% to 1% of internet videos [27].

Rape

The role of consent was examined across several studies. To simplify data synthesis, instances of rape are categorized in accordance with definitions provided by the authors of the studies in the sample. Although not specifically defined by the authors as "rape," estimates by Garcia and Milano [37] and McKee [21] are included in this category due to descriptors including "force" and "nonconsensual" sexual relations. Coercive behaviors are not synthesized due to differences in definitions and conceptual overlap across studies [35-37,39,46].

A total of 10 studies examined rape. Most VHS and DVD studies found rape to be uncommon; depicted in 0% to 8% of scenes [17,21,36,39,40,42] or 0.17 instances per film [37]. However, 1 VHS study, which oversampled violent films, found rape in 31% of sexually violent scenes [35], Cowan et al [36] found that rape occurred in 51% of videos within their sample, and Garcia and Milano [37] found rape in 20% of videos in their sample. One internet study found that "explicit rape" (not defined) occurred in <1% of teen videos [48] while another internet study found rape in 6% scenes [27].

When studies explored rape by gender, most studies found that perpetrators of rape were typically men while victims were typically women. Specifically, Cowan et al [36] found that 90% of VHS instances involving a man raping a woman, while there were 3 instances (<1% scenes) of homosexual rapes (gender unspecified). Another study found that within sexually violent VHS scenes, 29% to 42% involved individual or group heterosexual rape, 3% to 10% involved female homosexual rape and 0% to 3% involved male homosexual rape [39]. Garcia and Milano [37] found 0.2 instances per film of men forcing women into sexual acts, 0.1 instances of female perpetrators and male victims, no instances of male perpetrators with male victims, and 0.1 instances of female perpetrators and female victims. McKee's [21] VHS and DVD study found that among the 1.2% scenes involving rape, there were 5 instances of men forcing women, 2 instances of women forcing men, and one instance of a man and a woman forcing another woman. The only internet study which examined rape by gender found that instances of rape occurred equally for male and female actors [27].

Discussion

Principal Findings

The aim of this study was to systematically review quantitative content analyses of video pornography. The 23 studies reviewed indicate that the pornography in these samples is diverse in terms of behaviors and themes; it is therefore impossible to make definite statements about the content of pornography in general. However, certain trends were noticed when synthesizing these samples.

First, the most common sexual behaviors observed in these are those that some argue to be mainstream, normative or nondeviant in Western culture. For example, in heterosexual pornography, the most common behaviors were fellatio and vaginal intercourse, whereas in in gay male pornography, the most common behaviors were fellatio and anal intercourse. Kissing and cunnilingus were also common (but not universally depicted) in heterosexual pornography, although estimates varied significantly by study. This content is most likely reflecting current sexual norms.

Of note, heterosexual anal intercourse was relatively common in the sample, depicted in 15% to 32% of Web-based videos

and up to half of DVD sex scenes, depending on the sample. A pattern was observed indicating the depiction of heterosexual anal intercourse may have increased since the mid-1980s and the early 1990s, but it has not necessarily increased since the 2000s or with the internet age of pornography. Meta-analytic evidence indicates significant increases in reports of anal intercourse prevalence since the 1970s in some populations [52]. This may be due to lessening of social stigma around anal intercourse [52] but may also be related to the depiction and normalization of anal intercourse in pornography [53]. While heterosexual anal intercourse is enjoyable for many people, for some it is unpleasant and painful; although not studied in this review, it is presumed that pornography does not often show negotiations of consent or preparations for safe anal intercourse.

Paraphilias were very rarely observed in the sample. Bestiality and sexual acts depicting children were not observed in any of the samples. This suggests that these types of acts are very rarely found in general pornography samples, unless specifically searching for this content. While this content is known to be available Web-based, access may require use of the "dark web" or "deep web," parts of the internet not accessible via standard search engines. It is unlikely that people who view easily accessible, free samples (such as those generally included in the content analysis literature) are going to stumble across such content. Regardless, people have reported being exposed to this content; for example, in one study, 18% to 32% of young people reported ever being exposed to child pornography, and 9% to 15% reported ever being exposed to bestiality. However, the number of times participants had seen such images in their lifetime was very low on average, indicating they may have been accidentally exposed [54]. Interestingly, incest was more common than the other paraphilias in the sample, found in three-quarters of the studies which examined it. According to pornography websites, family role play or "faux-cest" videos (note that pornography actors are typically unrelated) increased in popularity between 2014 and 2015, particularly in certain US states [55]. However, PornHub data indicate that "incest" is not among the most popular search terms, but "step mom," "mom," and "step sister" were among the top 20 search terms of 2016 [56]. The implications of this are worth examining in future research.

The results of this study support the public health concern that condoms are rarely depicted in pornography, implying that some actors are at risk of sexually transmitted infection [57]. Condoms were nearly absent in heterosexual samples, and present more frequently in gay or male pornography. Of concern, research has demonstrated that seeing condomless sex in pornography is associated with higher incidence of condomless sex among both populations of heterosexual men [13,58] and men who have sex with men [7]. Although pornography producers have reported concerns that viewers do not wish to see condoms in pornography and are concerned about condoms making sex painful for actors [59], research suggests that most heterosexual men and men who have sex with men are supportive of condom use in pornography [60]. Further research is needed to determine whether such measures would result in meaningful changes in real-life behavior, with considerations of other factors such as perceptions of peers' use of condoms [61].

Contrary to concerns cited by many commentators [19,62], some types of aggression and violence appear to be more common in older forms of pornography compared with the internet pornography. Explicit acts of violence, including rape, appear to be rare in internet mainstream pornography based on the available data. Most studies found that forms of violence such as punching, kicking, torture or murder were only observed a handful of times in the pornography they sampled. However, it is important to note that certain authors (eg, Palys [35]) were able to seek out violent genres of pornography, suggesting that more violent pornography is readily accessible. One study not included in this review demonstrated that it is easy to access internet rape videos if specifically searching for such content [63].

Other forms of aggression appear to be reasonably common, although there was significant variability across estimations. An interesting pattern was observed with spanking, with it not being studied in any VHS studies, being common in 2 DVD studies (ie, Sun et al [44] and Bridges et al [17], who both found spanking in the majority of popular DVDs), while internet studies found spanking in up to a third of content. This pattern suggests that spanking is fairly normalized in mainstream content, although it is difficult to interpret whether spanking is becoming more or less common. Regardless of the nature and frequency of these behaviors, a clear pattern emerged indicating that in general or heterosexual pornography, when aggression and violence occurs, it is more commonly directed toward women, by men. This pattern has also been observed across several studies which used summary measures of violence, which could not be synthesized in this review [17,20,42,44,50].

Other gender inequalities were observed in studies of heterosexual pornography. Orgasm inequalities were universally observed across the literature, with many scenes involving visible male ejaculation and female orgasms rarely depicted (even if they appeared to be fake). Cunnilingus was less common than fellatio, suggesting a pleasure divide. Most dominant actors were men and most submissive actors were women. This suggests that pornography may contribute toward the heterosexual stereotypes that men should dominate or lead sexual activity, that women should be willing to engage in whichever acts are desired by the man, and that both men and women will find such roles normal and enjoyable. Although not able to be systematically reviewed due to differences in definitions and paucity in the literature, studies also noted that unequal power dynamics were fairly common the samples. For example, Monk-Turner and Purcell [42] found that 19% of VHS vignettes involved marked status inequalities based on age, role or occupation in a manner that favors the man. An internet study found that men were more likely to be depicted as having sex for their own pleasure and enjoyment than were women (94 vs 85% of Web-based video scenes) [27]. More studies are needed to explore these dynamics systematically. Further, acts that have been argued to be degrading or demeaning [64] were not uncommon. Ejaculation onto a woman's face or into her mouth was often observed. Ass to mouth penetration was observed in around a third of DVD studies that examined this behavior.

Context of Findings

The varied prevalence of violence and degrading acts in this sample is at least partially influenced by different definitions of violence. The role of consent, which was not systematically studied in this review, is somewhat controversial in the literature. For example, McKee [21] only counted aggressive acts if they appeared to be consensual, arguing that as acts are consensual acts if they do not intend to do another person harm, and the recipient is not motivated to avoid such acts. A distinction is drawn between explicit consent versus coercing another participant into submission [21]. However, Bridges [17] argues that representations of consensual aggressive acts may lead viewers to engage in such acts in a real life, nonconsensual manner. Further, Dines [65] argues that pornography may "hijack" a viewer's sexuality. Despite claims perpetuated by the industry that female actors experience pleasure when participating in a range of sexual acts, the representation of pleasure in pornography can be both complex and ambiguous [22]. Debates about the agency versus exploitation of actors make interpreting these images difficult for audiences and researchers alike [66]. This is important when interpreting findings of content analysis studies to support hypotheses about the impacts of mainstream pornography.

These findings can be considered within the context that pornography viewers are not necessarily passive consumers; opinions of pornography range from extremely negative to extremely positive [4,12,54]. Viewers generally set standards about what they find appropriate or objectionable and likely expose themselves to media that is congruent with their values [67]. For example, it is unlikely that someone opposed to violence against women will purposefully seek out pornography depicting such acts. Regardless, it is possible that some viewers may unintentionally be exposed to and internalize the messages described below, and pornography may subtly shift ideas about which sexual acts are normal, pleasurable, and what their partners expect and desire.

Many viewers are critical consumers of pornography and distinguish between pornography and real-life behaviors. However, other studies have acknowledged that some young people do not demonstrate such critical awareness. For example, one qualitative study [12] of young men identified that many young men have seen pornography depicting violence, even if they did not deliberately seek it out. These viewers may continue watching these videos if they perceive the recipient of the violence is consenting. However, these participants perceived extreme acts of violence and degradation to be normal in this media, speaking about them with detachment and acceptance. The study's authors argued that pornography potentially reinforcing these viewers' understandings of masculine and feminine sexual roles [12].

Limitations

This systematic review only synthesizes a small portion of available pornography. In total, the content analyses in our sample analyzed over 8000 scenes and over 5000 videos. It is difficult to estimate how much pornography is available, although it is estimated that 4% to 15% of internet use involves pornography [68]. The types of pornography analyzed in the studies do not necessarily reflect the types of pornography consumed by viewers. Studies that purposefully sampled more "popular" videos may thereby be more relevant than those that did not, particularly for viewers who purposefully seek out certain videos instead of using random searching to find pornography to watch.

Although most studies in the sample were of moderate to high quality, differences in definitions and methodologies across studies made synthesis challenging. Few details were provided regarding coder characteristics and many studies did not use best practice estimates of interrater reliability [31]. Several studies, particularly older studies, used nonrandom sampling or studied very limited populations. This is understandable as collecting a random sample of VHS pornography would have been very difficult at this time. Sampling methodologies will continue to be a challenge in the future if trends in pornography use and mediums change. Without clear estimates about the number of pornographic videos available, or one source of all videos, it will be impossible to ever obtain a true random sample of internet pornography.

Some studies reported much higher estimates of certain behaviors than others. For example, 2 DVD studies by Bridges et al [17] and Sun et al [44] reported much higher estimations of violent and aggressive behaviors than other DVD studies, or internet-based studies. Further, one study reported a very high prevalence of rape in their sample of video cassettes due to oversampling violent videos [35]. This illustrates how different operationalizations and sampling methodologies can result in very high estimations of certain acts [22].

The authors acknowledge the limitations of this systematic review. It was difficult to identify all pornography content analyses, particularly as some older studies do not use this term. Although the bibliography search attempted to compensate for this, it is possible that the systematic search missed some studies. However, any articles not identified in the search would have been missed systematically [25]. Further, the authors created a custom risk of bias assessment tool due to no appropriate existing tool being identified. Although this tool was based on a pre-existing tool and adapted collaboratively by the authors, it has not been published.

Conclusions

The major implication of this study is that video-based pornography is diverse in its depiction of sexual behaviors and relationships. Owing to there being only being a small number of studies, and inconsistent methodologies, it is difficult to ascertain whether video-based pornography has substantially changed over time. The results tentatively suggest that heterosexual anal intercourse is more common in DVD and internet pornography compared with VHS pornography, several aggressive behaviors (name calling, spanking, hair pulling, gagging, choking, and slapping) are more common in DVD samples than internet and VHS samples, and rape is more common in VHS pornography than newer mediums.

This systematic review indicates that "normative" sexual behaviors are the most frequently depicted in pornography, while extreme violence is rare. Condom use was rare, although

more commonly depicted in gay male pornography. More minor forms of aggression, such as spanking, were more common, and unequal sexual relations (eg, bondage and domination) were also common in general or heterosexual pornography. These behaviors were nearly ubiquitously directed toward women and men were usually depicted as dominant over women. This suggests that gender inequalities are common in pornography, which has implications for the development of healthy sexual relationships among pornography's viewers. Higher quality research, including study replication and consistent methodologies between studies, is needed.

Abstract

Background: Electronic health (eHealth) is a rapidly evolving field informed by multiple scientific disciplines. Because of this, the use of different terms and concepts to explain the same phenomena and lack of standardization in reporting interventions often leaves a gap that hinders knowledge accumulation. Interventions focused on self-management support of cardiovascular diseases through the use of remote monitoring technologies are a cross-disciplinary area potentially affected by this gap. A review of the underlying frameworks, models, and theories that have informed projects at this crossroad could advance future research and development efforts.

Objective: This research aimed to identify and compare underlying approaches that have informed interventions focused on self-management support of cardiovascular diseases through the use of remote monitoring technologies. The objective was to achieve an understanding of the distinct approaches by highlighting common or conflicting principles, guidelines, and methods.

Methods: The metaethnography approach was used to review and synthesize researchers' reports on how they applied frameworks, models, and theories in their projects. Literature was systematically searched in 7 databases: Scopus, Web of Science, EMBASE, CINAHL, PsycINFO, Association for Computing Machinery Digital Library, and Cochrane Library. Included studies were thoroughly read and coded to extract data for the synthesis. Studies were mainly related by the key ingredients of the underlying approaches they applied. The key ingredients were finally translated across studies and synthesized into thematic clusters.

Results: Of 1224 initial results, 17 articles were included. The articles described research and development of 10 different projects. Frameworks, models, and theories (n=43) applied by the projects were identified. Key ingredients (n=293) of the included articles were mapped to the following themes of eHealth development: (1) it is a participatory process; (2) it creates new infrastructures for improving health care, health, and well-being; (3) it is intertwined with implementation; (4) it integrates theory, evidence, and participatory approaches for persuasive design; (5) it requires continuous evaluation cycles; (6) it targets behavior change; (7) it targets technology adoption; and (8) it targets health-related outcomes.

Conclusions: The findings of this review support and exemplify the numerous possibilities in the use of frameworks, models, and theories to guide research and development of eHealth. Participatory, user-centered design, and integration with empirical evidence and theoretical modeling were widely identified principles in the literature. On the contrary, less attention has been given to the integration of implementation in the development process and supporting novel eHealth-based health care infrastructures. To better integrate theory and evidence, holistic approaches can combine patient-centered studies with consolidated knowledge from expert-based approaches.

Introduction

Holistic Electronic Health Research and Development

Electronic health (eHealth) is the use of technology to support health, well-being, and health care [1]. Research and development approaches in this field are derived from multiple disciplines such as computer, medical, behavioral, and design sciences [2]. Because of this, the use of different terms and concepts to explain the same phenomena [3] and the lack of standardization in reporting interventions [4] often leaves a gap that hinders accumulation of knowledge across the field.

A holistic approach—to recognize the importance of the whole and the interdependence of its parts [5]—to eHealth development could bridge this gap. In practice, this proposes that the interaction and reciprocal influence between contextual, technological, and human factors should be emphasized early and often during eHealth development and be informed by multidisciplinary perspectives [5,6].

Frameworks, Models, and Theories for Development and Design

Researchers and practitioners of eHealth are frequently engaged in iterative phases of development that entail various activities aimed at increasing the success of an intervention (eg, exploring user preferences or assessing usability). These approaches to development are often grounded in a wide and overwhelming variety of frameworks, models, theories, guidelines, or methods [2] that extend across and within scientific disciplines. For example, a recently published framework for development of digital behavior interventions in health care outlines a process of conceptualization, development, implementation, and promotion [7]. In terms of holistic approaches, guidelines have also been used for research and development of eHealth [5,6]. Similarly, some frameworks focus on specific aspects or outcomes such as the adoption, scalability, and sustainability of health care technologies [8]. System development approaches like these are characterized by key ingredients that inform or guide eHealth research, development, implementation, or evaluation. Key ingredients can be principles, guidelines, assumptions, constructs, quality criteria, or grounding themes and ideas.

However, eHealth development is not just about the system's development but also the decision-making process of designing intervention content or features. To this end, system development approaches are often paired with models or theories that, through their own key ingredients, describe knowledge or phenomena or propose predicted relations of constructs. Such theoretical models can be used to understand what mechanism of the intervention works best for whom, instead of evaluating the intervention as a whole (ie, as in traditional effectiveness trials). Key ingredients from theoretical models often relate to behavior change, technology adoption, or the improvement of health [9,10]. While behavior change and improvement of health are typical ingredients of face-to-face interventions, technology adoption is seen as an important outcome of eHealth implementation (because the mode of delivery is often unfamiliar to the user and continued use must be promoted). For example, the persuasive systems design model proposes means for selecting persuasive technology features (ie, promoting adoption) that work best to help users reach their own personal goals (eg, change behavior or improve health) [11]. Considering this type of knowledge, it is plausible that analyzing the use of frameworks, models, or theories applied to system development or intervention design could be a way to understand the potential of eHealth applications to complex health care issues. This focus could enable an understanding of how different approaches can interplay to increase the impact and uptake of health care technology.

Case Study: Supporting Self-Management of Cardiovascular Diseases Through Remote Monitoring Technologies

The integration of self-management support for cardiovascular diseases (CVDs) in technology-based interventions is a case study of interest because it is a contemporary phenomenon, with boundaries not yet clearly evident, in need of answers to questions of how (ie, how does it work?) and why (ie, why does it work?) [12]. In general, CVDs constitute an alarming worldwide health care challenge [13,14] where the provision of remote self-management support is proposed to lessen their burden [15]. Because of the dynamic and continuous (daily) nature of self-management [15,16], monitoring technologies such as internet-enabled blood pressure monitors and weight scales have arguably become a prerequisite of remote care interventions. This approach can also go beyond simply

monitoring by integrating mobile apps or wearables that provide coaching on self-management [17].

The potential of technology-supported remote care relies on real-time monitoring by health care teams, which could facilitate the early detection of symptom deterioration and provision of personalized and timely feedback [15] and also create a feeling of safety for patients who know they are being monitored [18]. Accumulated evidence backs up this potential, as metareviews have shown that technology-supported interventions can be at least as effective as usual care in the promotion of self-management for chronic conditions [19,20].

The complexity of CVD self-management as a health care problem and the required adaptability of the proposed technological solutions [21] naturally cause research in this area to be spread across literature from medical, behavioral, and other disciplines. For example, the expert assessment and recommended treatment of a health care provider (medical science) must be translated into motivational prompts or messages that promote adherence to a desired behavior (behavioral science) and delivered in a salient and understandable way to the patient (human-technology interaction science). Thus, the multidisciplinary gap that characterizes eHealth could also be present in the case of CVD applications.

By and large, it can be recognized that much is generally known about eHealth development processes, based on the many examples that exist, and that research in self-management and CVD is at least equally extensive. Frameworks, models, and theories can be valuable sources of knowledge but are numerous and difficult to compare. Therefore, what is lacking at this point is an analysis that relates the knowledge across different disciplines, the variety of development approaches, and their operationalization in specific settings such as eHealth applications to self-management of CVD.

Aim and Focus

The aim of this review was to identify and compare the underlying approaches that have contributed to the research and development of interventions focused on self-management support of CVDs through the use of remote monitoring technologies. The focus was on frameworks, models, and theories and the reported operationalization of their key ingredients in published studies. The review aimed to create a synthesis that highlighted common (or conflicting) principles, guidelines, and methods to create an understanding of the distinct approaches that have been used for the case at hand.

The review seeks to answer the following research questions. First, what frameworks, models, or theories have been used to develop, implement, or evaluate interventions to support self-management of patients with CVD through the use of remote monitoring technologies? Second, what are the key ingredients of these frameworks, models, or theories that inform or guide the system's (1) development, implementation, or evaluation; (2) content design to promote behavior change and technology adoption; and (3) proposed effects in terms of health-related outcomes? Third, to what extent do the key ingredients of these frameworks, models, or theories fit with the principles of the holistic research and development approach of eHealth [5,6]?

Selecting Metaethnography

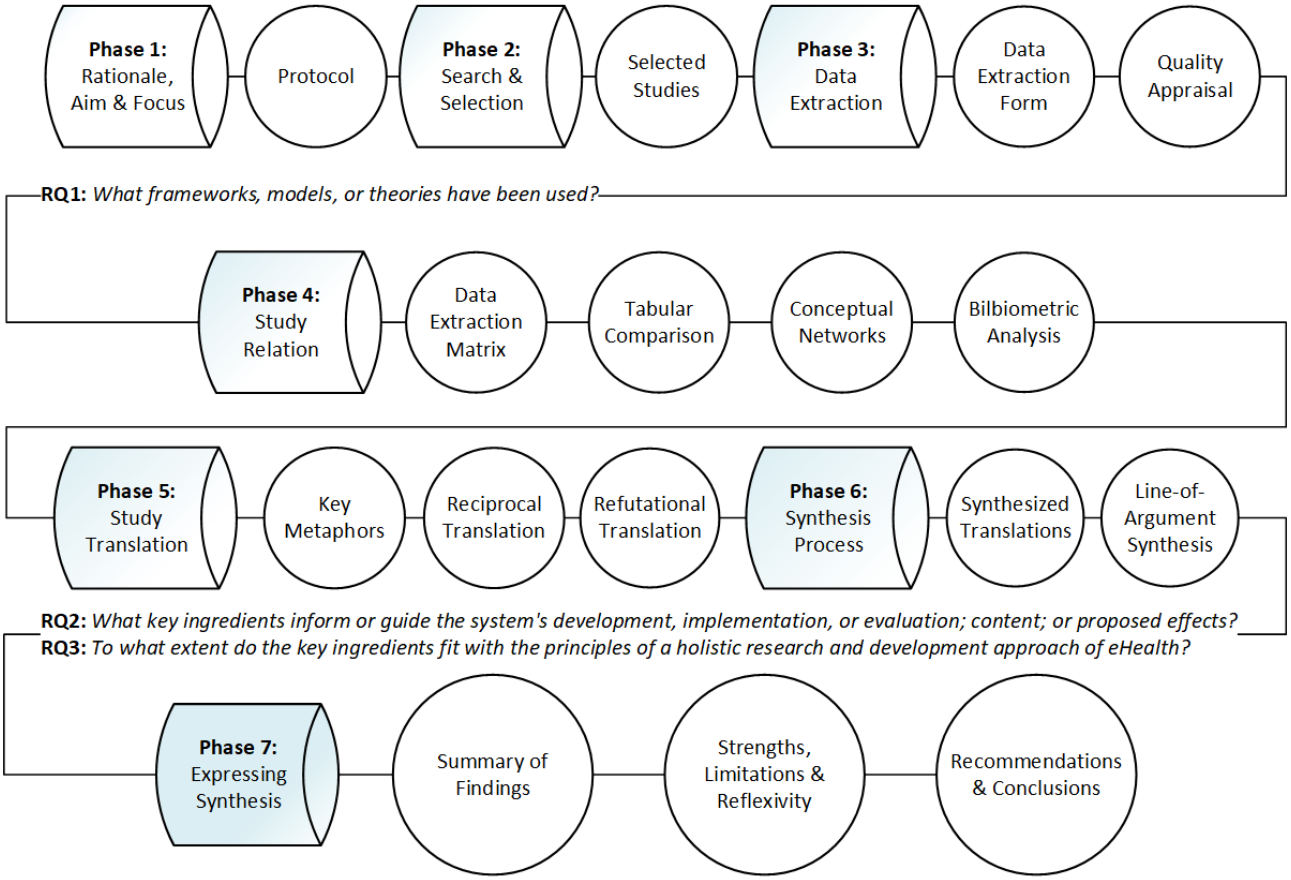
The review was based on metaethnography, a qualitative evidence synthesis method originally developed by Noblit and Hare [22]. Metaethnography is an interpretive approach that seeks to generate a new understanding of a topic. In practice, it involves open coding and constant comparison of key metaphors, which can be phrases, ideas, concepts, perspectives, organizers, or themes identified across the reviewed studies [22]. Metaethnography was selected by following guidelines on choosing qualitative evidence synthesis methods [23]. Mainly, metaethnography was preferred because it aims for an interpretive examination of themes, relationships, and contradictions in the literature, while preserving the social and theoretical contexts of the original findings [24-27]. Additionally, metaethnography fits perfectly with the study aims because it explicitly compares and analyzes texts with the intention to build a holistic interpretation [22]. The aims and methods of the review were described in more detail in a protocol that was preregistered [CRD42018104397] and published [28], complying with best-practice recommendations [24].

Methods

Review Phases

Figure 1 visualizes the phases and key output of this review in relation to the research questions. Phase 1 generated the published protocol [28]. Phases 2 and 3 sought to answer the first research question regarding the identification of frameworks, models, and theories [28]. Phases 4 to 6 operationalized an answer to the second and third research questions through an interpretive characterization of the key ingredients of frameworks, models, and theories [28]. This paper adheres to the recently developed Meta-Ethnography Reporting Guidance (eMERGe) [27].

Figure 1. Phases and key output of the metaethnography review. RQ: research question.



Search Strategy

A comprehensive search was conducted to find published studies (articles) of interest [28]. The search consisted of a systematic database search. Seven databases were used: Scopus, Web of Science, EMBASE, CINAHL, PsycINFO, Association for Computing Machinery Digital Library, and Cochrane Library. The databases were chosen based on their coverage of various fields of science related to eHealth. Multiple key terms were used as part of a highly structured query consisting of four sets aiming for results about frameworks, models, and theories (set 1), eHealth interventions (set 2), self-management (set 3), and cardiovascular diseases (set 4) [28]. The database search was conducted by the main reviewer (RRCM). The search results were uploaded to EndNote X8 (Clarivate Analytics), and duplicates were eliminated.

Study Selection

The selection was performed using the Covidence Web-based software platform (Veritas Health Innovation Ltd). Records were screened by two reviewers, first by title and abstract, and then by full text. The main reviewer conducted the screening throughout all stages. A co-reviewer (RAA) screened at least 15% of the records at each stage and also those tagged as maybe in Covidence by the main reviewer. While 100% dual review would be ideal [29], the approach taken strived for a balance between thoroughness and speed, which is a common strategy for systematic reviews [30] (for full details about study selection see the protocol [28]). Discrepancies between reviewers were discussed and resolved at every stage. Multimedia Appendix 1 presents the selection criteria.

Reading Studies and Extracting Data

The included articles were uploaded to the qualitative software package ATLAS.ti version 8 (ATLAS.ti Scientific Software Development GmbH). Their content was coded according to the elements of a highly detailed data extraction form created to fit the scope of this review (see Multimedia Appendix 1). The data extraction form was based on the Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth (CONSORT-EHEALTH) checklist v.1.6 [31,32]. The form was piloted and iteratively refined throughout all phases. All coded data were also translated to a single form per study. The main reviewer iteratively read, coded, and updated all of the data extraction output based on input from three co-reviewers (RAA, JW, and JGP). The main reviewer also appraised the quality of studies using items from the Critical Appraisal Skills Program's checklists. These checklists were employed because they are a suggested and frequently used tool for metaethnographies [25,26,33-38]. Quality appraisal is not a strict requirement for metaethnography because the richness and relevance of the content is more important [36], but it is considered good practice and was used to get further familiarized with the studies [26].

Determining How Studies Are Related

The relation of studies was performed at three levels with the aim to provide a deep analysis of the data and its context. At the first level, the frameworks, models, theories, and their key

ingredients were compared in tabular form, along with their definitions and occurrence in studies. Additionally, conceptual networks were created in ATLAS.ti using key metaphors as nodes to visualize and explore potential relations (see example in Multimedia Appendix 2).

At the second level, the characteristics of included studies and their overarching projects were compared in tabular form. Moreover, the general context of the underlying approaches was compared. To do this, a matrix was created to visualize the perceived level of clarity and extent of the extracted data [28].

The third level focused on the sources of the underlying approaches identified or cited in included studies (eg, the cited reference of a framework applied in a study). This approach used an explorative bibliometric analysis to assess the multidisciplinary range of such literature and investigate any potential relationships or trends. The references were snowballed and accompanied with co-citation analysis and topic modeling [39-41]. Snowballing can be an alternative to traditional systematic review methods used to identify literature pertaining to a topic of interest by scanning reference lists of studies [42].

Translating Studies

Key metaphors were systematically translated across studies in order to arrive at concepts that embodied more than one study [43]. The translation in a metaethnography is idiomatic (translating the meaning of the text) rather than literal (word for word), and it must take into account the context of the study [22,43]. This stage is characterized by two types of translation: reciprocal and refutational. Reciprocal translations aim to identify or generate metaphors that can better enable holistic accounts of phenomena [22]. On the other hand, refutational translations aim to give explicit attention to incongruities and inconsistencies in the data [43].

To avoid missing valuable insights, the review collected two types of metaphors distinguished by their source. Primary key metaphors were the key ingredients of frameworks, models, or theories operationalized by the authors of a study. Secondary key metaphors were remarkable phrases, concepts, ideas or perspectives by the authors of a study but not apparently derived from a structured underlying approach. Moreover, to assist the translation process it was decided to use the principles of the Center for eHealth Research (CeHRes) roadmap [5,6]. The roadmap is a guideline for holistic eHealth development that is itself based on a review of multiple frameworks and grounded in the integration of persuasive technology design [11], human-centered design, and business modeling [6]. It proposes five principles: (1) eHealth development is a participatory development process; (2) eHealth development creates new infrastructures for improving health care, health, and well-being; (3) eHealth development is intertwined with implementation; (4) eHealth development is coupled with persuasive design; and (5) eHealth development requires continuous evaluation cycles. The roadmap was only used to confront what has been done in the literature with an initial assumption of principles for a holistic approach. This step was operationalized by collectively characterizing both types of metaphors under one or several principles. This process created five clusters, each representing a principle. In the same manner, metaphors were also characterized to clusters of behavior change, technology adoption, or health-related outcomes if they were identified as potential enablers of intervention effectiveness. Clustering the metaphors allowed reviewers to deal with a smaller amount of metaphors at a time so idiomatic translations were performed under each cluster.

Synthesis Process

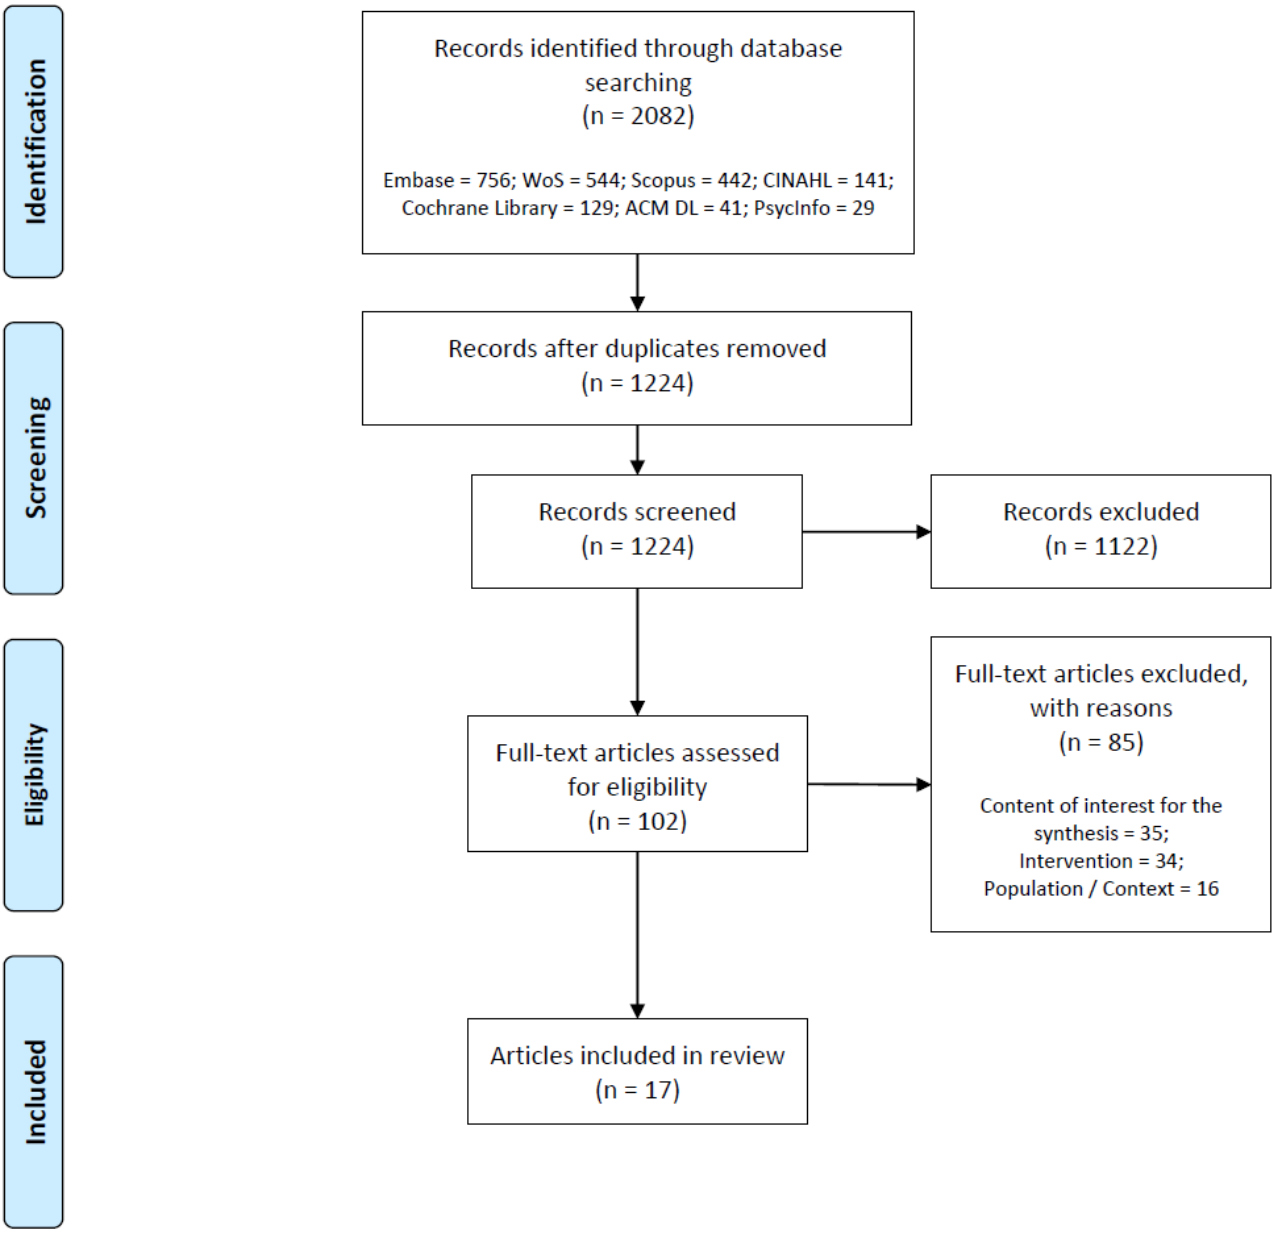
The relation and translation of studies as well as the synthesis process are considered complex analytical and highly overlapping phases of a metaethnography without a one-size-fits-all recipe [43]. To clarify the resulting approach of this review, Multimedia Appendix 2 includes an overview of the activities undertaken in phases 4 to 6 (see Figure 1). From the interpretive findings of the previous phases, a textual line-of-argument synthesis was created. A line-of-argument synthesis is a new storyline or overarching explanation of a phenomenon [43] (the third type of relation after reciprocal and refutational analysis). The synthesis was structured by revising the assumed holistic principles and emphasizing the key metaphors that extended over several themes. Each key metaphor could either contribute to the understanding of specific approaches, highlight important relations across multidisciplinary literature, or even suggest new knowledge derived from integrating unrelated approaches.

Results

Selected Studies

The initial search resulted in 1224 eligible records after removing duplicates. During the title and abstract screening, 1122 records were excluded; 85 more articles were excluded during full-text screening. Of articles excluded by full-text, 41% (35/85) had no relevant content for the synthesis (eg, no apparent framework applied), 40% (34/85) described an intervention that was out of scope (eg, not focused on self-management), and 19% (16/85) had an irrelevant target population or context (eg, not focused on CVD). Multimedia Appendix 3 lists all articles excluded by full-text. In the end, 17 articles were included for the review. Figure 2 summarizes the selection process via the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) flowchart [44]. The keywords, search string, and any additional settings used for the database search are reported as preliminary results in the protocol of this review [28].

Figure 2. Flowchart of included and excluded articles.



Study Characteristics

An overview of the characteristics of included articles can be found in Table 1 (see full table in Multimedia Appendix 4). The articles address 10 different overarching projects, identified as HeartMapp [45-47], Home and Online Management and Evaluation of Blood Pressure (HOME BP) [48-50], Seamless User-Centered Proactive Provision of Risk-Stratified Treatment for Heart Failure (SUPPORT HF) [51-53], PATHway [54,55], Congestive Heart Failure—Personalized Self-Management System (CHF PSMS) [56], MedFit [57], Smartphone Medication Adherence Stops Hypertension (SMASH) [58], Engage [59], MyHeart [60], and a mock-up [61] standalone study. The year of publication of the articles ranged from 2009 to 2018. The United Kingdom (n=7) and United States (n=5) were the most common affiliations of the authors. The most frequent journals in which the articles were published are the Journal of Medical Internet Research (3/17), BMC Medical Informatics and Decision Making (2/17), and Applied Nursing Research (2/17).

The articles were also divided across three target conditions: heart failure (9/17), hypertension (4/17), and CVDs in general (4/17).

Study design classification was done according to the Oxford Centre for Evidence-Based Medicine [62]. Analytic experimental studies are those in which the researcher manipulates the exposure, allocating subjects to the intervention or exposure group. Analytic observational studies are those in which the researcher simply measures the exposure or treatments of the groups without manipulating the exposure or allocation of subjects. Descriptive (qualitative) studies do not try to quantify the relationship but try to give a picture of what is happening in a population.

A total of 35% (6/17) of articles [46,48,49,52,54,60] focused on describing the development process of an intervention and often generally discussed results from more than one study. In these cases, classification by study design was not applicable. For the remaining articles, study design classification revealed

three types of study designs used for eHealth research: analytic observational [45,51,56,59,61], descriptive qualitative [47,50,53,55,57], and analytic experimental [58]. Multimedia Appendix 5 presents the quality appraisal of selected studies.

Table 1. Characteristics of included articles.

Project	Author; country[a]; year	Journal	Target
MyHeart	Villalba et al [60]; Spain; 2009	Conference publication; International Conference on eHealth, Telemedicine, and Social Medicine	HF[b]
SMASH[c]	McGillicuddy et al [58]; US; 2012	Conference publication; Wireless Health	HTN[d]
CHF PSMS[e]	Bartlett et al [56]; UK; 2014	BMC Medical Informatics and Decision Making	HF
SUPPORT HF[f]	Rahimi et al [51]; UK; 2015	European Heart Journal—Quality of Care and Clinical Outcomes	HF
SUPPORT HF	Triantafyllidis et al [52]; UK; 2015	International Journal of Medical Informatics	HF
SUPPORT HF	Chantler et al [53]; UK; 2016	Digital Health	HF
HOME BP[g]	Band et al [48]; UK; 2016	BMJ Open	HTN
HOME BP	Band et al [49]; UK; 2017	Implementation Science	HTN
HOME BP	Bradbury et al [50]; UK; 2017	BMC Medical Informatics and Decision Making	HTN
HeartMapp	Athilingam et al [45]; US; 2016	Applied Nursing Research	HF
HeartMapp	Athilingam et al [46]; US; 2018a	CIN: Computers, Informatics, Nursing	HF
HeartMapp	Athilingam et al [47]; US; 2018b	Applied Nursing Research	HF
Engage	Srinivas et al [59]; US; 2017	International Journal of Human—Computer Interaction	HF
MedFit app	Duff et al [57]; Ireland; 2018	JMIR Formative Research	CVDs[h]
no project	Baek et al [61]; South Korea; 2018	JMIR Cardio	CVDs
PATHway	Walsh et al [54]; Ireland, Belgium, Italy, Greece; 2018a	Translational Behavioral Medicine	CVDs
PATHway	Walsh et al [55]; Ireland, Belgium; 2018b	Journal of Medical Internet Research	CVDs

[a]Countries are included according to the reported affiliations of the authors.

[b]HF: heart failure.

[c]SMASH: Smartphone Medication Adherence Stops Hypertension.

[d]HTN: hypertension.

[e]CHF PSMS: Congestive Heart Failure—Personalized Self-Management System.

[f]SUPPORT HF: Seamless User-Centered Proactive Provision of Risk-Stratified Treatment for Heart Failure.

[g]HOME BP: Home and Online Management and Evaluation of Blood Pressure.

[h]CVD: cardiovascular diseases (in general).

Frameworks, Models, and Theories Applied to Research and Development

In total, 43 frameworks, models, or theories were identified as underlying approaches of the included studies. Textbox 1 and 2 present all of the identified approaches. Multimedia Appendix 6 includes the list of all key ingredients with their definitions per study. Multimedia Appendix 7 and 8 present the full relation between each underlying approach and the operationalized key ingredients by the included studies. In total, 27 different approaches were used to inform the system's development, implementation, or evaluation [52,58,63-92] (Textbox 1 and Multimedia Appendix 7). In contrast, 16 theoretical models were used to inform the system's content [50,93-113] (Textbox 2 and Multimedia Appendix 8).

Multimedia Appendix 7 shows that approaches to system development undertaken by the included studies often promote a participatory, user-centered approach—for example, the development and evaluation process for mHealth [71] or the person-based approach [81,82]. Several types of user-centered models were also identified [61,87,88,90]. Similarly, some frameworks were used to broaden the designer's perspective. For example, the systems engineering initiative for patient safety 2.0 [85] and the patient work lens for consumer-facing health [80] "encouraged the design team to 'think systems' and 'think bigger,' which in this case meant consideration of patients' long-term goals, overall workload, and integration of self-care recommendations into daily life" [59]. Among some focused approaches were, for example, the business-oriented frameworks applied in the HeartMapp project [47].

Textbox 1. Frameworks and models that informed the system's development, implementation, or evaluation.

- 5E usability approach [63]
- Action research [64,65]
- Agile software development [66]
- Behavior change wheel/capability, opportunity, motivation, and behavior model [68,69]
- Business model canvas
- Business research method [70]
- Development and evaluation process for mHealth [71]
- Goal-directed design [72]
- Holistic patient interaction model [73]
- Intervention mapping [74]
- Iterative design model [58]
- Iterative refinement and patient participatory approach [52]
- Iterative software design process [73]
- Iterative software development [75]
- Medical Research Council's guidance for developing and evaluating complex interventions [76-78]
- Multiphase optimization strategy [79]
- Patient work lens for consumer-facing health [80]
- Person-based approach [81,82]
- Practical guide to usability testing [67]
- Realistic evaluation framework [83,84]
- Startup owner's manual [86]
- Systems engineering initiative for patient safety 2.0 [85]
- User-centered design (ad hoc) [87,88]
- User-centered design [89]
- User-centered design of consumer-facing health information technology [90]
- User-centered design (International Organization for Standardization 1999) [91]
- Usability framework [92]

Textbox 2. Theoretical models that informed the system's content.

- Cognitive load theory [93]
- Cognitive theory of multimedia learning [94]
- Common sense model of self-regulation [95]
- Congratulate, ask, reassure, encourage approach [50]
- Control theory framework for personality—social, clinical, and health psychology [96]
- Domestication of technology theory [97,98]
- Information, motivation, behavioral skills model [99]
- Instructional design approach using a pedagogical agent [100]
- Multidimensional framework for patient and family engagement in health and health [113]
- Normalization process theory [101-103]
- Problem-based learning [104]
- Self-determination theory [105,106]
- Social cognitive theory [107-109]
- Social ecological model
- Technology acceptance model [110]
- Unified theory of acceptance and use of technology model [111,112]

Multimedia Appendix 8 shows the wide variety of theoretical models that were used to inform the system's content in the included studies. For instance, social cognitive theory [107-109] was used to outline the behavioral perspective of three different projects. Additionally, some theories were used to understand the process of technology adoption as an outcome, such as the domestication of technology theory [97,98] or the normalization process theory [101-103]. Comparably, technology acceptance was also analyzed through the unified theory of acceptance and use of technology model [111,112] and the technology acceptance model [110].

In general, the integration of multidisciplinary frameworks was frequent in the included studies and their overarching projects. Multimedia Appendix 9 presents how the overarching projects of included studies and their underlying approaches were compared across several levels. Multimedia Appendix 7 and 8 make evident that the HeartMapp [45-47], HOME BP [48-50], SUPPORT HF [51-53], PATHway [54,55], CHF PSMS [56], MedFit [57], SMASH [58], and MyHeart [60] projects were all informed by a combination of approaches from different areas of science. In contrast, the Engage [59] project focused on macroergonomic sociotechnical frameworks while the mock-up [61] study concentrated on a user-centered design research process. However, comparability across projects was influenced by the clarity and extent of the reported data in the selected articles. Multimedia Appendix 10 exemplifies the differences in clarity across studies and projects, while the full comparative analysis can be observed in Multimedia Appendix 9.

The multidisciplinary-based approach was sometimes an explicit goal of researchers. For example, the MedFit study aimed to adopt a "multidisciplinary approach to development [...] drawing on theories from engineering, computer science, and health psychology" [57]. In this line, frameworks were sometimes used to inspire tailored approaches. The most remarkable case was the guidance from the Medical Research Council (MRC) for developing and evaluating complex interventions [76-78], which informed four projects and in general was cited repeatedly in the included studies (see also its relative importance identified in the bibliometric analysis in Multimedia Appendix 9). However, sometimes how a framework informed another one was not completely clear. For example, the iterative software design approach of the MyHeart project [60] was stated to be informed by goal-directed design [72] and user-centered design [91] principles, but this statement was not elaborated in the selected article. Another example is the iterative refinement and patient participatory approach of the SUPPORT HF project [52], which is informed by action research [64,65] and agile software development [66] frameworks. Although such approach is clearly described, its explicit relation to the underpinning frameworks is not explicitly established.

Key Ingredients That Inform or Guide Development, Content, or Outcomes

The key ingredients as presented in Multimedia Appendix 7 and 8 facilitate a more detailed comparison of how underlying approaches were used. Mainly, the approaches to system development contain key ingredients that mostly represent stages of development, implementation, or evaluation. The stage-based ingredients that focus on creating a fit between the user and the proposed solution (eg, through co-design and formative evaluation) are eHealth-specific frameworks [71,81,82], guidelines for (software) iterative evaluation [52,58,73], or user-centered design methods [87-91]. On the other hand, some stage-based key ingredients guided systematic exploration, selection, and integration of theory with empirical evidence (eg, establishing why or how the intervention works through theoretical modeling). These ingredients are instead derived from research and intervention-building frameworks from behavioral [74], medical [76-78], or sociological [83,84] areas

of science. Other key ingredients did not represent stages of development but were constructs used to broaden the designers' perspectives—for instance, to understand human-technology interaction [73], the patient's work system [80,85] (ie, the workflow), ecosystem levels in health care [55], or key insights for business modeling [47]. The bibliometric analysis on the cited references of underlying approaches also observed a distinction between topics of intervention development, behavior change, and health care (see Multimedia Appendix 9).

In contrast, theoretical models provide key ingredients that were used to inform the content or outcomes of interventions. These ingredients could be psychological determinants [68,69,95,99,105-109] (eg, self-efficacy), mechanisms of action (self-monitoring [96]), or mediators (engagement [113]) for behavior change. Other key ingredients are about eHealth adoption, such as determinants of technology acceptance [110-112] (eg, ease of use) or processes and mediators of adoption [97,98,101-103] (eg, objectification).

In sum, the included studies highlighted participatory, user-centered, and iterative approaches with multiple perspectives about how to effectively influence the uptake of eHealth at several levels (eg, from individual cognition to the elements of a macroergonomic work system). Multimedia Appendix 6 shows how these ingredients and other insights (metaphors) of the included studies were compared and translated within and across studies. In the sections below, the included studies [45-61] (Multimedia Appendix 4) are mentioned by the first author's name in the text, their underlying approaches (Textbox 1 and 2 and Multimedia Appendix 7 and 8) are named and referenced when applicable.

Behavior Change

The effectiveness of eHealth systems in the included studies in terms of behavior change was operationalized by their success in improving self-management behaviors. In this regard, the operationalization of key ingredients could be better understood through the sociotechnical perspective which broadly conceptualizes self-management as a complex biopsychosocial process, as proposed by the systems engineering initiative for patient safety 2.0 [85] and the patient work lens for consumer–facing health [80] model. Throughout the included studies, the proposed general solution was the provision of tailored, personalized, or timely support (Band et al [48]), grounded in the potential of eHealth to deliver behavior change techniques that can facilitate long-term sustained behavior change (Duff et al [57]). Key ingredients were mostly informed by psychological theories such as social cognitive theory, which highlights determinants like self-efficacy, outcome expectancy, individual goals, and perceived impediments and facilitators [107-109]. Likewise, information, motivation, behavioral skills, and social opportunity were also parameters used by the selected studies to facilitate behavior change, based on the behavior change wheel [68,69] or the information, motivation, behavioral skills model [99]. Behavior change was also proposed to be at play during the adoption of a technology according to the normalization process theory [101-103]—for example, to explain how patients or health care providers must integrate several behaviors into everyday life (interactional workability) or how patients must be able to adapt their self-care routines when required (reconfiguration). Finally, the review collected a long list of practical applications (translations of behavior change techniques into intervention components) that showcased the similarity of current approaches to support self-management through remote monitoring technologies. For example, a familiarization phase (Walsh et al [54]) with the technology was an approach used by several studies. The most common features of the technologies included assessment, self-monitoring, feedback (during activity and after performance), behavioral change support (eg, goal setting, promoting home exercising), and education (eg, on disease management).

Technology Adoption

The effectiveness of eHealth systems in the included studies in terms of promoting technology adoption during the implementation process was operationalized mainly by the aim to create a fit between the system and the self-management routines of the patients. Primarily, technology adoption was informed in the included studies by the recognition of a diversity of user experiences (Chantler et al [53]), and the predominant strategy to undertake user-centered design [87,89] to address this heterogeneity. Once again, the tailored, personalized, and timely support (Band et al [48]) was the main driver during operationalization. Specifically, the adaptation to the personal routines of patients (Villalba et al [60]) was identified as a common idea across the included literature. In addition, the inclusion of a bidirectional service model (as in Baek et al [61]) or blended care which entailed communication between health care providers and patients was also an important theme across the included studies. This was in part because the sense of connection to a support team that a system provides to a patient could act as a key motivator for the use of the technology (Chantler et al [53]). Guidelines for health care providers to offer patient-centered support within a remote care context were applied by one of the included studies (Bradbury et al [50]). Remarkably, two major challenges of technology adoption were also identified. First, the technology knowledge gap (literacy) between younger and older generations (discussed by Duff et al [57]). Second, the inertia of disengagement, which was proposed to be tackled by the establishment of design goals that promote rather than assume baseline levels of engagement (Srinivas et al [59]). Technology adoption could also be assessed at multiple levels—for example, through a user interaction model (applied by Villalba et al [60]) that investigates the explicit and implicit interaction between the user and the technology or in terms of a multidimensional usability framework (applied by Walsh et al [54]). Notably, technology adoption could be explored through models such as the domestication of technology theory [97,98], which describes the processes of acceptance, rejection, and use of technology by its users (applied in Chantler et al [53]). Likewise, the unified theory of acceptance and use of technology and the technology acceptance model were other models of adoption that offered determinants such as behavioral intention, performance and effort expectancy, experience, and price value [110-112]. Finally, the key insights for building a minimum viable product (eg, value propositions), derived from the business model

canvas, were also interpreted as key ingredients to enable the desired adoption during implementation of the technology (Athilingam et al [47]).

Health-Related Outcomes

The paths to health improvement of the eHealth systems in the included studies were several. Overall, most of the listed ingredients could be categorized as engagement outcomes (eg, continued use and high usability), behavioral outcomes (eg, improved self-management), or health-related outcomes (eg, reducing admissions or increasing quality of life). In these terms, the operationalization of health-related outcomes in the selected studies focused notably on behavior change as the indirect path to increase health, an approach often grounded in the behavior change wheel and its capability, opportunity, motivation and behavior model [68,69]. For example, technologies were designed to include several intervention functions, such as enablement (increasing means and reducing barriers to perform the behavior), education (increasing knowledge or understanding), and environmental restructuring (changing the physical or social context). Moreover, the sociotechnical perspective of the systems engineering initiative for patient safety 2.0 [85] was used by Srinivas et al [59] to broaden the understanding of the various components of an intervention (eg, work processes) in relation to their impact on potential outcomes (proximal or distal, desirable or undesirable). An important challenge to improve health in the selected literature focused on hypertension (see Table 1 and Multimedia Appendix 4) was clinical inertia [58] (ie, the failure to establish appropriate targets and escalate treatment to achieve treatment goals). Additionally, the accurate measurement of changes in key determinants (eg, knowledge, as approached by Bartlett et al [56]) was also a possible methodological obstacle.

Fit of Key Ingredients With Holistic Principles for Research and Development

Projects at the intersection of self-management, CVD, and eHealth have directly or indirectly applied holistic principles for research and development. Namely, the principle of eHealth as a participatory development process and the principle that eHealth development is intertwined with implementation have been explicitly endorsed in the included studies. On the other hand, the principle that eHealth development creates new infrastructures for improving health care, health, and well-being has been partially operationalized through the use of various frameworks but has remained unacknowledged as a key underlying theme. Similarly, the principle that eHealth requires continuous evaluation cycles has been indirectly addressed by a wide variety of aims and methods operationalized across many phases of the eHealth development process. Ultimately, the principle that eHealth development is coupled with persuasive design was unacknowledged across included studies, although varied and generic approaches to inform design were found. Multimedia Appendix 11 illustrates the terms and definitions (metaphors) that constituted each cluster through conceptual networks.

Development Is a Participatory Process

The principle of participatory development has been widely operationalized as part of a fundamental integration of person-based approaches with theory and evidence (Band et al [49]) and directly grounded in the concept of user involvement, which was promoted throughout the included literature to conform with the guidelines of the MRC [76-78]. Moreover, the participatory approach was complemented with a socioecological perspective to secure inclusion of a diversity of user experiences (Chantler et al [53]) and multiple levels of the target group's ecosystem (as applied by Walsh et al [55]). The aims and methods for participatory development of the included studies have been extensively underpinned by user-centered design [87,89] and applied to the full extent of eHealth development phases (from planning to deployment [80-82,88]).

Development Creates New Infrastructures for Improving Health Care, Health, and Well-Being

Initially, the principle that eHealth development creates new infrastructures for improving health care, health, and well-being was thought to be self-evident given the scope of the review (remote care). The established aims of researchers and developers in the selected studies endorsed this principle, such as providing tailored, personalized, and timely support (Band et al [48]) or the unobtrusive remote delivery of system refinements (Triantafyllidis et al [52]). Key contextual factors were also highlighted by the included studies, such as the facilitating conditions (perceptions of the resources and support available to perform a behavior) defined by the unified theory of acceptance and use of technology model [111,112]. In this regard, as posed by the behavior change wheel [68,69], context can also include the policy categories surrounding technology-supported interventions (decisions made by authorities that help to support and enact an intervention). An early step to create an infrastructure can be to develop a program plan to describe the scope and sequence of intervention components, its required materials, and the protocols for implementation (as in intervention mapping [74]). In addition, the use of interdisciplinary methods (eg, factorial or fractionated evaluation designs discussed by Walsh et al [54]) and a socioecological perspective (Walsh et al [55]) are approaches that can facilitate the understanding of eHealth infrastructures and ecosystems (ie, identifying what works, who should be involved, and how in remote care support).

Development Is Intertwined With Implementation

An implementation focus such as the one promoted by the development and evaluation process for mHealth [71] was prominent across the selected literature, directly supporting this principle. However, the aims and methods to accomplish this were often vaguely and partially described. For example, business modeling [70,86] approaches have been used for research (Athilingam et al [47]), but only for an initial conceptualization of the technology (a first concept of the solution that still requires validation, as defined by the iterative software design process [73]). A highlighted example of development intertwined with implementation was the aim to provide remote delivery of system refinements as proposed in

the iterative refinement and patient participatory approach applied by Triantafyllidis et al [52]. This approach intended to facilitate continuous system updates without the use of valuable human resources. For this principle, only formative research (eg, focus groups in Duff et al [57]) and field studies (eg, Bartlett et al [56]) have been employed as methods that can be intertwined with the development process to understand and ideally increase the uptake of the technology.

Development Integrates Theory, Evidence, and Participatory Approaches for Persuasive Design

The term of persuasive design, prominent in the field of human-computer interaction, was completely omitted in the included literature. However, it was evident that the integration of theory-, evidence- and person-based approaches (Band et al [49]) was used to increase persuasiveness. In other words, the selected studies implicitly set persuasiveness as part of their development aims—for example, by the proposed personalization and tailoring (Chantler al [53]) of the intervention, the creation of habits in the use of a technology, or the leverage on the hedonic (fun, pleasure) (Duff et al [57]) and automatic motivation (emotional reactions) of end users (Band et al [49] or Walsh et al [54]). In this regard, theoretical approaches were often related to theoretical modeling (eg, the logic model of Band et al [49]), while evidence was explored through preclinical or theoretical research (eg, literature reviews) conforming to the MRC's guidelines [76-78]. As mentioned before, participatory or person-based approaches were more often applied as part of user-centered design. Hence, this revised principle highlighted how the included studies coped with the challenge of knowledge translation across different areas of research and its application to a specific aim (ie, integrating multidimensional ingredients that contribute to a common goal). To exemplify this, the aim for personalization and tailoring was derived from evidence that prioritized "the need to tailor...systems to user's capacity and preferences" (Chantler et al [53]), rather than preassuming these aspects as key principles to increase technology persuasiveness via the facilitation of task support (as proposed by the persuasive systems design model [11]). One trade-off made apparent by this revised principle and example is that the identified approaches were not related to theory developed specifically for technology-based interventions, and therefore their application to this area seemed to be open to the interpretation of researchers and developers.

Development Requires Continuous Evaluation Cycles

The requirement of continuous evaluation cycles in eHealth development revealed a contradiction within the included literature. The contradiction was outlined by the MRC's [76-78] proposed stepwise development of complex interventions, as opposite to its own practical recommendation to undertake a parallel approach that can integrate stages with distinct aims into larger phases of development. For example, a large phase of development can include preclinical or theoretical research (eg, understanding the users and their environment through literature reviews) [76-78], early solution finding (eg, discussing solutions with the target group as defined by the iterative design model [58]), and an initial theoretical conceptualization (as defined by the development and evaluation process for mHealth [71]) or modeling of the eHealth technology and its components (eg, deciding on the theoretical basis and proposing how an intervention could work) [76-78]. In practical terms, evaluation cycles were often defined by either the choice of an agile (rapid and cyclical stages) or waterfall approach (long and sequential stages) to product development (as discussed by Srinivas et al [59]). This principle also highlighted the importance of integrating interdisciplinary methods (as proposed by Walsh et al [54]) that accommodate to the planned evaluation cycles. In this regard, the creation of an evaluation plan (as in intervention mapping [74]), where variables are defined in a measurable way in relation with the intervention objectives, methods, and strategies, seemed to be a key phase to bridge early design with formative evaluation processes of eHealth. To apply continuous evaluation cycles, the included studies made wide use of user-centered design methods [87,89] such as usability testing but also other frameworks such as realistic evaluation [84], which is a theory-driven approach to evaluate the complexity of social programs (applied by Bartlett et al [56]).

Discussion

Principal Findings

The findings of this review confirm and exemplify the remarkable challenges posed by the multidisciplinary gap in the field of eHealth. Mainly, the review listed 43 multidisciplinary frameworks, models, theories, and guidelines that have informed interventions within the scope of eHealth applications to self-management of CVD. Multidisciplinary approaches were often integrated and aimed to create a fit between users, the content of an intervention, and its context. The following sections summarize and assess the contributions of the principal findings with prior and related works.

Bridging the Multidisciplinary Gap in Electronic Health Research and Development

In terms of development, the findings of this review place the integration of theory-, evidence- and participatory approaches to inform persuasive design as a newly generated overarching principle [49]. To do this, the studies often integrated knowledge from several disciplines, which in general has been argued as positive and desirable for eHealth [2]. However, in terms of design, one downside from the selected studies was that the approaches considered were often constrained to behavioral or sociological perspectives that were not focused on increasing the use and uptake of technology. In terms of implementation, this review suggests the importance of interdisciplinary methods that integrate broad perspectives such as the socioecological, sociotechnical [80,85], or business modeling [70,86] approaches. Specifically, the importance of workflow for the success of eHealth interventions has also been observed in another review [114]. Workflow can be defined as the way people interact with their work, communication pathways, and other people [114]. The inclusion of novel technological tools in the workflow of patients and health care providers was addressed in the reviewed studies through the lens of models such as the systems engineering initiative for patient safety 2.0 [85] framework or the domestication of technology theory [97,98]. For evaluation of eHealth, the reviewed literature acknowledged the iterative

nature of this process, but some of the identified approaches seemed to still be restrained by fixed stages of postdevelopment testing of effectiveness. It must be noted that these fixed research programs can hinder the adaptability of interventions to the dynamic and flexible reality of the patients [115]. In this light, a previous review on the adoption of self-management solutions has also showed that a broad "consideration of preconceived barriers and facilitators for adoption" might be too simplistic, because what is perceived as a barrier or facilitator for one individual could have the opposite effect for another [116]. To maximize adoption, it is therefore recommended to iteratively reevaluate key social, motivational, cultural, moral, and financial factors [116]. The continuous evaluation of these factors can be matched with participatory and user-centered principles.

Challenge of Reporting Intervention Content and Design

Overall, the findings of this review are in line with the general literature addressing several advantages to the use of theoretical frameworks for eHealth development and design and the different ways in which they can be operationalized [3]. However, the major challenge of adequate reporting of intervention design and content was also recognized (as discussed by Walsh et al [54] and Srinivas et al [59]). The lack of specification of the underlying approaches and their operationalization is still "suspected to be an artifact of publishing conventions and space constraints, as much as if not more than the nature of actual research being performed" [59]. All in all, the review included exemplary cases of publications with rich conceptual and descriptive data about eHealth development and design [46,49,54,56,57,59,60].

Strengths and Limitations

This is considered to be the first metaethnography focused on bridging knowledge from multidisciplinary fields of science to better understand and improve eHealth research and development approaches. The review made great efforts to follow a thorough, systematic, multilevel approach [28], adhere to recently developed guidelines [27], and be informed by similar studies [22,25,26,33-35,37,38,43,117-121]. Although the number of papers included was relatively low, metaethnography is a complex methodology and synthesis process that entails numerous challenges and limitations [122]. For this review, a main limitation in the search phase was that no efforts were made to contact the authors to request additional information on their studies. This would have added additional time constraints that were not seen as feasible. For the same reason, although reference tracking was originally planned [28], no further inclusions through this method were considered. Although it was an exclusion criterion, it could arguably be seen as a limitation that some studies were excluded because they did not explicitly describe their underlying approaches. Including more papers could have arguably added new perspectives to the synthesis, but the added time to the interpretive task would have been too burdensome. In the translation phase, several concepts and themes required a high level of interpretation and study contextualization acquired by rereading the articles several times and with different intentions (eg, for data extraction, comparison, or verification) [25]. The main reviewer applied this approach, but co-reviewers followed a sequential approach focused on validation or identification of inconsistencies. Finally, it should also be noted that the key ingredients were sometimes extracted from the sources cited by the selected studies. Hence, the review could have missed updates and refined assumptions or principles. For example, the intervention mapping protocol has been continuously upgraded in comparison with the cited source of the selected studies [123].

Conclusions and Recommendations

The multidisciplinary gap naturally constrains eHealth research and development to the structures and perspectives of discipline-specific frameworks that often miss key factors of the complex reality in health care. A holistic approach to the problem should consider multidisciplinary principles, such as those outlined by this review, to better define, structure, and report the underlying approaches to research and development of future eHealth interventions. The principles of the CeHRes roadmap mapped fairly well to what has been done in the selected literature. Positively, the use of participatory, user-centered design, and continuous evaluation cycles were commonly applied principles. On the contrary, less attention was given to the integration of implementation in the development process and implications of the new eHealth-based health care infrastructures as a whole. The integration of theory and evidence to inform (persuasive) design was an important principle that arose from the included studies, but the frameworks or models used to this purpose are not focused on creating a fit between human and technology.

Overall, it is recommended that researchers and developers make explicit and concrete statements about their approaches to eHealth. For instance, once a thoughtful decision has been made on guiding frameworks, models, or theories, it would be useful to also underline the holistic principles that are considered valuable by the research team (eg, will the approach consider existing evidence and theory or will it be solely guided by new data?). Unfortunately, there are no gold standards to report the content of eHealth interventions, beyond the CONSORT-EHEALTH checklist v.1.6 [31,32], which is specific to trials, and even less so to report underlying guiding principles. In the future, clearer operationalization (and reporting) of guiding frameworks and theoretical models is seen as vital to advance such knowledge in the field, as better predictive theories could provide an answer to the question "what works, for whom, in what settings, to change what behaviors, and how?" [124]. By and large, both theory and evidence must converge to determine the most effective mechanisms for technology-supported interventions. To accomplish this and move beyond what can be learned from published literature, holistic approaches can integrate patient-centered studies with consolidated knowledge from expert-based approaches (eg, via Delphi or other group decision-making methods [125]).

Finally, many questions still remain regarding the optimal use and advantages of specific frameworks or theories for eHealth development. Future reviews could aim to compare the effectiveness of theory-based eHealth interventions with those that do not make use of any. Moreover, more exploratory work

is needed to understand how different frameworks or theories are more relevant or useful for specific settings and contexts (eg, which types of theories or frameworks are better suited to inform remote care interventions and why?).

Acknowledgments

This review is part of the PhD project of RRCM, funded by the Mexican National Council for Science and Technology (CONACYT, in Spanish).

Authors' Contributions

RRCM led and was involved throughout all stages of the review process and managed the preparation of the manuscript. PDN assisted on the selection of the review method and provided methodological input at various stages. RAA contributed as co-reviewer for the selection process. RAA, JW, and JGP contributed to the translation and synthesis stages (see Multimedia Appendix 2). RS contributed in the ideation and early stages of the review process. JMN conducted the explorative bibliometric analysis. All authors critically evaluated the article and gave their final approval before submission.

Abstract

Background: Data from electronic health records (EHRs) are increasingly used in the field of genetic research to further precision medicine initiatives. However, many of these efforts exclude individuals with intellectual disabilities, which often stem from genetic conditions. To include this important subpopulation in EHR research, important ethical, legal, and social issues should be considered.

Objective: The goal of this study was to review prior research to better understand what ethical, legal, and social issues may need further investigation when considering the research use of EHRs for individuals with genetic conditions that may result in intellectual disability. This information will be valuable in developing methods and best practices for involving this group in research given they are considered a vulnerable population that may need special research protections.

Methods: We conducted a scoping review to examine issues related to the use of EHRs for research purposes and those more broadly associated with genetic research. The initial search yielded a total of 460 unique citations. We used an evaluative coding process to determine relevancy for inclusion.

Results: This approach resulted in 59 articles in the following areas: informed consent, privacy and security, return of results, and vulnerable populations. The review included several models of garnering informed consent in EHR or genetic research, including tiered or categorical, blanket or general, open, and opt-out models. Second, studies reported on patients' concerns regarding the privacy and security of EHR or genetic data, such as who has access, type of data use in research, identifiability, and risks associated with privacy breach. The literature on return of research results using biospecimens examined the dissension in the field, particularly when sharing individualized genetic results. Finally, work involving vulnerable populations highlighted special considerations when conducting EHR or genetic research.

Conclusions: The results frame important questions for researchers to consider when designing EHR studies, which include individuals with intellectual disabilities, including appropriate safeguards and protections.

electronic health records; privacy; informed consent; intellectual disability; genetics

Introduction

Background

The field of genetics has grown exponentially over the last decade. Advances in whole genome and exome sequencing have made the diagnosis of genetic conditions easier than ever before. Conditions diagnosed through these approaches run the gamut from cancer to rare diseases [1-4]. Genetic testing also is increasingly being integrated into clinical care and viewed as a common practice to detect genetic causes of conditions [5]. Another mechanism for genetic discovery lies with the increasing use of electronic health records (EHRs). EHRs have become a more commonplace tool in genetics, allowing researchers to conduct studies on specific genetic conditions, including observational, epidemiological, descriptive, and comparative effectiveness studies, among others [6,7]. EHRs are also being used to recruit participants for research studies and clinical trials [8].

Adding to their utility, EHRs can be linked with biobank data to answer genotype and phenotype research questions [9]. For example, the Electronic Medical Records and Genomics (eMERGE) network, which began in 2007, uses biorepositories linked to EHRs to conduct electronic phenotyping to identify patterns and diagnose disease [10-12]. More recently, the movement toward precision medicine has inspired other similar initiatives, such as Geisinger's MyCode Community Health Initiative [13] and *All of Us*, sponsored by the National Institutes of Health [14]. Other work has focused on phenome-wide association studies that analyze different phenotypes to determine a genetic variant [15].

All of these programs are designed with the promise of providing tailored health interventions based on an individual's genetic makeup. Ultimately, this may lead to a reduction in health disparities but only if a diverse array of individuals is included [16]. With this in mind, there have been calls to expand enrollment to underrepresented individuals, including those with intellectual disabilities [17,18]. Given that many conditions that results in intellectual disability can have genetic underpinnings, the inclusion of this subgroup in EHR research can provide insights into biological causes to various diseases and comorbidities [17].

Objectives

Previous work has examined ethical, legal, and social issues related to EHR use as well as combining EHRs with genetic data. However, research conducted to date has focused on typically developing individuals (ie, individuals with no known or suspected genetic conditions) who wanted to contribute their data to advance science and clinical practice [19], and thus, has predominantly excluded individuals with specific genetic conditions or those with intellectual disabilities. The inclusion of this group of individuals achieves the goal of making research, in particular the precision medicine initiative, more representative and patient-centered, and also aligns with the desires of those with disabilities [20]. Thus, there is a need to further explore the barriers or challenges of including this group of individuals in EHR research.

The goal of this study was to review existing studies to better understand what ethical, legal, and social issues may need further investigation when considering the research use of EHRs for individuals with genetic conditions that may result in intellectual disability. This information will be valuable in developing methods and best practices for involving this group in future research.

Methods

Design

We conducted a scoping review of the literature to examine ethical, legal, and social issues related to the use of EHRs for research purposes or issues more broadly associated with genetic research. We chose a scoping review approach given the breadth of literature in this area. This also enabled us to synthesize information from diverse sources, including theoretical and narrative reviews, qualitative studies, and quantitative research. We first identified our search terms; conducted a search of relevant literature; reviewed, charted, and collated the information; and summarized key findings [21,22].

Search Terms

Given that we were interested in ethical, legal, and social issues related to the inclusion of individuals with genetic conditions that resulted in intellectual disability in EHR research, we conducted searches for the following two topic areas: (1) research use of EHRs and (2) ethical, legal, and social issues of genetics research. The research team developed search terms for each topic area **(**Textbox 1**)**. Inclusion criteria included peer review articles published in English between 2000 and 2018. We conducted our search using the following databases: PubMed (Medical Literature Analysis and Retrieval System Online, MEDLINE), Cumulative Index to Nursing and Allied Health Literature (CINAHL), Cochrane Review, PsycINFO, and Web of Science.

Textbox 1. Search terms by topic area.

Research use of electronic health records

- medical record, health record, electronic record, electronic health information, health data, clinical record, clinical data, Health Insurance Portability and Accountability Act, HIPAA, PHR, EMR, EHR, eHealth, or e-Health, and
- outcome, research, measur*, assess*, evaluat*, analy*, study, or studies, and
- cognitive decline, cognitive impairment*, intellectual disabilit*, developmental disabilit*, autism, fragile X, Alzheimer*, genetic*, genomic*, vulnerable population, cognitively impaired, intellectually disabled, developmentally disabled, autistic,

Ethical, legal, and social implications of genetics research

- ethical issue, legal issue, social issue, ethical implication, ethical requirement, guardian, ethic, or social, and
- consent issue, informed consent, consent, medical record, health record, electronic record, electronic medical record, electronic health record, electronic health information, health data, clinical record, clinical data, Health Insurance Portability and Accountability Act, HIPAA, PHR, EMR, EHR, eHealth, or e-Health, and
- cognitive decline, cognitive impairment, intellectual disabilit*, developmental disabilit*, autism, fragile X, Alzheimer*, genetic*, genomic*, cognitively impaired, intellectually disabled, developmentally disabled, autistic

Abstract Review

The initial search yielded a total of 447 unique citations (duplicates removed): 206 in the research use of EHRs topic area and 241 in the ethical, legal, and social issues of genetics research topic area. We identified an additional 13 articles outside our initial search parameters, mainly from ethics journals that were not indexed in MEDLINE. The study team developed a coding structure in which each article was scored on a 4-point scale, with 0 being not at all relevant and 3 being extremely relevant. A pair of researchers were assigned the same abstracts and conducted blind coding of each to determine relevance for inclusion and whether a full-text review of the article was appropriate. The pair met to review and compare scores. In cases where scores did not match, researchers discussed and arrived at a consensus score. In total, 243 abstracts were deemed relevant (scored a 2 or 3) to obtain the full text. This included 120 in the research use of EHRs category and 123 in the ethical, legal, and social implications of genetics research category. The full-text articles were then reviewed, key findings were extracted and charted, and themes were categorized. The scoping review culminated in a total of 62 articles: 26 on the research use of EHRs and 36 on the ethical, legal, and social issues of genetics research. These full-text articles were reviewed, and themes were extracted (see Figure 1).

Results

Overview

We grouped the results into four broad ethical, legal, and social issues related to EHRs and genetic research that would applicable to those with intellectual disabilities (see Figure 2). The first section covers issues related to informed consent for the use of EHRs in research. This section includes a review of the legal requirements in the United States and also describes possible models of obtaining informed consent for EHRs and genetics research. The next section provides an overview of issues related to the privacy and security of EHRs and genetics research, including studies that examined preferences for who has access to information in the health record and what information is accessed. The third section examines the return of research results, which is most often considered within the context of genetics and biobank research. The final section discusses unique considerations for conducting research with vulnerable populations.

Informed Consent

Legal Requirements of Informed Consent

The first issue faced when conducting research with EHRs or on genetic conditions is whether informed consent is needed [23,24]. As set forth in the Common Rule and specified in US regulatory requirements, anyone conducting research with human subjects must have an institutional review board (IRB) review their study before initiation. Under the new federal regulations, referred to as the Final Rule [25], the definition of research remains unchanged as "a systematic investigation, including research development, testing, and evaluation, designed to develop or contribute to generalizable knowledge" (see 45CFR46.102(l)). However, the classification of "human subjects" now includes detailed definitions about identifiable private information (ie, "private information for which the identity of the subject is or may readily be ascertained by the investigator or associated with the information") and identifiable biospecimens (ie, "a biospecimen for which the identity of the subject is or may readily be ascertained by the investigator or associated with the biospecimen;" see 45CFR46.102(e)).

If informed consent is required, it can be obtained directly from the research participant or the participant's legally authorized representative. A legally authorized representative is determined by law or court authority. Under the Final Rule, individuals with intellectual disabilities or those with genetic conditions are not specifically referenced. However, research participants who may be "vulnerable to coercion or undue influence" or those with "impaired decision-making ability" are mentioned. Examples of these potential participants may include children, prisoners, or those with intellectual disabilities.

In the informed consent form, researchers need to include whether any identifiable private information will be used as part of the study. It is unclear if a specific genetic condition, intellectual disability would fall under the definition of private identifiable information within the Final Rule. The code simply mentions that definition of will be reviewed regularly and updated as needed. Until then it appears that agencies who implement this policy will need to define what falls under the umbrella of identifiable private information. The Health Insurance Portability and Accountability Act (HIPAA) Privacy Rule (see 45CFR160-164), which covers EHRs, does define genetic information and considers it protected health information. Like the Final Rule, HIPAA has specific requirements about sharing information, including data from an individual's EHR. Thus, EHR research on specific genetic conditions would need to be reviewed by an IRB to determine whether informed consent should be obtained from participants.

There are cases, however, when a waiver of informed consent can be granted. The following criteria must be met to request a waiver: (1) the research involves no more than minimal risk to the subjects; (2) the research could not practicably be carried out without the requested waiver or alteration; (3) if the research involves using identifiable private information or identifiable biospecimens, the research could not practicably be carried out without using such information or biospecimens in an identifiable format; (4) the waiver or alteration will not adversely affect the rights and welfare of the subjects; and (5) whenever appropriate, the subjects or legally authorized representatives will be provided with additional pertinent information after participation (see 45CFR46.116(f)). In general, local IRBs need to interpret the regulations and determine if a study qualifies as research on human subjects, and if so, whether a waiver of consent can be granted when conducting EHR research on genetic conditions.

When researchers meet all the requirements of a waiver of informed consent, it is often under the auspices of conducting research for the common good [26]. Examples include research

aimed at improving public health or the quality of medical care. However, EHR research without consent may violate the ethical principles of autonomy in the hopes of achieving beneficence and justice [27]. However, many bioethicists have argued in favor of EHR research without consent as long as the aforementioned requirements of a waiver are met, and proper privacy and security restrictions are in place [26,28,29].

Models of Informed Consent

If informed consent is not waived, several different models have been proposed for meeting human subject protection requirements and minimizing researcher burden. A tiered, or categorical, consent model that offers research participants options for how and when their data can be used has been espoused as best practice in the field on genetics research [30,31]. A tiered consent model allows participants to choose from many options, such as allowing their data to be used for the current study only, the current study as well as future studies about a specific condition or type of research, or unlimited use of their data [23,32,33]. This type of consent model could also include an option for reconsent, such as when a new subcategory of a genotype or phenotype for a particular condition is discovered that may need an additional level of consent before further research is conducted [34]. Although this approach is in line with the Belmont principle of *respect for persons* and encourages autonomy among research participants, some have criticized it given that it may be logistically challenging to implement and could potentially diminish the utility and applicability of clinical data, whether information in EHRs or biospecimens, for future research purposes [35,36]. A recent evolution of the tiered consent model is dynamic consent in which researchers and participants have ongoing communication that allows participants to update their consent preferences over time and enables researchers to return results to those interested [37].

A second approach to informed consent is the use of a blanket, or general, consent model [12,23,34]. Blanket consent can be described as an all-or-nothing option for using EHR data or biospecimens in future research. In other words, participants are given the choice to consent to all future research use of their data without being given the details of what that research may entail. The National Institutes of Health now asks funded investigators to include broad data sharing as part of their informed consent forms for genetic research studies [38]. Similar to the tiered consent model, there are advocates and critics of this approach. Proponents cite that it covers all the necessary ethical and legal requirements of informed consent, whereas detractors argue that the lack of specifics on future use means that it is more akin to providing permission than consent that is truly informed [39,40].

The open consent model, used by the Personal Genome Project, takes the blanket consent model a step further by stating up front that participants' data may be accessed broadly and there are no guarantees of anonymity, privacy, or confidentiality [34]. The goal of this approach is to provide more specifics about the possible ways data may be used and the risks of participating. Advocates of this approach argue that being open and honest about the study design and potential uses of data will promote trust and willingness to participate.

A final model of informed consent that has been proposed involves opting out of research participation. The opt-out model requires a participant to actively withdraw from the research. If they do not withdraw, it is assumed they passively consent to participate. This model was adopted by the Iceland biobank project, a national effort to merge three sources of data—EHR, genealogical, and genetic—into one database for research purposes [23]. The opt-out model, however, was not consistently applied across the data sources and was met with criticism by those who felt it did not offer adequate control for research participants or meet ethical and legal requirements [32]. It seems there is no uniform approach to seeking consent for biobank research [41].

Few studies have focused on informed consent models for accessing only EHR data, without a link to biospecimens. In a commentary on whether it is ethical to access EHR data, even identifiable information, without consent, Miller asserts the answer lies in the balance between risks and benefits [26]. In cases where the public good outweighs the personal risks to an individual, then informed consent can be waived under the auspices of a utilitarian philosophy. However, the objection to this approach is that it violates an individual's right to privacy.

Ultimately, under the Final Rule and HIPAA Privacy Rule, this decision rests in the hands of IRBs. However, in a study of IRB chairs and administrators that were presented with a hypothetical EHR research protocol, opinions varied widely as to whether informed consent was needed, even when identifying information was not included [42]. IRB chairs and administrators who stated that consent was needed reasoned that there was a risk for reidentification. Even though identifiable information (eg, last name) was not being extracted, other information such as birth date, postal code, and ethnic origin were included. IRB chairs and administrators who said consent was not needed stated that the data were anonymous or that the identifiability of participants was not relevant to determining if consent was required.

Patient Preferences Related to Informed Consent

Several US-based studies have examined the preferences of patients related to providing informed consent for use of clinical data, including both biospecimens and EHRs. In one large survey study, most patients were willing to participate in a biobank [43]. However, some studies suggest that participants tend to prefer a broad consent model, as long as no personally identifiable information is used [44,45]. In another study, public sharing of deidentified data was favored by the majority of participants when either a tiered or blanket option was given [46]. Sharing of data has not been shown to be related to level of understanding or recall of the informed consent process [47]. However, preferences for models of consent have been shown to vary by some sociodemographic factors, such as race, ethnicity, income, and education [43,45,46].

Consent preferences are also driven by what information is being accessed and how it is being used. Patients favored seeking consent for the use of medical history data and

treatment-related information [48]. Reconsent was preferred when researchers were investigating a health condition that was unrelated to the one for which they originally gave consent, if deidentified data were shared with an investigator at a different institution, and when a child for whom a parent had previously given consent had reached adulthood [43,49]. Patients' decision to consent to research use of their biospecimen is also related to personal characteristics, including whether a participant has an existing genetic condition [49].

Studies in Europe and Canada have found similar preferences. Surveys and focus groups with patients in Ireland and the United Kingdom indicated a preference for some level of control over use of EHR data for research, with many favoring a study-by-study or tiered consent model [50-52]. In an Italian study, over half of those enrolled in a national twin registry were against the use of their EHR data without informed consent [53]. Similarly, in Canada, participants preferred to be asked for consent either verbally or in writing before releasing their EHR data to researchers [54].

Privacy and Security

Who Has Access to Data for Research Use

One of the most common ethical, legal, and social issues related to using EHRs for research is who has access [27,33,55]. Patients often had the most concern about health insurance and pharmaceutical companies as well as government agencies using their EHR data for research purposes [44,54,56-58]. Pereira et al [59] found that 66.9% (328/490), 44.9% (220/490), and 40.0% (196/490), respectively, did not want insurance companies, pharmaceutical companies, and the government to have access to their health information. Patients worried that research conducted by pharmaceutical companies would be used to promote products, and there was potential for insurance companies to deny coverage for patients [54]. These companies were seen as less "legitimate" to patients because the research they were likely to conduct was not "pure science," which aimed to generate knowledge for the common good [58]. Patients were also concerned with unauthorized access to their medical information or sharing of EHR data with noncredible researchers [57]. One example cited was government researchers accessing EHR data but then selling it to a pharmaceutical company [56]. Therefore, patients often desired greater oversight of individuals who conducted EHR research within these organizations [44]. Typically, the amount of trust a patient had in the researcher or organization conducting the research was related to the patient's views on privacy [44,51,54,56].

What Type of Data Are Accessed for Research

Some patients reported that they would prefer to limit access to certain information in their medical records to maintain privacy [58,60]. Patients were less likely to share sensitive information such as substance abuse history, mental health information, sexual health information, domestic violence records, reproductive health records, and genetic information and would want to be asked permission before sharing this information with researchers [60]. In particular, patients were concerned with the disclosure of conditions viewed as stigmatizing, such as HIV/AIDS and mental illness, to researchers [56-58]. One study reported that patients viewed reproductive and mental health information as more sensitive than genetic data [58]. To ensure privacy, some patients wanted to limit access to portions of their EHR to their health care provider [61] or not include any sensitive information in their EHR [16,33].

Identifiability of Data

Despite widespread support for research use of EHR data and biospecimens, patients often preferred that their information remain anonymous [49,51]. Hull [62] conducted interviews with patients of academic medical centers to examine attitudes and preferences on the use of anonymous versus identifiable samples for genetic research. On the basis of responses to two hypothetical scenarios, 72.96% (850/1165) preferred to be informed about the use of their anonymous blood samples, whereas 83.35% (971/1165) of patients wanted to be told if it was an identifiable sample. However, only 23.38% (271/1159) of patients responded differently to the two scenarios, with most (196/1159, 16.91%) indicating they wanted to be notified about the use of an identifiable sample and did not need to know if it was done with an anonymous sample.

In biobanking research, similar privacy concerns have been raised about lack of oversight and the potential for biospecimens to be identified [63,64]. Although technology has enabled large-scale genomic studies to be conducted, the sharing of data with outside researchers and linking of biospecimens with EHRs has increased the potential for reidentification of participants [23,63]. Improved data mining technology has also contributed to privacy and identifiability concerns [65]. Despite the fact that some research has shown that reidentification of biospecimens and EHR data is difficult when proper security controls are in place [66,67], concerns about privacy and security are likely to be an ongoing issue.

Risks Associated With Breach of Privacy

Patients voiced concerns about the implications of breaches of privacy. Common fears were discrimination, stigmatization, or psychosocial discomfort if medical information was shared with insurance companies or employers [22,23,51,63]. Similarly, employment and life insurance discrimination concerns were raised by community advisory group members regarding the presence of genomic information in the medical record [68]. In addition, concerns were expressed by some that genetic health information may affect their medical care—specifically the discontinuation or withholding of treatment [68]. In genetics research, patients also cited worries about release of information to family members without their consent [22,63]. Moreover, genetic information about risk for having a late-onset disease, such as Huntington's, could lead to social stigmatization as well as insurance and employment discrimination [22,65,69].

Factors Related to Patients' Views on Privacy

Three studies identified some individual factors related to views on privacy. Older people, described as individuals aged 50 years and older, reported less concern with privacy of genetic information than did younger people in a focus group study [58]. Gender differences were found related to the potential consequences of a security breach. Male patients reported

concern about impacts on employment, finances, and insurance, whereas female patients were concerned about risks related to social discomfort and embarrassment [51]. Finally, those who had more experience with using computers were less concerned about security issues [59].

Return of Research Results

Return of Individualized or Aggregate Results

Bioethicists have debated whether to return the results of genetic research to biobank participants. Much of the discussion has focused on the return of individualized versus aggregate results. Most agree that returning aggregate or summary results, through a newsletter or website, is appropriate. This is seen as both a measure of accountability for the researchers conducting the study and a sign of respect for the participants [23]. The provision of individual genetic results from a research study, though, has been a more contentious subject. Ethical arguments in favor of returning results are grounded in the principle of *respect for persons* and *beneficence* [23]. Having access to genetic information about oneself may have an impact on one's health, quality of life, and future decision making. Returning individualized results to participants also prevents researchers from being gatekeepers of important information. However, those against sharing individual results cite that research and clinical care should not be blurred, and an investigator providing genetic results is acting more like a clinician than a researcher. In addition, those opposed state that research and clinical testing are quite different, with the goal of the latter being to provide better care to a patient, whereas the former is concerned with creating generalizable knowledge [23].

Given this debate, several ethics boards and research committees have created recommendations or guidelines for when to share individualized results, including for which genetic conditions [31,70,71]. The eMERGE network has also addressed this issue [72]. Among these guidelines, there is consensus that individual results should only be returned if they are medically actionable, even if they were incidental findings. Researchers are also encouraged to thoughtfully consider the language in the informed consent form that details what types of results will be shared with participants [22]. However, in a recent study that examined informed consent forms, the majority of consent forms did not discuss return of results [73]. The authors acknowledge, though, that many of these forms may have been created years before any guidance was offered on this issue.

Patient Preference for Return of Research Results

When patients have been asked about their preferences for the return of research results, most indicate they want to know. In a survey of patients enrolled in a Health Maintenance Organization (HMO) plan, about two-thirds said they would be willing to participate in research within the HMO if written information about the study was provided to them and almost three-fourths if results were provided [74]. Another study asked participants about their views regarding collection of tissue samples and genetic testing [49]. Return of test results was strongly supported by all participants, with the highest level of support among those who were concerned about having a health condition that may be genetic. In a survey of preferences for return of results using donated tissue samples, just under half (129/271, 47.6%) reported they always wanted to be given individual results, 25.1% (68/271) wanted results only after the researcher had assessed the risks and benefits of sharing the information, and 27.3% (74/271) wanted results if their doctor thought the information would inform decision making related to their care [75]. Respondents who thought genetic information was more sensitive than other types of health information were more likely to want to be told all individual results.

Research on Vulnerable Populations

Genetic Research on Vulnerable Populations

Important ethical, legal, and social issues are raised when vulnerable populations are involved in genetic research [76]. Although similar to the issues already discussed, concerns related to recruitment, informed consent, privacy and security, and disclosure of results are often amplified when conducting research with vulnerable populations [23,77].

A clear example is when children are recruited to be part of genetic studies. One study asked adults whether they would want to be reconsented if their parents enrolled them in a biobank study when they were children. Overall, most respondents (799/1186, 67.37%) said they would be willing to continue participation, but almost half (543/1186, 45.78%) wanted to be reconsented [78]. In a review of procedures used in 6 different birth cohort studies, investigators found that blanket consent was never used. However, the studies varied in their approach to returning research results; although some provided participants and their families with routine clinical information and test results, other studies only informed participants if test results were abnormal for a treatable condition. Finally, all studies recontacted participants when they reached adulthood and allowed them the opportunity to withdraw or reconsent [79]. A recent study, though, examined an alternative consent model. When presented with an opt-out model of enrollment into a study that linked the child's EHR with biospecimens, most parents were supportive [80]. Parents stated there was little risk given that the data would be deidentified. Although some were concerned about the security of EHR data, none raised reservations about access to genetic information.

Electronic Health Record Research on Vulnerable Populations

Although studies have been conducted using EHRs of vulnerable populations, such as epidemiological research [81-83], very few have examined the ethical, legal, and social issues related to this type of research. Simon and colleagues [84] discussed the risks and benefits of conducting research on individuals with psychiatric conditions using large medical databases. Although privacy risks are of critical concern, the authors argued that these population-based research methods have provided many benefits, including information on prevalence estimates, treatment effectiveness, and impact of health policy. With appropriate safeguards, this research can also lead to reducing stigmatization and discrimination through education and outreach efforts based on research findings.

Discussion

Summary of Findings

In this study, we sought to better understand the ethical, legal, and social issues related to the use of EHRs of individuals with intellectual disabilities by examining similar issues, as well as patients' preferences, that have been raised in EHR research among the general public and in genetics or biospecimen research. The main themes we highlighted were related to obtaining informed consent, privacy and security of data, and the return of research results. With the push to expand precision medicine initiatives and EHR research to a diverse group of participants, it is important for researchers to consider the implications of these issues for individuals with genetic conditions, particularly those that result in intellectual disabilities. Below, we pose questions about each of these issues that researchers should consider when designing methods to involve those with intellectual disabilities in EHR research.

Given the issues related to informed consent that have been raised in prior studies, what are the best models of informed consent for use with individuals with genetic conditions who have intellectual disabilities? Is a broad or blanket consent model appropriate for this population? Would an opt-out model be ethically acceptable? or is the tiered consent model the only viable option? and would the type of consent model applicable for adults also be applicable for children with genetic conditions that result in intellectual disability? To answer these important questions, researchers should consider the decisional capacity of the individuals being asked to participate in the study. For example, individuals with fragile X syndrome, the most common inherited form of intellectual disability, may present with a range of impairment, from normal or mild delays to severe intellectual disability. Young children with a genetic condition, no matter their level of functioning, will require permission from a parent or guardian to participate in EHR research. However, when children with fragile X syndrome or other genetic conditions that result in intellectual disability reach adulthood, their capacity to consent should be assessed to determine if they adequately understand the study, including the risks and benefits of participating.

A large body of research has examined the capacity to consent in individuals with Alzheimer or other forms of cognitive impairment [85-88], and a handful have examined decisional capacity in individuals with intellectual disability [89-91]. This literature, combined with the ethical, legal, and social issues raised in this study, will help to inform the proper consent models for EHR researchers interested in recruiting participants who have a genetic condition that may result in intellectual disability. Experts agree, though, that a shared decision-making process should be employed to support these individuals to make informed consent choices [92-94].

Another set of questions arise regarding the privacy and security of EHR research conducted with individuals with intellectual disability that stems from a known or suspected genetic condition. Will these individuals have the same concerns as the general public regarding privacy and security of their EHR data, including who has access and what information researchers can see? Will these individuals be more reluctant to participate in EHR research due to the risk of identifiability, even if data have been deidentified? Or will they be less worried given that they may have more to benefit from EHR research? Much of the potential vulnerabilities of individuals with intellectual disabilities is related to the fear of coercion or possible stigmatization or discrimination that could result from misuse of research data [95].

EHR research conducted by pharmaceutical companies may trigger either support or apprehension from individuals with intellectual disability. Pharmaceutical companies play important roles in partnering with researchers to develop and test treatments; however, pharmaceutical companies may also be viewed unfavorably given the high cost of orphan drugs for some rare genetic conditions [95-98]. Similarly, those with an intellectual disability may be more or less willing to share sensitive or identifiable data with EHR researchers. If an individual has already been diagnosed with a genetic condition that results in intellectual disability, the risk of identification may be less significant if the individual's diagnosis is commonly known. But, for those with very rare genetic diseases, there may be a heightened risk of identifiability, mainly because there are so few patients with a given condition [99]. It is difficult to answer these questions because few studies have examined the preferences of individuals with intellectual disabilities about participating in research more broadly [100], and none have asked about EHR research in particular. More work is needed to understand the implications of privacy and security issues for individuals with intellectual disabilities to help researchers determine how best to address them. At a minimum, the risks and benefits related to privacy and security should be carefully outlined in the informed consent form so individuals with intellectual disabilities and their parents or legally authorized representative can weigh the risks and benefits of participation and make informed decisions. Ideally, EHR research and informed consent forms will continue to evolve as laws and other privacy safeguards for the use of clinical data are updated [101].

The central question about the return of EHR research results for individuals with intellectual disabilities is whether individual or aggregate results should be provided to participants. The same potential for the blurring of the lines between clinical care and research applies here as it does for those in the general public who join biobanks as "healthy" individuals. If a secondary condition related to a genetic condition is discovered through EHR research, is it necessary to notify the participant? The answer may lie in what is contained in the informed consent form. If the secondary finding is medically actionable and participants agree to be informed, then results should be returned. But, if the result does not require immediate medical attention, then researchers may not necessarily need to disclose it. Researchers should carefully consider the types of information they may learn from EHR research involving individuals with intellectual disabilities and determine *a priori* what types of results would qualify as needing to be returned. Then, participants should be provided with a choice as to whether they wish to be notified. If individual results are not returned, then

aggregate results in the form of patient-friendly summary reports or newsletters should be considered [102].

Limitations and Future Research

It is important to note there were limitations in our approach. First, although we were broad in our search terms and criteria, we may have missed pertinent articles that should have been included. Similarly, because this was a scoping review and not a systematic review, there may be other ethical, legal, or social issues related to EHR research on individuals with intellectual disabilities that we do not cover. Finally, although we reviewed articles that included both US and non-US studies, our review of informed consent and federal laws were limited to those in the United States.

In conclusion, the issues highlighted in our review of the literature provide a framework for researchers to consider when conducting EHR research with individuals with intellectual disabilities. Future research should focus on further understanding the ethical, legal, and social issues in this type of research by asking individuals with intellectual disabilities, and their parents, for direct input on their preferences. Both qualitative and quantitative approaches will provide valuable information for researchers, so they can design studies that are more inclusive of this population using appropriate safeguards and protections, as needed.

Abstract

Background: The disproportionately high prevalence of HIV among men who have sex with men (MSM) is a global concern. Despite the increasing utilization of electronic health (eHealth) technology in the delivery of HIV prevention interventions, few studies have systematically explored its effectiveness and association with various intervention characteristics.

Objective: This study aimed to conduct a meta-analysis of the effectiveness of eHealth technology–based interventions for promoting HIV-preventive behaviors among MSM and to determine effectiveness predictors within a framework integrating design and implementation features.

Methods: A systematic literature search using terms related to eHealth technology, HIV, the MSM population, and an experimental study design was performed using 5 databases (ie, MEDLINE, PsycINFO, EMBASE, Web of Science, and ProQuest Dissertations & Theses) and other sources (eg, bibliographies of relevant reviews and JMIR Publications). First, primary meta-analyses were conducted to estimate the effectiveness of eHealth interventions (d_+) in changing 3 HIV-preventive behaviors among MSM: unprotected anal intercourse (UAI), HIV testing, and multiple sex partnership (MSP). Moderation analyses were then conducted to examine a priori effectiveness predictors including behavioral treatment components (eg, theory use, tailoring strategy use, navigation style, and treatment duration), eHealth technology components (eg, operation mode and modality type), and intervention adherence.

Results: A total of 46 studies were included. The overall effect sizes at end point were small but significant for all outcomes (UAI: d_+=−.21, P<.001; HIV testing: d_+=.38, P<.001; MSP: d_+=−.26, P=.02). The intervention effects on UAI were significantly larger when compared with preintervention groups than with concurrent groups. Greater UAI reductions were associated with the increased use of tailoring strategies, provision of feedback, and tunneling navigation in interventions with a concurrent group, whereas reductions were associated with the use of self-paced navigation in interventions with a preintervention group. Greater uptake of HIV testing was associated with longer treatment duration; computer-mediated communication; and the use of messaging, social media, or a combined technology modality. Higher intervention adherence consistently predicted larger effects on UAI and HIV testing.

Conclusions: This study provided empirical evidence for the effectiveness of eHealth interventions in promoting HIV-preventive behaviors among MSM. Features of treatment content and eHealth technology might best predict the intervention effects on UAI

and HIV testing, respectively. Most importantly, intervention adherence tended to play an important role in achieving better effectiveness. The findings could help inform the development of efficacious interventions for HIV prevention in the future.

Introduction

Background

In marked contrast to a declining trend in its global burden in the era of potent antiretroviral therapy, the HIV epidemic has continued to expand in the men who have sex with men (MSM) population across countries of all incomes in recent years [1,2]. The disproportionate burden is evidenced to be driven by a stable increase in HIV risk behaviors [3,4], which may offset the benefits of improved treatment coverage and biomedical advances [3,5]. Undiagnosed infections or infections diagnosed late arising from the relatively low uptake of HIV testing also fuel the epidemic by hampering treatment delivery and increasing transmission [6,7]. Therefore, the promotion of HIV-preventive behaviors is an indispensable part of comprehensive prevention efforts to control HIV [8]. Behavioral interventions among MSM have been found to significantly reduce risky sexual behaviors and increase HIV testing [9,10].

The global response to the ongoing epidemic warrants the application of innovative technology to develop efficacious behavioral interventions [7]. Electronic health (eHealth) is well recognized as the use of information and communication technologies for health, including websites, computerized programs or apps, social networking sites or chatrooms, email, or text messaging, that feature internet connectivity or digital interactivity via computer or mobile devices [11-13]. Previous quantitative reviews have shown that the impact of eHealth technology–based interventions on HIV prevention–related behaviors and theoretical correlates was significant but varied as a function of intervention characteristics [14,15].

New technology has been extensively used by MSM to socialize and seek sexual partners and to access information on sexual health [16,17]. An early meta-analysis revealed a significant effect of sexual health interventions delivered via interactive digital media for the overall population but not MSM, although a growing body of evidence has been accumulated since then [12]. Despite recent synthesis attempts focusing on MSM [18,19], the evaluation of effect magnitudes across outcomes and the disentanglement of efficacious components from complex intervention designs have been limited by the qualitative nature of the reviews. There is a lack of meta-analytic reviews that would allow rigorous testing of the a priori factors that predict intervention effectiveness [20] and thus inform the design and implementation of future programs.

Potential Predictors of Electronic Health Intervention Effectiveness

An eHealth technology–based behavioral intervention includes 2 elements: *behavioral treatment* (what type of intervention is designed and programmed to target behavior change) and *eHealth technology* (how the treatment is delivered via eHealth platforms). This study proposed a conceptualized framework to capture critical factors that are theoretically and empirically demonstrated to explain the effectiveness of eHealth interventions.

Behavioral Treatment Components

Treatment content is characterized by the *use of theory* for intervention development, as theoretical constructs can be operationalized into treatment techniques [21]. Significantly greater reductions in unprotected anal intercourse (UAI) among MSM have been observed for interventions reporting any use of theory [9], yet it is unclear whether the extent of use predicts intervention effectiveness, particularly in the eHealth context. A meta-analysis of internet-based behavioral interventions across health domains revealed a significant association between more extensive theory use and increased effect sizes [22].

Treatment content also features the application of *tailoring strategies*, defined as the integration of recipients' responses into the intervention system to generate user-driven content [23]. There are 3 tailoring types: (1) *feedback*: providing unique recommendations derived from an assessment of individual needs or characteristics related to a given behavior; (2) *adaptation*: matching content to a relevant group based on known behavioral determinants; and (3) *personalization*: customizing content with personally identifiable information [24]. Computer technology–based interventions with individually tailored content adapted to the stage of change were shown to be more efficacious in increasing condom use in the general population [14].

The programming features of a treatment can strongly determine the intervention intensity. The amount of accessible content per interaction with the intervention differs by *navigation style*: *tunneled* interventions deliver treatment through a predetermined sequence of steps, whereas *self-paced* interventions release content all at once and permit recipients to control the navigation [25-27]. Existing evidence is inconclusive regarding the influence of navigation style on the effectiveness of eHealth interventions [26,28,29]. *Treatment duration*, referring to the time span of delivery, represents the overall intervention burden. Larger effects and higher adherence have been generally reported for online behavioral interventions of a shorter duration [23].

Electronic Health Technology Components

On the basis of the nature of users' interaction with eHealth platforms, 2 *operation modes* of technology use for intervention delivery have been distinguished: (1) *human-computer interaction (HCI)*, featuring direct interaction with a computerized system and automated delivery of a

preprogrammed treatment and (2) *computer-mediated communication (CMC)*, featuring remote delivery through interpersonal communications via eHealth media. These are considered to be inseparable, albeit essentially different aspects of eHealth technology and capable of deploying similar treatment strategies [25,30]. It has been reported that the provision of remote therapeutic support, not fully automated treatment, achieved significantly better psychological outcomes than passive control [31].

Four *modality types* have been applied to eHealth interventions for HIV prevention, and each of them possesses a unique capacity to facilitate intervention delivery [11,19,32]. The 2 most common modalities are the *interactive module*, in which users actively engage in an intervention following a preset workflow, and the *static site*, in which users passively receive prescriptive information [30]. A previous review suggested the superiority of interactive over static interventions in predicting increased condom use and sexually transmitted infection (STI) testing [12]. The strength of *text messaging* lies in the ubiquitous use of mobile devices to deliver real-time personalized interventions [11,33]. It can incorporate effective communication techniques and has demonstrated its efficacy in promoting health behavior change [33,34]. This study uses the broader term, "messaging," to encompass related technologies that enable multimedia delivery [33]. *Social media* has emerged as a novel modality that features the creation and sharing of user-generated content in an online community [32,35], which can effectively promote HIV testing [35].

Exposure to Intervention Components

Intervention effectiveness observed in real-world practice can change with actual exposure to efficacious intervention components, and nonusage attrition is common in eHealth interventions [36]. *Intervention adherence* is conceptualized as the proportion of participants who engage in the intervention as prescribed to achieve a desired effect [29]. This allows for a comparable measurement of intervention exposure across use parameters, by contrasting the *actual usage* of an intervention during its implementation with the *intended usage* predefined at the design stage [25]. Adherence has been found to significantly predict the effectiveness of eHealth interventions [23].

This study aimed to conduct a meta-analysis of the effectiveness of eHealth technology–based interventions for promoting HIV-preventive behaviors among MSM and to provide an in-depth investigation of effectiveness predictors.

Methods

The guidelines of the Preferred Reporting Items for Systematic Reviews and Meta-Analyses were followed [37].

Search and Selection

A systematic search was first performed in the following databases: MEDLINE, PsycINFO, EMBASE, Web of Science, and ProQuest Dissertations & Theses. The search strategy comprised 4 categories of terms related to eHealth technology, HIV or AIDS, the MSM population, and experimental study design, which were tailor-made for each database with restrictions to the English language and human studies (Multimedia Appendix 1). We manually searched bibliographies of relevant reviews, initially retrieved articles, and JMIR Publications to identify additional eligible studies. The eligibility criteria are listed in Table 1.

After removing the duplicates, 3657 relevant articles were identified from all the search sources. The title- and abstract-based eligibility screening was first conducted by 2 independent reviewers, which led to a selection of 143 articles for further full text–based assessment. Finally, 45 articles with a total sample size of 27,704 were deemed eligible and included in this meta-analysis [38-82]. The selection process is shown in Figure 1.

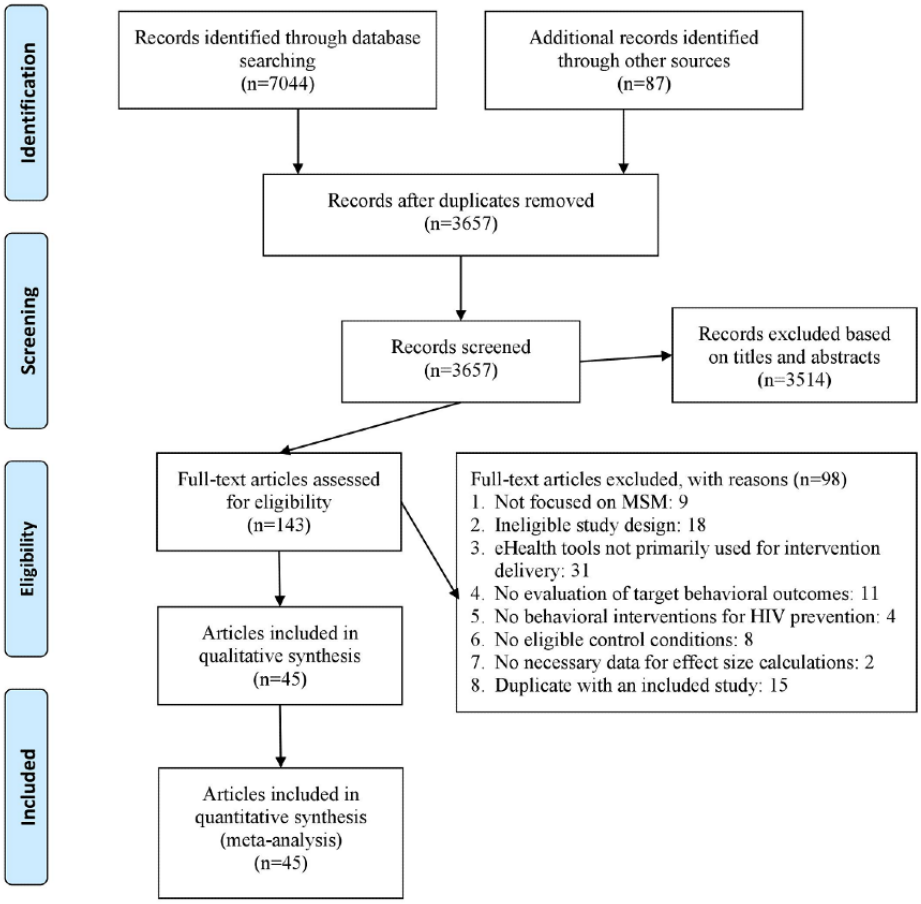
Table 1. Eligibility criteria for elements of a comprehensive search strategy.

Element	Inclusion and exclusion criteria
Population	• Included: being exclusively or primarily (accounting for at least 80% of the sample) focused on MSM[a] or specifically conducting the efficacy evaluation among the MSM subgroup
Intervention	• Included: delivering interventions largely via eHealth[b] technologies, including internet-based tools or interactive computerized programs and administering behavior change interventions for the prevention of HIV infection • Excluded: solely using non-eHealth technologies (eg, telephone-based communications); not specifying the role of eHealth components in a multimedia program; or solely adopting biomedical strategies (eg, pre-exposure prophylaxis) or targeting the HIV care continuum after diagnosis (eg, treatment as prevention) or other sexual health topics (eg, contraception)
Comparator	• Included: using control conditions that are different from interventions in the eHealth components • Excluded: solely aimed at testing a group difference in other factors (eg, sample characteristics or treatment approaches)
Outcome	• Included: measuring HIV-preventive behaviors as efficacy outcomes and providing necessary statistics to estimate the effect size • Excluded: treating HIV-preventive behaviors as confounders or compensatory outcomes (eg, condom use measured in interventions on promoting monogamy); solely measuring behavioral correlates (eg, intentions) or biomarkers of engagement in HIV risk behaviors (eg, sexually transmitted infection occurrence); or computing a composite score for a group of behaviors
Study design	• Included: a randomized controlled trial or nonrandomized experiment • Excluded: a single-group posttest-only experiment; an observational study; or a review or commentary

[a]MSM: men who have sex with men.

[b]eHealth: electronic health.

Figure 1. The Preferred Reporting Items for Systematic Reviews and Meta-Analyses flowchart of the screening process. eHealth: electronic health; MSM: men who have sex with men.



Quality Assessment

In all, 44 intervention programs were involved (2 articles reported outcome measures at different follow-up points for the same program). Program quality was evaluated using the assessment tool of Schnall et al [19], which was developed based on the reporting standards for HIV intervention studies established by the HIV Prevention Research Synthesis Team of the US Centers for Disease Control and Prevention [83] and has been well applied in previous reviews [9,19]. An overall percentage score (0%-100%) was computed as the extent to which each program fulfilled the criteria across 7 categories: representativeness, bias and confounding, description of intervention, outcomes and follow-up, statistical analysis, strength of evidence, and group equivalence.

Data Extraction

Program Design

Data were extracted from each eligible program and its supplementary materials by one coder (MX) and double-checked by a second coder (AL). Information was first gathered on factors related to the program design, which were used to define the coding unit and to determine the grouping sets for the primary meta-analysis.

One intervention condition and one comparator were selected to form an independent study (a pairwise comparison) for the meta-analysis. If more than one intervention group was reported, each of them was separately included, given the potential variation in interventions, while the initial control group was proportionally divided up among intervention conditions to ensure independence [84]. If more than one control group was reported, the less intensive one was included for ease of interpretation [85]. If an eligible concurrent comparator was not obtained, or independent group contrasts were not the program focus, the preintervention status was treated as the comparator [86]. Finally, for each established comparison, identification items (eg, author) and sample characteristics (eg, age) were coded.

Study design was classified according to the outcome assessment points and comparison status (ie, using a concurrent or preintervention group). *Comparator type* was coded as (1) passive, including blank, waitlist, and attention controls or (2) active, including non-eHealth and lower tech eHealth treatment. *Follow-up period* was classified according to the interval between the intervention end and the follow-up points: (1) immediately postintervention; (2) short-term: ≤3 months; or (3) long-term follow-up: >3 months. The *outcome measures* with adequate studies for effect size pooling were UAI, condom use, HIV testing, and multiple sex partnership (MSP).

Intervention Features

A cluster of prespecified factors that captured the intervention characteristics were coded within the conceptualized framework described earlier. A relative coding rule was applied, that is, where a certain item was identical across the paired conditions, the study was coded as not having that feature, as it could not explain the conditional difference in the effectiveness.

With regard to the key features of treatment content, the extent of *theory use* was first assessed using the modified Theory Coding Scheme [21]. A total of 11 items pertinent to intervention development were used to compute an overall score [22], with a higher value indicating more extensive use of the theory. The second content feature was the *use of tailoring strategies*, which was coded in both ways, binary (whether adopting the *feedback*, *adaptation*, or *personalization* strategy) and continuous (the number of strategies adopted). The programming-specific treatment features were categorized into mutually exclusive groups: *navigation style* (self-paced or tunneled) and *treatment duration* (single session, ≤1 month, >1-3 months, and >3 months).

The utilization of eHealth technology was characterized by the *operation mode* (ie, HCI and CMC) and the *modality type* (ie, static site, interactive module, messaging, and social media). For both variables, interventions with the presence of more than one feature were grouped into a combined category to allow for exclusive coding. As indicators of intervention exposure, *intended usage* was first extracted and varying levels of *actual usage* were identified accordingly. *Intervention adherence* was then calculated as the percentage of participants whose actual usage matched the intended usage [25].

Data Synthesis

Effect Size Calculation

Standardized mean differences between conditions (Cohen *d*) and their standard error at each follow-up point were derived to represent the magnitude of intervention effects [87,88]. Following Morris and DeShon's [89] procedures, the effect size estimate and its sampling error were computed or transformed to be scaled on a common "raw-score" metric, creating a synthesis across the study design. Unadjusted outcome measurements were retrieved to establish comparability across estimates. For studies in which means and standard deviations were not provided, effect measures reported in other forms (eg, risk ratio) were converted to the Cohen *d* statistic using well-developed calculators [90,91].

As recommended, UAI and condom use were combined into one outcome type, "UAI" [14]. For studies that used multiple instruments to measure an outcome, the most common instrument was chosen (eg, the frequency of UAI was prioritized over the count of UAI partners [56]). For studies measuring different subtypes of a certain outcome on the same scale (eg, serostatus-specific UAI [71]) or reporting subgroup effects by significant moderators that were unrelated to intervention components (eg, affect level [44]), all effect sizes were aggregated meta-analytically within the study. Consequently, each study yielded only one Cohen *d* value per outcome.

Meta-Analysis

With an assumption of the intervention diversity, pooled effect sizes (d_+) and 95% confidence intervals were generated using random effects models with the inverse variance weighting method. Values such as 0.2, 0.5, and 0.8 were interpreted as small, moderate, and large, respectively [92]. Primary meta-analyses were performed to combine effect sizes within different study sets for each outcome: (1) an overall estimate at

the end point (one effect arising per study); (2) group-specific estimates of the end point effect by comparison status (nested groupings); and (3) group-specific estimates by follow-up period (a multi-wave study contributing multiple effects). To maximize analytical power, the first type of estimation based on a full data set was used for further analyses.

Heterogeneity across studies was assessed by using the Q statistic with a *P* value <.05, indicating the presence of significant heterogeneity, and quantified by using the I^2 statistic, where a value of 30% to 60% denoted "moderate" and ≥75% denoted "considerable" heterogeneity [93]. Wherever considerable heterogeneity was found, outliers were identified as studies that significantly distorted the pooled effect using influence analyses [94] and were removed to ensure the accuracy and generalizability of the findings. Publication bias was then assessed by visually inspecting the funnel plot of effect sizes and conducting an Egger regression test to examine the plot asymmetry when there were at least 10 estimates [95].

Next, secondary analyses were performed to test the moderation effect of intervention features where adequate studies were available (n≥10) [96]. Subgroup and meta-regression analyses were applied for dichotomous and continuous measures, respectively; a significant moderator was indicated by a *P* value <.05 for the heterogeneity across subgroups (Q_b) or the regression coefficient (β). All analyses were conducted in R 3.5.2 with the metafor package (Wolfgang Viechtbauer) [97].

Results

Descriptions of Program Characteristics

Over half of the eligible programs (23/44, 52%) were conducted in the United States, and 10 and 8 programs were conducted in Asia and Europe, respectively. Among programs reporting the respective background characteristics, most of the samples had a mean age below 30 years (24/44, 54%), were multiracial or Asian (29/39, 74%), were mainly (≥70%) composed of homosexual males or gays (22/28, 78%), and were non-HIV positive or of mixed (both positive and negative) status (33/36, 92%). In addition, the median overall quality score was 84.2%; the assessment results are provided in detail in Multimedia Appendix 2. A total of 46 studies were further identified from these programs; most of them conducted a concurrent comparison (n=29) and used a passive comparator (n=39). The study characteristics are provided in detail in Multimedia Appendix 3.

Results of Primary Analyses

Unprotected Anal Intercourse

In combing all 35 studies that tested for UAI, a significant and small overall intervention effect was observed at end point (d_+=−.32; *P*<.001), albeit with considerable heterogeneity (I^2=83.3%). One study included subjects who reported recent condom-less sex with partners of either gender before enrollment; such a high-risk preintervention status might have contributed to the greatly decreased UAI (*d*=−1.13; SE 0.21) [49]. Moreover, the sample had the highest mean age of 45.1 years among all studies. Another study was focused on MSM sex workers and primarily addressed the context of transactional sex [63]. An extremely positive effect was found for reduced UAI with nonpaying male partners (*d*=−3.95; SE 0.35). Removing both outliers resulted in a smaller effect with moderate heterogeneity (d_+=−.21; *P*<.001; I^2=50.8%).

When stratified by the partner-specific outcome, a larger end point d_+ was shown for UAI with main partners than with nonmain partners. When stratified by the follow-up period, a significant d_+ was obtained at all points. The nested subgroup analysis found a significantly greater intervention effect when compared with preintervention groups than with concurrent groups (Q_b=13.38; *P*<.001); hence, the meta-analysis was performed separately for the 2 types of comparison status as recommended (Figures 2 and 3) [89].

Figure 2. A forest plot of intervention effects on unprotected anal intercourse against concurrent comparison groups.

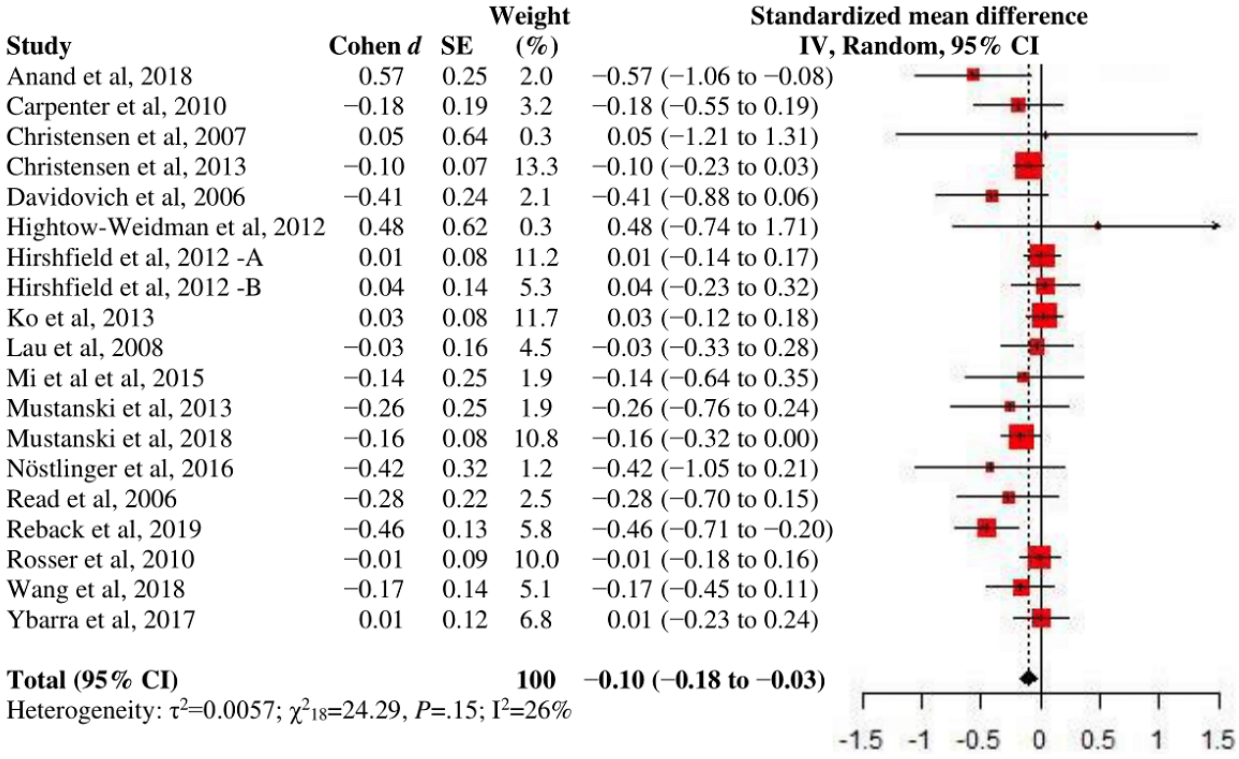


Figure 3. A forest plot of intervention effects on unprotected anal intercourse against preintervention comparison groups.

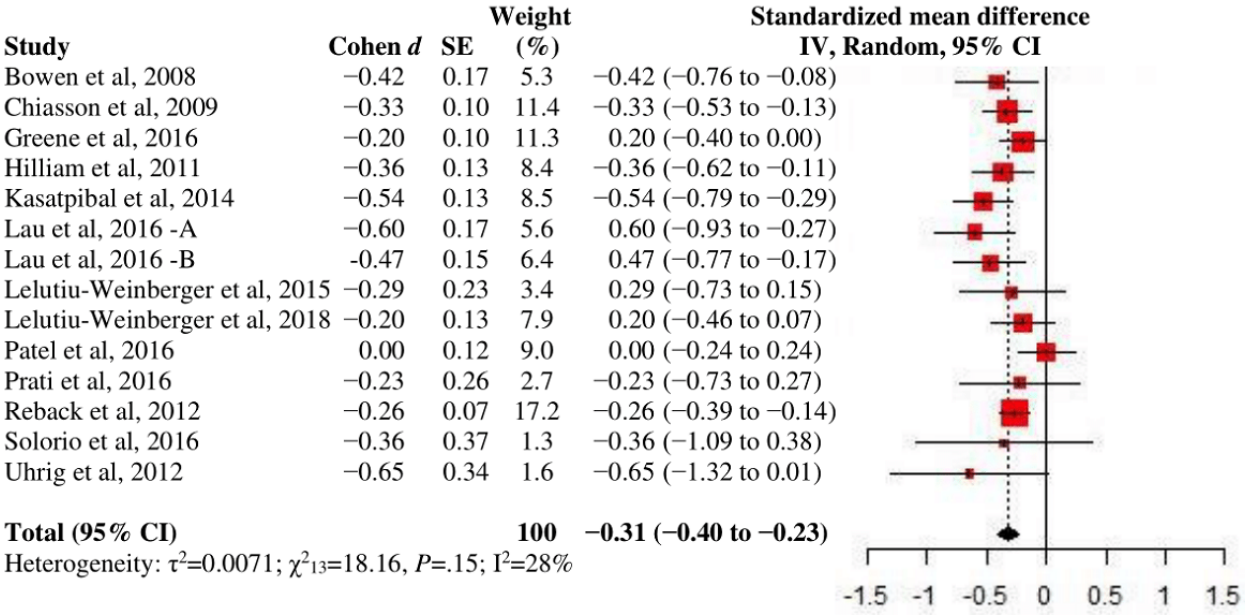
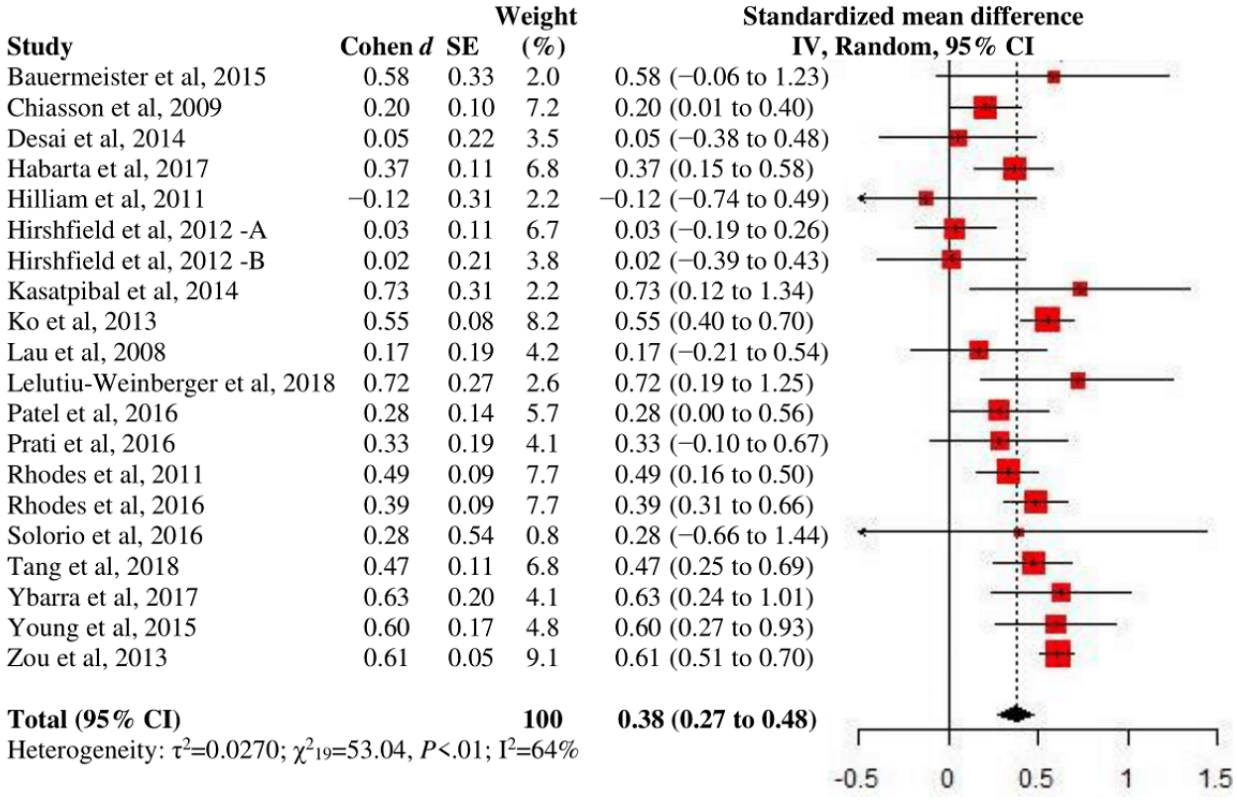


HIV Testing

Similarly, pooling the studies that tested for HIV testing revealed a significant, small overall effect at endpoint (n=23; d_+=−.32; P<.001). The considerable heterogeneity (I^2=84.0%) identified was largely attributable to the detection of outliers. Bourne et al [40] tested a texting reminder intervention against a blank control group involving participants who had refused such reminders; thus, the extreme effect size (d=.80; SE 0.06) could have been susceptible to volunteer bias. Wang et al [79] promoted a novel self-testing approach and distributed free home-based testing kits; the uptake of any type of testing was found to be considerably higher in the intervention group (d=1.18; SE 0.14). Mikolajczak et al [62] unexpectedly found a negative but nonsignificant intervention effect on HIV or STI testing relative to an active comparator (d=−.13; SE 0.12). The exclusion of outliers caused a slight change in the effectiveness but substantially reduced heterogeneity (d_+=.38; P<.001; I^2=64.2%; Figure 4). A larger d_+ was further shown at postintervention than at short-term follow-up; however, only one sample was followed up for more than 3 months. No significant group difference by comparison status was observed.

Figure 4. A forest plot of intervention effects on HIV testing.



Multiple Sex Partnership

A significant, small overall effect was observed on the reduced MSP at endpoint with moderate heterogeneity (d_+=−.26; P=.02; n=6; I^2=60.2%; Figure 5). The largest d_+ was shown at medium-term follow-up among all follow-up periods, although only a few studies were available for each grouping. No between-group test was performed for comparison status because of the small number of studies. Publication bias was detected for none of the outcomes. More results of primary analyses are presented in Table 2.

Figure 5. A forest plot of intervention effects on multiple sex partnership.

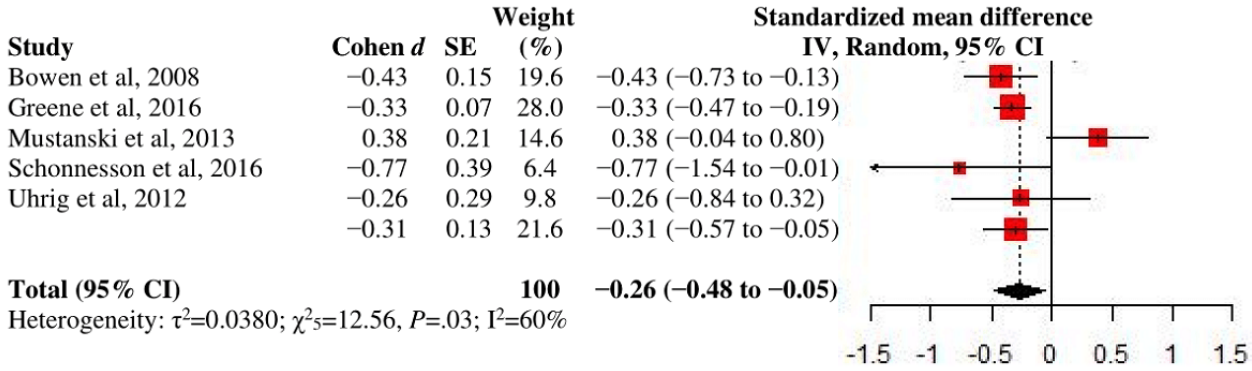


Table 2. Overall effect sizes and stratification by study design features.

[a]Q_w denotes the degree of within-group heterogeneity.

[b]Q_b denotes the degree of between-group difference in the pooled effect sizes.

[c]UAI: unprotected anal intercourse.

[d]N/A: not applicable.

[e]Studies with exclusion of outliers.

[f]Non-nested groupings: one study could contribute to more than one grouping.

[g]Effect sizes at the endpoint were pooled.

Results of Moderation Analyses

Behavioral Treatment Components

Most of the studies were designed based on a theory (n=37); the most common one was the information-motivation-behavioral skills model (IMB; n=14). The intervention effects on UAI and HIV testing appeared to be comparable regardless of whether any theory was used. Among the theory-based studies, IMB was significantly associated with greater UAI reductions than other theories for concurrent comparisons (Q_b=4.33; *P*=.04). The more extensive

use of tailoring strategies was significantly associated with decreased UAI for concurrent comparisons (β=−.08; *P*=.01). Specifically, feedback was the only strategy that had a significantly negative effect on UAI (Q_b=4.00; *P*=.04), whereas adopting the personalization strategy tended to have a positive effect on HIV testing (Q_b=2.76; *P*=.10).

Significantly greater UAI reductions were shown for the tunneled (Q_b=7.23; *P*=.01) and self-paced (Q_b=4.23; *P*=.04) treatments relative to concurrent and preintervention groups, respectively. Such a moderating effect of navigation style was not detected for HIV testing. Longer treatments showed a significantly greater increase in HIV testing than those with a single session or those lasting ≤1 month (Q_b=16.97; *P*<.001). However, the effects on UAI did not significantly differ across treatment durations.

Electronic Health Technology Components

Over half of the interventions were operated via HCI (n=26), and the others were in a CMC (n=10) or combined (n=8) mode. More studies used a single modality (n=32) than those incorporating multi-modalities in the same intervention albeit with varying combination patterns (n=14). No between-group difference was observed in the intervention effects on UAI by operation mode or modality type. The CMC and combined modes tended to present a larger d_+ value for HIV testing than did the HCI mode (Q_b=2.76; *P*=.09). When separately exploring the effect of specific modes, the use of CMC predicted a significantly greater increase in HIV testing (Q_b=4.38; *P*=.04), whereas HCI use showed no association with effectiveness. Moreover, a significantly larger d_+ value was found for the use of messaging, social media, and multi-modalities than for static sites (Q_b=12.79; *P*=.005).

Intervention Adherence

Among all interventions, the adherence rates ranged from 25.5% to 100%. A higher adherence rate was significantly associated with a decrease in UAI for concurrent comparisons (β=−.27; *P*=.03). Given the highly negative skewed distribution, the studies were evenly divided into 3 levels to reflect the degree of relative adherence; the adherence rates were above 91.6% in the first tertile and below 76% in the third tertile. Intervention effects on HIV testing significantly differed by adherence level (Q_b=7.28; *P*=.03). A moderate d_+ value was observed for high-level studies (in the first tertile) and a small one for mid- and low-level studies. Details of the intervention features are presented in Multimedia Appendix 4; more results of moderation analyses are presented in Multimedia Appendix 5.

Discussion

Principal Findings

This study identified 46 eligible studies published since 2006, which highlight the increasing application of eHealth technology in intervention delivery for HIV prevention over the last decade. Most studies tested the effectiveness of an entire intervention against a passive comparator. Those with an active comparator delivered a treatment that was either a basic component of a comprehensive intervention package [79] or existing online information that the intervention group might be exposed to as well [62]; hence, it is possible to isolate the effects of specific intervention components.

Effectiveness of Electronic Health–Based Interventions

The primary meta-analysis consistently revealed a significant and small overall intervention effect for all the behavioral outcomes at endpoint. Considerable heterogeneity was nevertheless detected for UAI and HIV testing, and some influential cases were further identified to show extreme effect sizes and distinctive study characteristics. Removal of the outliers weakened the pooled effectiveness for both outcomes to some extent. In line with extant reviews, eHealth-based interventions exerted a greater impact on HIV testing [12] and the number of sex partners [14] than on condom use. Notably, the magnitude of effectiveness observed is seemingly higher than that in the general population [12], which suggests that the MSM community may benefit more than others from eHealth-based interventions.

Furthermore, the meta-analysis within the groupings by outcome type demonstrated greater reductions in UAI with main partners than with nonmain partners. It is recommended that future interventions target the partner-specific determinants of risky sexual behaviors. Most of the studies evaluated the postintervention and short-term effects across outcomes. Only 6 study samples were followed up for more than 3 months and showed a comparable decrease in UAI to that at earlier timepoints. It was not possible to estimate the long-term effect on HIV testing and MSP owing to the lack of data. This finding emphasizes the need to explore the effectiveness of eHealth interventions in maintaining behavior changes, especially given the necessity for consistent condom use and regular HIV testing [7,98]. The greater effect on UAI found for the pre-post comparison was probably confounded by factors unrelated to the intervention (eg, fatigue). Nevertheless, the heterogeneity between comparison types may also have resulted from the different intervention components deployed by the 2 groups of studies, as has been discussed in the following sections.

Predictors of Intervention Effectiveness

Behavioral Treatment Components

This study confirmed the previous finding [14] that the use of the theory did not moderate the effectiveness of eHealth-based interventions for HIV prevention, although the majority of treatments were developed on a theoretical basis. The overall extent of theory use failed to significantly influence effectiveness across outcomes. However, this finding may merely reflect a lack of sensitivity in distinguishing an effect [99]. The number of tailoring strategies used significantly moderated effectiveness in reducing UAI, and only the most frequently used strategy, that is, feedback, was further shown to be effective. Treatments were less tailored for interventions promoting HIV testing, and only the moderating effect of personalization use reached marginal significance. Some evidence supporting the superiority of certain strategies has been reported [23]. The use of feedback and personalization commonly featured tailoring at an individual level, whereas the

use of adaptation generated content matched to group-level factors.

Inconclusive results were found for the role of navigation style. Tunneled treatments achieved greater UAI reductions than self-paced treatments in studies using a concurrent group but lower reductions in those using a preintervention group. A plausible explanation is that the tunneling pattern differed across comparison types. A tunneled treatment by definition requires multiple interactions with the intervention, which could impair the effectiveness of eHealth behavioral interventions [23]. Over 60% of treatments with a preintervention group involved more than 5 modules, whereas only 24% of those with a concurrent group did so. Above all, the efficacy of the tunneling design itself is controversial as, on the one hand, the sequential release could ameliorate information anxiety and enhance the behavioral change process, whereas, on the other hand, the artificial confines could inhibit typical information-foraging behavior and intervention participants may lack the motivation to accommodate such constraints [100,101].

Longer treatments significantly predicted higher uptake of HIV testing but not reduced UAI, which adds to the evidence in favor of a difference in the influence of treatment duration on sexual and detection behaviors [12]. However, this finding might merely reject a linear relationship between treatment duration and the effect on UAI. A recent meta-analysis even demonstrated a negative effect of increased intervention length on intervention adherence and behavioral impacts, driven by decreased motivation over time [23].

Electronic Health Technology Components

Taking advantage of both human communication (eg, flexibility and rapport building [49]) and eHealth-enabled capacities (eg, convenience and anonymity [30]), the use of CMC was shown to be effective in increasing HIV testing. There was little evidence for the moderating effect of the operation mode on UAI, although only 1 intervention used a CMC mode. The results illustrate the need to incorporate human involvement into eHealth interventions. A variety of communicative functions have proved their efficacy in promoting behavior change, including counselor- or user-initiated conversations and peer-to-peer interactions [22]. Moreover, the greatest effectiveness was obtained with a combined mode, so the relevant question is not whether HCI or CMC is superior but, rather, how to combine them to maximize persuasiveness.

Similarly, intervention effects on the outcome of HIV testing but not UAI varied by modality type. Messaging, social media, and the combined type achieved a comparably small-to-medium effect. Messaging, largely operated via portable devices, affords individualized interventions (eg, location-based services) and dynamic connections (eg, response on request) [11,102]. Social media stands out for its capabilities to influence social norms and create a peer-supportive environment [103], especially within a closely connected community such as MSM [35]. It also enables interventions to blend into users' daily lives by utilizing well-established platforms (eg, Facebook) [32]. The use of hybrid modalities may further generate a synergistic effect.

Intervention Adherence

Consistent with previous literature [23], a high degree of adherence to eHealth interventions predicted a protective effect on UAI and HIV testing. Assuming intention-to-treat as the motive to engage in an intervention, adherence is rooted in the properties of intervention design. Efficacious strategies (eg, self-monitoring), observable benefits (eg, health outcomes), and feasible programming (eg, appropriate workload) can all bolster engagement [26,36]. Usability of eHealth technology is also critical to minimizing discontinuance [36].

Limitations

This study focused on the behavioral aspects of HIV prevention. Notably, it did not indicate the superiority of stand-alone behavioral interventions over other prevention tools (eg, pre-exposure prophylaxis) but was, rather, an attempt to explore the possibility of leveraging technological advances to strengthen an integral part of comprehensive biobehavioral prevention efforts, especially at a transition stage when the role of biomedical prevention is limited by its slow and uneven scale-up [7,104]. It is also impossible to synthesize evidence for other preventive behaviors owing to insufficient data (eg, serosorting) or highly heterogeneous measurements (eg, substance use). The potential interplay among intervention components has not been examined because of the lack of statistical power. Some other effectiveness predictors may also be missed (eg, eHealth literacy [26]), although the key factors with recognized terminology and accessible coding sources were selected. Finally, these findings could not represent studies reported in a language other than English, although there was no evidence of biased effectiveness among previous language-restrictive meta-analyses [105].

Conclusions

This meta-analysis demonstrated eHealth technology to be a promising tool for delivering HIV prevention interventions among the MSM population. Nevertheless, there is limited evidence on the long-term impact of such interventions, and more research is warranted to investigate their application in non-Western contexts. Our findings suggested that enhanced behavioral treatment (eg, the use of tailoring strategies) determined the effect of eHealth interventions on UAI reductions, whereas appropriate programming (eg, longer treatment duration) and advanced eHealth technology (eg, the use of social media) predicted an increase in HIV testing. Future intervention design should focus on integrating efficacious treatment and technology components as well as on exploring their potential interplay. It is also recommended to incorporate implementation strategies to improve intervention adherence and, thus, achieve better effectiveness.

Acknowledgments

The authors would like to express their heartfelt gratitude to Ms Beizhu Ye and Ms Mei Zhao, who provided support with screening, and to the authors of the original studies, who provided additional information necessary for this review. This study was supported by the Early Career Scheme for 2017-2018 (reference no. 24106317), and the funding agent was the University Grants Committee of Hong Kong. The funding source(s) was not involved in the literature review, systematic review, meta-analysis, and writing of the report.

Abstract

Background: Supporting women to initiate and continue breastfeeding is a global challenge. A range of breastfeeding interventions employing electronic technologies (e-technologies) are being developed, which offer different delivery modes and features over the internet; however, the impact of internet-based e-technologies on breastfeeding outcomes remains unclear.

Objective: This study aimed to identify the characteristics of current internet-based breastfeeding interventions employing e-technologies and investigate the effects of internet-based e-technologies on breastfeeding outcomes.

Methods: A systematic search was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines in the following databases: Scopus, Web of Science, the Cochrane Database of Systematic Reviews, ScienceDirect, Google Scholar, the Association for Computing Machinery, SpringerLink, and Institute of Electrical and Electronics Engineers Xplore.

Results: This systematic review included 16 studies published between 2007 and 2018, with 4018 women in 8 countries. The characteristics of the interventions were grouped based on (1) mode of delivery (web-based, mobile phone apps, and computer kiosk), (2) purpose of the interventions (education and support), and (3) key strategies (monitoring and breastfeeding tracking, personalization, online discussion forum, web-based consultation, and breastfeeding station locators). Combining educational activities with web-based personalized support through discussion forums appeared to be the most effective way to improve breastfeeding outcomes and long-term exclusive breastfeeding rates. Monitoring and breastfeeding trackers appeared to be the least effective ways.

Conclusions: This study demonstrated a variety of internet-based e-technologies that professionals can use to promote, educate, and support breastfeeding women. Future internet-based breastfeeding interventions employing e-technologies might consider improving interaction with mothers and personalizing the content of the proposed interventions.

breastfeeding; mobile app; mobile phone; mHealth; internet; computers; systematic review

Introduction

Breastfeeding provides survival, growth, and health benefits for infants and promotes positive maternal health outcomes [1]. The United Nations Children's Fund and the World Health Organization (WHO) refer to breastfeeding as a cornerstone for child survival, nourishment, and growth and maternal health [2]. However, only 38% of infants aged under 6 months are exclusively breastfed worldwide, which is lower than the 2025 target of 50% [3]. In Australia, 96% of women initiate breastfeeding after birth, but the feeding practices significantly declined to only 15% to 25% at 6 months postnatally [4].

Early breastfeeding cessation has attracted the attention of clinicians, health care providers, and governments to develop

and assess new initiatives. The main interventions to promote and support breastfeeding include home visit counseling [5], peer counseling [6], peer support groups [7], and in-hospital educational intervention [8]. Breastfeeding education with support that starts from early pregnancy and continues to the late postnatal period was demonstrably one of the most effective interventions in long-term breastfeeding behavior [9]. However, providing traditional face-to-face education and support may require trained professionals [10], and it may not be easy for women and their families to attend educational sessions at an inconvenient time or place [11]. Hence, it has been argued that such traditional forms of support and education may not be beneficial or useful for younger generations [12]. Therefore, information and communications technology (ICT) may be suitable in transforming traditional education and support into a free and widely accessible mode of delivery [12,13].

ICTs are defined as digital technology tools and resources used to capture, handle, store, and exchange information via electronic communication [14]. The WHO indicated that ICT improves access to information, which will lead to an improvement in health care services around the world [15]. A study on mobile phone apps used by low-income participants in a public health nutrition program for Women, Infants, and Children in the United States revealed the need for improving and expanding technology in their program [3]. An international board–certified lactation consultant, Heinig [12], proposed that using the internet to deliver breastfeeding interventions is a way forward to promote breastfeeding. From April 2019, almost 4.4 billion people were actively using the internet [16]. Electronic technologies (e-technologies) are regarded as a revolutionary advance for providing health care services. The varied applications of e-technologies demonstrate improved operational efficiency and optimized time and productivity for both patients and health care professionals [10]. E-technologies such as web-based technologies, mobile apps, and computer kiosks use a broader range of ICTs to extend beyond the traditional health care facilities and provide support to geographically distant populations [17-19]. Evidence demonstrates that e-technologies can also deliver personalized web-based interventions that generate a longer-lasting health behavior change [20,21], such as in breastfeeding. Studies have shown a noticeable interest in more web-based options with personalized information, providing support to women on breastfeeding decisions [22-24]. Providing internet-based customizable support to mothers seeking information and help during their breastfeeding experience through e-technologies has the potential to impact any breastfeeding outcomes positively [25,26].

Many systematic reviews have assessed the efficacy of interventions employing e-technologies on maternity care and pregnancy outcomes [27-31]. However, only a few systematic reviews have reported on the effect of interventions employing e-technologies on breastfeeding outcomes. For instance, in a systematic review with 3 electronic interventional studies, using electronic-based interventions had a moderate effect on breastfeeding compared with provider-based interventions (OR 2.2, 95% CI 1.9-2.7; d=0.5 versus OR 1.1, 95% CI 1.0-1.2; d=0.0) [32]. Similarly, Giglia and Binns [33] reviewed references published between 2000 and May 2013 to assess the effect of using the internet on breastfeeding outcomes. The study found that among 1379 studies, only 1 study was eligible for inclusion and demonstrated a positive effect of using the internet on breastfeeding outcomes. The findings of another study on the efficacy of e-technologies in improving breastfeeding outcomes [34] suggested that interventions employing e-technologies are potentially valuable for improving breastfeeding knowledge, initiation, and duration of exclusive breastfeeding. However, there is no current systematic review to identify the different types of contemporary internet-based interventions employing e-technologies and assess their impact on breastfeeding outcomes. This study aimed to identify the features of the current internet-based breastfeeding interventions employing e-technologies and investigate the effects of internet-based e-technologies on breastfeeding outcomes.

Methods

Search Methodology

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines were followed in this review [35]. A PRISMA checklist and search terms are available in Multimedia Appendix 1.

Information Sources

A total of 8 electronic databases were searched to identify potential studies: Scopus, Web of Science, the Cochrane Database of Systematic Reviews, ScienceDirect, Google Scholar, the Association for Computing Machinery, SpringerLink, and Institute of Electrical and Electronics Engineers Xplore. The registers of the following trials were also searched to identify any existing relevant trials: Cochrane Central Register of Controlled Trials, WHO International Clinical Trials Registry Platform, International Clinical Trials Registry Platform, and ClinicalTrials.gov.

Types of Studies and Inclusion/Exclusion Criteria

Peer-reviewed studies, including quantitative and quality research, mixed methods, descriptive studies, randomized controlled trials, and quasi-experimental design trials with or without blinding, were included in the review. The research methodology was not limited in any way. Any papers examining interventions employing e-technologies that required internet access and aimed at addressing any breastfeeding outcome were included. Considering that SMS messaging can also be used without internet access, studies that used SMS messaging have been excluded from the review. The inclusion and exclusion criteria are shown in Textboxes 1 and 2.

Textbox 1. Inclusion criteria.

- Topic
  - Papers evaluating any internet-based breastfeeding interventions employing electronic technologies (e-technologies; web-based, computer kiosk, and mobile app)
  - Papers evaluating internet-based breastfeeding interventions employing e-technologies among women
  - Papers explaining, assessing, or reporting any internet-based breastfeeding interventions employing e-technologies with any breastfeeding outcome
- Settings
  - No restriction
- Type of publications
  - Papers published in peer-reviewed journals or peer-reviewed papers from an international academic conference or conference proceeding.
- Language
  - English
- Publication date
  - No restriction

Textbox 2. Exclusion criteria.

- Topic
  - Papers evaluating other breastfeeding interventions employing electronic technologies (e-technologies; eg, phone call, text messaging, and video or phone call)
  - Papers evaluating any internet-based breastfeeding interventions employing e- technologies targeted only at other relevant parties (eg, fathers, clinicians, providers, and health care worker or services)
  - Papers do not report on any breastfeeding outcome but focus on general maternal and child health
- Settings
  - No restriction
- Type of publications
  - Oral presentations, commentaries, policy briefs, and papers that described an app without evaluating its implementation and study protocol.
- Language
  - Not English
- Publication date
  - No restriction

Types of Participants

Participants were healthy pregnant or postnatal women, either primiparous or multiparous, who intended to breastfeed. In addition, studies targeting both parents as study participants were also included if the intervention targeting women was described separately. Women of all ages, ethnicity, occupation, and any socioeconomic status were included.

Search Strategy

The search was conducted on November 2018, whereas the screening stages occurred between January and March 2019. The following main key terms were used in the search strategy: nursing, breast-feed, “breast-feeding,” “breast feeding,” “breast milk” and lactation; and computers, telehealth, computer-mediated and mobile application. A detailed example of the search strategy tailored for Scopus is outlined in Textbox 3. This search strategy was adapted for each of the other databases (Multimedia Appendix 2).

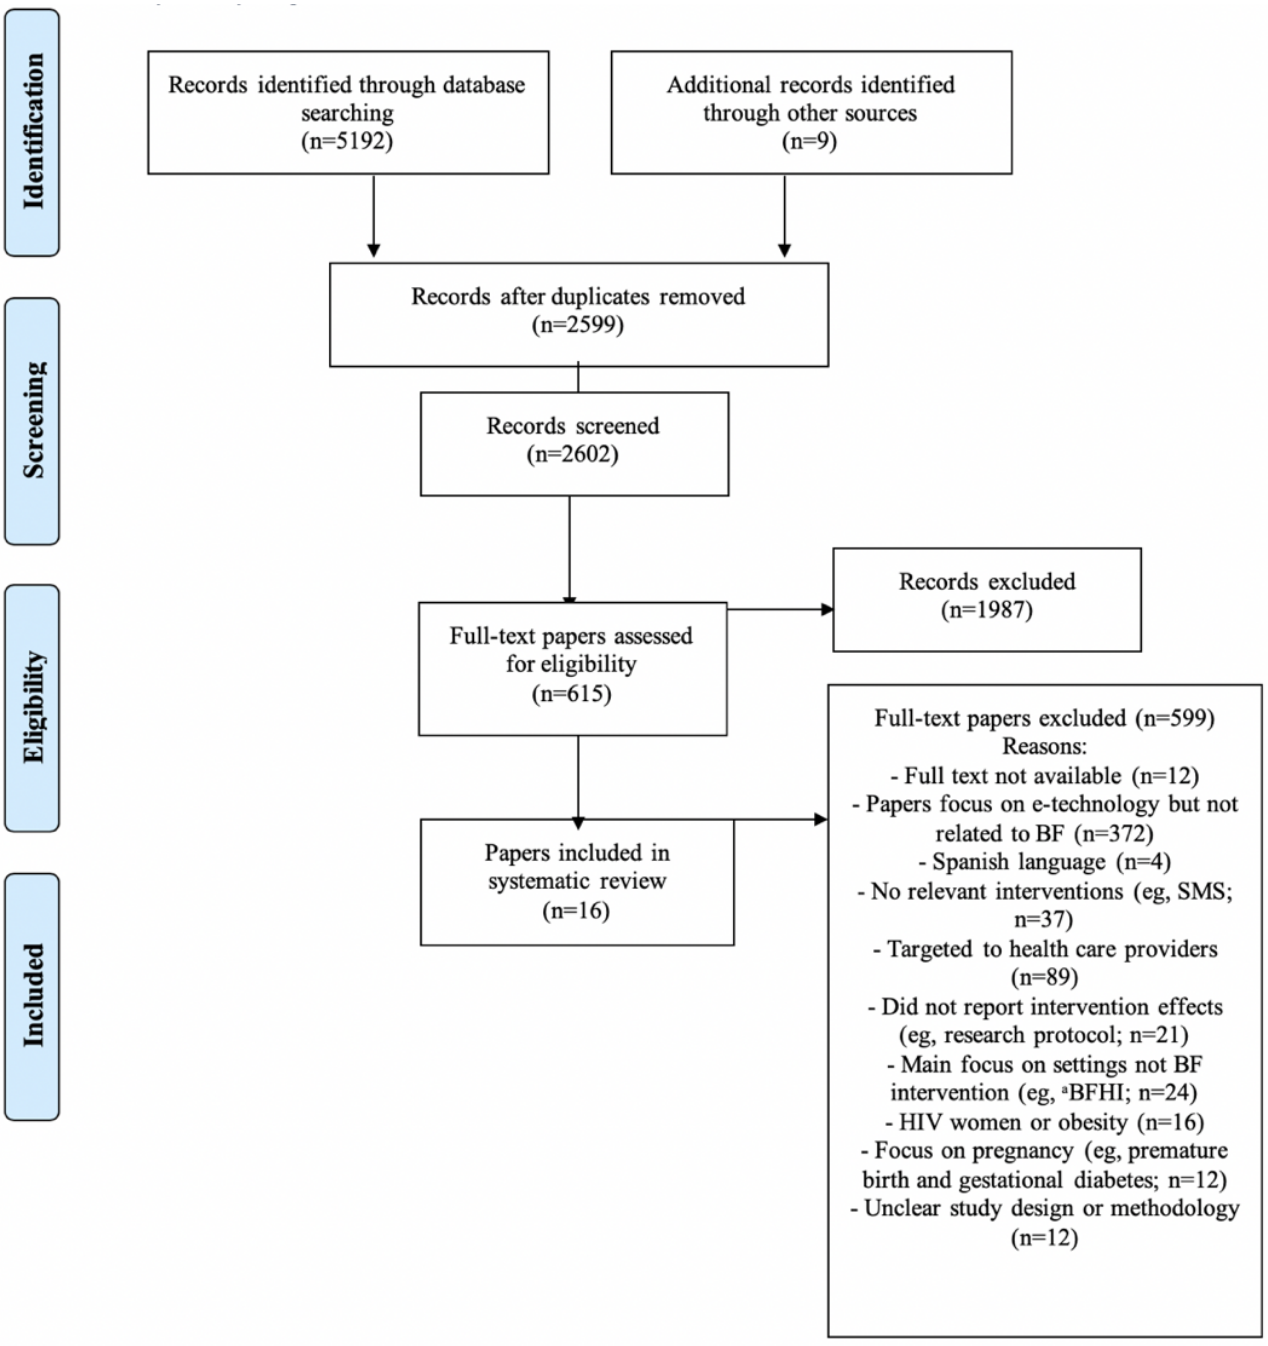
Textbox 3. Search strategy for the Scopus database.

(TITLE-ABS-KEY(Technology OR computer* OR web OR internet OR mobile* OR smartphone OR SMS OR video OR messag* OR application OR intervention OR promotion OR support OR cellphone OR ios OR android OR Cell* OR telephone OR text)) AND (TITLE-ABS-KEY("Mobile health" OR mhealth OR m-health OR e-health OR ehealth OR telemedicine OR Telehealth OR Telelactation OR Health Information Technology OR behavio*)) AND (TITLE-ABS-KEY(Breastfeed* OR Breast-feed OR "Breast feed" OR lacta* OR "nursing mother*" OR mother* OR maternal health OR maternal care OR pregnan* OR antenatal OR post* OR newborn* OR infant* OR child* OR baby OR Exclusive Breast Feeding OR Exclusive Breastfeeding))

Data Extraction

The retrieved studies for the search were transferred to Elsevier's Mendeley Desktop Reference Manager by the first author (AA) to download papers and remove duplicates. The first author screened all titles and abstracts of the papers, and the full texts were reviewed to identify eligible studies. Then, 3 authors (AA, SM, and KW) discussed the suitability of the eligible studies for the final review. Studies that investigated maternal depression, HIV/Hepatitis C virus, smoking, diabetes, alcohol, overweight/obesity, fertility, prematurity, or cesarean section were excluded from the review. A table of the excluded studies with reported reasons is included in Multimedia Appendix 5. A diagram of the systematic review and data extraction is presented in Figure 1.

Figure 1. Flow Diagram of the systematic review - data extraction (BF, BSES). BF: breastfeeding; BHFI: baby friendly hospital initiative.



Data Analysis

A self-adaptive narrative synthesis approach with thematic analysis [36] was used to categorize the purpose of internet-based interventions employing e-technologies and the strategies that were used in those interventions. Meta-analysis could not be processed because of the substantial heterogeneity existing among the studies. However, breastfeeding outcomes are presented in a narrative form.

Search Outcome and Quality Appraisal

The search identified 5201 papers. After excluding duplicates, 2599 papers were screened for eligibility and 615 remained (Figure 1). After examination of the full texts, 17 studies fully met the inclusion criteria. The quality of the studies was appraised by 2 researchers (AA and SM), using the mixed methods appraisal tool [37,38]. After the quality appraisal, 1 study was excluded [39], and a total of 16 studies remained (Figure 1). Any disagreement on quality checks was resolved through discussion between the 3 authors (AA, SM, and KW). Tables showing the quality appraisal process are presented as additional files in Multimedia Appendix 4.

Results

Description of Studies

The included studies involved 4018 participants from 8 different countries: the United States (n=5), Australia (n=3), Finland (n=3), Taiwan (n=1), Canada (n=1), Thailand (n=1), the Philippines (n=1), and Ireland (n=1). The interventions in the included studies were delivered to women prenatally or postnatally, and all reported one or more breastfeeding outcomes (Table 1). Only 3 studies reported using a theoretical framework to inform the design of the intervention: the sustained breastfeeding framework based on predicting and changing behavior theory [40], Bandura's [41] social cognitive theory [42], and Bandura's [43] self-efficacy theory [44]. The description of the included studies is provided in Multimedia Appendix 3.

Characteristics of Internet-Based Electronic Technology Interventions

Characteristics of the internet-based e-technology interventions in the 16 included studies were categorized by the mode of e-technology delivery, purpose of the intervention, and key strategies that were used in those interventions.

Mode of Electronic Technology Delivery

Electronic technology in the included studies involved a range of delivery approaches such as web-based interventions [42,44,46-54], mobile apps [55-57], and computer kiosk [40,45] (Table 2).

Purpose and Key Strategies Used in the Interventions

The purpose and key strategies used in the studies were coded using a thematic analysis. Overall, 2 main categories emerged based on the purpose of the interventions: breastfeeding education and breastfeeding support. On the basis of key strategies that were used in the interventions, 6 categories were identified: (1) monitoring and breastfeeding tracking, (2) personalization, (3) online discussion forum, (4) web-based consultation, and (5) breastfeeding station locator (Table 3).

Breastfeeding Outcome Measures

Breastfeeding intention, knowledge, exclusivity, and duration were the most reported outcome measures in the studies (Table 4).

Table 1. Characteristics of included studies.

Study reference	Setting, study country	Study design	Participants	Duration	Breastfeeding outcome measure	Theoretical framework	Assessment tool
Joshi et al, 2016 [40]	The Regional West Medical Centre in Scottsbluff, United States	Quasi-experimental study	46 women	Antenatal to 6 months postnatal	• Breastfeeding knowledge • Breastfeeding self-efficacy • Breastfeeding intention	Predicting and changing behavior theory	• Breastfeeding knowledge questionnaire • BSES-SF[a] questionnaire • Breastfeeding attrition prediction tool questionnaire
Zhang et al, 2014 [45]	Melrose-Wakefield Hospital in Massachusetts, United States	RCT[b]	15 women	Antenatal to 6 months postnatal	• Breastfeeding knowledge • Breastfeeding intention	NR[c]	• Questionnaire • BSES-SF
Ahmed et al, 2012 [46]	Two Midwestern hospitals, United States	Mixed methods	26 women	Postnatal to 30 days	• Breastfeeding support • Breastfeeding education	NR	• Breastfeeding diary • System usability scale • Perception survey
Ahmed et al, 2016 [42]	3 hospitals in the Midwestern, United States	RCT	141 women	Postnatal to 3 months	• Exclusive breastfeeding • Breastfeeding duration • Breastfeeding intensity	Social cognitive theory	• Paper-based forums • Surveys (online follow-up forums)
Alberdi et al, 2018 [47]	The National Maternity Hospital (Dublin, urban) and Wexford General Hospital (Wexford, rural), Ireland	Feasibility study	100 women	Antenatal to 3 months postnatal	• Breastfeeding duration	NR	• Web-based questionnaires
Geoghegan-Morphet et al, 2014 [48]	Hospital, Canada	Qualitative study	200 women	Postnatal to 6 months	• Breastfeeding education • Breastfeeding outcomes • Breastfeeding support	NR	• Surveys
Giglia et al, 2015 [49]	Hospitals from 4 regional areas, Australia	Longitudinal cohort study	414 women	Postnatal to 12 months	• Breastfeeding support • Breastfeeding initiation • Breastfeeding duration • Exclusive breastfeeding	NR	• Modified tool based on Perth infant feeding study mark II
Grassley et al, 2017 [50]	Website, United States	Cohort study (1 group pre + post)	41 women	Antenatal to 1 month postnatal	• Breastfeeding self-efficacy • Breastfeeding intention • Breastfeeding education	NR	• Questionnaire (pretest and posttest) • BSES-SF
Hannula et al, 2014 [51]	3 public maternity hospitals in the Helsinki Metropolitan area, Finland	Quasi-experimental study	705 women	Antenatal to first week postnatal	• Exclusive breastfeeding • Breastfeeding attitude • Breastfeeding confidence • Breastfeeding coping	NR	• Iowa infant feeding attitude scale • BSES-SF • LATCH[d] assessment tool

Study reference	Setting, study country	Study design	Participants	Duration	Breastfeeding outcome measure	Theoretical framework	Assessment tool
Huang et al, 2007 [52]	Hospital in Taipei, Taiwan	Quasi-experimental study	120 women	Antenatal to 6 weeks postnatal	• Breastfeeding duration • Breastfeeding knowledge • Breastfeeding attitude	NR	• Questionnaire
Newby et al, 2015 [53]	Feeding Queensland Babies, Australia	Prospective cohort study	488 women	Antenatal to 12 months postnatal	• Breastfeeding support • Breastfeeding education	NR	• Web-based questionnaires
Salonen et al, 2008 [44]	Two public university hospitals, Finland	Quasi-experimental study	863 women	Antenatal to hospital discharge	• Exclusive breastfeeding	Self-efficacy theory	• Questionnaire
Salonen et al, 2014 [54]	Hospital, Finland	Quasi-experimental study	760 women	Antenatal to 12 months postnatal	• Exclusive breastfeeding	NR	• Structured questionnaire
Dela Cruz et al, 2017 [55]	The Philippine Human Milk Bank, Philippines	Qualitative study	32 women	NR	• Breastfeeding support • Breastfeeding education	NR	• Web-based questionnaires
Wang et al, 2018 [56]	Website, Thailand	Mixed method	21 women	Postnatal to 4 weeks	• Breastfeeding support • Breastfeeding education	NR	• Surveys • Structured interview
Wheaton et al, 2018 [57]	4 local hospitals at Southwest Victoria, Australia	Prospective cohort study	46 women	Postnatal to 6 months	• Breastfeeding duration • Breastfeeding confidence	NR	• Web-based questionnaires

[a]BSES-SF: breastfeeding self-efficacy scale—short form.

[b]RCT: randomized controlled trial.

[c]NR: not reported.

[d]LATCH: breastfeeding charting system and documentation tool.

Table 2. Description of internet-based electronic technology interventions.

Study reference	Type of technology intervention	Purpose/objectives	Providers
Joshi et al, 2016 [40]	Computer kiosk	To provide breastfeeding knowledge and enhance self-efficacy through an interactive computer kiosk and a bilingual breastfeeding educational program	• Nurses
Zhang et al, 2014 [45]	Computer kiosk	To promote breastfeeding through a virtual lactation consultant on a computer kiosk	• University staff
Ahmed et al, 2012 [46]	Website	To provide breastfeeding education and support through an interactive web-based breastfeeding monitoring system (LACTOR)	• Trained research team • Lactation consultants
Ahmed et al, 2016 [42]	Website	To increase breastfeeding duration, exclusivity, and intensity through a web-based interactive breastfeeding	• Research scientist and a lactation consultant
Alberdi et al, 2018 [47]	Website	To assess breastfeeding initiation and duration using a web-based breastfeeding support	• Lactation specialists
Geoghegan-Morphet et al, 2014 [48]	Website	To provide breastfeeding education with integrated peer and professional support through a web-based breastfeeding support clinic	• Academic Medical Organization of Southwestern Ontario study team
Giglia et al, 2015 [49]	Website	To provide breastfeeding support using a website	• Midwives and/or research staff • Nurses
Grassley et al, 2017 [50]	Website	To provide breastfeeding education, assess breastfeeding intention, and promote breastfeeding self-efficacy using a web-based game-based learning platform	• Researchers' university
Hannula et al, 2014 [51]	Website	To provide an intensified support for breastfeeding using a web-based service	• Midwives
Huang et al, 2007 [52]	Website	To provide breastfeeding education, increase breastfeeding knowledge, and enhance breastfeeding skills using a web-based breastfeeding education program	• Midwives
Newby et al, 2015 [53]	Websites	To provide breastfeeding and education and support using web-based breastfeeding support and evaluate internet sources of infant feeding information	• The researcher
Salonen et al, 2008 [44]	Website	To support breastfeeding, parenting, and infant care through a web-based information website	• Nurses
Salonen et al, 2014 [54]	Website	To support breastfeeding, parenting, and infant care through a web-based information website	• Nurses

Breastfeeding Outcomes With Web-Based Interventions

Of 11 web-based breastfeeding interventions that had a combination of education and support focus, 8 demonstrated improvements in breastfeeding outcomes [42,44,47-49,51,52,54].

For instance, Huang et al [52] evaluated breastfeeding knowledge in a quasi-experimental study (n=120) where there was a significant difference in breastfeeding knowledge level between the intervention and control groups in the posttest results (P<.001), with no differences in the pretest knowledge level. In addition, the exclusive breastfeeding rates were statistically higher at 3 to 5 days and at 2, 4, and 6 weeks in the intervention group (n=60) compared with the control group (n=60; 48.3%, 45%, 31.7%, and 26.7% versus 38.3%, 20%, 20%, and 20%, respectively) [52].

Exclusive breastfeeding during hospital stay has been shown to improve with web-based interventions [44,51,54]. Hannula et al [51] evaluated the effect of a web-based breastfeeding educational support system on exclusive breastfeeding rates in 705 women in Finland. The intervention group (n=431) had access to a website that offered articles, pictures, videos, and an educational game. During hospital stay, the intervention group breastfed exclusively more often than the control group (71% versus 58%; P<.001) and likewise on discharge (76% versus 66%; P=.01). In addition, 2 other quasi-experimental studies conducted in Finland with a convenience sample of 1300 [44,54] also indicated higher exclusive breastfeeding rates in a group of women who used web-based interventions compared with the control group during their stay in the hospital. Salonen et al [44] reported that exclusive breastfeeding was more common in the intervention group (51.0% versus 27.4%; P<.001) and similar findings were also reported by Salonen et al [54] (50.1% versus 30.4%; P<.001).

Providing web-based breastfeeding intervention with an interactive and asynchronous online discussion board was found useful in motivating intervention mothers to continue breastfeeding for longer periods of time [49]. For instance, in a longitudinal cohort study among regional Western Australian women, using online support and discussion forums was associated with higher exclusive breastfeeding rates at 6 months among women who lived in remote areas (n=10; 5.9% versus 0.6%; P=.01) [49].

Access to a website with information on breastfeeding has also been offered to 127 women in a recent study in Ireland along with sending emails up to 6 months postpartum and providing access to a breastfeeding helpline and support group [47]. The study demonstrated a positive impact on breastfeeding duration, as participants from both urban and rural areas acknowledged an increase in breastfeeding duration because of participation in the study, 42.2% and 86.7%, respectively. However, urban women (42% at 6 weeks and 53.3% at 3 months) reported no impact on the length of time they breastfed from participation in the study, compared with rural women (26.7% at 6 weeks and 13.3% at 3 months). This study found that providing additional support postnatally, including exclusive access to the educational website, was more preferred by women in rural areas compared with those in urban areas, with 46.7% and 22%, respectively [47].

Geoghegan-Morphet et al [48,58] designed a web-based breastfeeding support clinic called the Maternal Virtual Infant Nutrition Support clinic to offer evidence-based breastfeeding education combined with peer and professional support. The resource had 4 aspects: (1) text, graphics, and video breastfeeding educational resources; (2) an interactive discussion forum for participants, which is supervised and facilitated by an international board–certified lactation consultant; (3) data collection capacity; and (4) a web-based infant journal for text and photo entries. The study found that 60.8% of mothers were exclusively breastfeeding at 6 months postpartum in the intervention group compared with 28.2% of mothers, similar to statistics from the Canadian 2010-2013 data for Ontario mothers [58].

A US-based pilot study [50] designed the *HealthyMoms* intervention aimed to educate women about breastfeeding using a game-based learning platform (3D Gamelab) on the web. A total of 3 quests on the 3D Gamelab platform were completed by the study participants and focused on three main topics: deciding about breastfeeding, feeding your baby, and getting support. Each one of the quests focused on a specific breastfeeding topic using web-based education activities, such as watching a video, reading a short introduction, or adding posts and responses to the information. Breastfeeding self-efficacy was measured with the 14-item breastfeeding self-efficacy scale—short form (BSES-SF), and breastfeeding intention was assessed using a 1-item measure with 4 categories (eg, *just breastfeed/no formula*, *just formula/no breastfeeding*, *both*, or *unsure*). The majority of mothers (68%) reported a high intention for exclusive breastfeeding; however, a one-way analysis of variance test found no significant differences among the groups in mean BSES-SF scores before (P=.26) or after (P=.68) the intervention [50].

Furthermore, 2 studies evaluated the impact of web-based breastfeeding monitoring systems among breastfeeding mothers [42,46]. Of the systems, one [42] found no significant differences in breastfeeding outcomes between the women in the intervention group (n=49) and the control group (n=57) upon discharge (P=.71). However, the women in the intervention group had better exclusive breastfeeding rates (63%, 63%, and 55%, respectively) at 1, 2, and 3 months, respectively, compared with the control group (40%, 19%, and 19%, respectively). Participants (n=26) in a study by Ahmed and Ouzzani [46] also received postdischarge breastfeeding support through web-based breastfeeding monitoring systems and reported that the system helped them to minimize breastfeeding problems [46].

The Key Strategies Used in the Web-Based Interventions

Monitoring and Breastfeeding Tracking in the Web-Based Interventions

Only 2 studies [42,46] provided web-based breastfeeding diary interventions and used data monitoring strategies to promote breastfeeding.

Providing a web-based breastfeeding diary [42] designed to record breastfeeding data for 30 days had a significant effect on breastfeeding intensity between the intervention and control groups at 3 months (P=.002). Ahmed and Ouzzani [46] evaluated the impact of a web-based breastfeeding monitoring system (LACTOR) designed to record breastfeeding and infant output data for 30 days. The system has 2 modules: (1) the mothers' portal, where mothers can record their daily breastfeeding data and get notifications; and (2) the lactation consultant's portal. The study found that more than 77% of the mothers reported infant feedings ≥8 times per day and reported that the system provided motivation to continue breastfeeding. Although 70% of mothers stated that breastfeeding data entry was not time-consuming, they reported that monitoring did not substitute face-to-face consultation with a lactation consultant.

Personalization in the Web-Based Interventions

Delivering personalized support was cited in four studies [42,46,48,49]. In all, two web-based breastfeeding monitoring systems [42,46], asked participating mothers to enter their breastfeeding data daily where both systems are capable of generating an automatic feedback sent via notifications with tailored interventions depending on the entered breastfeeding problem. These systems are capable of detecting patterns from responses of mothers and recognizing different breastfeeding problems. The system also provided motivation for mothers in the intervention group by sending a positive notification when a mother breastfed 8 to 10 times per day [42]. A website breastfeeding intervention in Australia enabled the intervention group (n=207) to post on discussion forums, start a new email conversation with others, and use a webcam to contact lactation consultants and receive a tailored response [49]. A more personalized intervention was proposed in a study by Geoghegan-Morphet et al [48], where a lactation consultant offered live help sessions through the web-based clinic and real-time response; however, these help sessions were not utilized by any of the participating women.

Online Discussion Forums in the Web-Based Interventions

Providing a web-based breastfeeding intervention with an interactive and asynchronous online discussion board was found to be effective in increasing rates of exclusive breastfeeding [52] and useful in motivating mothers in the intervention group to continue breastfeeding for longer [49]. Discussion forums were also used by mothers to contact a registered nurse/midwife to ask questions and receive credible information [44,54]. However, no relationship was discovered between accessing online chatrooms/discussion forums for breastfeeding support and providing breast milk for infants [53]. Remarkably, the breastfeeding helpline in an Irish cohort [47] was accessed by 30.6% of urban women and only 12.5% of rural women.

The web-based breastfeeding support clinic developed in a study in Canada [48] improved access to specialized professional breastfeeding support and offered communication and engagement through discussion forums. The intervention group received full access with peer and professional support in the discussion forum, and the control group received full access except for the interactive discussion forum [48].

Web-Based Lactation Consultant in the Web-Based Interventions

In an internet-based intervention study by Giglia et al [49], which was effective in long-term breastfeeding outcomes, women in the intervention group were provided with access to a certified lactation consultant through web-based posts or using a webcam with any of their concerns or questions regarding breastfeeding. Although women in this study reported several breastfeeding issues at each time point, none of them contacted a lactation consultant through webcam services.

Similarly, a web-based breastfeeding support clinic [48] offered support and educational resources to mothers facilitated by a lactation consultant where they could monitor, facilitate, and encourage discussions on the discussion forum. They could also post information and resources, set questions for additional details, answer questions, and offer suggestions. However, the post topics from the intervention group tended to be on more subjective (eg, lifestyle based) rather than technical topics (eg, breastfeeding problems) [48]. In 2 studies [42,46], the breastfeeding data of mothers were continuously monitored on the web by lactation consultants. Early detection and resolution of breastfeeding problems by lactation consultants presented improvements to breastfeeding continuation.

Breastfeeding Outcomes With Using Mobile Apps

A total of 3 studies reported on the usability of mobile apps without examining the effectiveness of the app on breastfeeding outcomes [55-57]. One Australian study evaluated the usability of a smartphone breastfeeding app, *Breastfeeding Solutions*, among rural Australian breastfeeding women [57]. The app was an interactive guide to resolve breastfeeding problems, provide functions for searching for problem solutions, and deliver timely information for mothers. The results of the study demonstrated its usability by a longer duration of breastfeeding compared with general statistics from southwest Victoria [57].

A total of 2 other studies with small sample sizes evaluated the usability and usefulness of the mobile phone apps *MoomMae* [56] *and Milktrack* [55] designed to provide support to breastfeeding women. The *MoomMae* [56] intervention aims to support mothers in feeling more comfortable breastfeeding in public and efficiently track their feeding and pumping logs.

Key Strategies Used in Mobile Device Apps

Monitoring and Breastfeeding Tracking in Mobile Apps

Only one breastfeeding mobile app intervention [56] offered breastfeeding tracking features to enter pumping/feeding data and save the history of all feeding records.

Personalization in Mobile Apps

Participants enrolled in 3 studies [55-57] received a personalized breastfeeding intervention through mobile apps. The interventions were designed to enhance the breastfeeding experience by providing feeding and pumping volume control [56], offering a platform to donate human milk [55], and providing an interactive guide to solving the breastfeeding problems of mothers [57].

Breastfeeding Station Locator in Mobile Apps

In all, 2 studies in Thailand [56] and the Philippines [55] developed mobile apps with breastfeeding station locators with an embedded strategy that can locate nearby places accessible for breastfeeding using the user's GPS location. In both studies, women perceived that locating places for breastfeeding through the app was easier, but the *feeding room* feature still had some negative feedback because of the limited number of feeding rooms exhibited in the app [56].

Breastfeeding Outcomes Using a Computer Kiosk

A total of 2 studies used computer kiosk interventions [40,45]. The main purpose of using computer kiosks was to provide breastfeeding education and support by incorporating several educational modules such as basics of breastfeeding, benefits of breastfeeding, and coping with breastfeeding [40,45]. A pilot evaluation study [45] showed significantly greater breastfeeding knowledge in the intervention group (n=7) after they interacted with the prenatal module (P<.05) in comparison with the control group (n=8). This study showed significantly greater intention to exclusively breastfeed after women interacted with the prenatal module (P<.05) and improvement in breastfeeding confidence compared with the control group [45]. Similarly, Joshi et al [40] reported a significant improvement in breastfeeding knowledge scores (P=.03) only at week 6 of the follow-up between the control (mean 23.2, SD 3.7) and intervention (mean 25.3, SD 2.6) groups. However, no significant differences were perceived in the average change in knowledge scores between the control and intervention groups at any other follow-up time points. This study also reported a gradual increase in the breastfeeding self-efficacy scores until week 6, followed by a decrease in self-efficacy scores at 3 months (P=.46) and 6 months (P=.54). Moreover, the intervention group reported significantly higher intention to breastfeed (P=.049), and the results indicated a significant improvement in breastfeeding intention scores over a 6-month period with all study participants (P<.05).

Key Strategies Used in Computer Kiosks

Monitoring and Breastfeeding Tracking With Computer Kiosks

Only the computer kiosks in the Zhang et al [45] study had a longitudinal breastfeeding tracking feature, which enabled the system to examine breastfeeding records and monitor breastfeeding practices to ensure optimal infant growth.

Personalization With Computer Kiosk

Zhang et al [45] developed a virtual lactation consultant on a computer kiosk to interact with women in the intervention group. The intervention included motivational interviewing techniques to motivate and social cognitive techniques to reinforce positive behaviors. The intervention enabled adaptive interaction, where the interactive component was modifiable based on a mother's own progress and her previous interactions with the kiosk. Joshi et al [40] designed an interactive kiosk to present breastfeeding information and messages adjustable depending on the psychosocial elements, including self-efficacy, influence of attitude, expectancies, personal norms, and social effect.

Discussion

Principal Findings

This study presents a review of internet-based breastfeeding interventions employing e-technologies; investigates their purpose, mode of delivery, and key strategies; and systematically describes their effectiveness on breastfeeding outcomes. The main purpose of the reviewed studies focused on education and support in 3 modes of delivery: web-based interventions, mobile apps, and computer kiosks. Among the 5 key strategies, personalization and web-based discussion were the most common strategies used in the interventions. This review provides evidence that internet-based interventions employing e-technologies that provide a combination of early interactive antenatal breastfeeding education with postnatal web-based discussion support can improve breastfeeding outcomes in hospital stay [44,47,48,51,52,54] and exclusive breastfeeding rates up to 6 months [49]. These results are supported by similar face-to-face interventional studies where there is a combination of antenatal education and postnatal support [59-61].

Interventions with personalized feedback and tailored information to mothers through their support systems were found to be motivational and led to positive breastfeeding outcomes. These effective strategies point toward a need for informed, highly interactive, and tailored-designed breastfeeding interventions employing e-technologies. Consistent with other effective clinical interventions, conducting multimodal, multiphased, and interactive interventions are successful in breastfeeding practices [60,62,63]. Web-based support could be offered informally, such as peer communication through online discussion forums, or formally, such as web-based lactation consultation. The interactivity, connectivity, and two-way communication provided between mothers and lactation consultants in breastfeeding interventions may expand the opportunities for educating and engaging mothers and thus improve breastfeeding outcomes. Providing access to timely and qualified lactation consultants in similar interventions has been found to be particularly attractive to mothers experiencing some breastfeeding complications [64]. In a Cochrane review of support interventions, the findings demonstrated that women who receive any form of support are less likely to stop exclusive breastfeeding before 5 months postpartum [65].

In this review, interventions that provided monitoring and breastfeeding tracking appeared to be least effective in improving breastfeeding outcomes, which could be because of a lack of meaningful educational and supportive interactions for different breastfeeding challenges. It is important to note that women in the included studies had higher prenatal breastfeeding intention rates, which could be a confounding factor in the effectiveness of the interventions [40,45,50]. Breastfeeding women are very likely to seek out extensive evidence-based information on breastfeeding information from reliable sources. The acquired breastfeeding knowledge is presumed to have positive influences on their feeding decisions [66].

In terms of the mode of delivery, web-based platforms were the dominant and more effective mode of delivering breastfeeding

internet-based interventions employing e-technologies. Several studies used web-based interventions, and the majority of them reported an increase in exclusive breastfeeding after the intervention and overall positive outcomes in their results [42,44,47,49,51,52,54]. This finding may be explained by the ability of web-based interventions to sustain their effects in terms of providing early education and continued support to participants during the intervention from a variety of care providers (eg, peers and lactation consultants) in a range of settings (eg, hospital and home). Another reason could be related to the reliability and credibility of the governmental web-based platforms [67]. Women need to make informed decisions regarding the health and well-being of their babies. Having a trusted resource would empower women to make their own choices in breastfeeding. However, many studies have reported the lack of a regulatory system to assist end users in identifying the best available web-based e-technologies [68-70].

Although the delivery of breastfeeding interventions through mobile apps is encouraging because of their relative simplicity and continuous availability [71], the mobile apps in this review focused on supporting women to access milk banks or express their breastmilk among small groups of women. Furthermore, the studies mainly aimed at assessing the usability of the apps rather than examining their effectiveness without any theoretical framework. Although a significant absence in reporting a theoretical framework was observed in the majority of the included studies, none of the interventions with mobile apps reported using any type of behavior change theoretical framework. Using theory to inform intervention development or evaluation can play a key role in breastfeeding interventions as a strong predictor of breastfeeding behavior [72].

Finally, computer kiosk interventions seemed to be effective in enhancing women's knowledge and short-term confidence level. Creating an interactive platform coupled with continuing, accessible support can aid mothers in having specific information to suit their personal needs [45,73]. The use of conversational computers could provide affordability and portability, as observed in other health-related interventions [74,75]. However, for long-term effects, there is a need to incorporate personalized approaches and professional support into interventions to create a practical response to the personal needs of mothers. In addition, sustainability remains an issue because these types of interventions could be outdated [76], and findings cannot be generalized to other settings.

A lack of detailed reporting of rigorous intervention development, evaluation, and the content of the implementation intervention was also observed, which makes it difficult to determine the impact of interventions on breastfeeding outcomes [77]. Future studies could design intervention implementation and evaluation guided by a theory toward a comprehensive intervention development process and for a better chance of effective breastfeeding intervention.

Limitations

This systematic review has as a key strength that it followed the PRISMA guidelines [35], an established methodology for ensuring transparent reporting of systematic reviews. However, there are several limitations to this study; for example, it was difficult to generalize the findings observed from several studies because of their small sample size, different timing of studies, and lack of clarity on start and end points. The substantial heterogeneity of the intervention's outcome measures and lack of clear definitions of breastfeeding outcomes in all the included studies added more complexity and prevented meta-analysis.

Another limitation of the study is that most of the included interventions were delivered and published in developed and high-income countries with good quality health care systems [78], which may not be generalizable to women in developing countries or those with diverse socioeconomic status and cultural background [29]. Setting up breastfeeding intervention in regions with inadequate health care providers and resources should be prioritized to improve breastfeeding practices [79]. Furthermore, the approaches of the interventions were focused on changing the behavior of individuals and lacked some key aspects related to cultural differences that may influence the breastfeeding practices of women and could impede them from achieving the desired outcome. This is particularly essential as the breastfeeding decisions women make differ according to whether their own culture is supportive of breastfeeding or not and on the cultural context in which they live. Thus, findings need further investigation regarding their transferability. Applicability needs to be considered when delivering breastfeeding interventions to women in different social milieu.

Conclusions

The findings of the study demonstrate that internet-based e-technologies are transforming the access and delivery of breastfeeding interventions and that they have a considerable potential to assist breastfeeding mothers when seeking support and advice about breastfeeding. The results show that web-based interventions that provide a combination of education and ongoing support are the best models of interventions employing e-technologies to support long-term breastfeeding outcomes. In addition, the review reveals that the two dominant effective strategies are personalization, and online discussion forums form credible sources. Further studies need to explore the usability and effectiveness of interventions employing e-technologies that have theory-based systems designs that could incorporate encouragement and discussion opportunities from credible social and professional sources. The sociocultural needs of women also need to be integrated into these technologies to provide culturally tailored breastfeeding support.

Abstract

Background: Research using genomic data opens up new insights into health and disease. Being able to use the data in association with health and administrative record data held in safe havens can multiply the benefits. However, there is much discussion about the use of genomic data with perceptions of particular challenges in doing so safely and effectively.

Objective: This study aimed to work toward a risk-utility data governance framework for research using genomic and phenotypic data in an anonymized form for research in safe havens.

Methods: We carried out a multifaceted review drawing upon data governance arrangements in published research, case studies of organizations working with genomic and phenotypic data, public views and expectations, and example studies using genomic and phenotypic data in combination. The findings were contextualized against a backdrop of legislative and regulatory requirements and used to create recommendations.

Results: We proposed recommendations toward a risk-utility model with a flexible suite of controls to safeguard privacy and retain data utility for research. These were presented as overarching principles aligned to the core elements in the data sharing framework produced by the Global Alliance for Genomics and Health and as practical control measures distilled from published literature and case studies of operational safe havens to be applied as required at a project-specific level.

Conclusions: The recommendations presented can be used to contribute toward a proportionate data governance framework to promote the safe, socially acceptable use of genomic and phenotypic data in safe havens. They do not purport to eradicate risk but propose case-by-case assessment with transparency and accountability. If the risks are adequately understood and mitigated, there should be no reason that linked genomic and phenotypic data should not be used in an anonymized form for research in safe havens.

KEYWORDS

genomic data; data safe havens; data governance

Introduction

Background

The use of genomic data to revolutionize health research and clinical care is a major expanding area of investigation and development. Research using genomic data opens up new insights into health and disease to inform population health [1] and to develop precision medicine, namely, treatment based on a person's biological constitution, lifestyle, and environment [2]. Being able to use genomic data in association with health and administrative record data can multiply the benefits by including information such as comorbidities, medication histories, laboratory tests, education records, social issues, and lifestyle factors. This creates a more rounded and realistic picture to avoid genetic determinism and to ground phenotypically observed phenomena. Genomic data can be defined as the totality of a person's DNA sequence, and genetic data can be defined as the parts of the DNA that code for genes [3]. In this paper, we will refer to genomic data unless we are specifically mentioning genetics. We will refer to health and administrative data as phenotypic data for convenience, while acknowledging that not all the information in these records is ultimately or attributably genomic.

By their nature, genomic data are commonly considered to be among the more sensitive types of personal data for various reasons. These include their persistence through a person's life (barring a degree of plasticity), their role in predicting disease onset or likelihood, stigmatization for insurance or employment, and impact on kin [4,5]. This has led some to the concept of *genetic exceptionalism*, proposing that genetic data should be subject to new, particularly stringent use restrictions, whereas others argue that, although careful control measures are needed, the fundamental issues are largely the same as for other health data [6]. At the other end of the perception scale, some believe that all human genome sequence arising from publicly funded research should be freely available in the public domain [2]. Crucially, the ability of genomic data to provide in-depth information about a person is the defining factor in their added value for research and clinical care. Debates continue, and we have a conundrum in terms of how to progress the use of genomic data for public benefit while safeguarding individuals from harm.

We believe that there is a need for guidance toward a risk-utility data governance framework to simultaneously mitigate disclosure risk and retain maximum data utility. This is because of the nature of the data and ongoing discussions about the ability to truly anonymize genomic data. Some of this debate arises from a conflation of unique versus identifiable data, which we will return to later in this paper. In the absence of absolute certainty about the anonymization of genomic data beyond a shadow of a doubt, we propose that the framework needs to be practical, enabling research while safeguarding against all manageable risks. In this endeavor, privacy protectionism must be avoided, that is, the application of superfluous control measures that do not enhance privacy but do damage data usefulness [7]. Commonly used nonperturbative disclosure controls include suppression of variables or entire records, aggregation (such as age into bands), and masking (such as of clinic identifiers to protect professional reputation). Further methods include data perturbation (such as variable swapping between records), homomorphic encryption (a technique enabling computations on encrypted data), and other privacy-enhancing technologies [8]. Many of these are still in developmental stages and might not ultimately prove suitable for real-world application without reducing data utility. Even when algorithms are brought to encrypted data, they might not be immune to reidentification risk [9,10].

In a previous study, we explored the views of the general public on access models for genomic data in conjunction with health data [11]. Because so far genomic analyses have not yet revolutionized medical care and the majority of testing in clinical routine is still conventional, the study focused on genomic data that had been primarily collected for research. The 3 models of access presented were open (such as via a website), released externally to approved researchers, and within a data safe haven. We refer to a data safe haven as an infrastructure enabling data access within a secure environment subject to procedural, technical, and physical controls, in combination with disclosure controls applied to the data, to safeguard data subject privacy [12]. Although some people were comfortable with data being open access and more with release to named researchers, the overall preference was for access via data safe havens [11]. It can be argued that dangers differ between researcher-hosted data being unintentionally released externally leading to disclosure, compared with data hosted in a safe haven being reengineered to reveal personal data, as the latter is generally perceived to be more computationally intensive. Even so, because genomic data (largely) persist over the course of a lifetime and are passed to the offspring, it is important to remember that what is impossible today may be achievable within minutes in the not-too-distant future. Nonetheless, at this point in time, we acknowledge the appropriateness of all 3 models in their place and ongoing work to strengthen governance arrangements, for example, in Web-based access to large-scale genomic sequence for genome-wide associations and similar studies [13].

Objective

Many countries worldwide are investing in infrastructures that enable extensive, population phenotypic data to be accessed in an anonymized form via a data safe haven, and some are also incorporating genomic data (in various forms) to add to the research potential [14-16]. Being able to link data at the individual level while safeguarding privacy is an essential part of these enterprises, enabling information from multiple disparate datasets to be used in research. However, because of the nature of, and perceptions around, genomic data, there are challenges to be overcome to incorporate genomic data in a lawful, ethical, and socially acceptable way. Consequently, the aim of this paper was to work toward a risk-utility data governance framework for using genomic data in conjunction with phenotypic data in an anonymized form for research in data safe havens. We propose that the findings of this study will have particular value in developing guidelines for safe havens and augmenting existing operating models and will also be relevant to some extent for other data access models.

Methods

We took a multifaceted approach drawing upon data governance arrangements in published research papers, case studies of organizations working with genomic and phenotypic data, public views and expectations for the use of genomic data, and example studies using genomic and phenotypic data. The findings were contextualized against a backdrop of legislative and regulatory requirements and used to create a set of recommendations to inform a risk-utility data governance framework for using genomic and phenotypic data in safe havens. We set out our considerations of these elements in the Results section to draw together the findings to inform the recommendations. Ethical approval was not required for this study because the engagement with members of the public as research participants took place in our previous study [11].

Legislation and Literature Review

We carried out a summary (nonexhaustive) review of the legislative and regulatory backdrop to gain an insight on issues associated with the use of genomic data in principle. For this, we focused on the European Union (EU) because wider consideration was beyond the scope of this paper and would warrant a separate study. The elements considered were the European Convention on Human Rights and Biomedicine [17] and the General Data Protection Regulation (GDPR) [18] of 2016, augmented by national legislation and official guidance, such as the UK Data Protection Act of 2018 [19] and the work of the UK Information Commissioner's Office. We appreciate that legislation in other jurisdictions will vary, but we use the ones we have mentioned here as illustrations. In addition to compliance with data protection legislation, there are ethical issues to consider and address. The Global Alliance for Genomics and Health (GA4GH) has several working groups focusing on particular issues and has produced a high-level framework for the use of genomic and health data [20] to be implemented in line with jurisdictional requirements.

We used our previously conducted literature review on uses of genomic and routinely collected phenotypic data to guide this study (Daniels H et al, unpublished data, 2019). As part of the review, we drew out various pieces of information to categorize the studies and the details of data governance arrangements to the extent that they were presented in the publication. The relevant variables were genomic data and source, phenotypic data and source, data access model, and details of data governance. This information enabled us to create examples of data use to consider relative risks for data access via a safe haven. We did this using factors including the format of genomic data being used, the type of health condition being studied, and the extent of data linkage. We note that many of the published studies used an external data release model, but we used them in this context simply as examples of research using genomic and phenotypic data. We also drew upon a series of interviews we had conducted with representatives from safe haven enterprises in Germany, Australia, the United Kingdom, and Canada to add depth to the information in published studies. The relevant questions were on types of genomic data integrated with phenotypic data, main governance challenges encountered and how they were addressed, main access model, and access conditions [21].

Public Views

Recognizing that public engagement on the use of health data and specifically genomic data is an active area of investigation [22], when we carried out public engagement on the use of genomic and health data, we focused specifically on access models, as noted above [11]. The public engagement activities took the form of 8 workshops with a total of 116 people. As well as taking part in free-form discussions, the participants completed an anonymous exit questionnaire to provide their personal views on the relative benefits and risks of each access model: open, external release, or data safe haven. This had previously not been explored and provided new insights into public preferences to inform this paper.

Results

Legislative and Regulatory Backdrop

The EU has expressly recognized the use of genetic information in the European Convention on Human Rights and Biomedicine (1997), which provides for the misuse of biological and medical advances and sets out prohibitions in respect of bioethics and the right to a private life [17]. It further bans decisions made on the basis of genetic characteristics and governs predictive genetic tests for medicinal purposes. Personal data processing is largely governed by the GDPR [18] of 2016, augmented by national legislation and official guidance, such as the UK Data Protection Act of 2018 [19] and the work of the Information Commissioner's Office. Personal data are defined under Article 4 of the GDPR as "any information relating to an identified or identifiable natural person who can be identified, directly or indirectly in particular by reference to an identifier such as name...or to one or more factors specific to the physical, physiological, genetic specific to that natural person." Recital 34 of the GDPR defines genetic data as "personal data relating to the inherited or acquired genetic characteristics of a natural person which result from the analysis of a biological sample from the natural person in question, in particular chromosomal, deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) analysis or from the analysis of another element enabling equivalent information to be obtained." Processing personal data related to the health of an individual is provided for by the explicit provisions of GDPR Article 9. This provides differing lawful bases for processing and covers a range of data that are considered to be sensitive. Genetic data are expressly included within Article 9.

The key point in applying data protection legislation is that it applies to identifiable personal data from living individuals and not to data from which a person cannot be identified. Although the majority of the genome is identical in all humans, sequence variants occur across the genome that can be used to characterize people and groups. That is not to say that they can be used to identify an individual, as, although the information may be unique, this does not necessarily render it legally identifiable. Within the remit of the GDPR, data from which an individual cannot be identified are legally anonymous. However, identifiers as defined by law do not have to be direct and can be formed

from a number of pieces of information. As with any data source, genetic data linked to other data may give rise to a greater risk of identity disclosure, such that it is important to consider whether the combination of available data could lead to the identification of an individual. For example, Y-chromosome repeats were mined from the 1000 Genomes database and could identify people by cross-referencing them with ancestry databases [20]. As far as the GDPR is concerned, it is not correct to state that genetic data are always personal data or will always carry a high risk of disclosure. A proper legal approach would be to assess each use case with expert input to adequately understand the risk of identifiability. Applying legal governance to genetic data can be perceived as challenging because of the esoteric nature of the data, which, furthermore, can be shrouded in scientific terminology. This can appear to complicate the legal issues; however, in essence, data protection law governing genetic data is largely the same as for other health data types.

The GA4GH framework for the use of genomic and health data [21] is to be implemented in line with jurisdictional requirements. The framework establishes a set of foundational principles, namely, to respect individuals, families, and communities; advance research and scientific knowledge; promote health, well-being, and the fair distribution of benefits; and foster trust, integrity, and reciprocity. Furthermore, it proposes core elements of responsible data sharing: transparency; accountability; engagement; data quality and security; privacy, data protection, and confidentiality; risk-benefit analysis; recognition and attribution; sustainability; education and training; and accessibility and dissemination. It does not relate specifically to data safe havens and is broader in scope than our aim to work toward a risk-utility data governance framework for research using genomic data in conjunction with phenotypic data for research in safe havens. However, this valuable document formed a part of the backdrop and, along with the legislation, informed the development of the recommendations.

Forms of Genomic Data

The literature review on the use of genomic data with phenotypic data revealed a plethora of studies on many health conditions and using various forms of genomic data (Daniels H et al, unpublished data, 2019). Genome-wide association studies (GWAS) and phenome-wide association studies (PheWAS) use statistical methods applied to genomic sequence data to explore and correlate variants and phenotypic traits [22]. However, further processing often takes place so that data derivatives, or metadata, can be taken forward for use with phenotypic data for research or to inform clinical care. This is important when considering data governance issues because not all genomic data used in research are composed of sequence. In fact, the resulting metadata can take many forms of varying complexity. Some examples are as follows: Binary Alignment Map files, a compression of the sequence that can be annotated to explain particular details; Variant Call Format (VCF) files, providing information on the type, number, and position of nucleotide variants; single-nucleotide polymorphism (SNP) files detailing changes in single base pairs in the DNA sequence; risk score files, which contain information on risks of health conditions based on single or multiple genes; and among the simplest are files that detail the presence or absence of a trait of interest (Daniels H et al, unpublished data, 2019). Using genomic information in conjunction with additional data can add valuable detail and provide context in health conditions. However, importantly, the relative risks will differ depending on the form of genomic data being used, along with other factors. We take this into account in the development of the recommendations.

Examples Using Genomic and Phenotypic Data

We provide examples of studies using various forms of genomic data and phenotypic data to illustrate data use for research with a view to considering relative risks. As well as GWAS and PheWAS studies that require the full genome sequence for large-scale statistical analysis to identify variants of interest, many studies begin with sequence but subject it to further processing to create derivatives for linkage to structured phenotypic data. For example, polygenic risk scores derived from GWAS and SNPs then linked to an index of deprivation and individual postcodes to explore factors influencing alcohol dependence [23]. Genotyping at particular loci has been used with the number and duration of in-patient events in schizophrenia [24]. Gene expression profiling has been used in conjunction with electronic health records (EHRs) to compare breast cancer treatments and predict chemotherapy efficacy and outcomes across health care systems [25].

SNPs are among the forms of genomic data commonly used in conjunction with phenotypic data. These were used in a study on major depressive disease with linkage to health service data, including diagnoses, history of antidepressant prescribing, and referrals to secondary care for specialist treatment [26]. A study on dementia used a set of 6 SNPs linked to EHRs to establish and monitor the dementia status of participants [27]. A further example is the use of SNPs to study herpes zoster linked to EHRs to determine diagnosis in adults [28]. EHRs are often the source of phenotypic data, but information may also be drawn from registries [29,30], and in some cases, area-based measures, such as indices of deprivation, are included [27].

As for any studies using individual-level health data, risks will vary depending on the specifics of the use case. In relation to genomic data with phenotypic data, variables that may influence risk include forms of genomic data, common versus rare conditions, studying sensitive or stigmatizing conditions, and the extent of data linkage to phenotypic data. These are in addition to demographic factors such as extremes of age and small geographies, and all may combine to create the risk profile. As such, the degree of disclosure risk varies, but the repercussions of reidentification also vary. For example, the unauthorized disclosure that someone's close blood relative carries a high risk of developing a strongly hereditary condition such as Huntington disease will have serious implications for themselves and their kin. On the other hand, conditions such as heart disease and diabetes are multifactorial and, as such, are more complex and indefinite in terms of disease prediction. These and a myriad of other considerations lead us to propose that the risks and benefits of planned data uses should be taken into account on a case-by-case basis.

Data Governance Arrangements

We used information from the literature review and the series of interviews with representatives of safe havens on data governance arrangements in place. We refer only to governance arrangements in relation to the use of genomic data, rather than the work of these enterprises in general. We found that differing solutions have been put in place to enable genomic data to be used in conjunction with phenotypic data. Examples are given here to show variety.

The German Medical Informatics Initiative is a major infrastructural investment that has created multiple university hospital consortia to integrate clinical data, including genomics [31]. In terms of genomic data, the work of this new initiative is beginning with biosample collection before the results of genomic analyses will be shared across consortia. Germany is subject to the GDPR but also has stringent national privacy regimens for general and genomic data processing [32,33]. Moreover, apart from repositories holding data locally, methods for cross-center distributed analyses, such as DataSHIELD, are being employed [34]. These will bring the analysis to the data and avoid the need to share data where this is deemed unacceptable to oversight committees. Subject to approval, data can be used within consortia, across consortia, and by any approved researcher. However, as noted, this might not involve direct access to data but might depend on privacy-preserving analysis methods. There is a network of committees and working groups for the establishment of agreed standards.

The Sax Institute in Australia manages the *45 and up* study, a longitudinal cohort of over 250,000 people, including phenotypic and genomic data [35]. Sax works in partnership with the Garvan Institute of Medical Research, which acts as a genome sequencing facility and makes data available for research subject to conditions [36]. Sax operates as a repository for health and self-report data, whereas Garvan acts as a repository for the genomic data. Although the full genome data are generally too large to move, other data such as VCF files could be transported; thus, the decision to use a distributed model is based on data governance reasons. Researchers need to apply to both institutional data access committees before access to genomic and phenotypic data can be granted. Linked data can be accessed by public and private sector researchers via a portal subject to ethical and other relevant approvals. Following analysis, outcomes are released externally but not row-level data.

The UK Secure Research Platform (SeRP) is a data infrastructure housing the Secure Anonymised Information Linkage (SAIL) databank and various other initiatives [15,37]. UK SeRP can be customized to implement the data governance model required by particular programs of work. To date, SAIL has integrated genomic data on a project basis but is working to incorporate more genomic data as part of standard data feeds, along with phenotypic data from health and administrative records. Example projects involve a psychosis cohort and an epilepsy study. As the genomic data were brought into SAIL for particular projects, separate ethical approval including participant informed consent was obtained. The psychosis cohort brought in polygenic risk scores and copy number variants; the epilepsy study brought in VCF files. In both cases, the data were only made available to project researchers because of regulatory approvals. But in general, SAIL allows data access to any approved public sector researcher; the commercial sector must work with a SAIL analyst or another public organization to access data on their behalf. All proposals to access data for research must be approved by an information governance review panel that co-opts additional experts in assessing particular data types, such as genomic. Some data providers also reserve the right to review data use proposals, in addition to the panel.

The Institute for Clinical Evaluative Sciences (IC/ES) operates in Ontario, Canada [38], and holds a highly phenotyped cohort of over 2000 children and young people with a neurological development disorder, most frequently, autism. DNA samples were collected for whole genome sequencing from the entire cohort, and the ones who consented to linkage have their VCF file data linked to IC/ES health and administrative data. As such, this is a project-level development, but it is anticipated that linkage of genomic data to phenotypic data will become more routine in future. The privacy approval group at IC/ES was concerned about identifiability because the genomic data are often unique, particularly where there are rare variants. Owing to this, the arrangement at IC/ES has been to hold the genomic data separately and not on the main analysis platform. As the linked data are considered highly sensitive, only an IC/ES analyst has access. The project lead prepares queries to be executed on the data and receives the results from the IC/ES analyst.

From these examples, it can be seen that data safe havens are at different stages of development in terms of integrating genomic data, they are working with various formats of genomic data, and they have varying perceptions of risk leading to differing requirements for data access. These are just some examples, with others underway such as the Swiss Personalized Health Network and its associated BioMedIT project. Through this, there is a network of core facilities for the secure processing of biomedical data across Swiss universities, enabling research within a secure environment [39]. However, although models differ, one of the common beauties of safe havens (over open access or external release of data) is that they are able to apply a suite of disclosure controls directly to the data (in totality or at a project level) and across the whole environment, thus managing risk across all stages from data incorporation to archiving [14,15,38]. We used the information gained from these various models to guide the development of the recommendations.

Public Views

Having previously reported public perspectives on 3 models of accessing genomic data [11], here we draw upon the views gained on data use in safe havens, in line with the focus of this paper. In general, workshop participants were less concerned about the use of genomic data in safe havens than external release or open access. However, there were some provisos in relation to safe havens. Participants wanted to be properly informed on the purpose of data use and for analyses to be conducted by approved researchers, with concern expressed on misuse by commercial companies. They wanted to be reassured that appropriate safeguards would be in place, with data use

being auditable and controlled. The need for consent to reuse genomic data that had been primarily collected for research emerged strongly (for all access models) and led us to propose wording for the information sheet and consent form in prospective studies [11]. The use of anonymized data in safe havens was also seen as a way to mitigate risks of discrimination because access is limitable by systematic controls. The public viewpoints on the use of genomic data in safe havens guided us in the creation of recommendations.

Discussion

Principal Findings

Having considered the legislative backdrop in the EU, it can be seen that there is nothing inherently different in the EU GDPR about the lawful provisions for genomic data processing compared with other health data: all are classed as special category data. However, there is much debate about the effectiveness of anonymization processes for genomic data, and some consider that it is particularly difficult to produce genomic data that are both anonymous and useful [3,10]. This is not a new thought as it has long been noted in relation to demographic and health data [40], but it has been specifically applied because of the nature of genomic data leading to the concept of genetic exceptionalism [6]. Some of this is because of factors such as persistence, discrimination, and impact on kin, but there is an apparent mystique around genomic data that is proving challenging even if it is nonempirical, as beliefs play a significant role in policy making. The perceived complexities surrounding genomic material and data can lead to an overly cautious and proscriptive approach to the detriment of research [3]. We fully acknowledge that there are risks to be mitigated for safe data use and that data misuse can cause harm to individuals and professional reputations. However, it is also true that serious harm occurs because of data nonuse, far more than the missed benefits of proper data usage and leading to hundreds of thousands of lost lives and billions of dollars in financial burdens to societies [41]. In fact, it has been postulated that nonuse is often a greater problem than unauthorized data use [42].

A particularly important issue is the problem of conflating unique and identifiable. It cannot be overstressed that just because data are unique, this is not the same as being identifiable *per se*. If research had to rely on using only the data present in equivalence classes (ie, where there are no unique records, only sets of records [minimally 2] with identical variables), progress would be hampered. Even the fact that a person's full genome is unique does not render it identifiable without considerable effort, interpretation, and additional information to confirm identity. This has been shown in the debunking of a study purporting to identify individuals from genomic data, revealing that the work only narrowed down the information to a category of people based on phenotypic traits [43,44]. That is not to say that new insights on current limited knowledge of the genome will not change the likelihood of identifiability. Future proofing is important in the use of all personal data but more so in relation to genomics where successive new understandings are being revealed from previously unknown data content as the genomic revolution advances apace.

Another important factor to consider is what is meant by genomic data when special processing rules are suggested. As we have seen from the literature review and case study interviews, genomic data are used in various forms along with a variety of phenotypic data. Although GWAS and PheWAS studies rely on DNA sequence, many other studies use only DNA derivatives, or metadata, of varying complexity. We propose that it is not appropriate to bundle genomic data into one category and assume a uniformly high level of privacy risk. Even so, there is more than legislation to consider when seeking to use personal data for research, including ethical and social implications. Among the safe havens currently working with genomic data, there is a variety of approaches to data governance in accordance with their jurisdictional frameworks and interpretations. Depending on how the genomic data were collected, there may be a requirement for informed consent or data may be incorporated via standardized feeds along with health and administrative records based on sharing agreements with data providers. Data access might be limited to institutional employees or the public sector or might be open to all sectors. Researchers might be provided with direct access to linked data or to be limited to distributed queries. Genomic data are sometimes stored with the phenotypic data, but they might be on separate platforms and are sometimes held by separate organizations with access provided on a distributed model or with only limited derivative data imported. Commonly, safe havens do not generally release row-level data but export products of analysis following disclosure risk scrutiny. In terms of social acceptability, at least from our previous work, the public were generally favorable toward the use of genomic data in safe havens, subject to provisos including privacy safeguards and being provided with information about data uses.

Recommendations

We use the findings of the various elements of this study to propose a set of recommendations toward creating a risk-utility data governance framework and to augment existing operating models for using genomic and phenotypic data for research in an anonymized form in safe havens. We present the recommendations as overarching principles and practical control measures to mitigate risks and retain maximum data utility.

Principles

We propose that these principles be applied in general as part of the data governance framework for safe havens incorporating genomic data. We align the principles with the core elements presented in the high-level framework for the use of genomic and health data developed by the GA4GH [20], with the main relevant elements shown in italic text. The principles are as follows:

- Jurisdictional data protection legislation for general data processing, any specific provisions for genomic data processing, and relevant authoritative guidance and codes of practice should be examined and properly interpreted, with the input of legal expertise to ensure due compliance, *transparency,* and *accountability.*

- The need for regulatory approvals (including research ethics and informed consent) and data provider permissions for incorporating genomic data should be assessed, and all due diligence should be followed to demonstrate *transparency* and *accountability* and to support *recognition* and *attribution* in data provision.
- Members of the public should be provided with the opportunity to be properly *engaged* and involved at the strategic level to contribute their views to informing developments for the systematic incorporation of genomic data. The respectful need for a measure of *education and training* and the *dissemination* of information in *accessible* forms should be accommodated for transparency and accountability to the public, from whom the data arise.
- There is a need for a flexible, proportionate approach to consider proposed uses of genomic data, as they come in many formats with varying privacy risks, and (at least at present) it is incorrect to assume that genomic data are identifiable simply by reason of being unique. Assessment should be made on a case-by-case basis using *risk-benefit analysis* and with *education and training* to support data access committees.
- Safe havens should use their combination of data environment, physical, technical, and procedural controls, coupled with disclosure controls applied directly to the data, to maximize *data quality and security, privacy,* and *data protection and confidentiality.*
- As knowledge in the field of genomics is advancing rapidly, it is especially important to ensure future proofing of individual *privacy, data protection, and confidentiality* of genomic information. For *accountability* and *sustainability* of data use, we recommend that the practice of only exporting products of analysis should be the general policy, particularly for linked genomic and phenotypic data. Exceptions could be made if all relevant approvals are in place and the data are to be moved to another safe haven.

Practical Control Measures

The following is a selection of practical control measures that can be applied to specific cases where genomic and phenotypic data are used in combination to mitigate risk and retain maximum utility. They are not sequential or hierarchical but can be used in various combinations. The proposed control measures are as follows:

- All relevant project-level regulatory approvals for the collection and processing of genomic data should be checked by the data access committee, as part of their assessment of data use suitability.
- Researchers should consider opportunities for public engagement on their proposed use of genomic data to gain input on direction and preliminary findings.
- Along with the standing membership of the data access committee, a genomics expert should be co-opted to review particular proposals.
- Case-by-case review should take into account factors including the form and extent of genomic data to be used and the rarity and sensitivity of health and lifestyle factors to be studied, in addition to the criteria generally used by the data access committee.
- Reviews should include who will be permitted to access the data, depending on perceived risk and regulatory and data provider requirements. If deemed necessary, data access should be limited to the project team, a single researcher, or only to an analyst employed by the safe haven host, tasked with producing results to share with the project team.
- Many safe havens provide remote data access for approved researchers at their desktop, wherever they are based. If deemed necessary, data access should be physically restricted to a designated safe room so that a researcher has to be present on site when analyzing the data, and data access should be subject to stringent monitoring.
- Data granularity can be curtailed using a variety of disclosure control techniques applied to the data. The choice of methods should be selected with care in discussion with the researcher to retain maximum utility and safeguard the data.
- If available to the safe haven, the option of using distributed queries where the researcher is not provided with a view of the data but sends their query to the server and receives results should be considered for proposals deemed particularly risky.
- Where genomic data cannot be moved from the source, a hybrid model should be considered. Instead of incorporating the genomic data into the data safe haven, a federated access model may be used. However, the feasibility of this will depend on available technology and resources.

From our findings we anticipate that, in many cases, genomic data can be used safely and appropriately in conjunction with phenotypic data within a safe haven without many (if any) major changes to the current operating models, making use of the suite of controls available. The use of various forms of genomic data with phenotypic data will often be unlikely to present significant additional risks over and above those posed by the use of multiple linked health and administrative records within the safe haven. Provided that a case-by-case assessment is made, and proportionate controls are applied to mitigate risks while transparently acknowledging that they might not be totally eradicated, there should be no reason for not permitting the use of genomic data for research in safe havens.

What This Study Adds

This is the first known study to propose recommendations toward a risk-utility data governance framework for the use of genomic and phenotypic data in safe havens. It has brought together findings from published research, case studies of data safe havens, and public views against a backdrop of (EU) data protection legislation to inform the perspectives presented. It is a novel, evidence-based study that can be used to guide existing and newly developing data safe havens on working with genomic data to safeguard the data without falling into the trap of privacy protectionism [7], but still ensuring risks are properly mitigated while retaining maximum data utility. We do not claim to have solved all the challenges or that risk can be totally eradicated, but the study has shed new light on routes toward a risk-benefit data governance framework to use genomic and phenotypic data safely and effectively.

Limitations

We acknowledge limitations to this study. It is based on a nonexhaustive literature review, views of a limited number of people based on a variety of settings in Wales, case studies of some data safe havens, and the main EU data protection legislation. It is possible that various other pieces of information pertaining to other jurisdictions, organizations, and cultures may differ. However, we are not proposing that our findings are ultimately definitive but that they can be used toward a data governance framework, taking necessary differences into account.

Conclusions

This study acknowledges the benefits and challenges in using genomic data in conjunction with phenotypic data and the need for guidance to promote the safe, socially acceptable use of data in data safe havens. We used a multifaceted approach to propose evidence-based recommendations toward a risk-utility data governance framework based on a suite of controls applied to and around the data to mitigate risks and retain data utility. They do not purport to eradicate risk but propose case-by-case assessment with transparency and accountability. If the risks are adequately understood and mitigated, there should be no reason that linked genomic and phenotypic data should not be used in an anonymized form for research in safe havens.

Acknowledgments

This study received funding from the UK Medical Research Council (MC_PC_16035).

Abstract

Tremendous growth in the types of data that are collected and their interlinkage are enabling more predictions of individuals' behavior, health status, and diseases. Legislation in many countries treats health-related data as a special sensitive kind of data. Today's massive linkage of data, however, could transform "nonhealth" data into sensitive health data. In this paper, we argue that the notion of health data should be broadened and should also take into account past and future health data and indirect, inferred, and invisible health data. We also lay out the ethical and legal implications of our model.

Introduction

Background

Data intensive software, such as social media, wellness, and mobile health (mHealth) apps, have become ubiquitous in everyday life and are frequently used in a variety of situations. Years ago, social media networks were mostly accessed from traditional computers, but the rising use of smartphones and apps to access those networks has opened a Pandora's Box regarding data collection, including geolocation, motion data, health-related data, and behavioral data [1]. The collection of additional behavioral data about users was initially very limited, and only a fraction of basic data was collected (eg, IP address, operating system, and browser version). In contrast, current apps on smartphones have begun continuous monitoring of users by harvesting geolocation and motion data, and thus, they have the ability to infer users' physical and mental health states, for example, to detect signs of depression [2,3] and predict their next likely location [4,5]. Moreover, app companies have collected a tremendous amount of data on individuals' public and private activities in the digital world, which are being reused not only for the sake of their primary platforms, but also in other lucrative business sectors, such as robotics, life sciences, car manufacturing, and health data provision. Previously, users were able to simply opt out of these services, but this is becoming increasingly challenging nowadays given the monopoly market structure instilled by the companies that drive digital transformation. Indeed, customers are increasingly forced to use these services because they either do not have any other equivalent alternatives in terms of services provided or they are influenced by their peers or parents (in case of children) to use the services. Sometimes these companies nudge users with marketing strategies, such as substantial advantages and discounts offered only on these platforms. This proves to be problematic since to use these now important services, at least to some extent, users have to consent to some mandatory data sharing [6] and consequently expose their privacy.

Ambiguous Terms and Conditions

In view of the aforementioned facts, it is vital that the relationship between users and companies is transparent and regulated. This relationship is currently mostly defined in the terms and conditions (T&Cs), terms of service, and data privacy notices, which are unfortunately lacking in several aspects in term of enabling potential users to make an informed decision when signing up for a service. For instance, users are not warned about possible harms that might result from their activities on

the platforms (eg, linkage of several anonymous data sources could lead to reidentification of otherwise anonymous datasets and lack of awareness of secondary use could undermine user privacy and confidentiality). Additionally, the information provided in the T&Cs of different platforms is not reader-friendly and not succinctly summarized to nudge users to read them thoroughly. They are also not harmonized in the sense that each platform has its own implementation or they are simply not prominent enough during the process of signing up for the service [7,8]. Another weakness of T&Cs is that they do not make it clear that social media and the linkage of several independent unique databases can yield health data. Health data represent a special data category [9], requiring special security and privacy policies for governance. Indeed, many international legislations define health data as special data needing more protection than "usual" nonhealth-related data. The flipside of current legislation is that nonhealth-related data is subject to less strict governance. In the era where a digital phenotype [10] is emerging, data linkage can be very predictive and can be used to, for example, derive personal traits [11], predict psychosomatic diseases [2], and obtain other types of behavioral information.

Aim of the Paper

This paper presents a new approach for considering data, with the four categories of *direct*, *indirect*, *inferred*, and *invisible health* data, and suggests different types of possible consent frameworks that are up to this challenge, especially as data might not be conceived as distinct health data when produced. We first describe the already recognized categories of direct and indirect health data and then present the other two categories, describe the legal framework in the European Union and United States, and explore the different potential consent mechanisms and their suitability for these four categories of data.

Ubiquity of Health Data

Evolution of Health Data

Until the end of the last decade, health data were easily defined, and they included medical records, diagnostic images, laboratory testing data, and data produced by biomedical or clinical means. However, as rightly pointed out by Vayena et al [12], the notion of what is considered health data has considerably evolved. So-called biomedical big data nowadays ranges from data produced by health services, public health activities, and biomedical research to data registering exposure to environmental factors, such as sunlight and pollution, or data revealing lifestyle, socioeconomic conditions, and behavioral patterns, such as those from wellness and fitness apps, social media, and wearable devices. There is thus a paradigm shift from the notion of individual data producers and distinct categories to a more complex notion of a data ecosystem [13].

Implications of Massively Interlinked Data

The massive amount of data produced and interlinked has an effect on the characterization of individuals today, including their behavioral profile. Jain et al [10] developed the concept of the *digital phenotype*. The digital phenotype, an enlarged notion of the extended phenotype, encompasses the ubiquity of digital technologies and linkage of their data to virtually any other data, possibly resulting in potentially health-relevant data [14]. This notion is underpinned by not only the large numbers of studies conducted by universities that take advantage of the ubiquity of massive amounts of publicly available data, but also research involving the use of apps to predict individual behavior [15].

Further complicating these issues is the possibility that other types of data could be health data one day [16]. For example, some social media data concern exercise, which is highly relevant to health. Most people would agree that exercise data are health-related data and represent an example of indirect health data [10]. However, it is less obvious that other data, such as address and shopping data, location data, smart home data (eg, Amazon Alex and Siri data), smart car data, and articles shared on social media, can be combined with other datasets to infer health data [1,11], and this needs to be made more transparent in the future. It is already possible to use data to infer the degree of exposure to pollution and its likely health effects over long periods, and driving behavior data, such as acceleration patterns, can indicate the risks people take, which again could be used to infer their health conditions when combined with other elements.

Digitalization of Past Paper-Based Data

At another level, digitalization of past paper-based data could also yield direct or indirect health data (either through digitalization of paper medical records or fitness diaries), and future technologies, such as machine learning, may be able to identify health-relevant uses for data that have not yet even been conceived.

Thus, the days of health data as a distinct category are numbered, and soon, we will have not only direct health data, but also what we term indirect health data, inferred health data, and currently invisible health data (where the relevance to health might be perceptible only by machine intelligence in the future). This new understanding indicates the need for new governance, compliance, and regulatory mechanisms to handle data, protect individuals' privacy, and uphold the security of such new sensitive data. We briefly examine the current legislation that is relevant to these different categories of health data before continuing our ethical analysis.

Legal Situation in the United States and European Union

In contrast to the European Union, the United States is not subject to a single overarching data protection law. Data protection issues are implemented at the federal and state level. Table 1 summarizes some of the major federal laws that deal with data protection issues.

Table 1. Overview of the most important federal laws on data protection in the United States.

Law	Scope	Main points
Gramm Leach Billey Act	Governs protection of the personal information in the hands of banks, insurances companies, and other companies in the financial service industry.	Addresses "nonpublic information" (NPI) that institutions collect from their customers in connection with the provision of services. Imposes requirements for securing NPI, restricting disclosures, and using NPI. Obligation to notify customers when NPI is improperly exposed.
Fair Credit Reporting Act	Federal law regulating the collection of consumer credit information and access to credit card reports.	Governs how credit bureaus can collect and share information about individual consumers. Businesses check credit reports for many purposes, such as deciding whether to provide a loan or sell insurance to a consumer. This act also gives consumers certain rights, including free access to their own credit reports.
Health Information Portability Act	Protects information held by covered entities concerning health status, provision of health care, or payment for health care.	Breach notification. Data handling by covered entities and definition of safeguards.
Telephone Consumer Protection Act	The order is relevant to any company that uses automated technology to phone or send text messages to consumers.	Regulates telemarketing and forces companies to respect do not call registries.
Family Educational Rights and Privacy Act	Federal law that protects the privacy of student education records.	Offers students the right to correct information about themselves.

In the United States, some privacy frameworks provide a different definition of personal data and the notion of sensitive personal data varies among several federal state laws, with the Californian legislation being the most comprehensive, and among different economic sectors. Health data regulation is mostly included in the Health Insurance Portability and Accountability Act (HIPAA), which only covers entities that are directly related to health care operations, such as health care providers, health plans, and health care clearing houses, and the statement is as follows: "Except as otherwise provided, the standards, requirements, and implementation specifications adopted under this subchapter apply to the following entities: (1) a health plan; (2) a health care clearinghouse; and (3) a health care provider who transmits any health information in electronic form in connection with a transaction covered by this subchapter" (45 CFR § 160.103; 45th Code of Federal Regulations, Office of the Federal Register, United States of America). When data leave these entities, the imposed safeguards by HIPAA do not apply anymore, resulting in less strict regulations. A further guidance issued by the US Food and Drug Administration (FDA) concerns mHealth apps. It addresses, for example, apps that pose a high risk to the public. Apps only fall within its scope if they transform a mobile phone or any other electronic device into a medical device. As the FDA acknowledges in its guidance document, it does not address a substantial number of health data collectors, such as wellbeing apps; websites, especially patient centered portals like PatientsLikeMe; and social networks, and thus, it excludes most indirect, inferred, and invisible health data, which subsequently are subject to the US Federal Trade Commission guidance, resulting in lower safeguards of potentially highly personal data [17].

In contrast, the European Union General Data Protection Regulation (GDPR) offers a comprehensive framework for any kind of personal data and adds different notions to, for example, health or research data. The GDPR treats health data as a special category of data, which is sensitive by its nature, along with several other types, and the statement is as follows: "Processing of personal data revealing racial or ethnic origin, political opinions, religious or philosophical beliefs, or trade union membership, and the processing of genetic data, biometric data for the purpose of uniquely identifying a natural person, data concerning health or data concerning a natural person's sex life or sexual orientation shall be prohibited." (Article 9, section 1; General Data Protection Regulation, The European Union). Two key points are illustrated by this quotation. First, it is clear that social media data could reveal any of these different sensitive types of data. Second, the term "health data" is not actually mentioned; the phrase used is "data concerning health." This opens the door to indirect and inferred health data falling within the scope of the GDPR.

Processing of health data is prohibited unless exceptions apply, and one of them is the provision of the individual's explicit consent. The collection of consent from the data subject remains one of the most common exceptions that organizations processing health data will be able to rely on when it has been explicitly provided and the purpose for processing the data has been explicitly defined.

Comparing the two legislations (EU and US), it can be said that most US regulations on health data remain at the national or state level, such as the HIPAA in the US, which is tightly attached to parts of the health system, such as hospitals, health insurance companies, and pharmacies. Other important data stemming from social networks and other providers are not

covered by many of these regulations because they are out of their scope. Furthermore, there are no specific regulations other than broad principles, such as the fair information principles, issued by the US trade commission. In contrast, the GDPR offers at least some boundaries, but there are a number of serious questions on how to interpret the approach of the GDPR to the regulation of social media data. Our broadening of the notion of health data implies both that higher safeguards are applied to nonspecial categories of data and that the lawful grounds for processing such kinds of data need to take care of this situation, and imposing implicit consent could be one approach. As today's consent mechanisms are unable to handle this extra burden, there is an urgent need to foster the development of an alternative consent mechanism. Some examples are delineated later in this article.

The issue of different approaches to data protection has been the subject of disagreement in the literature. Cate et al, who are opponents of a more liberal approach, have argued for self-regulation of data protection principles [18], shifting the burden to users. In view of the recent scandals involving major data intensive companies, this view seems rather inappropriate and neglects the ethical responsibilities of companies toward their customers [19,20].

In contrast, authors like McDermont et al advocate data protection as a human right, with its underpinning ethical principles of privacy, transparency, autonomy, and nondiscrimination. These principles are particularly important in light of the increasing use of large amounts of data and algorithmic prediction [21]. This is also highlighted by Wachter et al, who called for a new right of reasonable inferences to close the accountability gap currently posed by "high-risk inferences," especially regarding predictions drawn from big data analytics with low verifiability and thus possible damaging effects on individuals [22].

Extended Notions of Health Data and Consent

Until now, we have assumed that data used in research are primarily generated prospectively (ie, right now or recently) and have excluded data from the more distant past. However, research projects, such as the Time Machine project [23], aim to generate digital copies of vast amounts of past paper-based data. Indeed, digitization of past data is progressing rapidly, for example, in the digital humanities and in the digitalization of large amounts of business and health data [24]. A new notion is thus introduced to the concept of consent. As today's consent is based on the assumption that the future use of data must be regulated, the linking of old or past data in connection with digitalization would also require consent when an identified or identifiable person is concerned. Consent will therefore have to deal with the past, present, and future use of both past and prospective data.

Consent to use pre-existing data is dealt with in a variety of ways. In medicine, research participants are sometimes invited to give "broad consent" to future reprocessing of data, which is subject to review by a research ethics committee. Such consent is necessarily broad because those giving it will often have no idea of the specific research projects that might use their data in the future. Other models require recontacting participants in order to obtain specific consent for each future project. More radical is the concept of "data donation," where people grant access to their data under very few limited conditions, if any [25]. However, all of these models are derived from health care and medical research. In the wider context of social media, financial, and location data, consent is based on the initial agreement to the T&Cs as described above and is mostly of a commercial background. Despite the fact that the data could be used in a myriad of ways, even if not ultimately health related, this consent is often entirely uninformed. This is even the case for data that are currently being generated. Awareness and transparency are even lower in terms of possible uses of past paper-based data that are digitalized or future data that might seem irrelevant now but could yield highly relevant health data when combined with other datasets. Current consent for data sharing is to a large extent blind owing to its broad nature. Consent systems actually need to look far back and far forward, as well as in close detail at the present. In essence, consent must be capable of time travel, just as data are capable of time travel.

Toward Comprehensive Consent in a Hyperconnected World

Several scholars have pointed out that traditional models of obtaining consent have reached their limits in today's highly data-driven and data-intensive research, and this articulates the need for new forms for obtaining participant consent [26,27]. Concretely, the traditional form of obtaining consent by individually informing participants about their rights and protections is practically impossible in such environments [28-30] owing to the sheer scale and challenges associated with such an endeavor. Several scholars have proposed possible ways to tackle this issue, ranging from information technology-based systems like dynamic consent [31], which offer a better way to inform and maintain a relationship between researchers and participants, to stewardship-based solutions, such as those where a community-based approach assures data governance [32], and radical solutions like data donation [25]. However, most of today's research projects simply use a digitized version of traditional consent procedures.

As we have already pointed out, past data will become increasingly health relevant. This applies particularly to public and commercial research where it is expected that increasingly more research will be data driven and data will stem from many disparate data sources, including commercial sources. There is thus an urgent need for a better approach of informing customers in a truly informative way. However, as stated above [16], the current approaches are ineffective as T&Cs are too long and written in a too complicated way, undermining what is at the heart of genuinely informed consent, namely the prevention and hold up of basic ethical principles [17,18]. A possible way to tackle this is to introduce harmonized T&Cs, which would need stronger government interventions. Further possibilities are to move toward comic-based consent as developed by

Brunschwig for contract law [33] and to implement "nutrition label-like" consent [34] for T&Cs.

The four distinct categories of direct, indirect, inferred, and invisible health data mentioned earlier in this article may each require a differentiated consent solution, and the past, present, and future aspects of consent for the use of big data complicate the situation further.

Direct health data are most easily governed, although they have their own set of challenges. A specific consent system may seem simple but can impose substantial limitations on researchers and prove very burdensome for patients. Broad consent poses its own set of problems, particularly in terms of future data linkage. Even with specific consent to use an individual's data in a particular project, researchers might also want broad consent to access a participant's entire medical history and link it to medical records to facilitate follow-up, meaning that consent is provided for health data generated in not only the project itself (the present), but also the years or decades before it (the past) and the many years to come (the future). The growing discussion around data donation illustrates the ethical and legal challenges related to providing consent to ongoing use beyond death for an entire lifetime of genetic and nongenetic health data, some of which may have implications for relatives. In fact, most of the current data protection frameworks, such as GDPR, neglect data donation, and use of data after death is not within their scope (Recital 27 EU GDPR). At least until the point of death, a dynamic consent system seem to be a promising means of controlling different users' access to past and present medical data and for controlling data linkage with other studies. Another issue complicating the use of direct data concerns mHealth data (ie, data that are gathered when using mHealth solutions). Such apps are mostly overseen by national authorities, and, for instance, in the United States, they need approval from the FDA. Data gathered by those apps need higher protection by law than US regulations and GDPR provide at present. In particular, the issue of consent is rather unregulated, and what could be seen as possible consent (the acceptance of the T&Cs) does not meet the high standards as imposed by traditional consent in research.

Indirect health data, such as exercise, social media, and movement data concerning an individual, are not currently regulated within the health data model in the United States. In the European Union, the GDPR covers such data, but they are not regarded as distinct health data and thus benefit from less protection, as is the case for inferred data. As stated above, consent is usually given via the T&Cs of relevant apps. This must change in the future. Either T&Cs must become much more user friendly and accessible or an entirely different consent model and system more akin to direct health data governance will have to be adopted.

Inferred data are particularly problematic in terms of consent, as they are the result of the combination of two or more datasets of one individual. Consent may have been given to the processing of each of these data points (or sets) but not to their combined processing, which can yield more revealing data not anticipated at the time consent was provided. One way to approach this problem is to make it clear at the point of consent to use direct and indirect health data that their combination with other datasets is a real possibility despite goodwill and efforts on the part of researchers, companies, and other users to prevent it. With further technical developments, it might even be possible to send an alert to a dynamic consent portal for each new instance of combining data points of the individual, enabling tighter and more finely grained control of inferred data. This would ensure that consent is provided when new inferences are made. It is important to bear in mind in the discussion of inferred health data that some data, particularly genetic data, affect not only the data subject but also family members, which is also true for social media data when parents share information of their close relatives and children. Some individuals might be very happy to share all types of data, but this can have ramifications for close relatives, particularly identical twins, in the case of genetic data. In such cases, some form of collective consent may be required.

By its very nature, consent to use invisible health data cannot currently be provided, as we are still blind to the very nature of such data and their potential relevance to health. However, consent can be "future proofed" to a limited extent with careful legislation and regulation. By adopting a similar level of oversight for all types of data concerning a person (the GDPR is a step in this direction), safeguards will be in place once it emerges that seemingly entirely innocuous data can be used by artificial intelligence technologies to yield health findings. Once this transpires, alerts to dynamic consent systems will be a sensible precaution.

As the future use of data cannot be foreseen at present, alert mechanisms play a particularly important role, especially for inferred health data and invisible health data. Given our thesis that any data could turn out to be relevant to health, alerts might well be essential to ensure that people are kept informed when their data are put to a novel use with health implications. Whether citizens would or could have any right to stop the processing of such "new" health data is a difficult question that is outside the scope of this paper, but informing them seems to be a basic ethical requirement. If, as we suggest, all data will become health relevant, it might be impossible or, at least, very impractical for people to stop the processing of all data relevant to their health. Laws, such as the GDPR, will have to keep pace with developments in the conception of health data, as imposing current GDPR standards on all data that might be relevant for health in the future could have great implications for the processing of data, particularly in research. Table 2 summarizes the different categories of health-related data and how consent to use past, present, and future data could be approached.

Table 2. Consent based on different health data types related to their temporal origin.

Data type	Past data	Present data	Future data
Direct health data	Specific/broad consent	Direct/specific/broad consent	Direct consent
Indirect health data	Direct consent/terms and conditions	Direct consent/terms and conditions	Direct consent
Inferred health data	N/A[a]	Alerts to dynamic consent systems	Alerts to dynamic consent systems
Invisible health data	N/A	N/A	Alerts to dynamic consent systems

[a]N/A: not applicable.

Conclusion

With each passing day, billions of gigabytes of direct, indirect, and inferred health data are being recorded, with massive implications for privacy and harm prevention if adequate consent mechanisms for their use are not in place. The possibility of invisible health data complicates the situation further. If all our data will be health data one day, we need to start treating consent to data use with the respect that it deserves. Currently, most data collectors are gaining access to vast amounts of behavioral and health data effectively for free, without having to comply with any safeguards. Broadening the notion of health data, as we have suggested, would cause companies to give more thought to ethical acquisition and processing of data. However, broadening the notion of health data could have an adverse effect on research if it results in excessively burdensome regulations.

Our argument that all data are health data is primarily ethical, but it could have important legal ramifications. In jurisdictions where health data can only be processed with consent, widening the scope of health data in this way would vastly increase the burden on, for example, private companies who process indirect and inferred health data. This might be difficult but ethically appropriate, and the development of more modern and dynamic consent mechanisms could facilitate this shift. Alternatively, legislation could limit the legal scope of health data to direct health data, leaving soft laws and guidelines to regulate other categories of health data.

Abstract

Digital health interventions (DHIs) are increasingly becoming integrated into diabetes self-management to improve behavior. Despite DHIs becoming available to people with chronic conditions, the development strategies and processes undertaken are often not well described. With theoretical frameworks available in current literature, it is vital that DHIs follow a shared language and communicate a robust development process in a comprehensive way. This paper aims to bring a unique perspective to digital development, as it describes the systematic process of developing a digital self-management program for people with type 2 diabetes, MyDESMOND. We provide a step-by-step guide, based on the intervention mapping (IM) framework to illustrate the process of adapting an existing face-to-face self-management program (diabetes education and self- management for ongoing and newly diagnosed, DESMOND) and translating it to a digital platform (MyDESMOND). Overall, this paper describes the 4 IM steps that were followed to develop MyDESMOND—step 1 to establish a planning group and a patient and public involvement group to describe the context of the intervention and program goals, step 2 to identify objectives and determinants at early design stages to maintain a focus on the strategies adopted, step 3 to generate the program components underpinned by appropriate psychological theories and models, and step 4 to develop the program content and describe the iterative process of refining the content and format of the digital program for implementation. This paper concludes with a number of key learnings collated throughout our development process, which we hope other researchers may find useful when developing DHIs for chronic conditions.

diabetes mellitus, type 2; technology; self-management

Introduction

Background

Type 2 diabetes (T2D) is a progressive lifelong condition affecting over 422 million people worldwide [1] and is associated with a number of severe macrovascular complications (damage to large blood vessels leading to coronary heart disease and stroke) and microvascular complications (damage to small blood vessels leading to kidney disease, blindness, and amputation). Diabetes self-management has been shown to reduce the risk of these related complications, improve one's well-being, and reduce the UK National Health Service's (NHS) health costs [2].

Self-management education can be delivered in several forms; one of these forms is via structured education programs. Structured education programs are nationally and internationally recommended for all people with T2D and meet nationally agreed criteria, including following an evidence-based curriculum that is theory-driven, evidence-based, and resource-effective, carrying out quality assurance of teaching standards and delivering regular audits [3]. Examples of such self-management education programs are diabetes education and self-management for ongoing and newly diagnosed (DESMOND) [4,5] and X-PERT (Diabetes education programme for people with T2D) [6] in the United Kingdom, Rethink Organization to iMprove Education and Outcomes [7] in Italy, and Structured Intensive Diabetes Education Program in South Korea [8]. These programs are available for people with T2D, both newly diagnosed and established [9].

In 2008, the National Institute of Health and Clinical Excellence published guidelines to recommend the availability of group-based structured education programs as a key priority for diabetes management [10]. Evidence has shown that group-based structured education programs are essential for effective diabetes management, aiming to improve people's knowledge, skills, and confidence, enabling them to take control of their own condition. Effective education programs have also been shown to improve biomedical (weight and glucose levels), behavioral (ie, physical activity), and psychosocial outcomes (ie, diabetes-related distress and self-efficacy) [9]. Various barriers, however, appear to be associated with low uptake and attendance at structured education programs [11,12], with suboptimal access to programs commonly noted [13]. Attendance and accessibility for patients may also be compromised by health care professionals' insufficient advocacy for structured education programs, as well as limited infrastructure and capacity to offer face-to-face programs [14].

Although referrals to structured education have increased over the last 3 years, attendance at such programs have decreased, and attendance rates are as low as they were in 2009 [15]. This is why a recent call by NHS England in the UK advised that people with diabetes are offered face-to-face programs, and those who cannot attend must, then, be offered a digital alternative [16].

Digital health interventions (DHIs, which are any digital-based intervention, such as smartphones, websites, text messaging) [17] have become a means of delivering care and offering support to facilitate behavior change in individuals with long-term conditions. Mounting evidence indicates that the use of digital technology for diabetes self-management is an effective way to support people to live well with their diabetes [18,19], with programs showing improvements mainly in glycemic control [18,20].

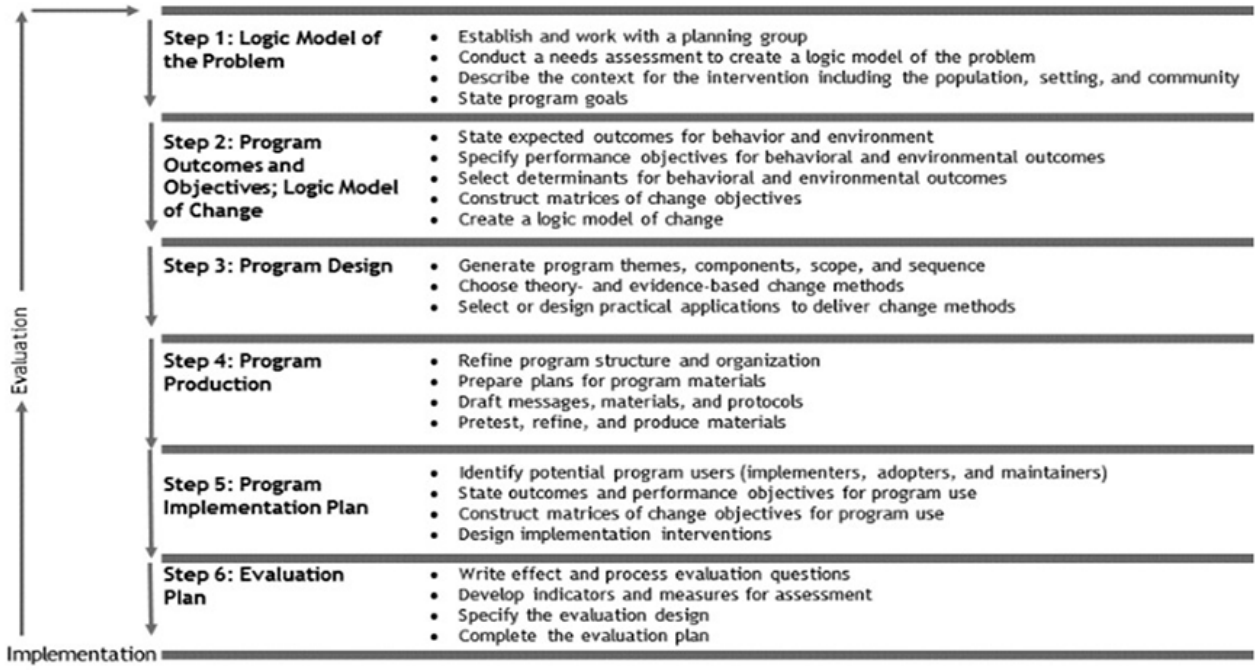
DHIs in other chronic conditions have been shown to be cost-effective, with a recent cost-effectiveness study depicting the benefits and cost-effectiveness of digital-based psychological interventions for reducing behavioral stress management and anxiety [21,22]. Information derived from DHIs can be kept up to date more easily with local and national guidelines and recommendations. DHIs are neither geographically nor time restrained. Indeed, barriers associated with face-to-face structured education programs, such as time and transport, are often easier to address with digital interventions, as users have the opportunity to access Web-based programs and read the material at their own time and pace.

Appropriate steps are essential when developing evidence- and theory-based digital programs to ensure they are implemented effectively in the real world [23]. Despite DHIs becoming more and more available to people with diabetes, the development strategies and processes undertaken can be somewhat unclear. With theoretical frameworks available in the current literature, such as Bartholomew's intervention mapping (IM) framework [24], it is important that DHIs follow a shared language and communicate a robust development process appropriately and systematically [25].

Intervention Mapping

IM, a 6-step framework, is often applied to guide behavior change interventions and health education development. This evidence-based approach, although presented as a series of 6 steps, follows a more iterative process that bridges the gap between theory and practice. With this in mind, we aimed to develop our digital program based on a systematic and robust process such as IM, to ensure that our evidence-based program can be implemented in real-world settings. The development process for MyDESMOND was guided by the first 4 steps of IM, as illustrated in Figure 1: (1) conduct a needs assessment, (2) specify program outcomes and objectives, (3) design program and apply theory, and (4) refine program development. The last 2 steps (5) and (6) of the IM framework for MyDESMOND (adoption, implementation, and evaluation plan) are currently being evaluated.

Figure 1. Intervention mapping framework, Bartholomew.



Aim

This paper describes the systematic developmental process that we undertook to adapt the content and evidence of an existing face-to-face structured self-management education program (DESMOND) for T2D and translate it into a digital self-management program (MyDESMOND). This process is presented based on the IM framework [24].

Methods

Step 1: Needs Assessment

Establish and Work With a Planning Group

A multidisciplinary team (psychologist, dietitian, diabetes specialist nurses, and experts in physical activity and digital health) was brought together to provide expertise in the psychosocial and clinical aspects of T2D, digital health, and behavior change research. Throughout the design process, our planning team worked alongside a Web-designer to ensure that the logistics and digital platform would be appropriate for a UK-based program.

Patient and public involvement was essential for our development process [26]. Throughout our process, we worked closely with people with T2D who provided feedback on the content: format and usability of MyDESMOND (see Step 4 Program Development for further details).

Conduct Mixed Methods Needs Assessment

We conducted a preliminary scoping search, and together with the findings of our existing research studies, we aimed to collate key learning points to explore and identify the key program goal and key behavioral determinants of MyDESMOND.

Scoping Literature

Self-management involves 3 key tasks (medical, role, and emotional) and consists of core self-management skills, including problem-solving, decision making, resource utilization, and action planning [27]. Digital self-management interventions over recent years have provided users with the knowledge and skills required to make a lifestyle change and improve their self-care. Enabling people with diabetes to better understand their conditions has been shown to improve coping strategies and reduce health-related anxiety and depression [18].

In addition to knowledge and improved coping skills, social support has also been linked as a major predictor of, and positive influence on diabetes self-management. A systematic review, which explored the role of social support on biomedical and psychosocial outcomes, as well as behavior change, reported a positive impact on the aforementioned outcomes [28]. In addition, recent diabetes literature has also illustrated a strong association between social support and improved diabetes self-management and self-efficacy [29].

A qualitative evaluation of patient and health care professional (HCP) views on barriers to self-management and multimorbidity (including diabetes) identified 3 main factors that influence self-management: (1) capacity (access and availability of resources, time, and knowledge), (2) responsibility (the degree to which patients and HCPs agree about self-management), and (3) motivation (willingness to take-up types of self-management practices) [30].

Systematic Reviews

We conducted focused synthesis of work in 2 areas: (1) a systematic review and meta-analysis to critically appraise and quantify the evidence on the effect of digital interventions that aim to improve well-being in people with T2D [31], and (2) a more recent systematic review of systematic reviews to explore

and synthesize evidence around the applications of digital patient education in T2D and cardiovascular disease [32].

Systematic Review and Meta-Analysis

The systematic review and meta-analysis [31] identified preliminary evidence suggesting that digital interventions with significant well-being outcomes (in this case, depression or diabetes-related distress outcomes) shared common characteristics: (1) all interventions provided professional-led support, (2) interventions consisted of both asynchronous and synchronous communication, and (3) intervention duration was between 2 and 6 months. This review also identified that the common behavior change techniques (BCTs) adopted by effective digital interventions were *information provision* and *monitoring*.

The aim of this review was to examine if digital-based interventions improve well-being outcomes such as depression and diabetes-related distress; however, no significant improvements were found following a meta-analysis in depression (P=.15) or distress (P=.43). Nevertheless, the review did take into consideration that the number of studies included in the meta-analysis was low, and thus, conclusions on the meta-analysis were considered with caution.

On the basis of the findings above, we considered the following elements in our development work: (1) to have a professional-led, rather than peer-led program, (2) to include some form of *monitoring* element and feedback to users, and (3) to include both direct and indirect communication, in the form of a chat forum or messages.

Systematic Review of Systematic Reviews

This systematic review of the reviews [32] explored and synthesized the scope of digital patient education in T2D on patient outcomes. Our findings indicated that biological, behavioral, and psychological outcomes, as well as knowledge and self-efficacy for people with T2D, had shown examples of benefits from digital patient education. In addition, outcomes that most consistently showed improvement with the intervention (irrespective of effect size) were weight, physical activity, knowledge, social support, and quality of life. These findings suggest that digital patient education has a wide range of benefits for people with T2D. Therefore, we considered these findings in our development work and ensured that our program incorporated biological, behavioral, and psychological outcomes. Self-efficacy was also another crucial outcome, which we felt was important for behavior change (see additional information in theories, Step 3).

Our Current Face-to-Face Self-Management Program (DESMOND)

Our face-to-face self-management program [33] was developed for people with newly diagnosed T2D with the aim that participants would focus on lifestyle behaviors (such as food choices and physical activity), consider their personal risk factors, and choose a specific achievable goal to work on. This program is delivered for 6 hours in the community by 2 trained educators and is based on psychological theories of learning: Leventhal common sense theory [34], dual-process theory [35], and social learning theory [36], and the philosophy of the program was grounded on patient empowerment [37]. On the basis of the evaluation of DESMOND [33], this group self-management program showed greater improvements in weight loss and positive improvements in illness beliefs. Our aim was to adopt key elements of DESMOND that we considered crucial to the effectiveness of this program, including group dynamic and peer support, interactive activities, and setting a personal goal to help with behavior change. To ensure that elements were retained in the adapted format and remained suitable for a digital format, we found it was essential to revisit and underpin theories to our digital program that focused on the process of change. Thus, with the aforementioned key elements in mind, we aimed to provide a virtual environment whereby Web users would have the opportunity to share thoughts and experiences in the form of a chat forum and retain the peer support element. Interactive activities were developed to ensure that information was not provided in a didactic way, but instead was provided in a way whereby Web users could reflect on answers and aid their confidence. Similar to DESMOND, MyDESMOND users were able to assess which behavior change is important to them and tailor a personal action plan suitable to their environment and needs. Users would then be able to revisit their action plan to assess their progress. From preliminary feedback, participants expressed satisfaction with the content of the program (lifestyle behaviors) and reported they had gained knowledge and learned new skills in healthy living.

Our Digital-Based Self-Management Program

BabySteps

In 2017, we developed our first digital-based self-management program on a responsive digital platform to promote physical activity in women with a history of gestational diabetes (BabySteps) [38]. This digital program consisted of functions such as information material, step challenges, chat forums, and health trackers, and these functions were based on gamification and BCTs, including problem-solving, coping skills, and action planning. With the BabySteps trial coming to an end, we carried out feedback sessions with 12 participants to explore user experience and satisfaction. Preliminary findings have helped structure MyDESMOND in several ways: (1) DHIs are needed for chronic conditions, (2) to adopt a new behavior, people need to learn and practice self-care skills, (3) the navigation on apps plays a crucial role in digital uptake, (4) people engage with digital programs if it comes from a trustworthy source, and (5) peer support is essential in DHIs.

MyWellbeing

It was important to consider that BabySteps was a prevention program with a focus on physical activity (ie, increase steps and reduce sedentary behavior). We therefore supplemented our needs assessment step with further work conducted by our lead author [39] to develop a digital emotional support program to improve diabetes-related distress in T2D (MyWellbeing). This additional work aimed to complement the evidence behind MyDESMOND by incorporating the element of emotional management. This work adopted a person-centered approach [40] and gathered evidence from exploratory mixed methods research work (which will be published elsewhere). Most

importantly, this work was based on ongoing patient and public involvement (PPI) engagement to support the development of this digital-based program. Key learnings from the PPI groups (which consisted of people with T2D and carers) were as follows: (1) incorporate links to useful external resources, (2) design a program with a positive language and motivational content, (3) incorporate *ask the expert* function, (4) use short videos to provide information, (5) include quizzes as a form of interactive learning, and (6) consider a *frequently asked question* page to enhance engagement.

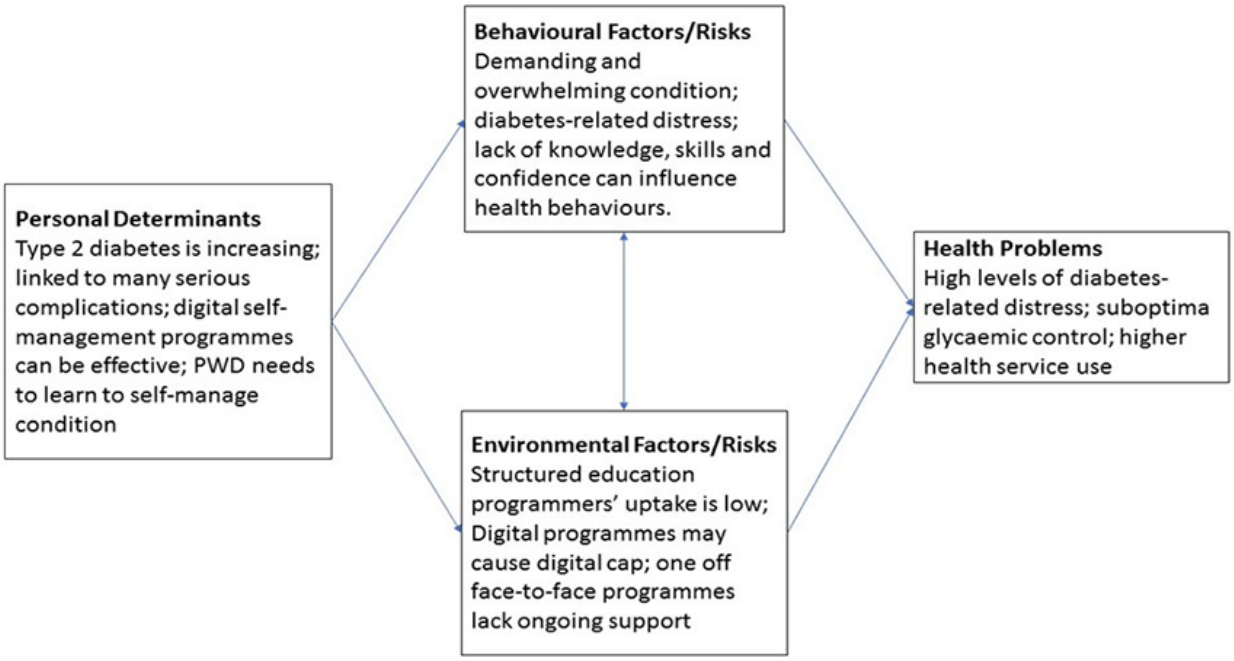
Identify Program Goals

Overall, the outcomes of the needs assessment provided the evidence for our program goals and defined the purpose of our digital program, which was to provide a digital self-management program to people with T2D to improve medical, behavioral, and emotional self-management. This was developed with the aim to improve and maintain self-management behaviors, improve knowledge, promote self-care skills, increase self-efficacy, and improve well-being.

Create a Logic Model of the Problem

On the basis of our scoping literature and mixed methods studies (as part of step 1), we produced a logic model of the problem, illustrating the link between behavioral determinants and the behavioral and environmental factors, which lead to the targeted health problems (Figure 2).

Figure 2. Logic model of the problem, step 1 IM.



Step 2: Behavioral Determinants and Performance Objectives

Select Behavioral Determinants and Performance Objectives

This step involved developing the specific change objectives and identifying specific behaviors that determine behavior change for this target population. Informed by the findings from our needs assessment, our planning group identified 5 key behavioral determinants and 5 performance objectives (objectives to be accomplished by the individual to achieve the program goals), which we anticipated would influence the behavioral outcome (Table 1). In detail, behavioral determinants were identified as follows: (1) knowledge, (2) self-efficacy, (3) social support, (4) intention, and (5) behavioral skills. Performance objectives were defined as follows: (1) learn about T2D, (2) be motivated to self-manage, (3) increase access to resource, (4) engage with the digital program, and (5) learn about self-care behaviors. The behavioral determinants listed in the matrix table (Table 1), derived from the Capability, Opportunity, Motivation, Behaviour (COM-B) model (which we explain in the following section), focus on factors that we identified as important in this target population. In this step, we elaborate on the strategies required to ensure that performance objectives are met, and subsequently, determinants are addressed (Table 1).

Table 1. Matrix of objectives.

Behavioral determinants	Performance objectives	Strategies
Knowledge	Learn about T2D[a]	Users gain knowledge; Information on healthy living, stress management, medication, physical activity, and diet
Self-efficacy	Be motivated to self-manage	Users formulate their own goal setting and action plan via patient testimonials and *expert* videos; Users are exposed to modeled behavior
Social support	Increase access to resource	Users become aware of local support; Users receive support not only from HCPs[b] but also from peers
Intention	Engage with the digital program	Users engage with program functions tailored to their needs; intention to change behavior
Behavioral skills	Learn about self-care behaviors	Users practice self-care behaviors

[a]T2D: type 2 diabetes.

[b]HCP: health care practitioner.

Step 3: Theory-Based Intervention Methods and Practical Applications

Identify Theory-Based Methods and Select Practical Applications

In a complex environment, dealing with influences on an individual, social, and cultural level, we aimed to adapt and develop a digital program that was theory-based to break down targeted health behaviors. Theory-based interventions are more effective than non–theory-based interventions and can provide a clear understanding of what works in terms of adapting interventions across populations, behaviors, or contexts [41]. Thus, we adapted the following theoretical frameworks and models to the development of our digital program.

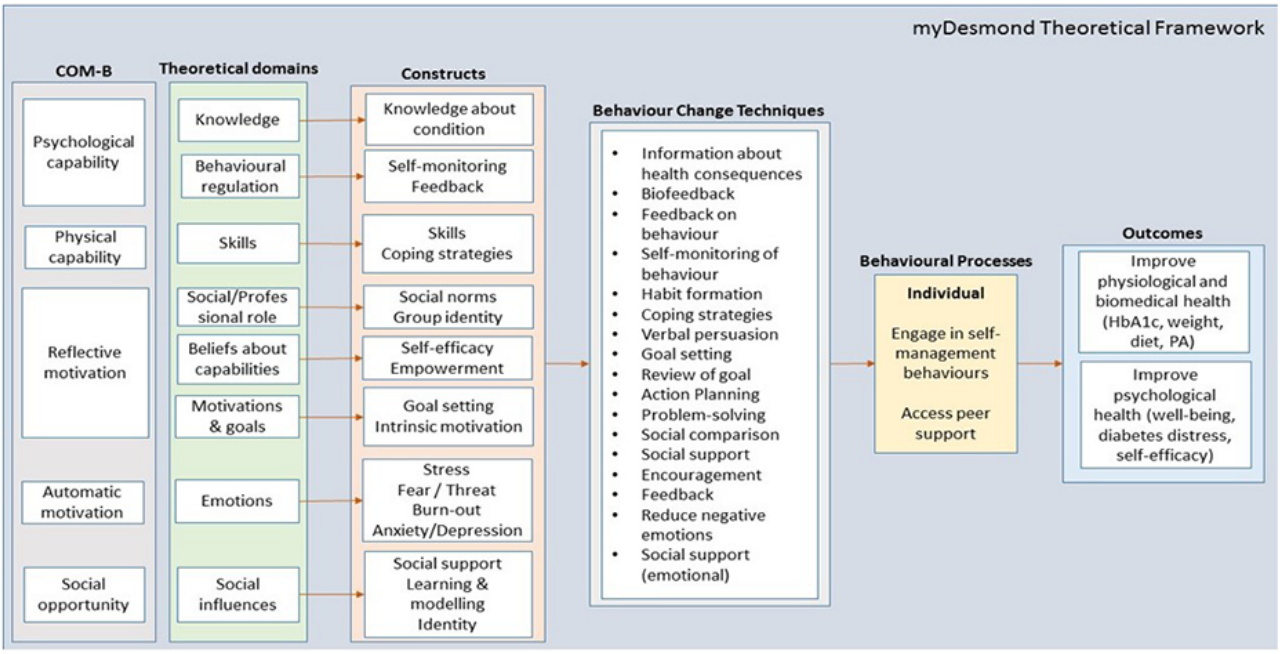
Corbin and Strauss Model on Self-Management Framework

A key conceptual framework of self-management was developed by Corbin and Strauss. Self-management programs (face-to-face or digital) often include at least one of the three main overarching areas: cognitive (such as knowledge, understanding, and self-efficacy), behavioral (such as lifestyle changes and managing medication effectively), and emotional (such as distress, shame, and depression) [21]. On the basis of the Corbin and Strauss model, we aimed to adapt and develop an effective program that considers all three elements for self-management equally: cognitive, emotional, and behavioral [42].

Capability, Opportunity, Motivation, Behaviour Model and the Taxonomy of Behavior Change Techniques

We applied the COM-B model as it provides a common language for the reporting of behavior change interventions [43]. Atkins et al argued the importance of including behavioral determinants and BCTs in the development process of interventions, as these may influence and change health behavior [44,45]. Interventions targeting behavior determinants and behavior change have also been shown to be more effective [46]. Informed by Michie's Behavior Change Wheel (a systematic guide to designing interventions) [43], we populated a theoretical framework for MyDESMOND to identify the relevant mechanisms of action, component constructs, and BCTs, all aimed to inform the individual and organizational processes and health outcomes (Figure 3). Our mechanisms of action, which are processes that influence behavior, included key constructs: knowledge (an awareness of the existence of a condition), behavioral regulation (self-efficacy and feedback), skills (an ability acquired through practice), beliefs about capabilities (belief and acceptance of one's ability to perform), social and professional role and identity (one's displayed behaviors and qualities within a social setting), emotions (one's reaction and attempt to deal with a significant event), and social influences (interactions that influence one's thoughts, feelings, emotions). Table 2 illustrates the relationship between the mechanisms of action, BCTs, and the practical application to implement change methods in MyDESMOND, an important factor for program development.

Figure 3. MyDESMOND theoretical framework.



Health Action Process Approach Model

Despite the application of the behavior change taxonomy, it was still essential to adopt a model that helped explore the process of change and helped explain how individuals decide to engage in healthy behavior. Known as a *process* model, the Health Action Process Approach (HAPA) model informed the development of our digital program. Intention alone does not always change behavior [47], thus with the guidance of action planning and coping planning (both incorporated in our digital program), we aimed to build a program that focused on two processes: goal setting and goal pursuit. With self-efficacy as an additional HAPA construct, we know that people with higher self-efficacy are more likely to sustain the behavior; thus, we ensured that MyDESMOND also incorporated elements for this construct.

Social Support Theory

Social support plays an integral part in the management of diabetes and is often associated with health behaviors such as physical activity. Thus, it was deemed appropriate to base our digital program on a social support-focused theory. We considered all 4 types of social support [48]: *emotional support*, which focuses on sharing life experiences and reassurance; *instrumental support*, which can include practical support such as material or services that users can access directly; *informational support*, which involves evidence-based information or advice; and *appraisal support*, which includes concepts such as constructive feedback and affirmation. Lakey and Cohen's [49] Social Support Theory was adopted to illustrate the relationship between *digital* social support and individuals' appraisals and coping skills, which can, in turn, mediate distress levels and improve overall well-being and T2D self-care.

Table 2. Design of practical applications.

Mechanisms of action (accompanied by BCTs[a])	Practical applications	Text description
Knowledge (information about health consequences, biofeedback, feedback on behavior)	Educational material; Interactive quiz; Animation videos; Decision tracker	Provide information about T2D[b], complications, medication, and healthy lifestyle, including weight, diet, and physical activity; track and receive feedback on health.
Behavioral regulation (self-monitoring of behavior)	Sync steps; Leader board; Track daily targets	App users are encouraged to record dietary habits, weight, HbA_{1c}[c], well-being, blood glucose, cholesterol, and smoking habits, to sync and monitor steps, and complete an action plan for desired behavior.
Skills (coping strategies and habit formation)	Educational material; Interactive quiz; Chat forum	Provide information about a healthy lifestyle; encourage app users to record their tracks; opportunity to share strategies and experiences with other users.
Social and professional role (no BCTs linked to this domain)	Expert videos; Ask the expert	Highly respected experts provide (in the form of videos or emails) and present information and key messages about T2D, well-being, diet, physical activity, and other relevant information.
Beliefs about capabilities (verbal persuasion to boost self-efficacy)	Ask the expert; Chat forum; Patient testimonials	Verbal reassurance and encouragement among users that may boost their confidence and encourage them to continue with their action plan and behavior change
Motivations and goals (goal setting, review of goal, action planning, problem- solving)	Action Plan; Daily targets; Leader board; Personal achievements; Challenges	App users have access to functions and are encouraged to take part in challenges and set their daily targets. They are also encouraged to complete an action plan for target behaviors.
Emotions (reduce negative emotions, social support [emotional])	Chat forum; Whiteboard animation; Educational material; Decision tracker; Quiz	Provide information in the form of whiteboard animations, quizzes, and educational material around burnout, distress, depression, and well-being; use of a chat forum to provide an additional element of peer support.
Social influences (social comparison, social support, encouragement)	Patient testimonials; Chat forum; Leader board; Personal achievements; Challenges	App users have access to videos of peers discussing and sharing experiences of their journey. Chat forums are available for users who wish to share questions and thoughts—this platform acts as a mode for users to encourage one another.

[a]BCT: behavior change technique.

[b]T2D: type 2 diabetes.

[c]HbA_{1c}: glycated hemoglobin.

Step 4: Program Development

Develop Program Content

On the basis of key learnings from our face-to-face program (DESMOND) and our digital programs (BabySteps and myWellbeing) in combination with our theory-based approach, we had a clear idea of the program themes, material list, and aim of MyDESMOND. With the involvement of our multidisciplinary team, we designed scripts and material in line with the Corbin and Strauss self-management framework, incorporating content around medical, role, and emotional management. Once the content was adapted and developed, we liaised with our Web-designer and information technology team to map the material (ie, text, videos, and quiz) onto an appropriate digital platform that was easy to access from any electronic device (ie, desktop computer, smartphone, and tablet). MyDESMOND was developed to meet the objectives detailed in step 3. The following topics are included in MyDESMOND: *What is T2D, Medication, Complications of diabetes, Food choices, Physical Activity, Sedentary behavior, Emotions, Diabetes-related distress, Setting goals, and Relapse*.

Refine Content and Format

In addition to our previous work mentioned in the above sections, it was essential that we also involved patient and public feedback throughout the development of MyDESMOND. Furthermore, PPI work with early users helped inform and refine the content and format of our digital program. PPI work took place based on an iterative process, whereby 9 PPI members were provided logging details to *have a go* at MyDESMOND at various points of the development phase and provide feedback. Examples of PPI feedback and suggestions, which refined MyDESMOND included the following: (1) to provide the chat forum function as optional to the user (and not mandatory), as not all users would seek Web-based interaction with peers; (2) to include a separate section on well-being and discuss about diabetes-related distress and negative emotions in a nonjudgmental way—this suggestion from the PPI members reiterated issues around stigma and blame; (3) to provide weekly additional sessions on well-being, physical activity, and food choices—this change resulted in the development of additional mini videos to ensure that the users received regular information on important topics; and (4) to introduce mini videos of testimonials of MyDESMOND users sharing personal

experience. Additional feedback received from our PPI members included (1) the navigation system of MyDESMOND was easy to use, (2) to make our logo clear to reassure that we are a reliable and trustworthy source; (3) digital ongoing support is much needed poststructured education programs; therefore, all content must be available at all times to the users.

MyDESMOND Platform

The interface and features were designed as such to improve diabetes self-management practices. The focus was directed toward daily step count, challenges, notifications, and the release of weekly education bite-sized sessions. These short sessions consisted of animations, gamification, quizzes, and games designed to be no more than 5 min in duration. Features include interactive learning, monitor health, activity tracking, ask the expert, community (share ideas, experiences, and questions with others in a chat forum), goal setting, challenges (complete challenges with other users on global leader boards to increase steps and focus on personal achievements), and invite a buddy (invite family and friends to join the program). Figures 4-6 present examples of features and description of MyDESMOND content.

Figure 4. Users can learn about T2D and self-management activities and refresh knowledge with 8-weekly additional sessions (educational material, interactive quiz, animations) on MyDESMOND.

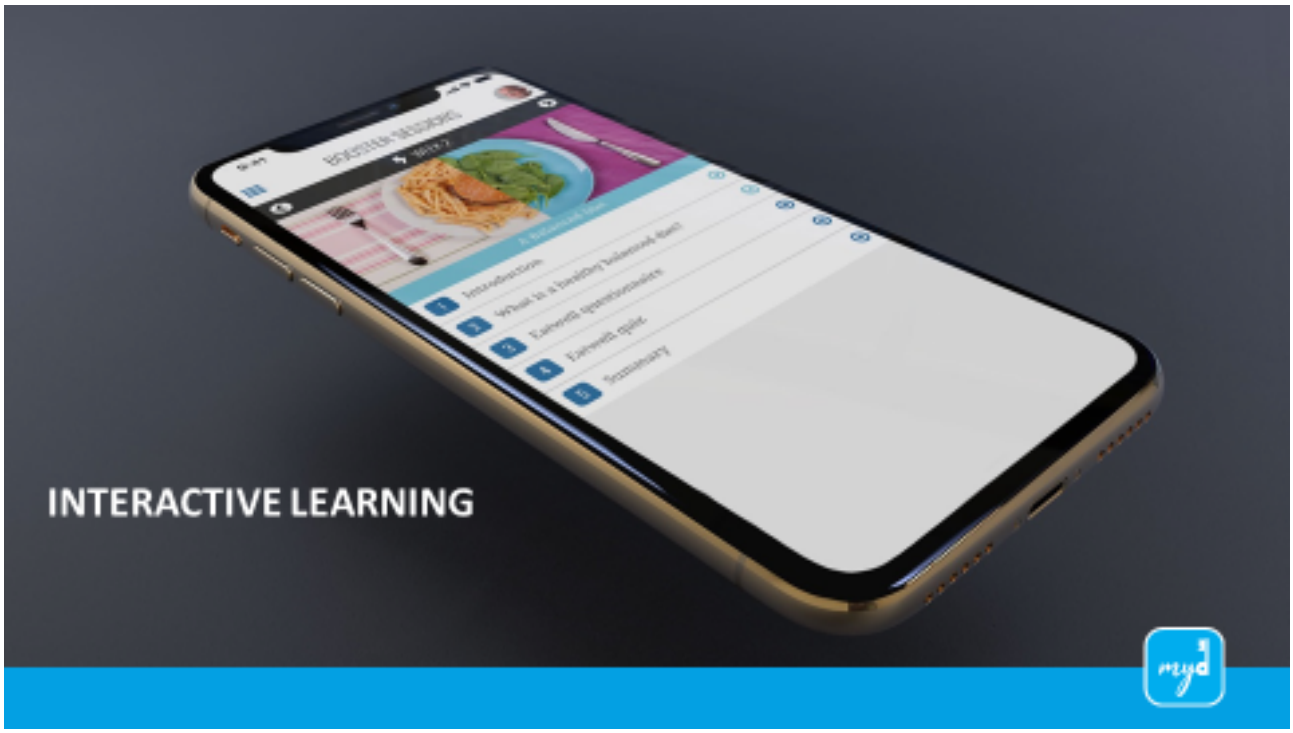


Figure 5. MyDESMOND can track weight, blood pressure, HbA_{1c}, diet, and cholesterol.

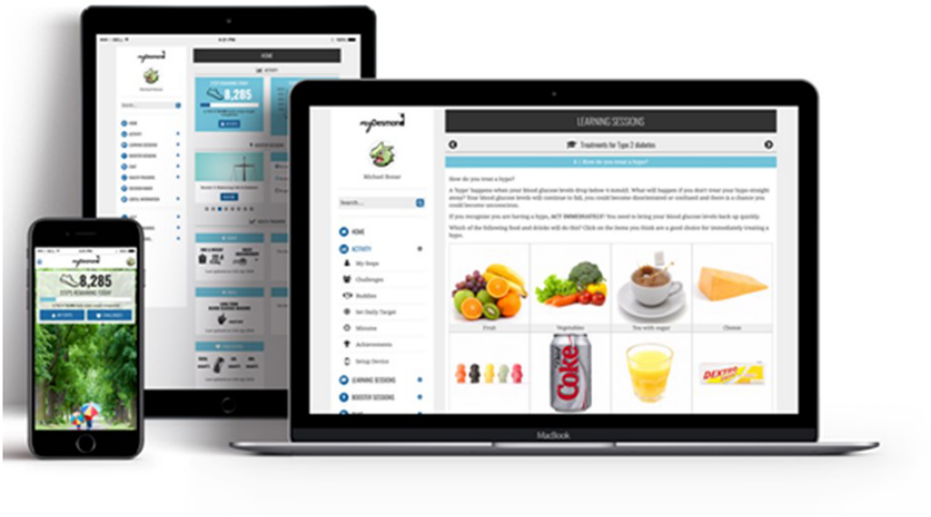
Figure 6. MyDESMOND can track activity levels and steps.

MyDESMOND is accessible on any digital device (tablet, desktop computer, and smartphone). The platform was built using progressive Web applications (PWAs), a type of mobile app delivered through the Web. It operates similar to a native app, but its responsive design allows it to work across all modern browsers and devices (smartphone, tablet, and desktop computer; see Figure 7).

Figure 7. MyDESMOND operates like a native app.



The system was developed using the Zend framework [50] and a MySQL database [51]. The app includes an application programming interface built with Zend that is used to manage data between the AngularJS PWA and the database. All identifiable user data, comments, and *Ask the expert* messages are encrypted and stored securely on the database. All data are stored on servers in the United Kingdom and are fully compliant with the latest industry standards for security and General Data Protection Regulations.

Both functional and nonfunctional testing was carried out throughout each step of the development phase by our research team, project-development team, Web-designers, PPI group, and external subject matter experts (SMEs). External SMEs carried out a number of security tests, including penetration testing (to ensure data remains safe) and a source code review (to ensure it complied with Open Web Application Security Project level 2). The purpose of this security testing was to attempt to identify any potential or actual vulnerability to an attack launched across a computer network that could threaten the confidentiality, availability, and integrity of the information being stored and processed.

Discussion

Summary

In this paper, we described the application of the IM framework for the adaptation and development of a digital self-management program, MyDESMOND. This paper brings a unique perspective to digital development, as it illustrated the process from adapting and translating the evidence and content of a face-to-face education program (DESMOND) to developing a digital version of it.

We described the 4 IM steps that were followed to develop MyDESMOND. In step 1 of the IM process, we established a planning group and a patient and public involvement group and described the context of the intervention and program goals. In step 2, we identified objectives and determinants at early design stages to maintain a focus on the strategies adopted. Step 3 focused on generating the program components underpinned by appropriate psychological theories and models. This led to step 4, which described the adaptation and development of the program content and the iterative process of refining the content and format of MyDESMOND.

Strengths and Limitations

This paper has described in detail the three key perspectives of IM that informed the development of MyDESMOND: the use of evidence, the participation and engagement of stakeholders, and the use of theories and BCTs. Overall, our development work was based on a well-established and comprehensive theoretical framework, which has been used extensively in the development of behavior change programs.

The development process was heavily guided by stakeholder and PPI input, to ensure that we received regular feedback throughout the development phase and to ensure that the program was designed appropriately and was relevant to the target population, culturally and contextually. This approach helped refine and structure the format and content of MyDESMOND to reflect the unmet needs of this population accordingly. It is also important to highlight that although our needs assessment and evidence synthesis were predominantly based on findings from systematic reviews, our evidence was also based on rigorous research studies evaluating face-to-face and digital programs.

Some of the main limitations of IM, which we experienced during this development process, are the complexity and time-consuming aspects of this framework. Following a robust process such as IM, which included conducting systematic

reviews, synthesizing evidence from existing studies, obtaining regular feedback from stakeholders, and identifying key theories and BCTs, required substantial time and resources from our team. Nevertheless, we found IM to be an extremely useful resource, which helped develop the best possible digital self-management program for our people with T2D.

Lessons Learned

DHIs in diabetes self-management and other chronic conditions are increasing. It is important that future research recognizes the complexity of DHIs and continues to adopt a robust development process informed by evidence and theory. During the development of MyDESMOND, we identified key learning points that might be helpful to other researchers developing DHIs for chronic conditions.

Multidisciplinary Team

The expertise of our research, project development, and clinical team members was critical to the successful development of the content, including diabetes education, diabetes clinical expertise, and behavior change. Together with experts in Web-design and digital health, the infrastructure of the program was shaped in such a way that it is now usable on NHS systems and maintains the ethical administration of sensitive information. The collaboration between research teams and Web developers was essential so that the focus of development is not only on the content of the program but also on the user interface and functionality of MyDESMOND.

Interface Design

We followed a target population-centered approach, based on the taxonomy of approaches to developing DHI [52]. This approach suggests that any intervention must be informed by the actions and views of the people who are end users. Ongoing involvement of the target group and end users is fundamental for successful intervention design. We ensured that people living with T2D and stakeholders were regularly involved throughout the design of MyDESMOND. This co-design process meant that end users were part of an iterative refinement process to certify that the language and content were easy to understand, and to ensure the navigation system was simple to use.

Theoretical Framework

The role of theories in DHI is crucial, but yet not all programs are guided by theories [53]. It is integral that key theories and models are made explicit in digital programs to enhance understanding of the intended intervention, guide the evaluation process, and inform the implementation of the program in the *real world* [54]. We ensured that MyDESMOND was underpinned by a strong theoretical framework that embedded behavioral theories (HAPA model, Social Support theory, and COM-B model) and the BCT taxonomy to predict and understand behavior change.

Program Functions

Step 1 of the IM process, which included the mixed methods needs assessment, allowed us to collate findings and insight not only from our own work but also from the current literature. This helped identify a number of key functions that were eventually incorporated in MyDESMOND, including information, personal stories, interactions with other app users, and *buddies*. Literature in chronic self-management has an established series of evidence to confirm that providing a secure platform for communication (ie, in the form of chat forums), allows the end user to share personal experiences, increase their knowledge, and improve self-care [55-57]. In addition, literature around gamification suggests that virtual support from friends and family is associated with increased physical activity and that game design and social incentives (*buddies*) can enhance collaboration, accountability, and peer support [58].

Future Directions

The evaluation and implementation of MyDESMOND is currently ongoing in the United Kingdom and Australia, and results on its effectiveness will follow [59]. A follow-up paper on evaluation and implementation (step 5 and step 6 of the IM framework) is also currently in working progress. Despite the focus of the program aiming at adults with T2D, the IM framework could help adapt the current digital platform to new populations and health conditions and provide a taxonomy of behavior change that would inform the content and functionality of new digital programs.

Conclusion

IM framework was an effective approach to bring together research evidence and theoretical concepts to guide the adaptation and development of MyDESMOND. Our evidence- and theory-based digital program provides ongoing support and guidance to people with T2D. We hope that our paper can be used as an example for other researchers and HCPs who are developing similar digital self-management programs across chronic diseases.

Acknowledgments

The authors would like to thank the Web developers and the PPI group for their invaluable input in the development of MyDESMOND. The authors would also like to thank the multidisciplinary team and the individuals who contributed to the testimonial and expert videos. The authors also acknowledge support from the National Institute for Health Research (NIHR) Collaboration for Leadership in Applied Health Research and Care East Midlands, the NIHR Leicester Biomedical Research Centre, which is a partnership between University Hospitals of Leicester NHS Trust and the University of Leicester. The program was funded by the Leicester Diabetes Centre.

Authors' Contributions

MD and KK led on the idea of MyDESMOND; CB led on the development of MyDESMOND; AN led on the content development; MH led on the underpinning theories and behavior change; SS led on the implementation of MyDESMOND; and BS led on the content adaptation of MyDESMOND. BS, SS, MH, KK, and MD contributed toward the development of the content of MyDESMOND. MH led the development of the manuscript. SS, BS, AN, CB, KK, and MD revised the content and structure of the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

MD is the principal investigator on the DESMOND programme (Diabetes education and self-management for people with newly diagnosed Type 2 diabetes). KK, SS, CB and AN are employed by the University Hospitals of Leicester NHS Trust, which receives not-for-profit income for DESMOND. All authors are actively engaged in research and have previously received grants for DESMOND from NIHR, Medical Research Council, and Diabetes UK to develop and test Diabetes Self-Management Education and Support programmes such as DESMOND. The University Hospitals of Leicester (UHL) NHS Trust (for which KK, SS, CB and AN have a contract) receives licensing fees to support implementation of the DESMOND programme in Clinical Commissioning Groups in the UK, Ireland and Australia.

Abstract

Background: Type 1 diabetes (T1D) requires intensive self-management (SM). An insulin pump is designed to better support personal T1D management, but at the same time, it exacerbates the complexity and requirements of SM. Research shows that people with diabetes are likely to benefit from navigating and connecting to local means of social support and resources through web-based interventions that offer flexible, innovative, and accessible SM. However, questions remain as to which behavior change mechanisms within such resources benefit patients most and how to foster engagement with and endorsement of SM interventions.

Objective: The aim of this study was to evaluate the perspectives and experiences of people with T1D using an insulin pump and specialist health care professionals (HCPs) and determine what behavior change characteristics and strategies are required to inform the optimization of an existing web-based social network (SN) intervention to support SM.

Methods: Focus groups with insulin pump users (n=19) and specialist HCPs (n=20) in 6 National Health Service (NHS) trusts across the south of England examined the barriers and enablers to incorporating and self-managing an insulin pump. An analysis was undertaken using the Behavior Change Wheel and Theoretical Domains Framework, followed by a taxonomy of behavior change techniques (BCTs) to identify the contents of and strategies for the implementation of a complex health intervention.

Results: A total of 4 themes represent the SM perspectives and experiences of stakeholders: (1) a desire for access to tailored and appropriate resources and information—the support and information required for successful SM are situational and contextual, and these vary according to time and life circumstances, and therefore, these need to be tailored and appropriate; (2) specific social support preferences—taking away isolation as well as providing shared learnings and practical tips, but limitations included the fear of judgment from others and self-pity from peers; (3) the environmental context, that is, capacity and knowledge of pump clinic HCPs—HCPs acknowledge the patient's need for holistic support but lack confidence in providing it; and (4) professional

responsibility and associated risks and dangers, whereas HCPs are fearful of the consequences of promoting non-NHS SM support, and they question whether SM support fits into their role. BCTs were identified to address these issues.

Conclusions: The use of behavioral theory and a validated implementation framework provided a comprehensive approach for systematically identifying barriers and enablers of self-managing T1D with an insulin pump. A web-based SN intervention appears to offer additional forms of SM support while complementing NHS services. However, for intervention implementation, HCPs' apprehensions about responsibility when signposting to non-NHS SM support would need to be addressed, and opportunistic features would need to be added, through which pump users could actively engage with other people living with T1D.

Introduction

Background

In the United Kingdom, approximately 400,000 people are currently living with type 1 diabetes (T1D), and both the prevalence of T1D and the health care costs of managing T1D are increasing [1,2]. An improvement in blood glucose levels is viewed as a primary goal of self-management (SM) efforts, as it delays the onset and progression of diabetes-related complications (stroke, heart disease, and neuropathy). However, only 30% of the people with T1D are achieving the recommended glycemic targets [3], and attaining these targets is complex. There is recognition of the need for more tailored interventions to enhance the opportunity to improve blood glucose levels [4]. Theoretically founded web-based interventions in particular are seen to offer the opportunity to support flexible, innovative, and accessible SM to address this growing crisis [5].

The Complexities of Treating and Managing Diabetes

Treatment of T1D comprises demanding SM requirements, including insulin therapy (multiple daily injections [MDI] or insulin pumps); self-monitoring of blood glucose; and comprehensive understanding of nutritional, hormonal, and physical impacts on glycemia [6,7]. MDI is the most common insulin therapy method, but interest in and uptake of insulin pumps have risen over the past 20 years, and predictions suggest that this will continue because of the growing global interest and evidence supporting their use [8]. The Diabetes Attitudes, Wishes, and Needs second study (DAWN2) found that the outcomes are better for people with diabetes when they have greater access to diabetes SM education and positive social support [9]. A recent review suggested that interventions to improve these aspects are necessary and require more flexible and personal SM support for those using these devices [10]. The review highlighted how the process of incorporating an insulin pump often changes treatment expectations and experiences and comprises a distinct and potentially difficult process of learning, exploration, and adaptation. People with T1D initiating a new health technology need to self-manage, but they need appropriate options to do so, and web-based interventions have unlocked potential in this regard.

New Approaches to Self-Management of Type 1 Diabetes

Technology can play a key role in bringing diabetes care to the individual [11]. Interest in web-based SM interventions has increased over the past decade [11,12], as web-based elements (or electronic health) offer opportunities to take pressure off the National Health Service (NHS) while supporting flexible and accessible SM [5]. In addition, interventions that take into account the individual's social context in behavior change are relevant in improving health outcomes [13]. It is well recognized that poor psychological well-being can have a significant impact on glycemic control, which consequently increases the risk of diabetes-related complications and leads to increased health care costs and lost productivity [11,14-18]. Increased valued social involvement is linked to greater SM capacity and potentially lower formal health care costs, especially when this involvement is from a diverse set of network members [19,20]. Network members can be health care professionals (HCPs), family, friends, colleagues, community groups, objects (eg, a bicycle), pets, and spiritual groups. Social networks (SNs) and good social support have been shown to promote diabetes SM and assist in physical and mental well-being [21-27]. An SN approach focuses on available and underused collective support from network members as well as on behavior change at a cognitive level [21-27]; therefore, a web-based social support network intervention could provide a currently underutilized avenue for improved psychological well-being and blood glucose levels.

Blakeman et al's [28] randomized controlled trial of an early version of the Generating Engagement in Networks InvolvEment (GENIE) SN intervention demonstrated improved quality of life, engagement in health care, and health outcomes. GENIE is a web-based SN tool that provides SM support by helping participants map their personal community of support and make the best use of existing contacts and add new ones where needed, as well as signposting (and providing a nudge) to personalized resources in their locality [29]. Despite this demonstration of success, little progress has been made in implementing and spreading psychosocial or social support interventions, in general, into clinical practice to improve SM [6,30-33]. There are challenges in the implementation, sustainability, and accessibility of these interventions in local contexts and to relevant stakeholders (patients and HCPs) [34]. The consideration of the mechanisms of success is often missing

[35]. For example, Mulvaney et al's [36] review of the diabetes mobile intervention design found that there was often little consideration for what SM barriers were addressed or the likely motivation for potential users. They suggested tailoring health intervention content and design (such as GENIE) to stakeholder characteristics to improve patient engagement and outcomes.

The Medical Research Council has identified the importance of utilizing theory and incremental stepped approaches when developing behavior change interventions [37]. In this instance, the Behavior Change Wheel (BCW) and the Theoretical Domains Framework (TDF) were selected because of their focus on the context (the physical setting) in which a behavior occurs, the reflective processes that are involved in behavior change, and the provision of a clear and direct strategy to foster change [38-40]. The evidence base for digital SM interventions in long-term conditions may be able to progress more effectively if we not only focus on measured outcomes but also document and examine the dimensions and processes of interventions most important to stakeholders.

This paper provides a comprehensive needs identification of the specific insulin pump SM needs and perspectives of people with T1D and HCPs working in T1D pump clinics. This will identify recommendations to adapt and optimize the preexisting web-based intervention GENIE, both in terms of the content of the existing intervention and the implementation of the intervention with the aim of improving the SM of people with a long-term condition (such as diabetes) while implementing a new health technology (such as an insulin pump) from the point of technology initiation.

Methods

Study Design

This qualitative study consisted of focus groups, which provided the opportunity to explore the range of views and perspectives of the support required and resources used by current pump users, from pump initiation to current point of use. Focus groups were used as a means to facilitate discussion [41], and focus groups are known to stimulate enhanced disclosure and a supportive environment, which incites elaborated accounts and clarification of experiences [42]. Focus groups with HCPs allowed for the exploration of how a web-based SM support tool could fit into NHS practice. The group environment was considered a strength for discussions of implementation and offered an opportunity for individual HCPs to respond to and build on colleague's comments and brainstorm ideas. Focus groups were undertaken until "saturation" (ie, no significant new insights emerged) [43].

Ethics

Ethical approval for this study was granted by the University of Southampton (Reference 26208) and the National Research Ethics Service (Reference 17/NS/0089).

Setting

The study took place between July 2017 and January 2018 in the south of England. The focus groups took place within 6 NHS trusts, which represented varying levels of deprivation and population density across the region.

Population Sample

Pump user participants were purposefully sampled to ensure a range of pump user ages, length of diagnosis, marital status, sex, and employment status to reflect differing perspectives. Clinics were purposively sampled to represent natural variation across different secondary care settings (urban/semirural, varying deprivation levels, and commissioning procedures). Participants in the focus groups held an advisory capacity for the adaption of an SN SM intervention; therefore, variation was prioritized to improve the likelihood of the resulting intervention being fit for purpose, and it was developed appropriately according to the needs of a variety of pump users and within the context of secondary care.

Eligible patient participants were aged 18 to 65 years, had been diagnosed with T1D for more than 1 year, and had an insulin pump for more than 6 months. Participants who had lived with a pump for less time were excluded to focus on the experiences of overcoming, and reflection of, the initial period of adjustment. Diagnosis of diabetes for less than 1 year was also excluded so as to not obscure the experiences of incorporating a new technology with those of a new diagnosis. Participants were invited to take part through social media, posters in local pump clinics, local diabetes charities, and peer support groups.

All HCPs in insulin pump clinics working directly with patients were eligible to participate in the study and were invited to attend focus groups through direct contact with the clinic.

Theory

The BCW [39] is an overarching framework from a synthesis of behavior change interventions providing a clear all-encompassing model of behavior change (see Figure 1). This synthesis integrates theoretical constructs leading to successful behavior change in a variety of health settings. The central cog of the BCW comprises the Capability, Opportunity, Motivation-Behavior (COM-B) components (see Figure 2). This is based on the premise that to initiate behavior change, there is a need to maximize physical or psychological "Capability" to regulate behavior (ie, develop relevant skills), increase or decrease automatic or reflective "Motivation" to engage in desired/undesired behavior, and target the physical or social "Opportunity" to support behavior change. The COM-B offers an understanding of the barriers and enablers of behavior and underscores the potentially modifiable factors for an intervention to target. The BCW links the COM-B model results with intervention functions (see Figure 3). We also utilized the TDF [38,44] (see Figure 2) to provide specific and comprehensive behavioral domains to target in the intervention. The TDF compounds 84 constructs from multiple psychological theories (motivational, action, and organizational theories) and comprises 14 domains of theoretical constructs [44-46]. The TDF provides a useful framework for understanding the barriers and factors influencing specific behaviors [44,47,48]. It provides a detailed analysis of the potentially modifiable factors linked with the BCW (the COM-B components in the central cog of the wheel) to target in an intervention. For example, if lack of

knowledge prevents SM, this would be coded as "psychological capability" in COM-B; thereafter, more specifically, "Knowledge" using the TDF and the intervention function mapping of the BCW might suggest an intervention function of "education." Using the BCW and the TDF in this way has been recommended elsewhere [38,44,47].

A taxonomy of behavior change techniques (BCTs) [49] then enables the specification of techniques describing the active components of the intervention to tailor and optimize an SN intervention. Focus group interview topic guides for both patients and HCPs were developed in consideration of the components of the COM-B model [39] and TDF [44] to ensure participants had the opportunity to explore each element (eg, physical opportunity to self-manage).

Figure 1. Determining the potential mechanisms of action of an intervention using the Behavior Change Wheel.

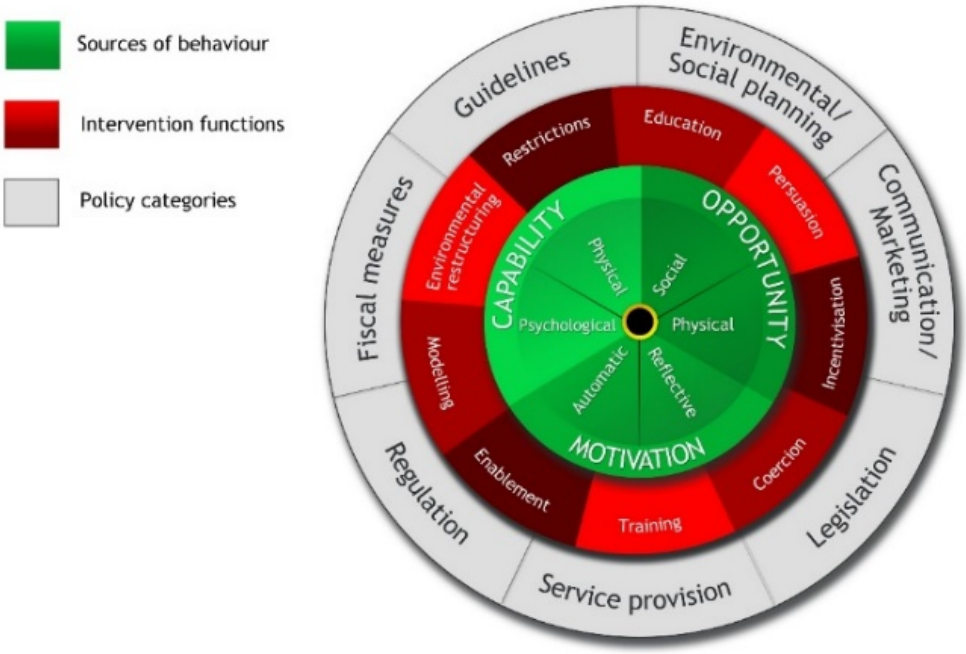

Figure 2. The 14 domains of the Theoretical Domains Framework, structured according to the Capability, Opportunity, Motivation-Behavior model. TDF: Theoretical Domains Framework; Soc: Social influences; Env: Environmental context and resources; Id: Social/professional role and identity; Bel Cap: Beliefs about capabilities; Opt: Optimism; Int: Intentions; Bel Cons: Beliefs about consequences; Reinf: Reinforcement; Em: Emotion; Know: Knowledge; Cog: Cognitive and interpersonal skills; Mem: Memory, attention, and decision processes; Beh Reg: Behavioral regulation; Phy: physical skills.

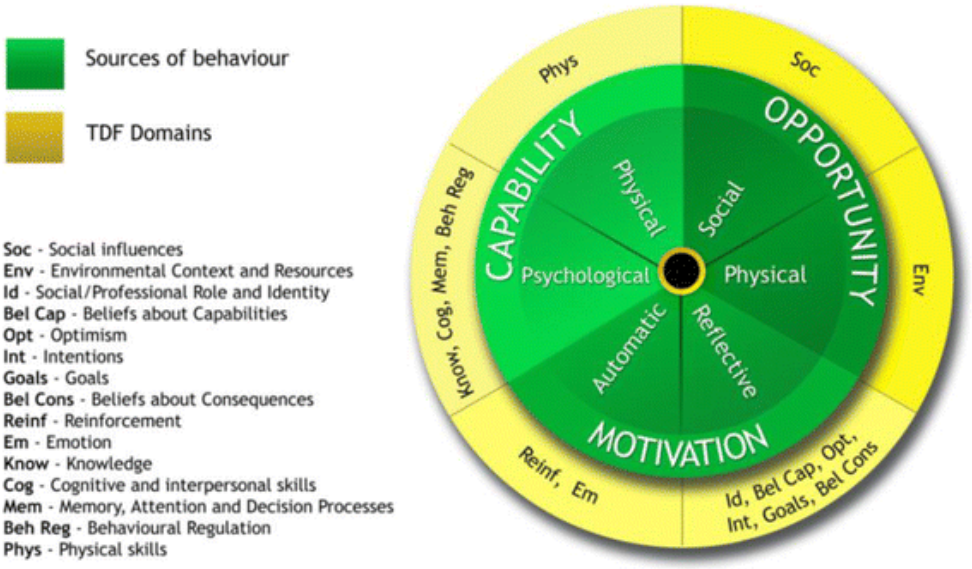

Figure 3. Intervention function mapping matrix.

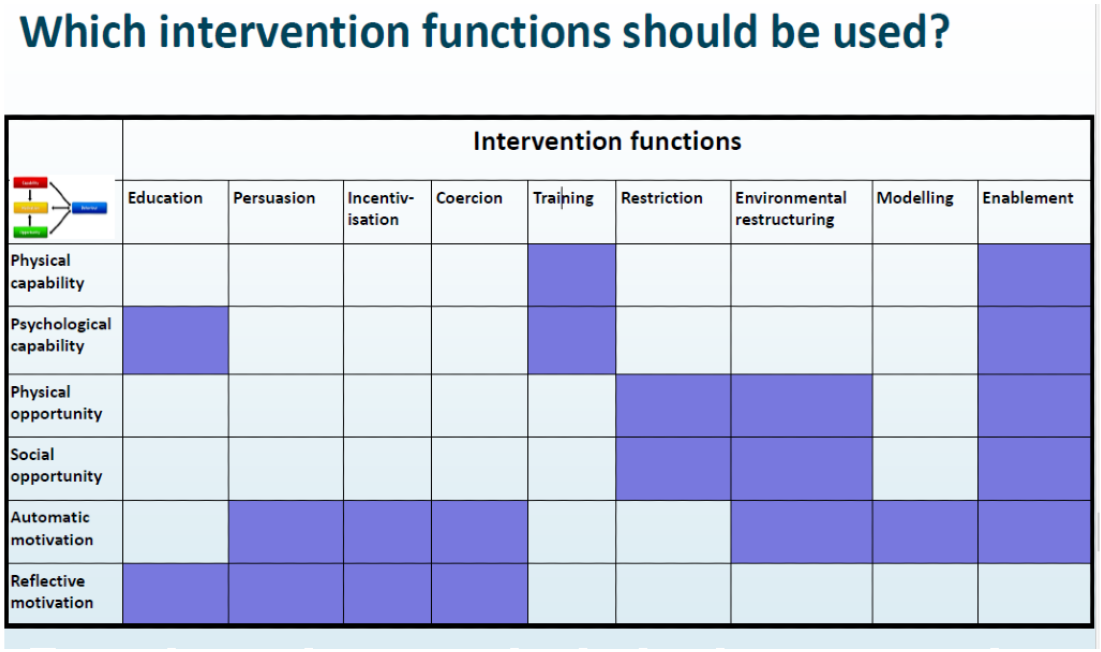
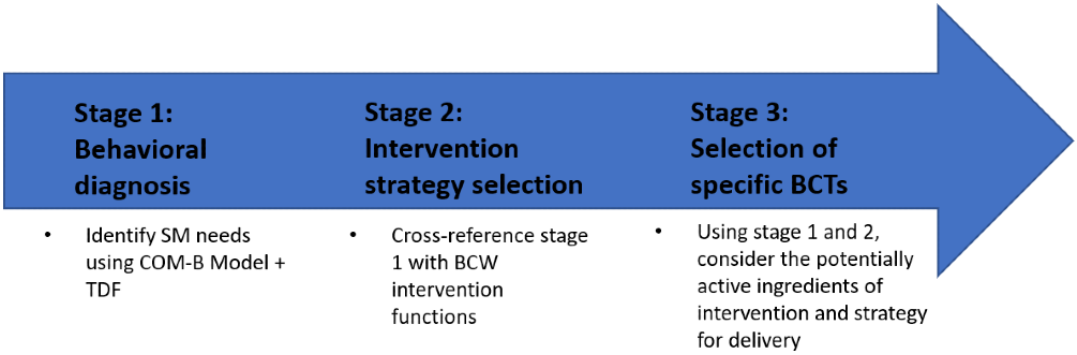


Behavioral Analysis

Behavioral analysis using the BCW and TDF and complimentary taxonomies of BCTs comprised 3 stages to systematically determine the necessary mechanisms of action for supporting SM and developing a suitable intervention (see Figure 4).

Figure 4. Determining the potential mechanisms of action of an intervention using the Behavior Change Wheel. BCTs: behavior change techniques; SM: self-management; COM-B: Capability, Opportunity, Motivation-Behavior; TDF: Theoretical Domains Framework; BCW: Behavior Change Wheel.



Stage 1: Behavioral Diagnosis

The first stage identifies the behaviors identified in the focus groups in context of using the COM-B model as a framework (stage 1a), broken down into physical or psychological capability, reflective or automatic motivation, and social or physical opportunity and determined as barriers and enablers. The COM-B model was then used alongside the TDF to provide a more comprehensive behavioral analysis by allocating more specific behavioral domains to focus on within the intervention (or delivery of the intervention, eg, a focus on addressing knowledge or skill; stage 1b). All focus group interviews were transcribed verbatim. A deductive approach to analysis was used for the initial analysis, using the theoretical framework provided by the COM-B model and the TDF [50]. The data were further analyzed inductively (by CR) to identify the overarching themes within the COM-B and TDF subcomponents to summarize quotes representing similar underlying ideas (see Figure 3) [51].

Stage 2: Intervention Strategy Selection

The second stage cross-references the behavioral diagnosis (stage 1a and 1b) with the BCW "intervention functions" ("education," "persuasion," "incentivization," "coercion," "training," "restriction," "environmental restructuring," "modeling," and "enablement"; see Figure 1).

The intervention mapping matrix (Figure 3) was employed to establish which intervention functions would be most pertinent in targeting the SM support required.

Stage 3: Selection of Specific Behavior Change Techniques

Stage 3 identified the BCTs that would be required in the facilitated web-based SN intervention—GENIE (components of the intervention such as goal setting, restructuring the social environment, and framing/reframing) [49]—according to the findings of stages 1 and 2. This allowed us to determine the necessary mechanisms of action for SM support intervention

(GENIE) and to which the Acceptability, Practicability, Effectiveness/Cost-effectiveness, Affordability, Safety, Equity (APPEASE) criteria were applied. The APPEASE criteria provide guidelines to consider for the content and delivery of the intervention, based on affordability, practicability, effectiveness and cost-effectiveness, acceptability, side-effects/safety, and equity considerations. In addition, a distinction was made regarding both the potentially active ingredients of the intervention (named "Reflective" processes) and the components and delivery of the intervention (context/setting; named "Strategic" processes).

Results

Results of Focus Groups

A total of 11 focus groups and 1 interview were carried out; 6 focus groups were carried out with insulin pump users (n=19; see Table 1), and 5 focus groups and 1 interview were carried out with diabetes specialist HCPs (n=20). We held 1 focus group per clinic (except one where we also undertook an interview). Conversations lasted from 40 to 72 min (average=56.33 min) with patients and 27 to 44 min (average=37.6 min) with HCPs.

Behavioral Analysis Stage 1 Results: Framework Analysis

The findings of the framework analysis providing a matrix of links among the COM-B model and the TDF are presented in Multimedia Appendices 1 and 2.

Stage 1 Results: Thematic Analysis

A total of 4 key themes were identified from the thematic analysis of transcripts; data and quotes are presented to illustrate each theme rather than theoretical subcomponent for conceptual accessibility: (1) desire for access to tailored and appropriate resources and information, (2) specific social support preferences, (3) the environmental context—capacity and

knowledge of pump clinic HCPs, and (4) professional responsibility and associated risks and dangers.

Desire for Access to Tailored and Appropriate Resources and Information

It was acknowledged that at the initiation of pump therapy, the pump can be complicated and difficult to master. Patients reported a desire for holistic support and flexible, convenient access to information and resources as well as access to the latest scientific research, but only at a time suitable for them (as and when). Web-based support was particularly salient because of ease of access. This kind of support, information, and resource was desired in times of heightened difficulty and situational change (eg, pregnancy, health complications, new employment arrangements, and experience of "burnout"). People's time was also limited; therefore, resources had to be used wisely, both in terms of attending clinics and accessing assistance. All the pump user focus groups included substantive discussions about access to tailored and advanced fitness-related information. Performing exercise along with others living with T1D or seeking advice from others about exercise were expected to ease some of the anxieties about experiencing (or preparing for) low (or high) blood glucose levels during exercise:

> *I don't know if any of you have heard of the website Runsweet or Ex-carbs or anything like that?...All of the rest of the Type 1 diabetes management was fine for me, but exercise was my big issue...Anyway, Ex-carbs is a website that helps you to come up with a good way to begin exercising.* [Dan, pump user]

In addition, relevant information was needed, which was specific to T1D and/or insulin pumps, rather than general information for any type of diabetes:

> *It would be nice to have access to a website that gives you information about diets and Type 1 diabetes. I go to [diabetes charity], but it's not up-to-date. It's for Type 2.* [Katherine, pump user]

Access to other holistic pursuits were cited as important, owing to the participants' desire for enjoyable activities for the promotion of positive mental health and/or finding that these activities also required some navigation in terms of the impact on their glycemic control:

> *I've never been really sporty...I also do get a little bit annoyed that every time anyone [in diabetes groups] does talk about any kind of social interactions, other than "meet-ups", it's always revolved around sports. I would love to see, or even run, some more diabetic-friendly groups that are, for example, theatre based. The pressure of being on stage is likely to cause hypos or have a high so you need a group which understands that, you know?* [Stephanie, pump user]

Specific Social Support Preferences

Social support was fundamental to most insulin pump users. Flexible and open contact with the clinic was valued, although this did depend on personal experiences with HCPs, but support from peers was equally valued. Being among other people with T1D, both on the web and offline, provided a wealth of otherwise unseen yet vital information for day-to-day life, such as practical tips and provision of assistance (faulty equipment and where to place the pump on the body). This need varied according to circumstance: T1D-specific support groups, especially if newly diagnosed, were desired, and diabetes-specific fitness groups were valued for the opportunity to determine how best to exercise without glucose levels rising too high or falling too low or how/where to carry the extensive equipment. Meeting peers was associated with taking away some of the isolation of living with a hidden condition:

> *[I would like] social things like groups that you can meet people who are in a similar situation to you...because you can't just walk down the street and ask "are you on a pump?"* [Mark, pump user]

> *But actually I had no idea that diabetes-- I remember thinking this condition was incredibly rare, because I never knew anyone else with it.* [Jenny, pump user]

Access to peer support was cited as important in sharing stories, troubleshooting, sharing illness burden, and speaking to people who understand this "invisible" condition. Some desired web-based support, whereas others desired face-to-face contact, and it was common to desire both. Although face-to-face interactions were important, web-based access allowed people to conveniently "dip in" or "lurk" from a safe distance. In addition, participants expressed wanting to be of assistance themselves, providing support of mutual (reciprocal) benefit. However, apprehensions were raised about accessing people who were in a similar situation. Identities began to be focused on the basis of being pump users:

> *Personally, I find having a one-on-one conversation with someone and asking questions...as wonderful as the nurses are, and the clinic nurses are fantastic, but having someone who uses a pump every single day-It was really positive being in a group setting and having conversations amongst ourselves...You could say "what do you do while you're asleep?" "Do you ever get over having something strapped to you?" Just basic questions.* [Harry, pump user]

> *I guess more links...I had some like issues with it [the pump] sticking on--and no one's ever told me about what kind of tapes that I can use to keep it on or stuff like that, or even nice covers for your pump, just like nice things that are easier to find through that [social-network intervention] rather than having to go through Amazon.* [Lauren, pump user]

There were distinct barriers to speaking to others with T1D, such as a lack of confidence, especially when there was a perceived risk of peer judgment or competition:

> *Because if you are nervous of -- If you don't have the best control or you have been through a bit of a rough patch, or you don't really know-you know-It must be daunting to meet other people so I think you have to be in the right kind of place to want to—* [Jenny, pump user]

The Environmental Context: Capacity and Knowledge of Pump Clinic Health Care Professionals

Many HCPs were positively encouraging of the psychosocial needs of patients and recognized that social and peer support were valuable for patients:

> *Yes, so, it is useful. It's very positive. The good thing I like about it is the opportunity to meet other people, network and do other things outside of diabetes, and for them to feel as normal as possible, but they are normal. You know what I mean?* [Diabetes Specialist Nurse 5, HCP]

HCPs were enthusiastic about supporting their patients to self-manage, especially in terms of patient's need for holistic support and resources, but they lacked confidence in addressing the psychosocial needs of patients themselves:

> *I think it's a question of whether we think we're skilled. I think it's more a part of taking history but it realms into the psychological support, psychology support territory and whether as nurses and dietitians and clinicians, we think we would have the skills to deliver that. I think it's something which if it was something very, do tick box; A, B and C, this is something which we don't do in our routine clinical basis...but a lot of the care is focused towards the more technical and medical and other supportive aspects.* [Consultant 4, HCP]

However, some HCPs expressed a lack of value for psychosocial support or SM support where it was not seen as part of their clinical remit:

> *So, realistically...resources that are available are something that you kind of say--, "oh look I know I've got my little 'talking change' thing" and my "little thing in there for somebody who" and "that's a resource that I can make available", but, I don't say, "Would you like to talk to a psychology person--?" to everybody that comes in…and I suppose that a lot of it is that if it's not broken what's to fix?* [Consultant 6, HCP]

Most clinicians were interested in innovative ways for patients to access other support. They were especially enthusiastic about their patient's needs, with an appreciation of the benefits of engagement with other people with T1D, especially others with a pump, for shared learnings and experiences. Some clinicians considered the potential facilitation of access to social support interventions in structured education sessions, whereas others considered approaches to such support via signposting through their clinic rather than providing access within. However, HCPs were concerned about competing priorities and the consequential lack of time/capacity in the clinic to engage in SM support or offer a facilitated web-based intervention:

> *...I think the CCG fund the pumps but we don't have an awful lot of funding for the team that supports the pump service, so whilst we had small numbers we could incorporate it into our service level agreement but as the pump service has grown we're struggling to offer the support we would like to offer. The feedback we're getting is our pump patients love our service and want more of it but actually we can't really give them anymore because we're not funded to.* [Dietician 4, HCP]

Professional Responsibility and Associated Risks and Dangers

Some HCPs were evidentially concerned about the risk and dangers of signposting or onward referral to a web-based SM support tool, and they held fears that such signposting to a nonclinical environment could have negative consequences in terms of their professional responsibility:

> *Yes, or, accuracy of...Or the potential dangers of peer-to-peer advice regarding immediate clinical matters. I think that's my opinion at the moment. Sharing it in a controlled way with the, you know, organizations that are available to have them. In terms of peer-to-peer advice, what if someone gives them the wrong advice? Maliciously, for instance.* [Consultant 7, HCP]

Some HCPs also felt that this could be "creating problems for problems sake" by offering SM support services within a clinical setting:

> *My first thought about this, is it bringing up things that we actually don't need to bring up, I would think that. I know we do want to make sure that everybody is well supported and has access to that support. At the same time, if somebody's absolutely fine...We don't want to be making them feel that there is something wrong when there isn't...What you don't want to be doing is creating problems. For problems sake.* [Dietician 3, HCP]

However, pump users referred to unhelpful experiences of HCPs blocking access to information, resources, or medical equipment. Patients demonstrated an understanding of risk, but they also demonstrated the need to make decisions themselves:

> *Going back to that idea of online groups, I understand that you would want to have a warning to say, "this is not NHS, this is not moderated. This is just a group that is publicly available and we're not recommending or making any sort of judgment". I'm fine with the warning but ideally would want to still have a link to it...I understand the caution but one of my pet peeves is when healthcare professionals make a choice for me [agreement in room] and say I'm not going to bother to give you the bigger picture and the different options because I think this one is best for you.* [Hugh, pump user]

HCPs considered an SN intervention especially useful for patients who were young adults going through transition or any patient experiencing loneliness. However, patients felt that they themselves would benefit from further support, no matter their circumstances, but according to when they needed it and on their own terms.

Stage 2 Results: Intervention Strategy Selection

Relevant Intervention Functions for Pump Users

Capability

Psychological capabilities were identified in the behavioral diagnosis, and using the intervention mapping matrix, (Figure 3) the following intervention functions were identified: Enablement (a means to increase capability or reduce barriers for SM through encouragement, practical and emotional support, and access to support and opportunities) and Education (increasing knowledge or understanding, including structured education, access to appropriate information, and instructions for performing pump tasks). Physical capability SM barriers and enablers pinpointed to the intervention functions of Training (imparting physical skills in relation to pump technicalities) and Enablement (as described above).

Motivation

Motivational factors of SM that were related to reflective reasoning (conscious intentions, decisions, and plans for SM) led to the intervention functions of Education (as described above). Where there were reflective motivational barriers preventing SM because of support not being seen as relevant or an intervention not being credible, then the intervention functions such as Persuasion through communication to introduce positive feelings to stimulate action or assurance of credibility through research were selected. Where an SN intervention enables SM with self-driven priorities, it increases the likelihood that users will be willing to commit time and that the time they commit will be well spent and valued. Appropriate intervention functions for automatic motivation for SM (emotional responses, desires, and habits) included Persuasion, Environmental restructuring (changing the physical or social context), Modeling (providing an example for people to emulate/aspire to), and Enablement.

Opportunity

Social and physical opportunity to access both emotional and practical support, especially in relation to the specificities and mechanics of a new health technology, was identified in the behavioral diagnosis, and this could be addressed by an SM support web-based intervention. These needs were described in terms of unconventional and flexible ways to self-manage, such as 24/7 access and web-based sources of education, peer support, and information. However, access to any support or resources had to be on the participants' terms, in line with personal needs and life demands, especially in response to concerns over uninvited sharing of SM strategies from others. This was linked with the intervention functions of Enablement and Environmental restructuring (providing access to support, information, and opportunities). Enablement intervention functions were identified to address physical opportunity barriers, such as lack of time to attend or access the clinic or other resources in relation to sourcing support that is physically closer to the individual.

Relevant Intervention Functions for Health Care Professionals

Capability

HCPs said that they believe in prioritizing the wider well-being of their patients and want to support SM, but although they were clear about the medical outcomes they must focus on in their professional role, the remit of SM support they should provide was unclear. HCPs voiced concerns over their lack of confidence, ability, or desire to offer SM support. This is where strategic intervention functions of Training, Enablement, and Education benefit, to instruct HCPs on how to facilitate signposting to an intervention, enable behavioral practice, provide verbal persuasion about capabilities, and educate about the importance of SM support.

Motivation

When it came to Reflective motivational factors, it is evident that buy-in is needed. Coercion (changing conscious evaluations of the SN approach for SM), Education (increasing knowledge or understanding of the importance of social support for their patients), Persuasion (using communication to stimulate action), and Incentivization (creating an expectation of reward—that patients will benefit from the access to SM support) were deemed as appropriate intervention functions, whereas Enablement, Environmental restructuring, and Modeling (comparisons with other clinics) were identified for automatic motivational factors.

Opportunity

Both physical and social opportunity pinpointed to Enablement and Environmental restructuring (provision of physical opportunities and socially acceptable environments to provide SM support) as necessary intervention functions (see Multimedia Appendix 2).

Stage 3 Results: Selection of Specific Behavior Change Techniques

The BCTs identified as likely to benefit the intervention are shown in Multimedia Appendices 1 and 2, with the distinction made between the potentially active ingredients of an intervention ("Reflective" BCTs), which would need to be contained within the SN tool, and the delivery of the intervention ("Strategic" processes), which would need to be integrated into the intervention implementation plan, demonstrated in Table 2. Table 2 also describes where or with whom the intervention reflective and strategic processes are to be implemented. These intervention "ingredients" are categorized as in terms of being; the role of the facilitator, an intervention function, within the study protocol, as an invitation to take part, within a site initiation visit, in training, or in future research. This addresses the varying needs and expectations of insulin pump users and HCPs, and this suggests how a web-based intervention designed to enable SM support can attend to these.

Table 2. Identified behavior change techniques of intervention (reflective or strategy processes).

Identified needs (behavior change techniques)	SN[a] intervention ingredients	Where change is to be implemented/delivered
Reflective processes		
Goal setting (behavior)	Agreement to attend a preferred activity identified in the intervention	Role of facilitator
Problem solving	An SN tool maps the participants social support network and examines whether the participant would like this to change at all. The intervention also inquires about their personal needs and preferences and then offers opportunities in their local community to address these needs. A discussion is then undertaken about how to access these, as well as barriers and facilitators	Intervention function and Role of facilitator
Feedback on behavior	The facilitator follows-up with the participants and discusses and informs them of how their circles have changed and what activities have been taken up	Role of facilitator
Social support (unspecified)	GENIE[b] facilitates discussion around who offers them social support in relation to their condition and allows facilitation/gives information about further personalized social support, that is, peer support groups, and asks who may help them participate in chosen activities	Intervention function and Role of facilitator
Social support (practical)	Discuss the practical support required, received, and desired from the participant and facilitate discussion over whether any changes are required and how to undertake these changes or discuss how existing members of the participant's SN can help them physically access groups	Intervention function and Role of facilitator
Social support (emotional)	Discuss the emotional support required, received, and desired from the participant and facilitate discussion over whether any changes are required and how to undertake these changes or discuss how existing members of the participant's SN can help them feel emotionally able to access groups	Intervention function and Role of facilitator
Instruction on how to perform a behavior	If a person wants to attend a course or education session, then GENIE can facilitate access to this, or if a person wants to learn from peers, then GENIE can point them in the direction of a peer support group	Intervention function
Prompts/cues	GENIE comprises concentric circles, which prompt the participant to prioritize certain SN members over others. GENIE then asks 13 preference questions to prompt the user regarding the user's preferred activities to support SM[c]. Participants are then followed up by a facilitator after 2 weeks	Intervention function
Comparative imagining of future outcomes	Prompt the participant to imagine and compare likely or possible outcomes following attending versus not attending particular groups or activities in which they took part	Role of facilitator
Reduce negative emotions	The facilitator advises to use members of the current social support network to reduce anxiety about attending groups	Role of facilitator
Conserving mental resources	The facilitator advises to utilize the social support network or access peer support groups to share the burden of diabetes or to find someone to troubleshoot with	Role of facilitator
Restructuring the physical environment	Enabling access to groups and information that can help them engage in SM	Intervention function
Restructuring the social environment	Enabling access to and restructuring groups, information, and support that can help them engage in SM	Intervention function
Framing/reframing	The facilitator reassures participant that it is okay to ask for help or support from others regarding SM and that others can offer practical tips	Role of facilitator
Focus on past success	The facilitator enquires about activities they used to do and whether the network members can assist their attendance at activities in which they are interested	Role of facilitator
Strategy processes		
Action planning	Steps would need to be taken to support each clinic to implement the intervention and identify pathways	Protocol and Site initiation visit

Identified needs (behavior change techniques)	SN[a] intervention ingredients	Where change is to be implemented/delivered
Review behavior goals	The clinic would need to be reviewed to identify whether further support is required to implement the intervention	Protocol and Continuous communication from the research team
Behavioral contract	The clinic would need to sign a contract to identify what they expect from the intervention and what support they require	Protocol and Agreements
Commitment	The clinic would need to make SM support a priority and normalized within the clinic setting and be committed to offering SM support	Site initiation visit and Continuous communication from the research team
Instructions on how to perform a behavior	Facilitators of GENIE receive training on how to deliver GENIE. The tool currently comes with a training program	Protocol and Training
Behavioral experiments	Pilot study intervention with clinics to demonstrate intervention benefits in this patient group/context	Future research
Demonstration of the behavior	Facilitators of GENIE receive training on how to deliver GENIE. The tool currently comes with a training program	Protocol and Training
Information about others' approval	Share experiences from other clinics/areas using the tool	Future research and Site initiation visit
Behavioral practice/rehearsal	Facilitators of GENIE receive training on how to deliver GENIE. The tool currently comes with a training program	Protocol and Training
Credible source	Buy-in from each area it is applied to is important for implementation. Participants (and HCPs[d]) are assured that GENIE has risen out of former research and that everything put on GENIE is checked	Invitation to take part; Protocol; Site initiation visit; and Training
Comparative imagining of future outcomes	Prompt the clinic to imagine and compare likely or possible outcomes following implementation of GENIE	Invitation to take part; Protocol; Site initiation visit; and Training
Restructuring the physical environment	Enabling access to SM support and information that can help patients engage in SM	Invitation to take part; Protocol; Site initiation visit; and Training
Restructuring the social environment	Enabling physical access to groups and information and support that can help patients engage in SM	Invitation to take part; Protocol; Site initiation visit; and Training
Framing/reframing	Draw attention to research suggesting that SM support can provide clinical benefits and reduced health utilization. SM support could therefore increase clinic time available rather than decrease clinic time.	Protocol; Site initiation visit; and Training
Incompatible beliefs	Draw attention to how restricting the provision of SM support is in contrast with national guidance (National Health Service England) which promotes SM support.	Invitation to take part; Protocol; Site initiation visit; and Training

[b]GENIE: Generating Engagement in Networks InvolvEment.

[c]SM: self-management.

[d]HCP: health care professional.

Discussion

Principal Findings

This study provides a model for supporting people who are incorporating a health technology that is new to them (such as an insulin pump), through consideration of key stakeholders' needs in developing an intervention that aims to provide SM support. This study puts the most important needs at the forefront (stakeholders' needs), providing evidence of the active components required in a translational web-based intervention. In this instance, the physicality of the pump (the new device) impacts the users' experience of SM, and the technicalities while using an advanced technology exacerbate SM needs. The specificity of the insulin pump changes people's priorities, as it impacts their day-to-day experiences and identity. Pump therapy means that users have a renewed need for HCPs, akin to the diagnosis of diabetes, but this need subsides. The pump requires access to a particular network of people for specific troubleshooting needs.

With this in mind, we identified that a long-term condition such as diabetes requires an array of SM approaches and the ability to master these. Utilizing a new health technology or device requires specific skills, understanding, confidence, motivation, and opportunity. The behavioral analysis used here signposted the necessary components of an intervention to support SM. For example, there lies a potential conflict for the person living with T1D, where "good" management takes considerable effort, and this can create a friction between freedom and clinical targets of blood glucose control or the opportunity for tighter control without sacrificing freedom. The question arises as to whether this extra attention will actually improve the quality and length of life. The current SM support options offered to

people with a long-term condition such as T1D can incite questions over whether life will be less or more enjoyable if they take part in them, for example, using 5 days of annual leave to attend an NHS structured–education class, not knowing whether this education class will actually be useful. There is a trade-off to be made. If we want to intervene, then we must consider these factors. We found that ultimate behavior change in the SM of diabetes and use of a health technology requires support and resources, the availability of which is personal/specific to the individual and varies according to time and life circumstances. Specific social support can take away some of the work of SM, as well as the isolation, providing shared learnings and practical tips, but limitations include fear of judgment from others and exposure to off-putting self-pity from peers.

We found that an intervention would be more successfully implemented if there were opportunities to access SM support and motivation from pump users by access to relevant disease/technology-specific resources and interests. For example, social opportunity needs to be addressed when HCPs do not entrust pump users with the ability to make their own choices or access nonclinical resources or when HCPs lack psychological capability and/or physical opportunity, with HCPs (even if willing) often not having the confidence or capacity in their clinic to amend or enhance their routine or psychosocial care and questioning whether and where SM fits into their role. The recommendations provided here for delivering training to HCPs to facilitate signposting to holistic SM support, enabling behavioral practice, providing verbal persuasion about capabilities, and educating about the importance of SM echo those given in the DAWN2 study [52,53]. Guidelines within the intervention could give assurances to HCPs about what they are signposting to. However, some HCPs' "if-it-isn't-broke-don't-fix-it" attitude highlighted that although NHS England is pushing for more SM support, it is not reaching or convincing to all clinicians on the ground. Fisher et al [54] suggest a clear 3-step framework for diabetes HCPs to support behavior change. The first step requires clinicians to shift their mind-set, moving from a hierarchal model to a more collaborative model, reorienting from information giving to nuances of patient-driven needs.

HCPs can be seen as gatekeepers or blockers of the provision of SM support necessary to manage a complex condition such as diabetes. There was little doubt among HCPs, even those with general concerns, that particular groups of patients would greatly benefit from being signposted to further support that the clinic did not provide. However, the discrepancies show contrasting beliefs between patients and HCPs, where patients themselves considered this access beneficial in a variety of ways, especially in terms of managing fitness activities, general practical advice, or emotional support. Credibility and likelihood of the effectiveness of an intervention are, unsurprisingly, important for both users and those who guard access (clinicians), particularly for clinicians who offer patients the opportunity to participate. Priorities vary depending on perspective, and understanding both perspectives at this stage can inform intervention design and how to determine and ensure credibility.

The SN intervention proposed here (GENIE) is structured around facilitating networks and collective, tailored forms of support through the building of dedicated resources in a database. Whether targeting particular groups or long-term conditions as a whole, a web-based SN tool can accommodate multiple SM needs [55]. However, limitations are evident where access to resources is only as good as the resources that are already in place locally. An SN intervention such as this would also benefit people by addressing the identified need to register collective interests and initiate peer support. For example, having the facility for people to "register their interests" in attending or creating groups in their local area or the ability to connect with others in their local area via the intervention platform.

The behavioral assessment of people with diabetes and HCPs draws parallels with past research. For example, Mulvaney et al's [36] review concluded that SM interventions in diabetes should integrate technology compounded with human contact for clinical support, as well as motivation and support to change behavior for SM (eg, goal setting and problem solving). In addition, the American Diabetes Association [56] considers behavioral elements such as problem solving, decision making, and providing access to electronic health tools as vital to support SM. A focused SN intervention with integral guided facilitation in place is likely to be sensitive to these needs, combined with participant follow-up from the facilitator. A facilitator also has the potential to provide a favorable supportive element to personalized goals in light of findings that the provision of human support was advantageous in other electronic health interventions [57].

People who are empowered and skilled to self-manage their diabetes have improved health outcomes [6,58,59]; therefore, appropriate and tailored access, as opposed to a one-size-fits-all model, is likely to support improved SM. HCPs need to accept patient priorities and means of information and advocacy [60,61] and understanding the importance of experiential evidence. Some noted factors of success in web-based interventions and acceptability have been the focus on psychosocial experiences, feelings of confidence and reduced fear, the availability outside of clinic hours, up-to-date evidence-based guidance, and access to both peer-generated and professional advice [55,58,59,61-65]. However, understanding the barriers preventing HCPs from supporting SM is fundamental too [61,65]. This comprehensive behavioral analysis provides a complete feedback loop for a web-based intervention, which is better equipped to facilitate ongoing SM, considering the needs and strategies for both sets of stakeholders, and determine how, when, and why SM support interventions can be best utilized.

Strengths and Limitations

The use of focus groups in this study allows an in-depth discussion and understanding of the collective experiences of SM and of patients' and HCPs' views, which would be impossible to explore using quantitative methods, and the use of the BCW and TDF-driven interview scripts provides a well-tested, evidence-based guideline and framework. For example, it has been noted that the automatic addition to the reflective process of motivation to enact behavior on the part

of HCPs is often overlooked and is important to enhance the behavioral approaches to implementation [66]. The use of theory-driven intervention development signifies areas of key importance to intervention implementation, both behavioral and reflective needs and contextual factors for implementation, and it is a key process to follow. It sensitizes the research to future intervention needs and considerations across different localities. However, although the proposed BCTs were carefully considered in response to stakeholder needs, these have not been developed in consultation with stakeholders, which future work needs to address to verify BCT feasibility. The recruitment of pump users from various clinics and the involvement of clinics in different settings were important elements of the expected variability among local health systems. Although the participants recruited represented a variety of ages and sex, education attainment, and parenthood, the clinicians represented a good and balanced spectrum of the kinds of professionals working in insulin pump clinics. However, the limitations to the study were that the recruited patients were more likely to be those that were particularly open to discussing personal elements of their diabetes management and willing to sit, in their own time, among a group of peers with the same condition, and therefore would not necessarily represent a number of people living with T1D.

Future Research and Conclusions

Technology is a means to deal with diabetes, and it opens new ways to manage the condition, but it takes time to master; therefore, appropriate support, skills, and information are crucial. People with T1D have a uniqueness of knowledge about their own body, which challenges professional dominance and creates an invisible barrier wherein despite HCPs possessing sound medical knowledge, they are unsure of what and when to share with their patients. HCPs can be gatekeepers for improving SM or for facilitating access to SM support. They are limited by time constraints and fear of professional responsibility. However, a web-based tool that is person based, appropriate, accessible, and adaptive to local needs, along with a strategic (and theoretically informed) approach, can provide a powerful tool for SM support, which can vastly enhance the support already being provided by HCPs [55,63]. This paper has strived to demonstrate the development of such an intervention. The study is particularly timely in that it coincides with The NHS Long Term Plan from NHS England, January 2019, which promises to expand the provision of digital SM support tools [67]. In addition, there has been a recent drive for the integration of psychosocial support into routine diabetes care [18,21], and this study provides an initial engagement with the factors that would impact how psychosocial support is taken up with HCPs and the priorities for patients. The next phase of development is to integrate these findings into strategic intervention implementation criteria for supporting people to engage in SM with a new device and technology such as an insulin pump.

Acknowledgments

The authors wish to specially thank all the participants of the study: people living with diabetes, specialist HCPs and clinics, and the diabetes voluntary organizations and peer support groups that kindly disseminated the advertising for the focus groups. The authors are grateful for the opportunity to undertake this doctoral research through funding from The Health Foundation, and this study was supported by the National Institute for Health Research (NIHR) Collaboration for Leadership in Applied Health Research and Care (Wessex). The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care.

Abstract

Background: Apolipoprotein E (APOE) ε4 allele is a major genetic risk factor for Alzheimer disease and mild cognitive impairment (MCI). Computer-based training programs can improve cognitive performance in elderly populations. However, the effects of computer-based interventions on MCI APOE ε4 carriers have never been studied before.

Objective: The effects of different web-based interventions and the APOE isoform-specific differences in training outcomes are investigated.

Methods: Using a quasi-experimental study design, 202 participants with MCI aged 60 years and older took part in three different intervention programs (physical and cognitive [Long-Lasting Memories, or LLM], cognitive [Active Control, or AC], or physical intervention [Physical Training Control, or PTC]) via an innovative information and communication technologies exergaming platform. Participants in each interventional group were subdivided into APOE ε4 carriers and non–APOE ε4 carriers. All participants underwent an extensive neuropsychological evaluation before and after the training, blood tests, and brain imaging.

Results: All interventions resulted in multiple statistically significant cognitive benefits after the intervention. Verbal learning (California Verbal Learning Test: immediate recall test score—LLM: P=.04; AC: P<.001), working memory (digit span forward and backward test scores—AC: P=.03; PTC: P=.02 and P=.006, respectively), and long-term memory (California Verbal Learning Test: delayed recall test score—LLM: P=.02; AC: P=.002; and PTC: P=.02) were improved. There was no statistically significant difference among the intervention effects. APOE ε4 presence moderates intervention effects as the LLM intervention improved only their task-switching processing speed (Trail Making Test, Part B: P=.03) and the PTC intervention improved only the working memory (digit span backward: P=.03). No significant performance alteration was noted for the APOE ε4+ cognitive AC training group.

Conclusions: None of the applied interventions could be identified as the optimal one; it is suggested, however, that combined cognitive and physical training and physical training via exergaming may be more effective for the high-risk MCI APOE ε4+ subgroup.

Introduction

Mild Cognitive Impairment

Mild cognitive impairment (MCI) can be defined as the condition between normal aging and dementia [1]. By the time older people meet the criteria for MCI, they have already exhibited measurable cognitive decline, and most of them have also accumulated the neuropathologic hallmarks of Alzheimer disease [2]. Heterogeneous etiology can cause MCI. Due to this heterogeneity, its progression is uncertain; patients may remain stable for years, a few could improve, and others could progress to dementia. Based on recent data, MCI presents a progression rate of 38.7% over 12 to 60 months. However, the progression rate across individual studies is quite variable, ranging from 6% to 39% per year [3].

Even though MCI is regarded as a preclinical stage of Alzheimer disease or other types of dementia, studies report neuronal loss of about 36.5% already at that stage as well as synaptic dysfunction [4]. MCI patients, however, seem to retain sufficient neuroplasticity to benefit from nonpharmacological interventions, which may, in turn, delay the progression to dementia [5]. Since there is currently no other treatment of dementia than the palliative one, research efforts are focused on possible ways that could delay disease onset, such as diet, cognitive, and physical training.

Nonpharmaceutical Interventions

The recent growing interest in investigating interventions capable of ameliorating or delaying aging and neurodegenerative effects has resulted in designing various projects for cognitive or/and physical training of the elderly [6]. There is no consensus about the best combination of training. However, findings suggest that interventions targeting multiple domains may be more effective and even provide a long-term benefit for individuals at risk [7].

Cognitive training is based on the idea that the brain function is modifiable even in old age [6]. It is claimed that cognitive training may contribute to the delay or even prevention of cognitive decline in older adults, although this claim remains controversial [8]. Cognitive improvement after cognitive training is generally associated with both compensatory and restorative mechanisms [9-12].

Physical training seems to promote multiple gains in both physical and cognitive states. Hippocampal neurogenesis [13], decrease of β-amyloid deposition [14], oxidative stress reduction [15], brain perfusion increase, and upregulation of neurotrophic factors [16] are a few of the widely studied and reported effects. These effects were presented as improved mood state, improved cognitive function, reduced comorbidities, and decreased risk of falls [17,18].

Combined physical and cognitive training may facilitate the neuroplasticity potential and enhance an individual's capacity to respond to new demands, resulting in mutual enhancement [19].

Recent advances in information and communication technologies (ICTs) and health informatics offer new and elderly-friendly training on web-based platforms [20]. These platforms may also serve people with limited access to an organized day care center, in their own home or an assisted living/nursing home facility, occasionally from a distance with remote surveillance by specialized personnel. Technology-assisted solutions for elderly physical training through gaming, termed exergaming, have been increasingly investigated [21,22]. Validation of the effectiveness of these approaches is currently a top research priority [23].

Apolipoprotein E

The ε4 allele of the apolipoprotein E (APOE) gene (APOE ε4) is the major genetic risk factor for Alzheimer disease. APOE ε4 carriers not only have a higher risk but also an earlier onset of Alzheimer disease by 10 to 20 years [24] in a gene dose-dependent manner. APOE ε4 (ε4/ε4) homozygotes compared with persons homozygous for risk-neutral APOE ε3 (ε3/ε3) may have up to 15 times the increased the risk for developing Alzheimer disease while APOE ε4 heterozygotes (ε4/ε3 or ε4/ε2) only have a 4 times higher risk [25]. Numerous studies have attempted to elucidate the underlying mechanism for APOE ε4 influences on Alzheimer disease onset and progression. It has been difficult to determine whether the APOE ε4 represents a gain of toxic function, a loss of neuroprotective function, or both [26]. It is noteworthy that APOE ε4 is associated not only with Alzheimer disease but also with altered brain metabolism and structure in young cognitively normal adults [27].

The presence of APOE ε4 significantly influences the progression of healthy elderly to MCI and Alzheimer disease, and the progression risk peaks between ages 70 and 75 years [28]. Studies are suggesting that the effect of the ε4 allele on cognitive decline is stronger in this earlier clinical stage in comparison with later and more severe stages [26]. Moreover, the more sedentary the lifestyle of the elderly person is, the higher the impact of APOE ε4 on cerebral amyloid deposition. However, not all APOE ε4 carriers will develop Alzheimer disease, thereby suggesting the interactive effects of APOE genotype with other genetic or environmental factors [25].

Our long-term study aims to investigate the cognitive effects of different computer-based interventions depending on the APOE isoform. Also, the follow-up reevaluations at 6, 12, and 24 months intend to determine which training program, if any, can postpone further cognitive decline and dementia onset. In this paper, which describes the first part of the study, the pre-post training evaluation of the interventional groups is presented. We assessed and compared the efficacy of the different web-based interventions and subsequently assessed whether the APOE genotype may influence the outcome. It is

expected that such a finding may be useful for the improvement of the currently existing and future designs of web-based, technology-assisted therapeutic interventions.

Methods

Study Design

We used a quasi-experimental study design [29] to explore the efficacy of different interventions on participants with MCI. Participants were allocated between 2009 and 2017 into three different interventional groups. Based on previous efficacy evidence of the Long-Lasting Memories (LLM) intervention, an integrated ICT platform combining cognitive exercises with physical activity [19,30], we did not use a passive group in the pre-post assessment due to ethical considerations. Thirteen participants, however, were evaluated in the same pre- and postintervention period without participating in the intervention for personal reasons. All other passive data were retrospectively collected from the database records of the Greek Association of Alzheimer's Disease and Related Disorders, matched for demographic data and initial diagnosis. This passive group was used only for the long-term follow-up.

Randomization of the participants was not feasible mainly for practical issues, time, and financial limitations of the study. Allocation to groups was driven by nonsystematic practical and logistic reasons (national holiday time, number of successfully screened participants at a given time point, etc) but was not influenced by participant choice, motivation, or compliance. The type of intervention applied each time in each place (spiritual center, open care center) was determined before the initiation of the screening procedure, and it was an open call to the elderly whether they were cognitively intact or not. Interventions took place both in the east and west areas of Thessaloniki, minimizing geographic socioeconomic differences of participants. From all the participants who enrolled in the LLM project, we analyzed those with an initial diagnosis of MCI fulfilling the selection criteria.

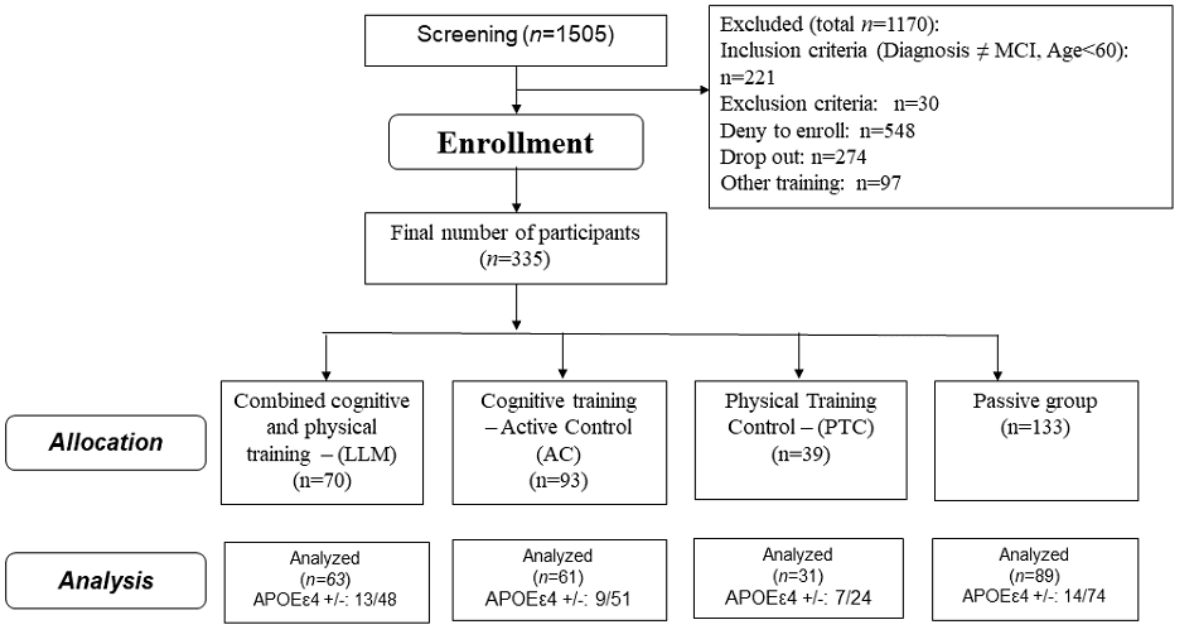
The training lasted about 8 to 12 weeks, and participants completed at least 24 sessions of cognitive training and 16 sessions of physical training. Screening evaluations were conducted 1 to 2 weeks before interventions, while posttest evaluations occurred 1 to 2 weeks after the end of the training. Neuropsychologists performing the pre- and postintervention neuropsychological assessments were generally different from those who administered the program.

Participant performance was assessed and compared among the different interventional groups to investigate a potential superiority of an intervention. Moreover, the performance of each interventional group, in each test between the two time points (pre-post), was assessed separately, investigating specific cognitive domain improvement. A second analysis, based on genotype, was performed subsequently. Each interventional group was subdivided into APOE ε4 carriers and non–APOE ε4 carriers. A comparison of each APOE subgroup among the interventional groups was performed to assess potential differences in efficacy in different genotypes. The performance of each APOE subgroup in the two time points was assessed separately within the interventional group as well.

Participants

A total of 215 MCI participants (intervention 202 [LLM 70; Active Control, or AC 93; Physical Training Control, or PTC 39] and passive 13; single and multiple domains) were recruited during a thorough screening procedure. The rest of the passive group data (n=120) was collected retrospectively as described in Study Design section (Figure 1). Males and females aged 60 years and older, fluent in Greek, were invited to participate. The call was made in church spiritual centers, open care centers for the elderly in east and west areas of Thessaloniki, and day care centers of the Greek Association of Alzheimer's Disease and Related Disorders. Participants provided written informed consent and were compensated for their participation in the study. The study protocol was approved by the bioethics committee of the School of Medicine of the Aristotle University of Thessaloniki (protocol no 38/5.6.2013).

Figure 1. Study flowchart with the number of the participants screened and allocated in each interventional group. MCI: mild cognitive impairment; LLM: Long-Lasting Memories; APOE: apolipoprotein E.



Exclusion criteria included any severe physical illness, current psychiatric or other neurological disorder (stroke, multiple sclerosis, Parkinson's disease, epilepsy, traumatic brain injury, etc), history of drug or alcohol abuse, and use of neuromodifying drugs (other than cholinesterase inhibitor).

All participants reported normal or corrected-to-normal vision and hearing. Before the training, all participants underwent an extensive neuropsychological evaluation performed using standardized Greek versions: Mini-Mental State Examination (MMSE) [31,32], Montreal Cognitive Assessment (MoCA) [33,34], and Trail Making Test, Part B (Trail B) [35,36] to examine task-switching, processing speed, and visuospatial ability; California Verbal Learning Test (CVLT) [37-39] and Rey Auditory Verbal Learning Test (RAVLT) in order to measure the ability of learning, long-term memory, and verbal episodic memory [40,41]; digit span forward and backward [42,43] to assess working memory; Instrumental Activities of Daily Living scale (IADL) [44,45], Functional Rating Scale of Symptoms of Dementia (FRSSD) [46], and Functional and Cognitive Assessment Test (FUCAS) [47] to assess daily functionality; Beck Depression Inventory (BDI) [48,49] and Geriatric Depression Scale (GDS) [50,51] to measure depression; and Beck Anxiety Inventory (BAI) [52,53] for anxiety evaluation. Participants were also subjected to blood tests and brain magnetic resonance imaging. A neurologist evaluated the neuropsychological, medical, and laboratory results. The Cumulative Illness Rating Scale-Geriatric (CIRS) was calculated based on their medical history to assess participant comorbidity [54]. Diagnosis and categorization were based on clinical criteria [1,55] and were made by a dementia expert neurologist (MT). A detailed description of the procedure is described by Bamidis et al [19].

Interventions

The first group attended the combined cognitive and physical training via the LLM project, using an integrated web service system through a universal interface, facilitated by touch screen systems [23,56]. Cognitive training was performed using a Greek-adapted version of the Brain Fitness software (later branded as BrainHQ, Posit Science Corporation) [57], and all physical exercises were implemented in the FitForAll (FFA) platform, an innovative ICT exergaming platform designed by Aristotle University of Thessaloniki [23]. FFA has four levels of difficulty and combines aerobic exercise; exercises of endurance, strength, and balance; and a cooling down process to recover normal cardiac rhythm.

The second group was the AC group, which was exposed to a homemade computerized cognitive training software suite (Video GRade, Lab of Medical Physics at the Aristotle University of Thessaloniki [58]), encompassing short documentary videos with themes from nature, art, history, and culture. At the end of each video, participants digitally performed a multiple-choice questionnaire about the documentary, following the same training dosage as the first group. The third group was the PTC group, which was exposed to computerized physical training using the FFA platform for the same number of sessions as the others. The fourth group was the passive control group, which did not follow any training program.

Apolipoprotein E Genotyping

Blood samples used for genotyping were collected in EDTA-containing receptacles. DNA was extracted from peripheral blood using the QIAamp Blood DNA purification kit (Qiagen Inc). To determine the APOE genotype, part of the APOE gene (228 bp) containing both polymorphic sites (amino

acid positions 112 and 158) was amplified by polymerase chain reaction analysis using the following primers: forward: 5″-GGCACGGCTGTCCAAGGAGCTGCA-3″ and reverse: 5″-GCCCCGGCCTGGTACACTGCCAG-3″, according to the method described by Koutroumani et al [59].

Statistical Analysis

Multiple Imputation

In clinical and epidemiological research, the problem of missing data is almost unavoidable. In our study, missing data were handled using multiple imputation [60] tackling the missing data problem from three aspects: (a) the missing data proportion, (b) the mechanisms of incomplete data, and (c) the missing data patterns as suggested by Dong and Peng [61]. The missing data proportion was calculated, and missing data mechanisms were assessed using the Little multivariate test [62] and performing *t* tests of mean differences between the complete and missing data groups following the guidelines illustrated with a sample dataset from IBM SPSS Missing Values 20 [63]. The missing data pattern was explored using the command Analyze Patterns, which provides descriptive measures of the missing data patterns and could be useful as an exploratory step (see Multimedia Appendix 1 for methodology details). The analysis was performed using SPSS Statistics version 23 (IBM Corporation).

In our model, demographic data along with the scores of different neuropsychological tools and questionnaires were included following the guidelines incorporated in Dong and Peng [61]. Twenty imputations were chosen to remove noise from estimations, such as reducing sampling variability from the imputation procedure [64]. Following the completion of the multiple imputation, the 20 complete datasets were handled by standard statistical procedures after splitting the imputed dataset based on the imputation number. As many procedures in SPSS Statistics do not support pooling, we decided to report mainly pooled mean ranks that are naïve pooled. Even though we lose some of the descriptive power we could get from medians, we still gain valuable information about our groups in terms of our dependent variables. Moreover, we calculated the averaged median across the 20 complete datasets, as suggested by van Ginkel and Kroonenberg [65].

Demographics

During the baseline neuropsychological evaluation, a battery of tests was administered to participants including various neuropsychological tests and questionnaires assessing different cognitive aspects, performance in daily life activities, and the affective state of the participants. The scores collected by the tests and questionnaires used were tested for the normality assumption similarly to demographic data. As scores were not approximately normally distributed in all imputations, nonparametric analysis (Kruskal-Wallis test) was employed to explore differences between groups. When differences among groups reached statistical significance ($P<.05$), the Mann-Whitney *U* test was performed pairwise. Alpha inflation due to multiple comparisons was prevented using a Bonferroni correction.

Performance of participants was further discriminated depending on the presence of the APOE ε4 genotype. More precisely, scores on neuropsychological tests and questionnaires were also compared between APOE ε4 carriers versus non–APOE ε4 carriers. The normality assumption of test scores was explored, performing the described methodology between the two groups. As normality assumption was not met for both groups, a nonparametric analysis was performed (Mann-Whitney *U* test).

Neuropsychological Evaluation

Among-Group Analysis

Neuropsychological evaluations were administrated to the intervention groups (LLM, AC, and PTC) before and after the training completion. Scores of neuropsychological tests and questionnaires were analyzed using the group (LLM, AC, and PTC) as between factor and the time (pre- and posttraining) as within factor. The assumptions of mixed-model analysis of variance were not met in each cell of the design. Thus, an alternative analysis was followed using nonparametric procedures. Differences in scores at the two time points were computed for each test and questionnaire and then tested for normality. The Kruskal-Wallis H test was performed in differences (post-pre) of scores between groups. When differences among groups reached statistical significance ($P<.05$), the Mann-Whitney *U* test was performed pairwise. In this case, *P* values were corrected for multiple comparisons using a Bonferroni correction.

Within-Group Analysis

After grouping our dataset by the imputation number and group, Wilcoxon signed-rank tests were run to investigate possible differences of each group at different time points (pre- and posttraining) in M (M=20) complete datasets. Additionally, we examined a small sample of the passive group (n=13) regarding their performance in several tests such as the MMSE, MoCA, CVLT total, Trail B, IADL, and GDS at the two time points. Depending on normality assumption, different analyses were performed: either paired *t* test or Wilcoxon signed-rank test.

Among-Group Analysis Based on Genotype

Data were split not only by imputation number but also by genotype (carriers, non-ε4 carriers). Differences in scores at the two time points were computed for each test and questionnaire and then tested for normality. As normality assumption was not fulfilled for all imputations and groups, respectively, nonparametric analysis for between-group comparison was determined. Kruskal-Wallis H tests were run for the post-pre differences in scores having as grouping variable the group (LLM, AC, PTC). Results were split depending on the genotype. Significant differences among groups were explored running post hoc tests (pairwise comparisons using Mann Whitney *U* tests) and correcting for multiple comparisons.

Within-Group Analysis Based on Genotype

Data were split by imputation number, genotype (APOE ε4 carriers, non-ε4 carriers), and group. As violations of normality were observed, nonparametric analysis for within-comparison (pre, post) was performed.

Results

Demographics

A total of 335 participants in total were allocated to one of the four different groups (LLM, AC, PTC, passive). The baseline comparisons revealed significant differences between the four groups regarding demographics and cognitive performance. Therefore, a smaller sample of 244 subjects without differences in baseline evaluation scores was used for the pre-post comparison to evaluate the potential effect of the intervention without major confounding factors. Between and within-group comparisons at the first analysis stage were performed in LLM, AC, and PTC participants (see Table 1).

Table 1. Demographic characteristics of participants included in the study.

[a]LLM: Long-Lasting Memories.

[b]AC: Active Control.

[c]PTC: Physical Training Control.

[d]CIRS: Cumulative Illness Rating Scale–Geriatric.

[e]APOE: apolipoprotein E.

Discriminating the participants with regard to the presence of APOE ε4 genotype, we found that there were 43 APOE ε4 carriers, 197 non–APOE ε4 carriers, and in 4 cases there were missing data. Planned analysis of available data showed that the two groups did not differ in age (*U*=4022.00, *P*=.60), education years (*U*=4041.50, *P*=.62), and CIRS scores (*U*=3267.00, *P*=.69). Additionally, the two independent binomial proportions regarding the proportion of gender across groups were statistically significantly different (χ^2_1=3.9, *P*=.048; see Table 1).

In more detail, participants who were APOE ε4 carriers were barely older (age [pooled mean ranks] APOE ε4 carriers: 125.47; non–APOE ε4 carriers: 119.42) and more educated than noncarriers (education years [pooled mean ranks] APOE ε4 carriers: 125.01; non–APOE ε4 carriers: 119.52). Moreover, they had elevated CIRS scores relative to noncarriers (CIRS [pooled mean ranks] APOE ε4 carriers: 123.83; non–APOE ε4 carriers: 119.77).

Neuropsychological Evaluation

Among-Group Analysis

Nonsignificant changes have been observed between groups in most of the neuropsychological tests comparing the scores' differences at the two time points. Significant differences have been found only in the post-pre comparisons on the MMSE and GDS tests (Table 2). Based on the post hoc analysis, the LLM group seems to have a significantly lower performance on

MMSE compared with AC participants and considerably more depressive symptoms relative to the PTC group.

Table 2. Presentation of among-group comparison results along with descriptive measures (pooled mean ranks of post-pre scores) for each group (Long-Lasting Memories, Active Control, and Physical Training Control).

Within-Group Analysis

Long-Lasting Memories Group

LLM participants scored significantly higher in RAVLT1, RAVLT total, CVLT1, CVLT total, and CVLTD tests after their training compared with the baseline (Table 3). The within-group comparison did not reveal any significant differences either in functionality test scores of FUCAS, FRSSD, and IADL tests or emotion test scores of GDS, BAI, and BDI scores when comparing pre- and posttraining scores (Multimedia Appendix 2 Table A).

Active Control Group

The AC group showed significant improvement in their performance on the MMSE, RAVLT total, CVLT1, CVLT total, CVLTD, and digit span backward test when comparing the test scores before and after their training. They also showed significantly higher scores in the FUCAS test after training compared with the baseline evaluation, possibly indicating a decrease in their functionality in daily life activities (Table 3). Significant changes in the performance of the AC group at GDS, BAI, and BDI tests were not found when comparing scores at the two time points (Multimedia Appendix 2 Table B).

Physical Training Control Group

The PTC participants scored significantly higher in MoCA, RAVLT total, CVLT total, CVLTD, digit span forward, and digit span backward tests at the posttraining screening relative to the baseline. A significant decrease was also observed in scores on the GDS test at the posttraining neuropsychological screening relative to those of the baseline evaluation (Table 3; see Multimedia Appendix 3 Figure i for detailed results). Functionality scores of FUCAS, FRSSD, and IADL tests did not change significantly at the two time points (Multimedia Appendix 2 Table C).

The passive group (n=13), which was reassessed after the 12 weeks, did not reveal significant changes in their performance on the tests MMSE (t_{12}=2.082; *P*=.059), MoCA (W=–0.319; *P*=.75), Trail B (t_{11}=–0.656; *P*=.53), IADL (W=–0.577; *P*=.56), and GDS (W=–0.852; *P*=.39) at the two time points. However, a significant increase of 8.385 score units (95% CI 3.39 to 13.38, Cohen *d*=1.015 [38]) was found in CVLT total (t_{12}=3.659; *P*=.003; CVLT baseline: 38.00; CVLT after 12 week: 46.38).

Table 3. Test scores with significant improvement for each interventional group when comparing their scores at the two time points.

Among-Group Analysis Based on Genotype

Non-ε4 Carriers Among Groups

Non-ε4 carriers appear to significantly alter their performance neither in any cognitive tests nor in any test assessing their functionality in activities of daily living at the two time points depending on the group. Significant among-group differences were observed only in GDS tests. Planned post hoc tests revealed that LLM showed a considerably greater change in their geriatric depressive symptoms than the PTC group (Table 4 and Multimedia Appendix 3 Figure i).

Apolipoprotein E ε4 Carriers Among Groups

The ε4 carriers did not change their cognitive status significantly depending on the training given as evaluated by post-pre differences between groups. Furthermore, ε4 carriers seem to

preserve their functionality and mood status as evaluated by respective tests at the two time points (Table 5 and Multimedia Appendix 3 Figure ii).

Table 4. Among-group comparison results in non-ε4 carriers. Descriptive measures (pooled mean ranks of post-pre scores) for each group (Long-Lasting Memories, Active Control, and Physical Training Control) are displayed.

Within-Group Analysis Based on Genotype

Long-Lasting Memories Group

The ε4 carriers in the LLM group significantly improved their performance at Trail B while non-ε4 carriers considerably improved their performance on many cognitive tests such as the MMSE, MoCA, RAVLT1, RAVLT total, CVLT1, CVLT total, and CVLTK, comparing their test scores both before and after the training (Table 6 and Multimedia Appendix 3 Figure iii). Neither ε4 carriers nor non-ε4 carriers considerably altered their functional status in activities of daily living and depressive and anxiety symptomatology (Multimedia Appendix 2 Table D).

Active Control Group

AC ε4 carriers did not significantly change their scores on cognitive tests before and after training (Multimedia Appendix 2 Table E), while non-ε4 carriers showed a considerable improvement on the MMSE, MoCA, digit span backward, RAVLT total, an on different categories of the CVLT test. The ε4 carriers did not considerably change their functionality in activities of daily living as assessed by different tests at the two time points while the non-ε4 carriers significantly altered their scores on the FUCAS test, indicating a decrease in their functionality (Table 6 and Multimedia Appendix 3 Figure iv). Nonsignificant changes were observed in both ε4 carriers and non-ε4 carriers with regard to their depressive and anxiety symptomatology (Multimedia Appendix 2 Table E).

Physical Training Control

The ε4 carriers of PTC scored significantly better on digit span backward tests after training compared with the baseline, while non-ε4 carriers of the same group showed considerable improvement in a couple of tests such as RAVLT total, CVLT total, CVLTK, digit span forward, and digit span backward (Table 6 and Multimedia Appendix 3 Figure v).

PTC ε4 carriers did not show a significant change in their functionality in activities of daily living as assessed by the FUCAS, FRSSD, and IADL tests (Multimedia Appendix 2 Table F). However, non-ε4 carriers showed a marginally significant change only in FUCAS scores when comparing their scores at the two time points. Both ε4 carriers and non-ε4 carriers seemed to significantly improve their geriatric depressive scores after the training compared with the baseline screening (Table 6). Scores on BAI and BDI tests at the two time points did not change significantly in either group (Multimedia Appendix 2 Table F).

Table 6. Significant score changes in the performance of ε4 carriers and non-ε4 carriers of the Long-Lasting Memories, Active Control, and Physical Training Control groups.

Discussion

Principal Findings

To our knowledge, this is the first quasi-experimental study to investigate in elders with MCI the impact of a combination of computerized physical and cognitive training not only in terms of cognitive decline in general but also based on the different APOE isoforms. Our results indicate that MCI APOE ε4 carriers respond differently and less prominently in web-based interventions.

Since there are no previous data about nonpharmacological computerized interventional outcomes on APOE ε4 carriers, we cannot possibly make direct comparisons with past research, but we do underline the importance of these new findings and the likely key role of future investigations with longitudinal randomized trials.

There are, however, recent data on computerized training interventions in MCI subjects that present results in line with our findings, suggesting improvement of learning ability (RAVLT total, CVLT total) and short-term memory (RAVLT1, CVLT1, digit span), verbal memory (RAVLT, CVLT), task-switching, processing speed and visuospatial memory (Trail B), episodic memory (RAVLTD and CVLTD delayed recall) and attention (MMSE, MoCA), and a positive effect on depressive symptoms (GDS) as well (for a review see Klimova et al [66]). Although these outcomes appear promising, researchers underline the limitations of these studies because of their duration, small sample sizes, and methodological differences. A recent meta-analysis on classic cognitive interventions targeting multiple domains in MCI subjects presented cognitive benefits in working memory, attention, and verbal memory in a larger study series [5]. The above outcomes, which are consistent with ours, enhance the strength of the thesis that training in the MCI population is a promising tool against neurodegeneration.

The combination of physical and cognitive training has also been studied previously in this high-risk population, underlining not only the cognitive benefits [67,68] but also the improvement of biological parameters such as brain-derived neurotrophic factor levels, grey matter volume [69], and increased para-hippocampal cerebral blood flow [67].

Recent data on exergaming, using the latest technology of the virtual reality with low and high cognitive engagement, also demonstrated improvement in verbal memory, a cognitive parameter that showed improvement in all of our interventional groups [69].

In our study, the analysis among the groups did not reveal statistically significant differences in the effect of the three different interventions other than the MMSE (LLM<AC) and the GDS (LLM>PTC), so we could not possibly identify the best intervention. Assessment of activities of daily living revealed no differences, while changes in the affective domain underlined the positive effect of physical exercise on stress and depression.

Within each interventional group, statistically significant differences were more obvious. The LLM group showed significant improvement in episodic memory, learning ability, and long-term memory, while no significant changes existed in functionality and the affective domain. The AC group showed a considerable improvement in global cognition status as assessed by MMSE, episodic memory, learning ability, long-term memory, and working memory. Finally, the PTC group showed significant improvement in global cognitive status as assessed by MoCA and in working memory, learning ability, and long-term memory. The PTC group also had statistically diminished depressive symptoms, which is also repeatedly shown in literature to be a beneficial effect of physical exercise in mood disorders [70].

The small sample of the passive group reassessed at 12 weeks presented no change in most of the parameters under investigation. They only showed an improvement in learning ability. This result may be explained by the short interval between the pre-post evaluation and familiarization with the evaluation process.

When participants were divided by genotype into two subgroups of APOE ε4 carriers and non-ε4 carriers, comparisons among the groups showed statistically significant differences only for the non-ε4 carriers' depressive symptoms assessed by GDS between the LLM and PTC groups, with a less depressive burden for the PTC group. The ε4 carriers did not differentiate for any parameter between the groups.

Within-group analysis, however, revealed statistically significant improvements in the LLM group in working memory and visuospatial ability as measured by the Trail B test for the ε4 carriers, while the non-ε4 carriers showed considerable improvements in multiple cognitive domains. No changes have been noticed for either of the subgroups regarding functionality and emotional burden (Multimedia Appendix 3 Figure iii).

The AC ε4 carrier group showed no significant improvement in cognitive, functional, or emotional status. The non-ε4 carrier subgroup revealed multiple domain improvement once again but also a mild worsening of their functionality assessed by FUCAS. This functional decline drives us to the assumption that physical activity helps the maintenance of complex functional tasks in comparison with cognitive training alone (Multimedia Appendix 3 Figure iv).

Finally, the PTC ε4 carrier group showed the only improvement in working memory while non-ε4 carriers had significant improvement in multiple domains (RAVLT1, CVLT total, CVLTD, digit span). The non-ε4 carriers in this group also had

slightly worse functionality assessed by the FUCAS. Both subgroups, however, showed a statistical improvement in depressive symptoms (Multimedia Appendix 3 Figure v).

APOE isoforms have been used as potential predictor markers for examining cognitive intervention effects in the current literature. Peter et al [71] suggest that the presence of APOE ε4 was not a significant predictor of any change in the cognitive variables, while another study underlines the potential beneficial effect of its absence [72]. The above findings are in line with ours, as we found stability in cognitive performance in the case of ε4 carriers and a significant improvement in the case of non-ε4 carriers.

The presence of APOE ε4 has also been related to biological and cognitive outcomes in physical exercise. Different brain metabolic responses to exercise related to the APOE isoforms have been reported [73], although their significance remains to be elucidated. Hence, Makino et al [74] suggest potential memory function benefits of physical exercise for ε4 carriers among older adults, also consistent with our findings, showing improvement in working memory in both groups that used physical training.

In our study, the APOE ε4 presence was related to a resistance of cognitive improvement, while the non-ε4 carriers showed multiple cognitive benefits. Although nonresponders, the ε4 carriers seemed to improve at least one of the test scores under investigation with combined cognitive and physical training or physical training via exergaming but not with cognitive training only. That may be explained by the beneficial effects of physical exercise activity on systematic and neurological biological parameters [67,69,73-76]. The question that stems from the above findings is whether this is an interventional failure or the success of the disease progression postponement. The answer to the above question will be presented in a future paper on this study.

Limitations

Our study has certain limitations. Randomization and blinding of test administrators and participants was not feasible due to practical issues. However, the lack of randomization is unlikely to bias effects as demographic characteristics and baseline performance are comparable. In our sample, 17.6% (43/244) were APOE ε4 carriers (at least one ε4 allele), which is lower than the expected Greek population frequency of 25.5% [77]. That is due to the small sample size (n=244) regarding genetic studies, although other cognitive intervention studies recruited even fewer participants (n<100 [72,73]).

The short time to reevaluation may influence the described effect on neuropsychological test scores. However, the short-term interval of 12 weeks for intervention is commonly used in the design of similar studies. The missing values issue is a common problem in clinical research. It was handled in the most effective and statistically approved way as described in the literature, considering all the parameters and running all the necessary tests to avoid statistical analyses bias. Regarding future review and meta-analysis, we should declare that 35 participants in the LLM group were part of the interventional group of a previous study [19]. Future research in the field should consider these difficulties and may overcome them by using larger samples and long-term follow-up.

Conclusions

Exergaming is an effective intervention method for patients with MCI. None of the applied computer-based interventions could be identified as the best. Nevertheless, it seems that combined cognitive and physical training and physical training via exergaming tend to be more effective for the high-risk MCI APOE ε4+ subgroup.

Acknowledgments

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. However, parts of this work were supported by the LLM Care [58] self-funded initiative that emerged as the not-for-profit business exploitation of the Long-Lasting Memories (LLM Project) [78] originally funded by the ICT-CIP-PSP (Information and Communication Technologies–Competitiveness and Innovation Framework Programme–Policy Support Programme) Program of the European Commission.

Conflicts of Interest

PDB discloses potential (non-financial and beyond the context of the submitted work) conflicts of interest with PositScience: there is a co-marketing agreement between the company and the Aristotle University of Thessaloniki to exploit Brain HQ within the LLM Care self-funded initiative that emerged as the non-for-profit business exploitation of the Long-Lasting Memories (LLM Project) (www.longlastingmemories.eu) originally funded by the ICT-CIP-PSP Program of the European Commission. Brain HQ now forms part of LLM Care, a technology transfer/self-funded initiative that emerged as the non-for-profit business exploitation of LLM. FitForAll (FFA) has been developed in the Aristotle University of Thessaloniki during the Long-Lasting Memories (LLM Project) (www.longlastingmemories.eu) originally funded by the ICT-CIP-PSP Program of the European Commission. It now forms part of LLM Care, a technology transfer/self-funded initiative that emerged as the non-for-profit business exploitation of LLM.

Abstract

Background: Brief messages are a promising way to improve adherence to medication for people with type 2 diabetes. However, it is often unclear how messages have been developed and their precise content, making it difficult to ascertain why certain messages are successful and some are not.

Objective: The goal of the research was to develop messages that have proven fidelity to specified evidence-derived behavior change techniques (BCTs) and are acceptable to people with type 2 diabetes.

Methods: Four studies were conducted: (1) a workshop (n=21) where behavioral change researchers and health care professionals developed messages based on specific BCTs or beliefs or concerns related to taking medication, (2) a focus group study with people with type 2 diabetes (n=23) to assess acceptability of the approach, (3) a survey to ascertain the acceptability of a subset of messages to people with type 2 diabetes (n=61) and, (4) a survey with behavior change researchers to assess the fidelity of a subset of messages to their intended BCT (n=18).

Results: In study 1, 371 messages based on 38 BCTs and beliefs/concerns were developed. Workshop participants rated BCTs to be relevant to medication adherence (mean 7.12/10 [SD 1.55]) and messages to have good fidelity (mean 7.42/10 [SD 1.19]). In study 2, the approach of providing medication adherence support through text messages was found to be acceptable. In study 3, mean acceptability of all BCTs was found to be above the midpoint (mean 3.49/5 [SD 0.26]). In study 4, mean fidelity for all BCTs was found to be above the midpoint (mean 7.61/10 [SD 1.38]).

Conclusions: A library of brief messages acceptable to people with type 2 diabetes and representative of specific evidence-derived BCTs was developed. This approach allowed brief messages to be developed with known content that can be used to test theory.

KEYWORDS

behavior change; behavior change techniques; type 2 diabetes, brief messages; mHealth; medication adherence

Introduction

Type 2 diabetes leads to high levels of glucose in the blood; if left uncontrolled, the condition can lead to a wide range of micro- and macrovascular complications including problems with the heart, feet, and eyesight [1]. There are effective tablet medications available that can help control blood glucose and reduce the risk of complications in people with type 2 diabetes. However, adherence to and persistence with tablet medication is poor for at least half the population of people with type 2 diabetes prescribed these medications [2]. If less than 80% of the prescribed medication is taken, only half the expected reduction in blood glucose control is seen, increasing the risk of complications for this population [3].

A recent Cochrane review concluded that medication adherence interventions have led to only modest increases in adherence, and studies with the lowest risk of bias had the lowest efficacy [4]. The authors proposed that novel approaches to this problem are needed [4]. One approach that has shown promise to improve medication adherence in people with type 2 diabetes is the delivery of brief messages. In a review of 15 interventions, there was some evidence of effectiveness, but there were weaknesses in the study designs [5]. Further, the review authors commented that the interventions were not well described, and the majority did not report being based on any explicit theoretical framework [5]. It has been noted that for brief message interventions "the content is the central driver of the behavior change" [6]; it is therefore essential that the content is well described so that whether a change in behavior does or does not occur it can be explained, and the intervention can be improved as needed. However, in many published reports, in addition to the content of messages being unclear, the development process can also be unclear with little reported about exactly how information from formative work is incorporated into the final intervention. This lack of transparency has led to the development process being described as a black box [7].

There are multiple ways to develop interventions to change behavior, and different approaches may be suitable for different contexts [8]. These approaches vary in the emphasis they place on the extent to which interventions should be based on theory and evidence of effectiveness and whether they should be developed and/or extensively tested with the intended target population. More specifically in the electronic health area, there are a growing number of approaches that focus on developing technology-based interventions (eg, the person-centered approach [9], behavioral intervention technology model [10], intervention mapping combined with the behavioral intervention technology model [11], and the mobile health development and evaluation framework [12]). However, these models provide a broad overview for development of many different types of technology-based interventions, which are often complex with multiple components. For this reason, the actual process of writing content such as brief messages is not often explained in detail. In cases where the actual process of writing the messages is reported or is the focus of the suggested procedure [13], it seems that it is conducted by a small number of people in the intervention team. Having a small team of people involved in the intervention drafting the messages may lead to a similarity in the approaches used compared with what has gone before rather than exploring novel approaches to the problem of medication adherence.

This research developed and refined message content using specific behavior change techniques (BCTs) to develop messages or as a means to code messages for content. BCTs are described as the active ingredients of an intervention [14]. They are the irreducible components of the intervention such as goal-setting or self-monitoring of behavior. Thus far, 93 such BCTs have been identified and defined in a taxonomy [15]. In cases where the BCT content of brief messages related to diabetes self-management have been defined in published reports, thus far relatively few of the 93 BCTs identified in the v1 taxonomy [15] have been used. In two reviews in the area, one identified 8 BCTs across 7 studies [16] and the other 16 BCTs across 6 studies [17].

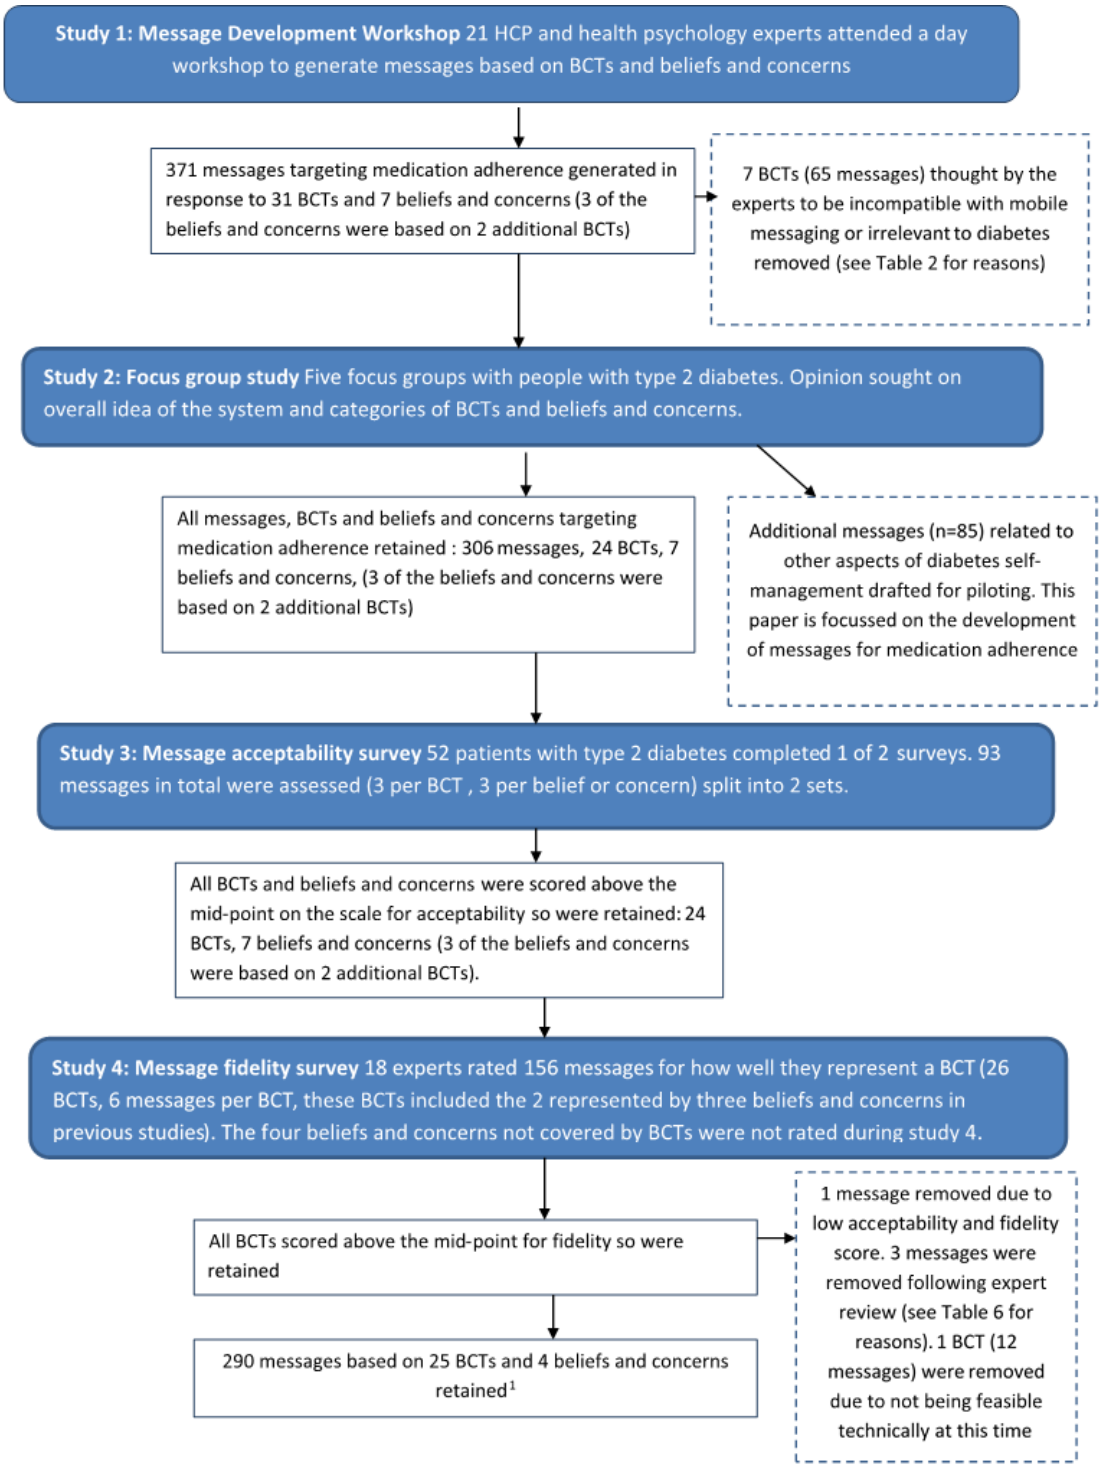
The studies described in this paper form part of a larger body of work to develop a brief message service that could be used by people with type 2 diabetes within the UK National Health Service (NHS). Given the lack of effectiveness of existing interventions to promote medication adherence [4], it was important to identify as many potentially effective BCTs that could be delivered by brief message as possible. Prior to the work reported here, a rapid systematic review of systematic reviews was conducted [18]. This review highlighted a wide range of BCTs that existing quantitative systematic reviews had previously identified as being associated with changes in medication adherence across a range of chronic physical health conditions. In addition, qualitative reviews were examined to identify specific beliefs and concerns associated with taking medication for people with type 2 diabetes to ensure that novel insights inductively obtained from people with type 2 diabetes regarding their medication adherence were included [18]. Of the 46 BCTs identified, 13 were either not considered suitable for delivery via brief messages or, in delivering through brief messages, the content could be covered by another BCT (for excluded BCTs and reasons see Multimedia Appendix 1, Table A), 2 of the BCTs were considered more appropriately represented by 3 of the beliefs and concerns (see Table A for details).

This paper presents a transparent process of brief message development that aimed to ensure the message content had high fidelity to the intended BCTs. Further, the inclusion of relevant stakeholders at all stages of the research was deemed essential to ensure that the messages were acceptable to the target population. People with type 2 diabetes were included both as participants in the research studies but also in Patient and Public Involvement (PPI) panels. Members of the PPI panel participated in key meetings and research decisions, as well as reviewing protocols and participant-facing materials prior to ethical approval.

This paper reports the process of message development through 4 studies and decisions taken following each study. The purpose of this research was to develop a library of messages that are acceptable and represent explicit BCTs, identify any BCTs that were not suitable for delivery through brief messages, and identify any messages or BCTs that should be removed prior

to further development. The studies reported on are (1) a workshop to develop a library of messages based on specified BCTs and beliefs and concerns, (2) a focus group study to look at acceptability of the concept, (3) an online survey to assess the acceptability of the BCTs and messages developed during study 1 to people with type 2 diabetes, and (4) an online survey to assess the acceptable messages from study 3 for fidelity to the intended BCTs (see Figure 1 for an overview of message development through the four studies).

Figure 1. Development of messages targeting medication adherence through the four studies. BCT: behavior change technique; [1]Three of the beliefs and concerns are represented by 2 additional BCTs here.



Methods

Ethical Approval

Ethical approval for the studies 1 and 4 was granted by the University of Oxford Central University Research Ethics Committee Medical Sciences Interdivisional Research Ethics Committee (ref: R50752/RE001). Ethical approval for studies 2 and 3 was granted by the NHS North West–Greater Manchester West Research Ethics Committee (ref: 17/NW/0224).

Study 1: Message Development Workshop

Aim

The aim of the workshop was to develop a library of messages based on specified BCTs and beliefs and concerns.

Recruitment

Participants were expert researchers in the fields of behavior change or medication adherence or health care professionals (HCPs) involved in diabetes care. Potential participants were identified from the research team's knowledge of those active in these fields in the United Kingdom or Europe. A total of 31 invitations were sent by email, with a single reminder email.

Procedure

Participants were invited to attend a 1-day workshop in Manchester, England. An information sheet was sent to participants ahead of time and informed consent was taken on the day of the workshop. The day was split into 4 sessions. For the first 3 sessions, behavior change researchers were split into 4 groups of 4 or 5 people and for each session were provided with the descriptions of 2 or 3 BCTs per group. HCPs were asked to generate messages to address specific beliefs and concerns. The 31 BCTs and 7 beliefs and concerns presented in study 1 were those identified by rapid review [18] and considered to be plausible for delivery via brief messages. Three of the included beliefs and concerns presented to HCPs represented an additional 2 BCTs. "Difficulties remembering and understanding the medication regimen" represented the BCT 4.1: Instruction on how to perform a behavior and "perceived risks of taking medication" and "beliefs about medication necessity" represented BCT 5.1: Information about health consequences (Table 1). Each group had a moderator who did not actively participate in writing messages but asked participants to develop brief messages based on each BCT that would target tablet medication adherence for people with diabetes. The moderator then entered any messages that were agreed by the group onto a spreadsheet. The messages generated by behavior change researchers were reviewed by a different group of behavior change researchers and rated according to how relevant the BCT was thought to be to improving diabetes tablet medication adherence (on a scale of 1 to 10), how far the aim of getting 8 to 10 messages that reflect the BCT well had been achieved (scale of 1 to 10), and the fidelity of each message generated to the intended BCT (scale of 1 to 10). The group of HCPs remained as a single group throughout and rated their own messages for how well they thought the messages addressed the beliefs and concerns raised in the rapid review, how relevant the belief/concern was thought to be, and how well the aim of getting 8 to 10 messages that reflect the belief/concern well was reached (scale of 1 to 10).

In the fourth session, the ratings for how well each BCT or belief and concern met the aim of generating 8 to 10 good quality messages were ranked, and those that scored lowest were discussed with all participants as a single group. Suitability of the BCTs for delivery through text message was discussed. Participants were asked to complete a survey describing their level of expertise and a brief workshop evaluation form. Participants were given an honorarium for their time, and accommodation, travel, and other subsistence costs were reimbursed.

Following the workshop, only those BCTs that were deemed compatible with delivery by text message and suitable for medication adherence for people with type 2 diabetes with an appropriate score for fidelity to the BCT were retained and used in study 2.

Study 2: Focus Group Study

Aim

The aim of the research was to ascertain the acceptability of the concept and types of messages to people with type 2 diabetes.

Recruitment

Five general practices sent letters introducing the study to eligible patients. Participants were eligible if they were aged over 18 years, taking tablet medication for type 2 diabetes, and had access to a mobile phone. Those who had been hospitalized in the last 3 months for hypo- or hyperglycemia, were pregnant or within 3 months postpartum, or had been diagnosed with a terminal illness were excluded.

Procedure

Participants were invited to take part in a focus group at the university or in a community location. Researchers facilitated the focus groups and presented the 31 BCTs that remained following study 1. As it would not be possible to discuss all 31 BCTs, these were grouped as potential strategies for behavior change grouped according to v1 taxonomy categories [15] with sample messages. As an example, BCT 1.2: Problem solving and BCT 1.4: Action planning are both grouped under goals and planning in the BCT v1 taxonomy [15]. Participants were given a description of the group "Messages that support and encourage you to plan to take your medication as intended, along with messages that encourage you to solve problems to help you achieve those goals" and some sample messages from those generated during study 1 were given (eg, "Plan when, where, and how you are going to take your medication" [BCT 1.4]).

The task of the groups was to discuss wording and acceptability of the idea of sending brief messages to encourage and support medication adherence overall rather than determine acceptability of individual messages or BCTs (the examples were given to provide a concrete grounding for discussion). Focus groups were recorded, transcribed, and analyzed thematically.

Following the focus group study, suggestions made by participants were reviewed and acted on as appropriate.

Study 3: Message Acceptability Survey

Aim

The goal of the research was to assess the acceptability of the BCTs and messages developed during studies 1 and 2 to people with type 2 diabetes.

Recruitment

Participants were aged over 18 years with type 2 diabetes and were taking tablet medication to control their diabetes (with or without concomitant insulin). Potential participants were invited from a nationwide database of individuals facilitated by the Greater Manchester Clinical Research Network. They had been diagnosed with diabetes, were interested in taking part in research, and had indicated on signing up to the database that they would be interested in completing online questionnaires (n=861). Advertisements were also posted on the Diabetes UK online support forum, and information about the study was distributed at a diabetes support group.

Procedure

The database facilitators sent initial email invitations containing a link to the participant information sheet, an online consent form, and 1 of 4 versions of the survey (see survey development and content section). Participants were screened for eligibility and required to agree with all consent statements before they could proceed to the survey. The advertisement also contained contact details if potential participants preferred to receive a paper version of the survey. In this case, the information sheet, consent forms, and 1 of the 4 surveys were printed and mailed to the individual with two postage paid return envelopes to keep consent forms and research data separate. No incentive was offered for completion.

Survey Development and Content

Two sets of messages from those developed in studies 1 and 2 were assessed for acceptability; 47 in survey 1, and 46 in survey 2. Messages were not grouped or ordered by BCT or belief/concern; both surveys were presented with messages in one order, and the reversed order, resulting in 4 versions of the survey. Participants were allocated sequentially to one of the versions of the survey. In total, 93 messages across the 31 BCTs and beliefs/concerns that remained after studies 1 and 2 were assessed (3 messages per BCT and belief/concern). Participants were asked to provide ratings for individual messages, and acceptability of each BCT or belief/concern was then considered across the 3 messages. The individual messages were selected by ordering per BCT or belief/concern according to the mean fidelity to the BCT or belief/concern score given to each message during study 1. For each BCT or belief/concern, one message that scored high, one that scored low, and one that was scored in the middle were chosen. This allowed examination of the acceptability across the range of fidelity to each BCT or belief/concern. Participants were asked initial screening questions, demographic questions, and whether they used a phone or tablet computer. Participants were then presented with either the 46 or 47 messages and after each message asked to provide 3 ratings of acceptability on 5-point Likert scales: How easy is the message to understand (very difficult to understand, difficult to understand, neither easy nor difficult to understand, easy to understand, very easy to understand)? How much do you like the message (do not like at all, do not like, neither like nor do not like, like, like a lot)? How useful would this message be for you (not useful at all to me, not useful to me, neither useful nor not useful to me, useful to me, very useful to me)? The final question was an open-ended comment box for any general comments about the messages. A panel of PPI representatives reviewed the survey, and changes were made in line with their suggestions prior to the survey being sent out. PPI representatives were reimbursed in accordance with the Involve guidelines from the National Institute of Health Research [19].

Analysis

For each facet of acceptability, individual message scores were examined to identify any messages that should be removed from the library. Mean scores for ease of understanding, liking, and usefulness were calculated across the messages for each BCT or belief/concern. An overall acceptability score was calculated as an average of the understanding, liking, and usefulness scores for each BCT or belief/concern.

Following the survey, only messages and BCTs, beliefs, and concerns that scored adequately in terms of acceptability were retained for study 4.

Study 4: Message Fidelity Survey

Aim

The goal of the research was to assess the extent to which the messages with any amendments following studies 2 and 3 had fidelity to the intended BCTs.

Recruitment

Participants were expert researchers in behavior change. Potential participants were identified from those who were invited but unable to attend study 1 and the research team's knowledge of those researching BCTs. Initial email invitations (n=32) were sent, and a single reminder email was sent to those who did not respond.

Procedure

If an individual responded positively to the invitation, they were sent a further email with a unique participant number, a link to the full participant information sheet, consent form, and 1 of 2 versions of the survey selected at random (one with the order of BCTs reversed). A random allocation sequence was generated in blocks of 10 using QuickCalcs (GraphPad Software), and the unique participant number was assigned the next allocation in the sequence. Participants had to agree to all consent statements before continuing to the survey. Participants were given an honorarium for completing the survey.

Survey Development and Content

Participants completed some brief questions about their expertise. For each BCT (n=26), participants were presented with the title and description of the BCT from the BCT v1 taxonomy [15], and then 6 sample messages were presented

with "How well does this message reflect the BCT *problem solving* as defined above?" under each message (italics adjusted for each BCT). Answers were given on a 10-point scale anchored with 1 (not very well) to 10 (very well). As participants were behavior change researchers, ratings were not sought for the beliefs and concerns but rather on whether or not the message reflected an underlying BCT. Three of the beliefs and concerns represented an additional 2 BCTs, resulting in 26 BCTs (eg, messages developed for the concern "perceived risks of taking medication" were presented under BCT 5.1: Information about health consequences). See Table 1 for details of beliefs and concerns and associated BCTs. For each of the 26 BCTs, 6 messages were rated, totaling 156 messages. The 6 messages chosen were those rated as having the highest fidelity to the BCT during study 1. The final question was an open-ended comment box for any general comments about the messages.

Results

Study 1: Message Development Workshop

Participants

A total of 21 participants attended the workshop. Participants were employed as either researchers (13/21, 62%), both researchers and HCPs (7/21, 33%), or as HCPs (1/21, 5%). Participants had been paid to conduct research and/or health care professional work for between 6 and 40 years (mean 15.95 [SD 9.94]). All participants (n=21) described behavior change interventions as either central or somewhat central to their work, 62% (13/21) described medication adherence as central or somewhat central, and 43% (9/20; 1 missing) of participants described diabetes as central or somewhat central to their work. Participants had published between 2 and 50 papers (mean 14.82 [SD 13.47]) related to medication adherence, diabetes or behavior change interventions (19/21, 1 missing and 1 clinician marked N/A).

Behavior Change Techniques

A total of 371 messages were generated during the workshop; 356 were scored and 15 were generated as additional suggested messages by the participants when they had finished scoring. There were between 6 and 15 messages per BCT or belief/concern (mean 9.76 [SD 2.07]). All subsequent BCT codes reference the v1 BCT taxonomy [15]. On a scale of 1 to 10, perceived relevance of the BCT or belief/concern to tablet medication adherence for people with type 2 diabetes ranged from 4.00 (BCT 13.1: Identification of self as a role model) to 9.75 (BCT 8.3: Habit formation) with a median of 8.00. When asked the extent to which the aim of writing 8 to 10 messages that reflect the BCT or belief/concern well had been achieved (from 1=not at all achieved to 10=completely achieved), the mean scores across reviewers ranged from 3.25 (BCT 8.4: Habit reversal) to 9.25 (BCT 5.3: Information about social and environmental consequences) with a median of 7.00. Across the messages, each BCT or belief/concern received mean fidelity scores ranging from 3.50 (BCT 8.4: Habit reversal) to 8.58 (BCT 3.1 Social support [unspecified]) with a median of 8.00. See Table 1 for details.

Decisions for Message Development

Following discussions in the fourth session of the workshop, 7 BCTs were identified as either incompatible with delivery via brief message during the workshop or unsuitable for medication adherence for people with type 2 diabetes: BCT 8.4: Habit reversal; BCT 11.3: Conserving mental resources; BCT 12.2: Restructuring the social environment; BCT 13.1: Identification of self as a role model; BCT 13.2 Framing/reframing; BCT 13.3: Incompatible beliefs; and BCT 15.3: Focus on past success. For detailed reasons, see Table 2. Following study 1, the library contained 306 messages based on 24 BCTs and 7 beliefs and concerns (3 of these beliefs and concerns were based on an additional 2 BCTs).

Study 2: Focus Group Study

Participants

A total of 23 participants with a mean age of 68 (SD 7.25) years and a mean of 11 (SD 5.94) years since diagnosis with type 2 diabetes took part in 1 of 5 focus groups; 17% (3/23) of the participants were female and 83% (15/23) were white British.

Behavior Change Techniques

Participants found the concept of sending messages related to medication adherence for diabetes acceptable, provided the messages were novel (eg, not using strategies the individual was already using). Participants were keen to introduce messages related to aspects of diabetes self-management beyond medication adherence and had suggestions for changes to the wording of some messages. The wider findings from these focus groups relating to the acceptability to people with type 2 diabetes of receiving short message service (SMS) messages in principle and what features the system should have are reported elsewhere [20].

Decisions for Message Development

Following the focus groups, suggestions were identified from the transcripts, and each was considered by the research team according to criteria adapted from previous research [21]. The criteria used to aid discussion were (1) how relevant the suggestion is to the target behavior, (2) how available the suggested content already is (if already widely available perhaps not needed in present intervention), (3) the ease of implementation from a technical perspective, and (4) support from theoretical findings and/or evidence. One researcher applied the criteria (with + for support, – for no support, and ? if unsure for each criteria on each suggestion); this was then brought to a multidisciplinary team meeting, agreements and disagreements about the rating were discussed, and a final decision was taken to accept or reject each suggestion. Following these discussions, messages related to other aspects of diabetes self-management were added in preparation for piloting (eg, links to verified sources of diet and exercise advice), and messages were reworded to use the word tablets rather than meds, medication, or pills in accordance with participants' preference. The number of messages targeting medication adherence remained at 306, based on 24 BCTs and 7 beliefs and concerns (3 of these beliefs and concerns were based on an additional 2 BCTs).

Table 1. Number of messages, mean perceived relevance of the behavior change techniques (BCTs) to medication adherence, mean score for how well the aim of 8 to 10 messages that reflected the BCT well was met, and mean fidelity of messages to the intended BCT or belief/concern from study 1. BCTs are identified through the codes from BCT v1 taxonomy [15] and beliefs and concerns are labeled A through G.

BCT[a] or belief/concern	Number of messages	Relevance to improving medication adherence for people with type 2 diabetes, mean (SD)	Aim to have 8 to 10 messages that reflect the BCT or belief/concern well, mean (SD)	Fidelity of messages to the intended BCT/belief or concern[b], mean (SD)
1.2. Problem solving	10	8.00 (1.41)	7.00 (0)	7.18 (1.36)
1.4. Action planning	8	8.50 (0.71)	7.25 (0.96)	7.94 (1.92)
2.3. Self-monitoring of behavior	11	9.00 (1.55)	6.75 (0.96)	6.86 (1.94)
3.1. Social support (unspecified)	9	9.25 (0.96)	9.00 (0)	8.58 (1.40)
3.2. Social support (practical)	8	9.00 (0.82)	8.50 (1.29)	7.83 (1.42)
3.3. Social support (emotional)	9	7.67 (1.15)	7.50 (1.00)	7.72 (1.75)
4.2. Information about antecedents	6	8.50 (1.29)	8.75 (0.96)	8.17 (1.34)
5.3. Information about social and environmental consequences	13	7.50 (1.91)	9.25 (0.50)	8.50 (1.13)
5.5. Anticipated regret	11	7.50 (2.38)	7.50 (0.58)	7.34 (1.36)
5.6. Information about emotional consequences	7	7.67 (1.15)	7.75 (0.50)	7.36 (1.91)
6.2. Social comparison	11	6.00 (2.45)	7.75 (0.96)	6.85 (2.63)
6.3. Information about others' approval	8	5.50 (3.54)	7.75 (1.71)	8.09 (1.84)
7.1. Prompts/cues	11	8.25 (0.96)	8.25 (0.50)	8.02 (1.34)
8.3. Habit formation	11	9.75 (0.50)	8.50 (1.00)	7.81 (1.48)
8.4. Habit reversal	3	4.50 (1.73)	3.25 (0.50)	3.50 (0.90)
9.1. Credible source	8	7.25 (2.22)	7.75 (0.50)	8.06 (1.64)
9.2. Pros and cons	11	6.67 (0.58)	8.25 (0.96)	8.31 (1.15)
9.3. Comparative imaginings of future outcomes	8	8.00 (1.00)	6.75 (0.50)	6.61 (1.99)
10.5. Social reward	12	7.50 (0.58)	8.50 (0.58)	7.71 (1.35)
11.2. Reduce negative emotions	8	6.50 (1.29)	6.75 (0.50)	6.97 (1.11)
11.3. Conserving mental resources	12	6.00 (2.16)	5.75 (1.26)	6.33 (1.02)
12.1. Restructuring the physical environment	13	9.00 (0.82)	8.50 (1.29)	8.25 (1.57)
12.2. Restructuring the social environment	9	6.00 (2.16)	4.75 (1.89)	7.00 (1.78)
13.1. Identification of self as role model	9	4.00 (2.45)	8.00 (0.82)	7.81 (2.14)
13.2. Framing/reframing	8	5.00 (1.00)	6.75 (0.50)	7.11 (2.16)
13.3. Incompatible beliefs	9	4.50 (3.87)	6.25 (1.71)	6.47 (1.92)
13.5. Identity associated with changed behavior	12	4.50 (3.00)	6.75 (0.50)	6.94 (2.44)
15.1. Verbal persuasion about capability	9	5.25 (0.50)	7.00 (0.82)	6.42 (2.06)
15.2. Mental rehearsal of successful performance	11	5.25 (0.96)	6.00 (0.82)	4.50 (2.82)
15.3. Focus on past success	8	6.75 (1.26)	7.50 (0.58)	7.00 (1.38)
15.4. Self-talk	5	5.25 (1.71)	8.50 (0.58)	7.70 (0.86)
A. Difficulties with side effects	8	8.25 (0.96)	7.75 (0.96)	7.06 (1.81)

BCT[a] or belief/concern	Number of messages	Relevance to improving medication adherence for people with type 2 diabetes, mean (SD)	Aim to have 8 to 10 messages that reflect the BCT or belief/concern well, mean (SD)	Fidelity of messages to the intended BCT/belief or concern[b], mean (SD)
B. Difficulties remembering and understanding the medication regimen (BCT 4.1: Instruction on how to perform a behavior)	8	7.50 (1.00)	7.50 (1.00)	7.22 (1.50)
C. Beliefs around medication in general and western medicines specifically	6	7.25 (0.50)	6.25 (0.96)	7.54 (1.28)
D. Perceived risks of taking medication (As E, BCT 5.1: Information about health consequences)	10	8.40 (0.89)	7.40 (0.55)	7.76 (1.02)
E. Beliefs about medication necessity (As D, BCT 5.1: Information about health consequences)	11	8.80 (1.30)	8.00 (0.71)	7.96 (1.07)
F. Social influence around taking medications	10	7.80 (0.84)	8.20 (0.45)	7.64 (1.24)
G. Health care system-related concerns	15	8.00 (0.71)	8.60 (0.89)	8.00 (1.01)

[a]BCT: behavior change technique.

[b]Mean is across reviewers per message and across messages per BCT.

Table 2. Reasons for exclusion of behavior change techniques following study 1.

Behavior change technique	Reason for exclusion
8.4. Habit reversal	Missing taking medication was not thought to be habit; therefore it was thought there was no habit to reverse in the sense psychologists think of habits
11.3. Conserving mental resources	Participants couldn't find a way to operationalize this that wasn't also habit formation. In addition, there was concern that suggesting people with type 2 diabetes focus on medication adherence alone could devalue other important lifestyle messages (eg, diet and physical activity) that are also key to diabetes self-management
12.2. Restructuring the social environment	Participants found it hard to structure messages that didn't seem to suggest stopping seeing people
13.1. Identification of self as a role model	Participants did not feel a single health behavior such as taking medication as prescribed constituted an identity and therefore would be hard to model oneself as a role model
13.2. Framing/reframing	Hard to use without interaction; would need to know how someone is framing to start with in order to initiate change. This was not thought to be possible in a text message
13.3. Incompatible beliefs	Thought to be better used in a therapeutic situation rather than via text message
15.3. Focus on past success	Designed to react to what someone has said, this would be difficult to deliver outside of a therapeutic situation as the text message system would not know if someone had had past successes or not

Study 3: Message Acceptability Survey

Participants

A total of 72 patients consented, of whom 11 rated no messages and 52 completed ratings for all messages. Patients who consented were aged between 30 and 83 (mean 62.0 [SD 11.3]) years, 39% (28/71; 1 participant did not specify) were female; 54% (39/72) of participants had had their last change in diabetes tablets over a year ago. See Table 3 for details and comparison with those who completed all the message reviews.

Table 3. Demographics and questionnaire responses for study 3 participants.

Characteristics	Consented (n=72)	Completed the message reviews (n=52)[a]
Female, n (%)[b]	28 (39)	21 (40)
Age in years, mean (SD)	61.99 (11.25)	62.81 (10.83)
Ethnicity, n (%)		
White	64 (89)	45 (87)
Asian/Asian British	1 (1)	0 (0)
Mixed/multiple ethnic groups	1 (1)	1 (2)
Did not answer	6 (8)	6 (12)
Time since diagnosis with diabetes in years, mean (SD)[c]	12.1 (5.38)	12.73 (5.76)
Time since last change to diabetes tablets, n (%)[d]		
≤1 month	6 (8)	3 (6)
>1 month to <3 months	6 (8)	6 (12)
≥3 months to <6 months	8 (11)	8 (15)
≥6 months to <1 year	9 (13)	6 (12)
>1 year	39 (54)	27 (52)
First prescription	3 (4)	1 (2)
Did not answer	1 (1)	1 (2)

[a]Includes postal response and 1 respondent who answered questions about all but the last message.

[b]n=71 consented, n=51 completed due to missing value.

[c]n=38 consented, n=26 completed; there was a problem with one of the 4 questionnaires, this question did not allow respondents to answer, some answered in the next question and these are included here.

[d]n=71 consented, n=52 completed due to missing value.

Behavior Change Techniques

Mean scores for BCTs were highest for ease of understanding (median 4.24, range 3.71 to 4.60), then liking (median 3.33, range 2.92 to 3.85), and lowest for perceived usefulness (median 2.88, range 2.49 to 3.41). Overall acceptability (median 3.49, range 3.10 to 3.89) was over the midpoint of the scale (see Table 4).

Decisions for Message Development

As none of the BCTs scored below the midpoint on the scale (midpoint=3) for acceptability, it was decided to retain all the BCTs in the library. The number of messages in the library therefore remained at 306, based on 24 BCTs and 7 beliefs and concerns (3 of these beliefs and concerns were based on an additional 2 BCTs).

Table 4. Ease of understanding, liking, usefulness, and acceptability scores per behavior change technique or belief or concern from study 3. All available message reviews from participants (n=61) were analysed.

BCT[a]/belief or concern	Ease of understanding, mean (SD)	Liking, mean (SD)	Usefulness, mean (SD)	Overall acceptability, mean (SD)
1.2. Problem solving	4.13 (0.16)	3.33 (0.26)	2.84 (0.17)	3.43 (0.17)
1.4. Action planning	4.24 (0.09)	3.34 (0.18)	2.99 (0.20)	3.52 (0.12)
2.3. Self-monitoring of behavior	4.48 (0.06)	3.45 (0.25)	2.76 (0.20)	3.56 (0.13)
3.1. Social support (unspecified)	4.30 (0.17)	3.41 (0.06)	2.95 (0.17)	3.55 (0.11)
3.2. Social support (practical)	4.25 (0.16)	3.20 (0.08)	2.68 (0.28)	3.38 (0.05)
3.3. Social support (emotional)	4.22 (0.15)	3.27 (0.05)	2.91 (0.24)	3.47 (0.04)
4.2. Information about antecedents	4.43 (0.10)	3.68 (0.22)	3.25 (0.14)	3.79 (0.14)
5.3. Information about social and environmental consequences	4.38 (0.25)	3.28 (0.17)	2.85 (0.27)	3.50 (0.15)
5.5. Anticipated regret	4.46 (0.22)	2.95 (0.20)	2.88 (0.70)	3.43 (0.37)
5.6. Information about emotional consequences	4.08 (0.14)	3.35 (0.21)	3.04 (0.45)	3.49 (0.26)
6.2. Social comparison	4.18 (0.13)	3.25 (0.38)	2.79 (0.15)	3.41 (0.22)
6.3. Information about others' approval	4.29 (0.15)	2.96 (0.43)	2.60 (0.42)	3.28 (0.24)
7.1. Prompts/cues	4.48 (0.10)	3.41 (0.26)	2.88 (0.30)	3.59 (0.18)
8.3. Habit formation	4.26 (0.21)	3.65 (0.10)	3.29 (0.40)	3.73 (0.13)
9.1. Credible source	4.53 (0.16)	3.56 (0.22)	3.11 (0.33)	3.73 (0.16)
9.2. Pros and cons	3.71 (0.56)	2.92 (0.42)	2.67 (0.31)	3.10 (0.41)
9.3. Comparative imaginings of future outcomes	3.92 (0.27)	3.12 (0.21)	2.93 (0.10)	3.32 (0.17)
10.5. Social reward	4.22 (0.53)	3.02 (0.39)	2.57 (0.43)	3.27 (0.45)
11.2. Reduce negative emotions	4.18 (0.06)	3.09 (0.27)	2.82 (0.14)	3.36 (0.10)
12.1. Restructuring the physical environment	4.60 (0.08)	3.62 (0.29)	3.09 (0.28)	3.77 (0.18)
13.5. Identity associated with changed behavior	4.00 (0.06)	3.20 (0.09)	2.93 (0.15)	3.38 (0.06)
15.1. Verbal persuasion about capability	4.22 (0.17)	3.32 (0.05)	2.73 (0.06)	3.43 (0.07)
15.2. Mental rehearsal of successful performance	3.87 (0.19)	2.95 (0.25)	2.57 (0.21)	3.13 (0.19)
15.4. Self-talk	4.35 (0.20)	3.25 (0.27)	2.88 (0.39)	3.49 (0.17)
A: Difficulties with side effects	4.40 (0.17)	3.85 (0.25)	3.41 (0.12)	3.89 (0.18)
B: Difficulties remembering and understanding the medication regimen (BCT 4.1: Instruction on how to perform a behavior)	4.11 (0.22)	3.33 (0.08)	2.83 (0.11)	3.42 (0.02)
C: Beliefs around medication in general and western medicines specifically	4.23 (0.10)	3.38 (0.16)	2.86 (0.06)	3.49 (0.09)
D: Perceived risks of taking medication (As E, BCT 5.1: Information about health consequences)	4.09 (0.56)	3.35 (0.55)	3.07 (0.45)	3.50 (0.52)
E: Beliefs about medication necessity (As D, BCT 5.1: Information about health consequences)	4.46 (0.12)	3.70 (0.05)	3.27 (0.09)	3.81 (0.03)
F: Social influence around taking medications (BCT 3.1: Social support unspecified)	4.35 (0.15)	3.23 (0.18)	2.49 (0.30)	3.36 (0.16)
G: Health care system–related concerns	4.04 (0.36)	3.48 (0.54)	3.10 (0.58)	3.54 (0.49)

[a]BCT: behavior change technique.

Study 4: Message Fidelity Survey

Participants

A total of 18 participants completed the survey; all identified themselves as researchers (rather than clinicians or researchers and clinicians). They had been paid to do research for between 6 and 31 (mean 14.6 [SD 6.0]) years and had published between 5 and 110 papers in the areas of diabetes, medication adherence, or behavioral interventions (mean 29.2 [SD 29.0]). Behavior change interventions were rated as being central or somewhat central to all 18 participants. Medication adherence was also reported as central or somewhat central to 13 participants, and diabetes as central or somewhat central to 7 participants.

Behavior Change Techniques

The mean scores of fidelity to the intended BCT ranged from 5.53 (BCT 4.1: Instruction on how to perform a behavior) to 8.87 (BCT: 5.3 Information about social and environmental consequences) with a mean of 7.61 (SD 0.93). See Table 5.

Decisions for Message Development

As none of the BCTs fell below the midpoint on the scale for fidelity (midpoint=5.5) it was decided that all the BCTs examined could be adequately represented by brief messages. At this stage of development, the findings related to individual messages from studies 2, 3, and 4 were considered together. One message was removed as it had scored below the midpoint for acceptability to patients in study 3 and for fidelity to the intended BCT in study 4 ("Diabetes tablets do not wear off over time" intended to represent BCT 5.1: Information about health consequences).

The final stage of message development was to review each message from the library with HCPs working on the project to ensure there was nothing either misleading or that could contradict current medical advice. One BCT (10.5: Social reward) was removed as the messages relied on a link to pharmacy pick-up that was not possible from the message delivery system at this time. A further 3 messages were removed and 7 were amended as a result of this review (see Table 6 for reasons). The final library contained 290 messages based on 25 BCTs and 4 beliefs and concerns (see Table B in Multimedia Appendix 1 for sample messages and Figure 1 for a flowchart of the message development process).

Table 5. Fidelity of the messages to the intended behavior change techniques from study 4.

Behavior change technique	Fidelity of messages mean (SD)
1.2. Problem solving	8.73 (0.54)
1.4. Action planning	7.54 (2.22)
2.3. Self-monitoring of behavior	7.79 (0.80)
3.1. Social support (unspecified)	7.91 (0.74)
3.2. Social support (practical)	8.73 (0.41)
3.3. Social support (emotional)	8.07 (0.20)
4.1. Instruction on how to perform a behavior	5.53 (0.93)
4.2. Information about antecedents	6.43 (0.62)
5.1. Information about health consequences	6.49 (1.97)
5.3. Information about social and environmental consequences	8.87 (0.19)
5.5. Anticipated regret	8.43 (1.16)
5.6. Information about emotional consequences	6.67 (1.69)
6.2. Social comparison	7.17 (1.45)
6.3. Information about others' approval	8.44 (0.92)
7.1. Prompts/cues	8.32 (0.45)
8.3. Habit formation	8.32 (1.06)
9.1. Credible source	7.49 (1.71)
9.2. Pros and cons	8.46 (0.65)
9.3. Comparative imaginings of future outcomes	7.02 (1.81)
10.5. Social reward	5.76 (0.55)
11.2. Reduce negative emotions	6.73 (0.49)
12.1. Restructuring the physical environment	8.40 (0.51)
13.5. Identity associated with changed behavior	7.03 (1.18)
15.1. Verbal persuasion about capability	7.75 (1.64)
15.2. Mental rehearsal of successful performance	7.48 (0.97)
15.4. Self-talk	8.13 (0.88)

Table 6. Reasons for message removal or amendment following health care provider review.

Message	BCT[a]	Action	Reason
If your blood sugar gets out of control, it could put you on an emotional rollercoaster. Taking your tablets as often as you should will stop the ups and downs.	5.6. Information about emotional consequences	Removed	Message implies a direct link between blood sugar control and an emotional rollercoaster—this is not true
Some people with diabetes who don't take their tablets lose their foot. Imagine how you feel if you let this happen to yourself.	5.5. Anticipated regret	Removed	Message implies a direct link between not taking tablets and losing a foot—smoking is a bigger risk factor.
Most religious leaders would agree that taking diabetes medication regularly is important.	9.1. Credible sources	Removed	Message flagged in qualitative comments of study 3; was not thought to be wholly accurate.
The tablets prescribed for your diabetes are very effective and can work alongside other treatments. Please let us know of anything else you may be taking.	C. Beliefs around medication in general and western medicines specifically	Amended	Confusing whom the message is seen as coming from.
If you don't understand don't be afraid to say so. There's a team of people here to help you.	G. Health care system-related concerns	Amended	Confusing whom the message is seen as coming from.
Taking your tablets can be as routine as having your morning coffee. Use this time as a prompt, and make your tablet taking a habit.	8.3. Habit formation	Amended	May have a morning coffee at 11:00 without any food—tablets should be taken with food.
Don't end up feeling guilty about extra diabetes complications caused by not taking your tablets as prescribed.	11.2. Reduce negative emotions	Amended	Complications may not be caused by not taking your tablets; referring to increased risk of complications is more accurate
If you lost your eyesight because you didn't take your diabetic tablets, would you regret it?	5.5. Anticipated regret	Amended	Loss is very final, seen to be too negative as this may go to people who have eyesight problems and these may not be linked to diabetic medication—a link implied that isn't necessarily there.
If you take your tablets as prescribed, it reduces your risk of serious complications by 50% (Diabetes UK).	9.1. Credible sources	Amended	Quantification hard to substantiate, so removed
Diabetes UK: Forgetting diabetes tablets just twice a week halves their overall benefit (hyperlink to webpage).	9.1. Credible sources	Amended	Quantification hard to substantiate, so removed

Discussion

Following this systematic development process involving four studies, we conclude that the messages produced have good acceptability and fidelity to their intended BCT. The retained BCTs were shown to be appropriate for delivery through brief messages, acceptable to patients, and clearly understood. All mean scores for retained BCTs were above the median point on the scales in studies 1, 3, and 4.

There are at least three key strengths of this research. First and most important, the systematic transparent process of message development allows for clarity in terms of message content; this will aid interpretation of any intervention effects. Second, the inclusion of people with type 2 diabetes, experts in behavior change research, and health care practitioners to ensure views of key stakeholders are incorporated. Third, as a consequence of the first two strengths, this research has resulted in the identification of BCTs appropriate for delivery through brief messages and development of a library of messages with evidence supporting their acceptability and fidelity to explicit BCTs that can be used in further research.

The majority of the sample of people with type 2 diabetes recruited for studies 2 and 3 were of white ethnicity, and this is acknowledged as a limitation. However, the work reported here is part of a larger program of work to develop evidence-based brief messaging for type 2 diabetes. Due to the increased risk of the condition among South Asian populations [22], these populations are a specific focus of this work. Focus groups with South Asian populations were run in parallel with those described in study 2 [23]. Further development will be needed to explore the similarities and differences between these two focus group studies and the potential tailoring, or additional messages needed, to ensure a library of messages that are acceptable to the whole population of people with type 2 diabetes.

As identified in a Cochrane review, novel approaches to medication adherence are needed [4]. We were therefore keen at this stage to include as many potentially effective components as possible for further testing in a trial setting while excluding any messages or BCTs that were definitely unacceptable to the target population. Currently there is not a widely recognized threshold for acceptability for these studies. A threshold for acceptability was set at the median point or above [24], as this seemed appropriate to meet our aims. In a recent definition of acceptability, cognitive and emotional reactions to an intervention and perceived relevance were identified as key facets in the definition [25]. In addition to formative assessment of the acceptability of the broad concepts used in study 2, these individual facets have been measured in study 3 through ease of understanding, liking, and perceived usefulness to an individual. Of the facets of acceptability measured, perceived

usefulness scored lower than either liking or ease of understanding. It should be noted that at this stage in development it was only possible to measure anticipated acceptability. As conceptualized by Sekhon and colleagues [25], acceptability should be measured across development of an intervention to assess both anticipated and experienced acceptability. It could be hypothesized that of the facets measured, perceived usefulness is the hardest to prospectively measure accurately. Future research could explore whether certain approaches may be perceived as more or less useful to different people in different contexts as this might be more appropriately done when people have had a chance to use the intervention in a more real-world setting and can report experienced acceptability. Future research could also explore the relationship between anticipated acceptability as we have measured here and experienced acceptability when participants are receiving these messages as part of their day-to-day lives.

Previous research in this area has found modest improvements in glycemic control in those with poorly controlled diabetes as a result of receiving brief diabetes-related messages in conjunction with blood glucose monitoring [26]. The messages in this previous research were generated within the research team and based on a review of previous research, existing mobile health interventions, and current patient resources [27]. The intervention was described as informed by 2 behavior change theories, and researchers incorporated 8 BCTs from an early version of the taxonomy [14] into the messages including "prompting self-monitoring" and "providing general encouragement" as well as reminders and feedback on blood glucose results through messages and an accompanying website [27]. It is not clear from the publications how the theories and BCTs were selected from the sources of information used (eg, the review, mobile health interventions, and patient resources). The messages were reviewed by diabetes experts and people with type 2 diabetes and piloted for acceptability and usability [27]. By contrast, the 4 studies reported in our research expand on this previous research by using a wider pool of individuals to generate the messages, looking beyond the individual theories and BCTs currently used to incorporate a wider range and back-checking with a separate group of researchers that the messages are good exemplars of the intended BCTs.

This approach may lead to more novelty in brief message interventions and greater confidence that individuals who receive the messages will be receiving the intended technique. This is important because if the intervention is found to be either effective or not effective, it will allow researchers to explain why, which will add to the empirical evidence in this area and allow researchers to optimize the intervention. Although some of the BCTs identified in the rapid review were deemed by behavior change researchers and health care professionals to be difficult to deliver through brief messages, we retained 29 BCTs and beliefs and concerns through to the final message library. This ensures that in addition to the more commonly used BCTs such as "self-monitoring of behavior," this intervention can explore approaches to this problem that are novel in brief message interventions.

This research provides a transparent development process for other researchers to use or improve upon. While this approach is not intended to be an alternative to other approaches of overall intervention development, to the authors' knowledge there is currently no guide for systematically developing the content of messages used in self-management interventions and ensuring that the content accurately represents the intended BCTs. This approach could therefore be used in conjunction with other approaches to intervention development [8]. The components of this approach were all important, however the order the studies were undertaken could have been altered. Initially, we planned to conduct the focus group study (reported here as study 2) prior to the message development study (reported here as study 1). As one of the aims of the focus group study was to ascertain people with diabetes' views on a system such as this, if these had been negative, the time and effort in developing the messages may have been wasted. However, due to delays in recruitment for the focus group study, we decided to go ahead with the message development study for two reasons: (1) the brief messages developed could be delivered in a number of ways (if participants had favored an app or Web-based system or even a paper-based system, the text of the messages could still have been used) and (2) it is easier for people to give opinions on a proposed system if they are provided with concrete examples. The opinions given by participants in study 2 were more useful as they were of actual messages we were planning to use rather than any that had been generated within the team. Overall, the process was relatively time consuming compared with other ways of generating messages; however, this is considered justified for the confidence we can now have that these messages are acceptable and have fidelity to the intended BCTs. Furthermore, there is the potential that some of this work could be adapted to other medication adherence interventions without repeating all stages; this may be less time consuming than developing those interventions from scratch. There were some decisions the team made about BCTs to include based on the available technology, which is constantly evolving. Because we have transparently presented the BCTs considered and reasons for exclusion, we hope if other researchers are considering other forms of technology or systems with a greater number of components, the excluded BCTs could duly be reconsidered.

Through developing a library of brief messages that are based on explicit BCTs and have been shown to be acceptable to a patient population, this research could also provide a valuable resource to develop theory in the area of medication adherence and diabetes and to optimize brief message interventions for this population. In a recently published review study, researchers explored how BCTs might have an effect on behavior by extracting the proposed links between BCTs and mechanisms of action [28]. However, the authors noted that the links proposed by intervention study authors were rarely tested empirically. Due to the fidelity of the messages to explicit BCTs, the messages developed here could be used to test theories of behavior change and the relationships between BCTs, mechanisms of action, and behavior change. The message library developed here will be further refined through our forthcoming pilot and feasibility work. Although messages were found to have good fidelity to their intended BCT, it was raised in qualitative comments that a single message may represent more than one BCT from within the taxonomy [15]; this could be

explored in future research. In addition, it was recognized that not all BCTs are suitable for delivery through brief messages. Specifically, those requiring interaction could not be facilitated by the current system. Further research could explore more advanced systems that could deliver these BCTs (eg, chat bots to allow lifelike automated responses during interactions), but it must be accepted that there may be some BCTs that are better delivered in person. In these cases, future research could explore the possibility of incorporating any of these techniques into medication reviews with an HCP.

Participants in the study 2 focus groups requested messages around diet and exercise management in addition to messages focused on medication adherence. A wariness was also expressed by the participants in study 1 that focusing solely on medication adherence may have the unintended effect of making other aspects of diabetes self-management seem less important. Messages that provide information from verified sources related to other aspects of diabetes care therefore may form an important part of engaging someone with the system and ensure a more holistic view of the condition. However, this will create a challenge when interpreting results and exploring the mechanisms of action. In addition, the focus here was on tablet medication adherence; further research would be needed to assess whether any of these messages would be acceptable and appropriate for people using only injected medication or what adaptations would be needed to ensure relevance. Our future work will aim to explore the potential mechanisms of action both qualitatively and quantitatively with participants while using the messaging system.

In conclusion, a library of brief messages acceptable to people with type 2 diabetes representing explicit BCTs has been developed using a rigorous, transparent process. This will provide the basis for a novel brief message intervention to improve medication adherence in people with type 2 diabetes and can be further used to develop the theory and understanding of behavior change in this area.

Acknowledgments

The authors would like to acknowledge the support of Katherine Grady and the Research for the Future/Help BEAT campaigns (National Institute for Health Research [NIHR] Clinical Research Network Greater Manchester), Northern Care Alliance NHS Group. Abstract

Background: Emotional exhaustion (EE) in health care workers is common and consequentially linked to lower quality of care. Effective interventions to address EE are urgently needed.

Objective: This randomized single-exposure trial examined the efficacy of a gratitude letter–writing intervention for improving health care workers' well-being.

Methods: A total of 1575 health care workers were randomly assigned to one of two gratitude letter–writing prompts (self- vs other focused) to assess differential efficacy. Assessments of EE, subjective happiness, work-life balance, and tool engagement were collected at baseline and 1-week post intervention. Participants received their EE score at baseline and quartile benchmarking scores. Paired-samples *t* tests, independent *t* tests, and correlations explored the efficacy of the intervention. Linguistic Inquiry and Word Count software assessed the linguistic content of the gratitude letters and associations with well-being.

Results: Participants in both conditions showed significant improvements in EE, happiness, and work-life balance between the intervention and 1-week follow-up ($P<.001$). The self-focused (vs other) instruction conditions did not differentially predict improvement in any of the measures ($P=.91$). Tool engagement was high, and participants reporting higher motivation to improve their EE had higher EE at baseline ($P<.001$) and were more likely to improve EE a week later ($P=.03$). Linguistic analyses revealed that participants high on EE at baseline used more negative emotion words in their letters ($P=.005$). Reduction in EE at the 1-week follow-up was predicted at the level of a trend by using fewer first-person ($P=.06$) and positive emotion words ($P=.09$). No baseline differences were found between those who completed the follow-up assessment and those who did not ($Ps>.05$).

Conclusions: This single-exposure gratitude letter–writing intervention appears to be a promising low-cost, brief, and meaningful tool to improve the well-being of health care workers.

burnout; health care; positive psychology; mental health; emotions

Introduction

Background

Emotional exhaustion (EE) among US health care workers has increased to 1 out of 3 nurses [1] and almost half of practicing physicians [2], with the highest rates among junior doctors and those working at the front line of patient care [3,4]. Many aspects of patient safety and quality of care appear compromised by EE, which is a key component of burnout [5]. EE has been linked to higher frequencies of medical errors, lapses in professionalism, impeded learning, and suicidal ideation [6-8]. As such, there is an urgent need for simple, brief, effective, and accessible EE and burnout interventions on a broad scale.

Unfortunately, existing remedies for EE are limited by time, effort, and cost. For instance, mindfulness-based meditation courses have empirical support for reducing EE [9]; however, courses of this type can be costly and typically require 8 to 10 weeks and approximately 90 hours of effort from health care workers who already skip meals and breaks, deprive themselves of needed rest, and get home late as a norm [10,11]. In contrast, this study examines the efficacy of a brief, single-use tool—writing a letter of gratitude—for reductions in EE and improvements in well-being. If there is a way to use bite-sized tools to provide a quick recharge in the face of EE, it could facilitate (not replace) the use of other, more elaborate remedies.

Gratitude has one of the strongest associations with better mental health and well-being of any personality trait, even more than hope, optimism, or compassion [12]. Several rigorous controlled trials demonstrate the beneficial effect of gratitude interventions [13-15]. For instance, participants randomized to gratitude journal keeping, compared with active control conditions, reported higher levels of energy, determination, enthusiasm, feeling more optimistic, being more likely to exercise, having fewer physical symptoms, sleeping longer, and sleeping with better quality [16]. Another study found that participants randomized to write a gratitude letter and visit the recipient of the letter reported significant gains in happiness and reductions in depressive symptoms, compared with a placebo control group, both 1 week and 1 month later [17]. In fact, this intervention exhibited the greatest benefits compared with four other positive psychology interventions that the authors tested (ie, 3 good things, you at your best, using signature strengths, and identifying signature strengths) [17].

Previous research on live interactions has shown that expressions of gratitude that focused more on the benefits that the person expressing the gratitude received (ie, self-focused) benefited the expresser, whereas gratitude focusing more on the positive attributes of the individual being thanked (ie, other focused) benefited the recipient of said gratitude [18]. We hypothesized that participants randomized to gratitude letter–writing instructions to focus more on personal benefits in their letters (ie, self-focus) would exhibit greater improvement in well-being than those randomized to focus more on the positive aspects of the letter recipient (ie, other-focused).

On the basis of previous linguistic studies that have identified a *language of depression*, we were interested in identifying a *language of burnout* within the gratitude letters [19]. As such, we developed a series of hypotheses regarding the frequencies of words in particular word categories and their associations with both concerning levels of baseline EE and EE improvement. More frequent use of first-person singular (eg, *I*) and negative emotion words and marginally fewer positive emotion words have been identified in those experiencing depression [19,20]. Greater use of cognitive processing words (eg, *because* and *realization*) predicts fewer posttraumatic stress disorder symptoms among trauma survivors [21], and in our own research, third-person plural use (eg, *we*) is higher in groups with lower EE [22]. Taking this research together, we expected participants with concerning levels of EE at baseline to use more first-person singular and negative emotion words and fewer third-person plural, positive emotion, and cognitive processing words in their letters. We expected that EE improvers would exhibit the inverse of this pattern.

Objectives

This trial examined the efficacy of a gratitude letter–writing intervention to improve health care workers' well-being measured in terms of EE, happiness, and work-life balance. The aims of this study were (1) to determine whether a onetime gratitude letter predicts improvements in well-being and to test whether self- vs other-focused instruction conditions differentially predict changes in well-being, (2) to measure participants' engagement with the intervention and their reactions to receiving feedback on their individual EE, and (3) to examine the linguistic content of gratitude letters for correlates of baseline EE and predictors of EE improvement.

Methods

Design and Patient Population

This randomized before-and-after trial of a gratitude letter–writing intervention was conducted between January 2018 and February 2019 (institutional review board approval: Pro00063703). Health care workers enrolled through a website link [23], having learned of the study through colleagues or by participating in a workshop conducted by authors KA and JS. All health care workers (clinical and nonclinical) aged at least 18 years were eligible to participate. Participants completed assessments and the gratitude letter–writing intervention at baseline and were given the opportunity to complete assessments again 1 week later. The intervention and assessments were completed on the web.

Among the 1575 health care workers who participated in the gratitude letter–writing intervention, 1179 (74.86%) wrote 15 words or more, a threshold at which we found letters were less likely to be left unfinished. A total of 17.59% (227/1575) participants completed both the pre- and postintervention assessments.

Measures

A total of 3 validated scales were used to assess aspects of well-being: EE, subjective happiness, and work-life balance. These scales were selected for the following reasons: (1) all are brief (8 items or less) and therefore are less onerous to busy health care workers to complete, (2) all are psychometrically

sound both in prior studies and in our own, and (3) all are sensitive to intervention in our prior studies [24]. Demographic questions on gender, race, ethnicity, and role were included at baseline.

Emotional Exhaustion

The Maslach Burnout Inventory (MBI) is widely used among professionals in human services, including health care workers, and is considered the gold standard survey instrument for assessing professional burnout [25]. The MBI includes 3 scales: EE, depersonalization, and personal accomplishment. EE consistently produces the largest and most consistent coefficient alpha estimates compared with depersonalization and personal accomplishment [5,26,27]. EE has also been used to discriminate between burned-out and nonburned-out outpatients suffering from work-related neurasthenia (according to International Classification of Diseases-10 criteria and Diagnostic and Statistical Manual of Mental Disorders-IV) [27,28]. We used a 5-item derivative of the original 9-item EE scale [25,29]. An example item is "I feel frustrated by my job." Participants respond using a 5-point scale (1=disagree strongly and 5=agree strongly), and mean scores are rescaled to 0 to 100, with higher scores signifying more EE. Internal consistency in this study was good (Cronbach alpha at baseline=.84 and Cronbach alpha at follow-up=.86).

To examine linguistic differences by level of EE, we compared the language of a priori selected word categories for those participants whose EE scores reflected moderate and severe EE (*concerning*) with participants without EE. An EE score greater than or equal to 75 was deemed concerning, which reflects, on average, agreeing slightly or strongly to EE items. The concerning threshold should not be considered clinically diagnostic, but rather, it identifies those whose scores suggest a pronounced level of EE [29]. Those determined as not having EE (not concerning) had scores less than 50, which reflects, on average, disagreeing slightly or strongly to EE items. Participants who scored between 50 and 75 (mild EE) were not included in these analyses. To compare linguistic markers of EE improvement, we identified *improvers* as having a reduction of their burnout score of more than 10 points and *decliners* as having scores that increased by 10 or more points.

Subjective Happiness

Lyubomirsky and Lepper's Subjective Happiness Scale (SHS) is a 4-item internationally used scale of global happiness [30,31]. An example item is "In general I consider myself (1=not a very happy person to 7=a very happy person)". SHS items are answered using a 7-point scale, and each participant's responses are averaged, with higher scores indicating higher happiness. Internal consistency in this study was good (Cronbach alpha at baseline=.83 and Cronbach alpha at follow-up=.87).

Work-Life Balance

The work-life climate scale evaluates individual differences in work-life infraction behaviors and has been shown to have good psychometrics when administered to health care workers [10,11,29,32]. The scale prompt asks *During the past week, how often did this occur*? Items include: *Arrived home late from work; Slept less than 5 hours in a night.* Responses include rarely or none of the time (less than 1 day), some or a little of the time (1-2 days), occasionally or a moderate amount of time (3-4 days), all of the time (5-7 days), and not applicable. Scale scores were computed by taking the mean of the items [10]. Internal consistency in this study was acceptable (Cronbach alpha at baseline=.71 and Cronbach alpha at follow-up=.77).

Intervention Experience

In addition, five questions assessed participants' experience with the tool. In the baseline survey, these questions were "Would you like a copy of this letter emailed to you?" (yes, no, or do not know) and "I completed this gratitude letter exercise before" (yes or no). The 1-week follow-up surveys included "Do you have other people in mind for whom you might write a letter like this?" (yes, no, or not sure), "Did you talk to anyone about your first gratitude letter"? (yes, no, or not sure), and "Since my first gratitude letter a week ago, it has gotten easier to think of things for which I am grateful" (1=very strongly agree and 8=very strongly disagree).

Emotional Exhaustion Feedback

After completing the items for the EE scale, participants were shown their scores and the quartiles of scores from our sample of over 135,000 US health care workers. Participants answered three Likert-like questions after receiving their scores and before the gratitude letter–writing intervention: "I was surprised by my burnout score," "Knowing my burnout score makes me want to work on it more," and "I would like to be more resilient." Response options ranged from 1 to 5 (disagree strongly to agree strongly).

Gratitude Intervention

The gratitude letter–writing intervention invited participants to spend approximately 7 min writing an appreciative letter to someone who has positively affected their lives.

Participants were given general instructions plus two text boxes (parts 1 and 2) to enter their letters. Participants were randomized, through an automatic randomizer within the survey software program, to receive either the *self-focus* condition or the *other-focus* condition as described below:

> *Think of someone who has done something amazing for you; this person can be alive or no longer with us. This person contributed to your well-being in a big way. Spend the next 7 minutes writing a genuine, kind and appreciative 2-part note:*

Self-focus condition:

> *Part 1:Tell this person what they did, how it impacted you, and the benefits you received.*
>
> *Part 2: Tell this person why it was important to you.*

Other-focus condition:

> *Part 1: Tell this person what they did, how it impacted you, how it made you feel, and why it was important to you.*
>
> *Part 2: Tell this person what it says about them, that they did this amazing thing for you. You might include what this says about your relationship to this person.*

Statistical Analysis

Demographic variables and evaluation questions were subjected to descriptive analysis. Cronbach alpha assessed the internal reliability of administered scales, with values above .70 considered acceptable [33]. Paired *t* tests assessed improvements in well-being between baseline and 1-week postintervention surveys. Independent-samples *t* tests compared changes in well-being scores between baseline and 1-week follow-up between gratitude letter–writing conditions. A manipulation check compared the linguistic use of first-person singular (eg, *I*) vs second person (eg, *you*) based on condition; the self-focus condition was expected to use more first-person words and fewer second-person words than the other-focus condition. Independent-samples *t* tests also compared EE feedback scores based on EE level at baseline (concerning vs no EE), EE improvement (improvers vs decliners), and baseline well-being scores in those who completed 1-week postintervention surveys vs those who did not. *P* values less than .05 were considered significant, and all tests were 2 tailed. Listwise deletion was used for missing data. Analyses were performed using SPSS version 24 software.

Linguistic Analysis of Letters

The Linguistic Inquiry and Word Count (LIWC) software program version 2015 was used to analyze text written in the participants' gratitude letters [34]. The LIWC dictionary consists of 6400 words, word stems, and select emotions, with each entry defining one or more of 80 language categories [35]. Word counts are expressed as a percentage of the total number of words, controlling for the length of the text file. Text from both parts 1 and 2 of the instructions were included in the linguistic analyses.

Independent-samples *t* tests compared differences in linguistic categories based on EE level at baseline (concerning vs no EE) and also compared differences in linguistic word count frequencies for EE improvers and decliners.

Results

Respondent Demographics

Overall, 1575 participants completed the onetime gratitude intervention and baseline assessments. The majority of participants were white and female (1165/1575, 73.84% and 1100/1575, 69.84%, respectively). The top 3 health care worker roles were those who classified as *other* (334/1575, 21.21%), *attending or staff physician* (266/1575, 16.89%), and *other manager* (260/1575, 16.51%). Nurse managers and charge nurses, when combined, accounted for 21.71% (342/1575). See Table 1 for additional demographic information.

Overall, 277 participants (self-focused condition=139 and other-focused condition=138) provided correct contact information and followed up at 1 week using a onetime email prompt. An independent *t* test revealed no differences in baseline EE, subjective happiness, or work-life balance for those who completed the 1-week follow-up and those who did not (*P*=.48, *P*=.44, and *P*=.12, respectively). At baseline, 38.02% (579/1523) participants met or exceeded the threshold for having concerning levels of EE.

Table 1. Respondent demographics of gratitude letter–writing participants (N=1575).

Demographics	Participants, n (%)
Health care worker role	
Other	334 (21.21)
Attending or staff physician	266 (16.89)
Fellow physician	6 (0.38)
Resident physician	6 (0.38)
Physician assistant, nurse practitioner, clinical nurse specialist	58 (3.68)
Nurse manager or charge nurse	175 (11.11)
Registered nurse (including certified registered nurse anesthetists)	167 (10.60)
Pharmacist	138 (8.76)
Therapist (respiratory therapy, physical therapy, occupational therapy, speech therapy)	5 (0.32)

Aim 1: Assessing Change in Well-Being Metrics Between Baseline and 1-Week Follow-Up and Differential Efficacy by Instruction Conditions

Table 2 shows the means and *t* test results across the sample of participants who completed the 1-week follow-up. Examined separately, both conditions showed significant reductions in EE and improvements in happiness and work-life balance (*P*s<.001).

Table 2. Independent samples *t* tests comparing changes in well-being for participants in the self- vs other conditions.

Variable	EE[a] change: self (N=134), mean (SD)	EE change: other (N=135), mean (SD)	*t (df)*	*P* value	95% CI	Happiness change: self (N=136), mean (SD)	Happiness change: other (N=137), mean (SD)	*t (df)*	*P* value	95% CI	Work-life balance change: self (N=132), mean (SD)	Work-life balance change: other (N=134), mean (SD)	*t (df)*	*P* value	95% CI
Self- vs other focus	−7.98 (17.30)	−7.81 (16.85)	−0.08 (257)	.94	−4.27 to 3.93	5.26 (11.01)	4.93 (11.66)	0.24 (471)	.81	−2.37 to 3.04	−0.26 (0.45)	−0.26 (0.42)	−0.12 (264)	.91	−0.11 to 0.10

[h]N=273.

[i]N=266.

When directly comparing change in well-being between self- and other-focused conditions, independent *t* tests revealed no significant differences across any of the three well-being measures (*P*s>.05; see Table 2). A linguistic manipulation check revealed that those randomized to the self-focused prompt used more first-person singular words (ie, *I*; self: mean 11.32, SD 4.021; other: mean 10.08, SD 3.66; t_{1496}=6.06; *P*<.001) and fewer second-person words (eg, *you*; self: mean 4.61, SD 4.04; other: mean 5.68, SD 4.47; t_{1496}=−4.85; *P*<.001) than those randomized to the other-focus condition, indicating that condition prompts did elicit differential linguistic self- vs other focus.

As conditions did not differ in their efficacy, we reran the paired *t* tests with the pooled sample to obtain the overall effects, which remained significant (*P*s<.001; see Table 3 and Figure 1). Participants with higher levels of EE at baseline were more likely to be improvers (mean 63.99, SD 23.17) compared with decliners (mean 50.21, SD 26.52) at the 1-week follow-up (t_{235}=3.89; *P*<.001). In addition, improvements in specific work-life balance behaviors were examined across the whole sample. Significant improvements were reported across all behaviors (see Table 4), with the biggest improvement in feeling *less* frustration with technology (t_{257}=6.18; *P*<.001).

Figure 1. Pre- and postintervention well-being scores. For demonstration purposes, the work-life balance variable was scaled 0-100 in this graph, original response range 1-4. Error bars represent SE means.

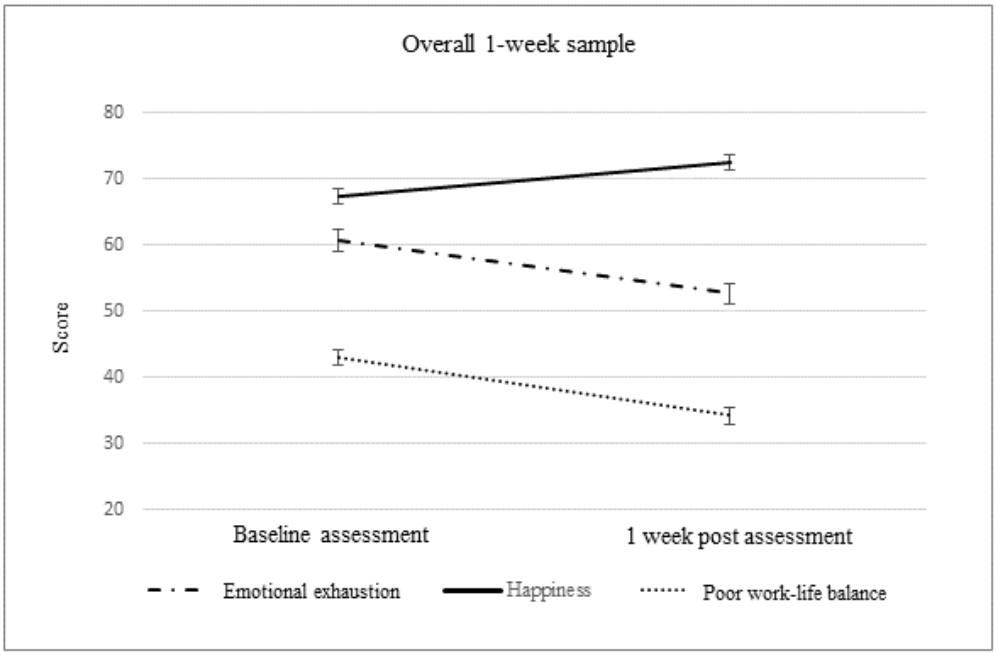

Table 4. Paired-samples *t* tests assessing work-life balance items across participants who completed the 1-week follow-up gratitude letter–writing intervention.

Variable	Baseline, mean (SD)	1-week follow-up			
		Mean (SD)	*t (df)*	*P* value	95% CI
Slept less than 5 hours in a night	1.91 (0.94)	1.76 (0.92)	2.68 (260)	.01	0.04 to 0.25
Worked through a shift or day without any breaks	2.32 (1.08)	2.09 (1.04)	4.23 (256)	<.001	0.13 to 0.35
Skipped a meal	2.13 (1.00)	1.88 (0.98)	4.49 (262)	<.001	0.14 to 0.36
Ate a poorly balanced meal	2.63 (0.93)	2.36 (0.99)	5.44 (263)	<.001	0.17 to 0.37
Had difficulty sleeping	2.40 (0.99)	2.10 (1.00)	5.36 (262)	<.001	0.19 to 0.42
Arrived home late from work	2.56 (1.03)	2.24 (0.96)	5.95 (256)	<.001	0.22 to 0.43
Changed personal or family plans because of work	2.07 (0.91)	1.80 (0.83)	5.86 (260)	<.001	0.19 to 0.38
Felt frustrated by technology	2.32 (0.95)	1.97 (0.90)	6.18 (258)	<.001	0.24 to 0.46

Aim 2: Engagement With the Intervention and Reactions to Getting Emotional Exhaustion Scores

Of 1575 participants who wrote a baseline gratitude letter, 1007 (63.94%) requested an emailed copy of their gratitude letter and 121 (7.68%) reported having completed this gratitude letter exercise before. At the 1-week follow-up, of 140 participants, 136 (56.7%) answered *yes* to the question "Do you have other people in mind for whom you might write a letter like this?" compared with 46 (19.2%) and 58 (24.2%) who answered *no* or *not sure*, respectively. In addition, 75.4% (181/140) participants agreed slightly, strongly, or very strongly with the statement "Since my first gratitude letter a week ago, it has gotten easier to think of things for which I am grateful," and 45.1% (125/277) participants responded *yes* to the question "Did you talk to anyone about your first gratitude letter?". Independent *t* tests revealed no significant differences in well-being change scores for those who shared their gratitude letters relative to those who did not (EE: t_{266}=1.36, *P*=.18; happiness: t_{270}=−1.04, *P*=.30; and work-life balance: t_{263}=1.04, *P*=.30).

Participants' responses to receiving their EE and work-life balance scores can be found in Table 5. It should be noted that 81.23% (1229/1513) of the respondents agreed slightly or strongly with "knowing my burnout score makes me want to work on it more," and 93.81% (1426/1520) of participants reported wanting to be more resilient.

Those with higher levels of EE at baseline were more likely to agree with all three of these questions (see Table 5). Notably, EE improvers were significantly more likely to agree with the question "Knowing my burnout score makes me want to work on it more" than decliners. Improvers were not more likely than decliners to report being surprised by their scores or a desire to be more resilient.

Table 5. Reactions to receiving burnout feedback, differences by baseline emotional exhaustion levels, and emotional exhaustion improvers vs decliners. Responses were on a 1 (disagree strongly) to 5 (agree strongly) scale.

Burnout feedback item	Severe baseline EE[a] (n=64): those who agreed slightly or strongly, n (%)	Moderate baseline EE (n=515): those who agreed slightly or strongly, n (%)	Mild baseline EE (n=472): those who agreed slightly or strongly, n (%)	No baseline EE (n=473): those who agreed slightly or strongly, n (%)	Concerning EE (n=579) vs no EE (n=473)			EE improvers (n=173) vs decliners (n=62)		
					Mean (SD)	*t (df)*	*P* value	Mean (SD)	*t (df)*	*P* value
"I was surprised by my burnout score"	18 (28.1)	267 (51.8)	211 (44.7)	142 (30)	M1[b] 3.12 (1.38); M2[c] 2.72 (1.26)	4.81 (1036.08)	<.001	M1 3.05 (1.25); M2 3.05 (1.26)	−.01 (233)	.99
"Knowing my burnout score makes me want to work on it more"	51 (79.7)	453 (88.5)	400 (85.5)	322 (67.8)	M1 4.50 (0.84); M2 3.92 (1.11)	9.28 (845.30)	<.001	M1 4.39 (0.91); M2 4.03 (1.16)	2.19 (89.10)	.03
"I would like to be more resilient"	62 (96.8)	490 (95.8)	197 (96)	416 (89.1)	M1 4.82 (0.56); M2 4.50 (0.84)	7.07 (761.00)	<.001	M1 4.74 (0.69); M2 4.56 (0.76)	1.64 (231)	.12

[a]EE: emotional exhaustion.

[b]M1: mean numerical response on a 5-point scale for the concerning EE group (moderate and severe EE) at baseline group.

[c]M2: mean numerical response on a 5-point scale for the no EE at baseline group.

Aim 3: Linguistic Differences Based on Emotional Exhaustion Level at Baseline and Improvements in Emotional Exhaustion

A small number of participants (4.9%) submitted only a few words in the gratitude letter text box. In some cases, it appears that the writer started but did not finish the letter, and in others, the writers engaged in the exercise briefly and superficially (eg, "Mom for raising me. She was amazing."). As word count scores are computed as a percentage of the total number of words, we were concerned that brief letters could bias the linguistic analyses. To reduce potential bias, we excluded letters in the linguistic analyses that were less than 15 words long (77/1575, 4.89% of the sample).

Linguistic category frequencies were compared for those with concerning levels of EE with those without EE at baseline (see Table 6). Negative emotion words were more frequently used in the gratitude letters by those with concerning levels of EE at baseline (P=.005). All other word categories were not used differentially by baseline EE level (P>.05).

Table 6. Independent *t* tests of linguistic differences in gratitude letters by baseline emotional exhaustion (concerning or not) and emotional exhaustion improved (or declined) at the 1-week follow-up.

Hypothesized categories	Baseline EE[a]				EE improvement 1 week later			
	EE concerning, mean (SD)	EE not concerning, mean (SD)	*t (df)*	*P* value	EE decliners (n=63), mean (SD)	EE improvers (n=175), mean (SD)	*t (df)*	*P* value
First person (eg, *I*, *I've*, and *my*)	10.96 (4.52)	10.91 (5.10)	0.17 (1070)	.87	11.88 (4.59)	10.65 (4.24)	−1.93 (236)	.06
First-person plural (eg, *we*, *let's*, and *us*)	0.74 (1.48)	0.84 (1.69)	−1.01 (981.69)	.31	0.82 (1.46)	0.81 (1.65)	−0.03 (236)	.98

Cognitive processing (eg, *accept*, *because*, and *realization*)	12.13 (5.28)	11.89 (5.42)	0.73 (1070)	.47	11.52 (5.28)	12.06 (5.27)	0.70 (236)	.48

[a]EE: emotional exhaustion.

The frequencies of word categories were compared for EE improvers vs decliners. There was a statistical trend, albeit nonsignificant, showing that improvers used fewer first-person and positive emotion words (*P*=.06 and .09, respectively). Otherwise, EE improvers vs decliners did not demonstrate different use across the remaining word categories.

Discussion

Principal Findings

This study examined the efficacy of a single-use gratitude letter–writing intervention with a diverse sample of health care workers. Between baseline and the 1-week follow-up, participants reported significant improvements in all three of the well-being measures: EE, happiness, and work-life balance. Participants across both randomized instruction conditions (self-focus vs other focus) reported equivalent improvements in well-being. To our knowledge, this is the first application of a onetime gratitude intervention in health care workers evidencing subsequent improvement in the EE component of burnout.

Participants reported high engagement with the intervention among those who completed the follow-up. Three-fourths of the participants (75.4%) reported that it was easier to think of things to be grateful for since writing their letter. A majority (63.9%) of participants requested an emailed copy of their letter, presumably to reflect on it and/or share with the recipient. Participants equally benefited from the tool regardless of whether they spoke with someone about the letter or not. Although nearly half (45.1%) of the participants reported talking to someone about their letter, we do not know if that person was the letter recipient or not. Previous research has indicated that writing a letter should be followed by a visit to the recipient of the letter [16,17]. It may be that speaking with the letter recipient confers additional benefits, whereas speaking with someone in general (recipient or not) about their letter does not.

Our intervention also gave participants immediate feedback about their EE score during the baseline assessment. Participants were split between being surprised and not being surprised by their scores; however, participants who had higher EE scores were more likely to be surprised. This suggests that a significant portion of health care workers may be burned out, yet they are either not aware of it or are in denial about it [36,37]. After receiving their scores, participants reported very high levels of motivation to reduce their EE (81.2%) and increase their resilience (93.8%). Receiving one's EE score might trigger behavioral change to improve well-being. Indeed, higher agreement to the question "Knowing my burnout score makes me want to work on it more" predicted greater improvement in EE. We cannot determine whether this improvement was because of behavioral change that occurred between the assessments or whether individuals who had higher agreement to this question experienced greater benefit from the gratitude letter–writing exercise or because of some other reason. However, considerable research has shown that greater awareness of a personal problem is a key step in behavioral change [38,39]. A recent meta-analysis of burnout prevalence in 109,628 physicians across 182 studies suggests that many physicians are answering burnout questions, but we believe that the proportion receiving feedback about their burnout is close to 0 [40]. It could be that burnout psychoeducation on its own may not be sufficiently motivating. Rather, receiving one's burnout score can be likened to someone *stepping on the scale* before engaging in more physical activity, bringing a personal awareness of his or her status to trigger behavioral change.

Linguistic analyses revealed that participants with moderate and severe EE at baseline used more negative emotion words in their letters compared with participants without EE. Similarly, previous research has shown that depressives use more negative emotion words in their writing samples [19]. Surprisingly, we did not find differences in the use of first-person singular or plural, positive emotions, or cognitive processing word categories by EE severity. Although we found a statistical trend associating greater reductions in EE with the use of fewer first-person singular words (eg, *I* and me) and fewer positive emotion words, neither of them reached statistical significance (*P*=.06 and *P*=.09, respectively; see the Multimedia Appendix

1). Differences in these categories have been found in depressives vs controls in prior research, albeit with very different writing prompts [19]. Writing a note of gratitude might draw out a different pattern of language compared with the expressive writing prompts often used by other linguistics researchers, which ask participants to write about their deepest emotions and emotional challenges over a 4-day period [41]. Thus, linguistic patterns in the gratitude letter tool may not reflect psychological well-being as clearly as was found in other studies. Given that the gratitude tool appears to be beneficial, it may be that an overall feeling of gratitude induced by this intervention drives improvement, rather than a complex linguistic pattern across word categories. In other words, it may simply be more important *that* you are grateful rather than *how* you are grateful.

In line with prior research, we expected that participants who were assigned to write more about themselves, rather than the recipient of the letter, would benefit more from the exercise. Although our prompts appeared to change the linguistic focus (ie, the self-focused condition used more *I* and less *me* language than the other-focused condition), one condition did not further enhance well-being relative to the other. Notably, prior research on the benefits of self-focused language examined verbal expressions of gratitude, rather than written letters [18]. It may be that in a letter format, the impact of focusing on oneself during expressions of gratitude is inherently weaker or diluted by the additional time spent writing.

This study and prior research indicate that the gratitude letter tool, and similar positive psychology tools, might improve well-being by shifting one's focus from what is *not* going well to what *is* going well. Indeed, the negativity bias makes people significantly more likely to pay attention to negative vs positive stimuli [42]. Individuals with higher levels of negativity bias are more likely to be depressed [43]. When prompted to positively reflect, participants appear to consider good things they had previously taken for granted, had not thought much about, or were formerly overshadowed by attention to negative experiences. By intentionally shifting attention to what is going well, participants may recalibrate their perceptions toward noticing more positive experiences and be primed to engage in other self-care activities such as exercising [44]. Indeed, 75.4% of follow-up participants reported that it became easier to think of things to be grateful for after writing their first gratitude letter.

We chose to implement gratitude letter writing as a web-based intervention to increase the availability of the tool and increase our sample size. In fact, our baseline sample size was larger than we anticipated. However, it is possible that a web-based format made it easier for participants to ignore the 1-week follow-up survey message. Web-based studies typically have high dropout rates, likely because of the ease of ignoring the request and reduction of interpersonal reciprocity norms. It is possible that personal characteristics make web-based tools more appealing to some, and this could have influenced enrollment and engagement in the study. Future research should explore what characteristics predispose individuals to benefit from web-based vs in-person well-being tools.

Limitations

Our study has several limitations. First, our study included randomization to two letter conditions, but there was no nonintervention control group. In addition, the intervention included both the gratitude letter activity and receiving one's baseline EE score, component effects of which we cannot disentangle. These aspects preclude our establishing a causal relationship between gratitude letter writing and improvement in well-being. However, prior randomized controlled gratitude interventions (eg, nightly gratitude log and gratitude visit) have demonstrated improvement compared with placebo controls, which bolsters confidence in the results of this study [16].

Nonetheless, the observed benefits of this intervention may in part arise from expectancy bias or placebo effects. We observe that participants who engaged in the gratitude letter tool and completed the 1-week follow-up reported significant improvements across all outcomes. It is possible that there were intrinsic characteristics of the cohort that completed follow-up assessments that predisposed them to improvement, whereas participants not completing postintervention assessments may not have benefited to the same degree.

Selection bias comprises another noted limitation. Our sample largely comprised women (69.9% of participants at baseline). Nevertheless, this approximates the base rates of women working in health care in the United States (in 2017, 75% of health care workers were female) [45]. Future research should employ a placebo-controlled design, examine the gratitude letter or EE feedback alone, and potentially oversample for men, all of which will serve to better determine causality, divine specific effects of the tool, and establish the extent of efficacy across genders. Overall, the high level of engagement observed within our cohort, significant participant interest in discussing letters, and self-reported improvements in the ability to identify that for which they were grateful suggest a meaningful impact of this short letter-writing activity.

Our study also suffered from what looks like attrition, with 18% of participants who completed a baseline assessment also completing the 1-week follow-up. A significant component likely arose from varied means by which health care workers were referred to the tool. In some cases, participants received a brief link at the conclusion of a talk or meeting, without mention of any follow-up evaluation: "Consider giving this just 7 minutes to see what you think of a bite-sized resilience activity." In other words, although many participants enrolled knowing that there would be a 1-week follow-up, some participants likely never intended on completing the follow-up at the outset. It is possible that individuals who failed to complete the follow-up did not benefit from the tool to the same extent as those who did complete it, overinflating the tool's effects. That said, our attrition rates are similar to comparable studies [46-48]. Attrition is a primary barrier to evaluating web-based interventions, with levels often reaching 60% to 80%. Among people seeking treatment for obesity using weight loss programs in medical centers, one-third to half discontinue their program and are lost to follow-up [49,50]. Similarly, over 40% of people seeking treatment through a smoking cessation clinic were lost to follow-up [51], and 48% of web-based

smoking cessation individuals were lost to follow-up [52]. Even when offered significant financial incentives (US $600) to participate in a cessation program, only 20% of those invited chose to participate [53]. In future iterations of this tool, we plan to improve the follow-up rates by setting clear expectations for receiving and completing follow-up assessments, identifying whether participants correctly entered their contact information into our system, and implementing reminders.

Perhaps most importantly, the gratitude letter tool is designed to build participants' personal well-being resources but does not address the demands placed upon them in their work environments. Ultimately, the pace and intensity of contemporary health care are major unaddressed sources of strain that impair well-being. The gratitude letter tool, although promising, should be part of a much larger toolkit of valid and accessible interventions facilitating individual well-being and institutional changes.

Despite these limitations, this study finds that the gratitude letter tool offers a simple, brief, and free individual intervention to improve health care workers' EE, happiness, and work-life balance. The flexibility of this single-use tool is highly desirable amid the fast pace of health care. Indeed, it can be inserted into a staff meeting, during a break, or completed briefly at home. In an era of alarmingly high levels of health care worker EE, the gratitude letter tool appears to be a promising arrow in the quiver to improve well-being.

Conclusions

A single-exposure gratitude letter–writing intervention is a promising tool to improve EE, happiness, and work-life balance in health care workers. There is preliminary evidence that receiving feedback about your EE serves to motivate further well-being action and, in turn, improve EE. The gratitude letter tool [23] is brief, simple, and free and requires no further action after writing a 7-min letter, which are all important factors for busy health care workers and overburdened health care systems. Given the relationship between health care workers' well-being and health care quality, engaging in the gratitude letter tool may help relieve EE and, in turn, improve patient safety and quality.

Acknowledgments

This work was supported by the National Institutes of Health grant number R01 HD084679-01. The authors would like to express their deep gratitude to Christen Noratel for her tireless efforts over the past 10 years in supporting trainings and seminars that shared the gratitude letter tool with health care workers.

Abstract

Background: Randomized controlled trials (RCTs) often provide accurate estimates of the internal validity of an intervention but lack information on external validity (generalizability). We conducted an RCT on the effectiveness of a self-management intervention among patients with lymphoma in a population-based setting.

Objective: The objectives of the current study were to describe the proportion of RCT participants compared to all patients invited to participate, and compare sociodemographic and clinical characteristics of RCT participants with all respondents, all patients invited to participate, and all patients selected from the Netherlands Cancer Registry (NCR) to determine the reach of the intervention. An additional objective was to assess differences on RCT outcome variables between RCT and paper respondents.

Methods: Patients with lymphoma or chronic lymphocytic leukemia ≥18 years old at diagnosis from 13 hospitals in the Netherlands were selected from the population-based NCR, which routinely collects data on sociodemographic and clinical characteristics. Eligible patients were invited to participate in an RCT and complete a questionnaire. Web-based completion determined RCT enrollment, whereas paper respondents were followed observationally.

Results: A total of 1193 patients were selected from the NCR, 892 (74.77%) of whom were invited to participate in the trial by their hematologist after verifying eligibility. Among those invited, 25.4% (227/892) completed the web-based questionnaire and were enrolled in the RCT. The RCT participants were younger and there was a higher proportion of men than nonparticipants (P<.001). In addition, 25.7% (229/892) of those invited opted to participate in the paper-based observational follow-up study. Compared with paper respondents, RCT participants were younger (P<.001), with a higher proportion of men (P=.002), and had higher education levels (P=.02). RCT participants more often wanted to receive all available information on their disease (P<.001), whereas paper respondents reported higher levels of emotional distress (P=.009).

Conclusions: From a population-based sample of eligible patients, the participation rate in the RCT was approximately 25%. RCT participants may not be representative of the target population because of different sociodemographic and clinical characteristics. Since RCT participants represent a minority of the target population, RCT results should be interpreted with caution as patients in the RCT may be those least in need of a self-management intervention.

KEYWORDS

reach; uptake; participation, web-based intervention; pragmatic; randomized controlled trial; population-based registry; lymphoma

Introduction

Randomized controlled trials (RCTs) are widely considered to be the gold standard for evaluating the effects of an intervention in behavioral and psycho-oncological research [1,2]. In contrast to the effects of interventions that are most often examined extensively in RCTs [3], much less attention has been paid to the proportion of patients who participate in these interventions and whether those who choose to participate are representative of the target population in terms of sociodemographic and clinical characteristics [2,4]. Thus, RCTs often provide accurate estimates of the internal validity (ie, effect of an intervention for the sample enrolled in the RCT), but do not typically provide information about the external validity or generalizability (ie, effect of an intervention in the target population) [5-7].

The reach of an RCT provides information on the absolute number, proportion, and representativeness of the sample that participates in the trial [8]. The absolute number and proportion of RCT participants are relatively easy to assess and are therefore most often reported. However, few studies report the representativeness of the sample enrolled in an RCT, which is a much more challenging metric to assess [8,9] since it requires sociodemographic information, and preferable psychosocial, clinical, or case mix information, on RCT participants as well as nonparticipants. It is particularly challenging to collect information on nonparticipants who typically do not consent to be included in the research [8].

Interventions with promising effects in RCTs have been implemented in daily practice without specific knowledge of the generalizability of the results. Therefore, more attention should be paid to providing information related to the representativeness of the sample enrolled in an RCT. Lack of representativeness may occur as a result of inadequate selection procedures (ie, sampling bias) or when the probability of nonparticipation in the study is related to the object of research (ie, nonresponse bias) [10,11].

To fill this gap, the aim of the current study was to address the reach of a web-based self-management intervention within the context of the Lymphoma InterVEntion (LIVE) trial (Netherlands Trial Register NTR5953), whose objectives have been described elsewhere [12]. For the LIVE trial, patients were selected from the population-based Netherlands Cancer Registry (NCR) that routinely collects data on sociodemographic and clinical characteristics. This can provide unique insight into the characteristic differences between RCT participants and nonparticipants to estimate the reach of this intervention. The primary objectives were to (1) describe the proportion of RCT participants compared to all patients invited to participate, and (2) compare sociodemographic and clinical characteristics of RCT participants with those of all respondents (ie, patients who completed a web-based or paper questionnaire), all patients invited to participate, and all patients selected from the NCR. In addition, as patients had the option of completing a web-based questionnaire (ie, enrollment in the RCT) or a paper-based questionnaire (ie, no enrollment in the RCT; observational cohort), a secondary objective was to assess baseline differences in psychological distress, self-management skills, and satisfaction with information provision (ie, RCT outcome variables) between the two groups.

Methods

Study Design

Baseline data were collected from an RCT embedded in a population-based registry [13] as an observational cross-sectional dataset without information on the effectiveness of the intervention. In short, the LIVE trial examines the effectiveness of feedback on patient-reported outcomes and a web-based self-management intervention on self-management skills, satisfaction with information provision, and psychological distress among patients with lymphoma [12].

Participants and Recruitment Procedure

From October 2016 to February 2019, patients who were diagnosed with lymphoma, including Hodgkin lymphoma, nonHodgkin lymphoma, or chronic lymphocytic leukemia (CLL) as defined by the International Classification of Diseases for Oncology-3 codes [14], from 13 hospitals in the Netherlands were selected for participation via the NCR. The NCR registers all patients newly diagnosed with cancer in the Netherlands within the first year after diagnosis and routinely collects detailed data on sociodemographic and clinical characteristics (eg, patient age and sex, date of cancer diagnosis, cancer type, and primary treatment). Patients had to be 18 years or older at the time of study invitation. Treating hematologists were asked to verify the patients' eligibility for the study and to exclude patients who were deceased, had severe psychopathology, were too ill, were not able to complete a questionnaire in Dutch, or had severe cognitive impairment. All eligible patients were invited by mail to participate by their own hematologist. Patients had the option to complete a web-based or paper-based questionnaire. Patients were informed that completion of the web-based questionnaire automatically resulted in enrollment in the RCT with randomization to one of the study arms, whereas completion of a paper questionnaire resulted in participation in the observational Patient Reported Outcomes Following Initial treatment and Long term Evaluation of Survivorship (PROFILES) registry [13] but not enrollment in the RCT. To address the primary objective of the current study—describing the proportion of RCT participants compared to all patients invited to participate—paper respondents were

assessed as nonparticipants as they did not participate in the RCT.

Measures

Sociodemographic and Clinical Measures

Sociodemographic characteristics (age and sex) and detailed clinical information (date of diagnosis, cancer type, primary treatment) were available from the NCR. Information on education level and marital status was assessed from the questionnaire (data only available for respondents).

Comorbidities at the time of questionnaire completion were assessed using an adapted version of the self-administered comorbidity questionnaire [15]. Patients were asked to identify comorbidities present within the past 12 months, including heart disease, hypertension, arthritis, stroke, lung disease, diabetes, stomach disease, kidney disease, liver disease, anemia, thyroid disease, and rheumatoid arthritis. Positive responses were summed to a total score ranging from 0 to 12 (data only available for respondents).

Personality Traits

Personality traits were assessed with the Big Five Inventory, a 44-item inventory designed to measure the Big Five dimensions of personality: extraversion, neuroticism, conscientiousness, agreeableness, and openness to experience [16]. Each item was scored on a 5-point scale. Scale scores were obtained by averaging all items for each domain ranging from 0 to 5. Each trait is assumed to represent a continuum from high to low on the specific attribute and is partnered with a trait on the opposite pole of the spectrum [17,18].

Information Preferences

One question from an adapted version of the Information Satisfaction Questionnaire was used to measure information preferences [19]. Patients had to categorize themselves into one of three groups: those who would like (1) all available information, (2) only positive information about the illness, and (3) only limited information. Patients were further asked whether they use the internet (yes/no).

Psychological Distress, Self-Management Skills, and Satisfaction With Information Provision

Primary outcomes to assess the effectiveness of the intervention were psychological distress, self-management skills, and satisfaction with information provision.

Psychological distress was assessed with the 14-item Hospital Anxiety and Depression Scale [20]. Each item is rated on a 4-point scale from 0 to 3. The total score was obtained by adding all item scores and ranged from 0 to 42, in which higher scores indicate higher levels of psychological distress [21]. Patients with a Hospital Anxiety and Depression Scale sum score ≥13 were categorized as “psychologically distressed” [22].

Self-management skills were assessed with the Health Education Impact Questionnaire (heiQ) that contains 40 items across eight scales: positive and active engagement in life, health-directed activities, skill and technique acquisition, constructive attitudes and approaches, self-monitoring and insight, health service navigation, social integration and support, and emotional distress [23]. Each item is scored on a 4-point scale. Scale scores were obtained by averaging all items for each domain and ranged from 1 to 4. Higher scores indicate better status or self-management, except for emotional distress in which higher scores indicate greater distress [23].

Satisfaction with overall information provision was assessed with one item from an adapted version of the Information Satisfaction Questionnaire [19]. Patients were asked to rate their level of satisfaction for overall information provision on a scale from 1 (“very unsatisfied”) to 5 (“very satisfied”).

Statistical Analyses

The proportion of RCT participants (ie, participation rate) was calculated by dividing the number of patients who were enrolled in the RCT by the total number of eligible patients who were invited to participate. Sociodemographic and clinical characteristics of RCT participants were compared with those of all respondents (ie, patients who completed a web-based or paper questionnaire), all patients invited to participate, and all patients selected from the population-based NCR. In addition, personality traits and information preferences of RCT participants were compared with those of all respondents. Differences on sociodemographic and clinical characteristics between RCT participants and nonparticipants were compared using analysis of variance for continuous variables and Chi-square tests for categorical variables.

Differences in baseline psychological distress, self-management skills, and satisfaction with information provision (ie, RCT outcome variables) between RCT participants and paper respondents were compared using analysis of variance for continuous variables and Chi-square tests for categorical variables. All statistical analyses were performed with SAS version 9.4 (Cary, NC, USA). $P \leq .05$ indicated statistically significant differences.

Results

Patients Selected From the Netherlands Cancer Registry

As shown in Figure 1, a total of 1193 patients with lymphoma or CLL who were ≥18 years old at diagnosis from 13 hospitals were selected from the population-based NCR. The basic characteristics of the invited patients are summarized in Table 1. The majority of patients were men, were diagnosed with high-grade nonHodgkin lymphoma, and were actively being treated, with chemotherapy as the most common treatment.

Figure 1. Flowchart of the data collection process. CLL: chronic lymphocytic leukemia; NCR: Netherlands Cancer Registry; RCT: randomized controlled trial; PROFILES: Patient Reported Outcomes Following Initial treatment and Long term Evaluation of Survivorship.

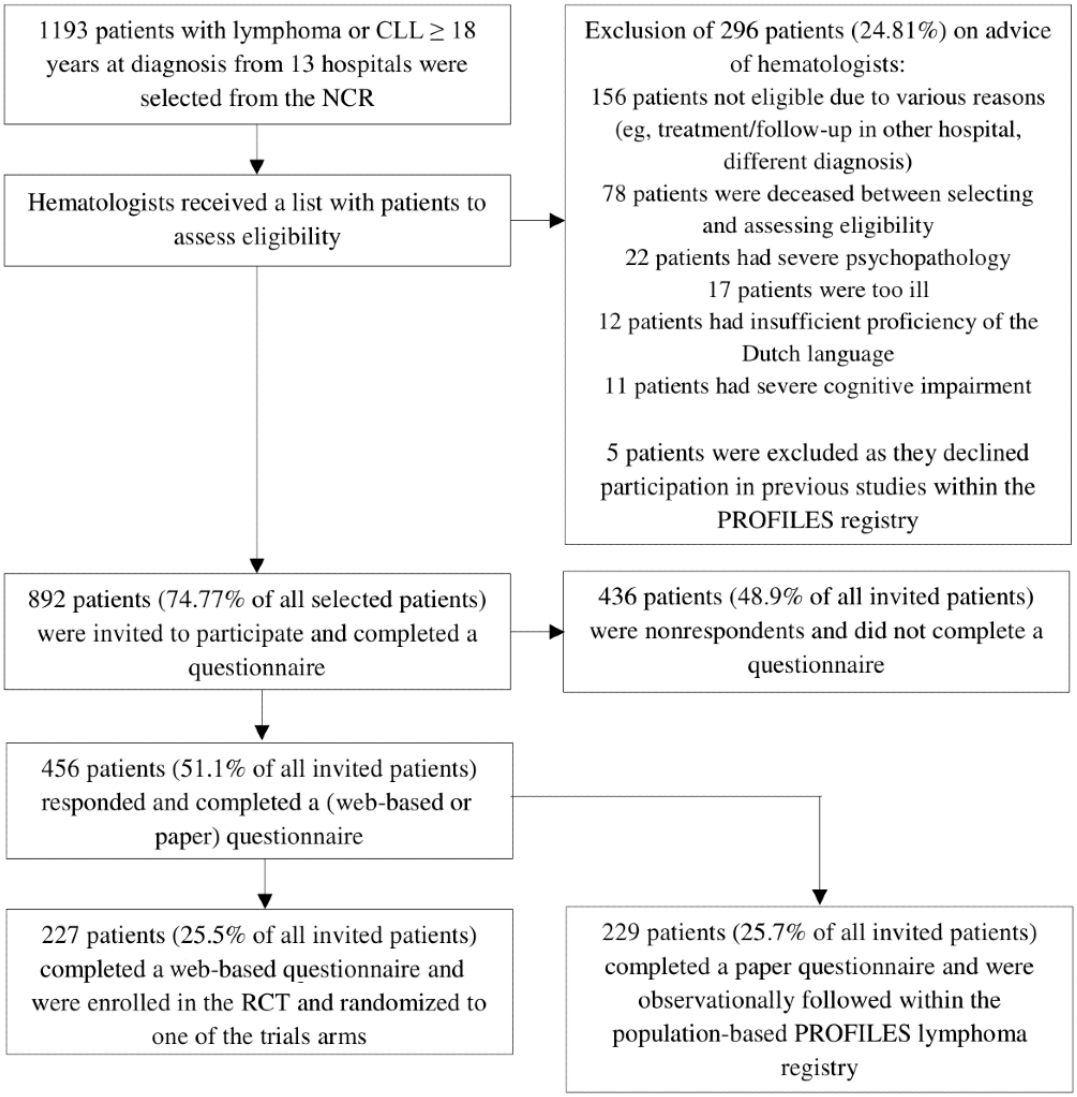

Table 1. Baseline characteristics of patients selected from the Netherlands Cancer Registry (NCR) according to participation[a].

Characteristic	Patients selected from the NCR (N=1193)	Patients invited to participate (n=892)	Respondents (n=456)	RCT[b] participants (n=227)

[a]See Figure 1 for the flowchart of patient selection. The groups in columns are not mutually exclusive; RCT participants are also included in the groups of the other 3 columns.

[b]RCT: randomized controlled trial.

[c]Low education level: none/primary school.

[d]N/A: data not available.

[e]Medium education level: lower general secondary education/vocational training.

[f]High education level: preuniversity education/high-level vocational training/university.

[g]HL: Hodgkin lymphoma.

[h]NHL-HG: high-grade nonHodgkin lymphoma.

[i]NHL-LG: low-grade nonHodgkin lymphoma.

[j]CLL: chronic lymphocytic leukemia.

[k]CT: chemotherapy.

[l]RT: radiotherapy.

[m]SCT: stem cell transplantation.

Patients Invited to Participate

A flowchart of the patient selection process is shown in Figure 1. Of all selected patients, 24.81% (296/1193) were excluded after verifying eligibility by their treating hematologists for the following reasons: deceased, severe psychopathology, too ill, insufficient proficiency of the Dutch language, and cognitive impairment. In addition, 156 patients were not eligible for other reasons, including 36 patients who received treatment or follow up in another hospital and 20 patients for whom the ultimate diagnosis did not meet our inclusion criteria (eg, myelodysplastic syndrome, acute lymphoblastic leukemia). The remaining 100 patients were excluded by the hematologists for unknown reasons. Furthermore, 5 patients were excluded as they declined participation in previous studies within the PROFILES registry. After exclusion of these patients, 892 patients (74.77%) were invited to participate and completed a questionnaire. Patients invited to participate did not significantly differ from all patients selected from the NCR in terms of age (P=.38) and sex (P=.07) (Table 1).

Respondents

Among the 892 invited patients, 456 patients (51.1%) responded and completed either a web-based or paper questionnaire. The mean age of all respondents (Table 1) was comparable with that of nonrespondents (63.8 years, P=.43), and the majority of the respondents were also men. Respondents did not differ from all patients selected from the NCR in terms of age (P=.81) and sex (P=.26). Respondents were more often actively treated than nonrespondents (75% vs 66%, P=.01). Half of the respondents (229/456, 50.2%) completed a paper questionnaire, whereas the other half (227/456, 49.8%) completed a web-based questionnaire and were enrolled in the RCT. Nearly half of the respondents stated that they would like to receive all available information, with a lower proportion preferring limited information, and even less indicating that they would like to receive only positive information about the illness (Table 1). Approximately 82% of all respondents reported using the internet.

Randomized Controlled Trial Participants

A quarter of all invited patients (227/892) participated by completing a web-based questionnaire, which resulted in a participation rate of the RCT of 25.4%. The mean age of RCT participants was slightly lower than that of nonparticipants (ie, nonrespondents and paper respondents (n=665, 65.3 years, P<.001) with a slightly higher mean time since diagnosis, and comprised a higher proportion of men (70.9%, 161/227 vs 57.0%, 379/665, P<.001). The proportion of patients who were actively treated were comparable between RCT participants and nonparticipants (75.8%, 172/227 vs 69.0%, 459/665, P=.13). In addition, RCT participants were significantly younger than respondents, patients invited to participate, and patients selected from the NCR (all P<.001). Furthermore, there was a higher proportion of men among RCT participants compared with all patients invited to participate and all patients selected from the NCR (both P<.001).

Randomized Controlled Trial Participants Versus Paper Participants

RCT participants were younger than paper respondents (60.7 vs 68.3 years, P<.001). In addition, RCT participants were more often male (71% vs 57%, P=.002), more highly educated (50% vs 20%, P<.001), and more often had a partner (84% vs 75%, P=.02). No significant differences were found between RCT and paper respondents regarding cancer type or primary treatment (P=.54 and P=.06, respectively). RCT participants also reported fewer comorbidities than paper respondents (1.1 vs 1.4, P=.02).

Concerning personality traits, RCT participants had lower scores on neuroticism (2.4 vs 2.6, P=.003) and higher scores on openness to experience (3.5 vs 3.4, P=.002) than paper respondents, although effect sizes were small (Cohen d=0.29 and 0.28, respectively). With respect to information preferences, the majority of RCT participants stated a preference for receiving all available information, whereas only 38.9% (89/229) of paper respondents indicated this preference (P=.001). Conversely, paper respondents more often preferred receiving limited information (41.9%, 96/227 vs 34.4%, 78/227; P=.001). Furthermore, RCT participants more often used the internet (96.9%, 220/227 vs 66.4%, 152/229; P<.001) (Table 1).

Emotional distress, as measured with the heiQ, was significantly lower among RCT participants compared with the score for paper respondents (Table 2), although the effect size was small (Cohen d=0.25). No significant differences were observed regarding other self-management skills between the RCT and paper groups. In addition, no significant differences were observed in the proportion of patients with psychological distress between RCT participants and paper respondents, although paper participants seemed to have higher mean scores. Furthermore, no differences were observed between RCT

participants and paper respondents regarding satisfaction with overall information provision (Table 2).

Table 2. Differences in randomized controlled trial (RCT) outcome variables at baseline between RCT participants and paper respondents.

Outcome variable	RCT participants (N=227)	Paper respondents (N=229)	*P* value	Cohen *d*
Psychological distress (yes), n (%)	34 (15.0)	45 (19.7)	.18	
Psychological distress[a], mean (SD)	6.5 (5.9)	7.5 (6.1)	.06	0.18
Self-management skills[b], mean (SD)				
Health-directed behavior	3.3 (0.6)	3.2 (0.6)	.12	0.14
Positive and active engagement in life	3.2 (0.5)	3.1 (0.5)	.05	0.18
Self-monitoring and insight	3.0 (0.4)	3.1 (0.4)	.62	0.05
Constructive attitudes and approaches	3.3 (0.5)	3.3 (0.5)	.66	0.04
Skill and technique acquisition	2.9 (0.5)	3.0 (0.5)	.33	0.09
Social integration and support	3.2 (0.5)	3.2 (0.5)	.77	0.03
Health services navigation	3.3 (0.4)	3.3 (0.4)	.54	0.06
Emotional distress	1.8 (0.5)	1.9 (0.6)	**.**01	0.25
Satisfaction with overall information provision, n (%)			.29	
Very unsatisfied	1 (0.4)	2 (0.9)		
Unsatisfied	9 (4.0)	8 (3.5)		
Neither	49 (21.6)	41 (17.9)		
Satisfied	126 (55.5)	143 (62.4)		
Very satisfied	41 (18.1)	27 (11.8)		

[a]Scale 0-42; a higher score indicates more psychological distress.

[b]Scale 1-4; higher scores indicate better status or self-management, except for emotional distress, in which higher scores indicate higher distress.

Discussion

Principal Findings

This reach analysis among RCT participants within a population-based sample showed a selective reach with an underrepresentation of older patients, women, and those with a medium to low level of education. In addition, our RCT participants may represent individuals with relatively better psychological well-being as scores for emotional distress were lower in this group.

Approximately a quarter of the population-based sample of patients with lymphoma and CLL were assessed to be not eligible for the study for various reasons (eg, deceased, severe psychopathology or cognitive impairment, a different diagnosis was ultimately made). Among the eligible patients who were invited to participate, 51% responded and completed a questionnaire, half of whom completed the web-based questionnaire and were enrolled in the RCT, resulting in a participation rate of 25%. This means that only one in four of all eligible patients actually participated in the RCT. This participation rate was lower compared with that of an RCT on the fully automated electronic health (eHealth) application Oncokompas that supports cancer survivors in their self-management (48%) [24]. Similar to the patients in our RCT, patients in the Oncokompas RCT were selected from the population-based NCR. However, cancer survivors in the Oncokompas RCT were first invited in an online survey study on supportive care and eHealth to assess internet use. Their participation rate was calculated as the number of RCT participants divided by the number of eligible respondents of the survey (access to the internet and email address). Thus, their group of eligible respondents was more selective compared with our sample. In our sample, only 82% of all respondents used the internet, and this percentage may be even lower among all patients invited to participate.

The results of the current study demonstrate that the RCT participants were younger, more often men, and more often actively treated compared to nonparticipants. Thus, the sample of RCT participants may not be representative of the target population. Therefore, even though the sample size reached the required number of patients [12], this sample may not be reliable for drawing conclusions about the target population. Furthermore, the effects of the intervention on the target population may be different from the effects that were found in the RCT sample [10,25].

These results also provide information about the response rate of observational research, which was 51%. This is comparable with response rates from other population-based studies on quality of life among lymphoma survivors in Germany (54.7%) [26] and the United States (54.8%) [27]. However, the current response rate is lower compared with that reported from earlier observational research within our study group at approximately

80%, despite similar patients and recruitment procedures [28]. This might be explained by the knowledge that the more information that is disclosed about the study—which is inherently more for an RCT than for observational research—the higher the proportion of nonrespondents [29]. Patients received abundant information along with the invitation, especially about participation in an RCT and randomization. The amount of information, as well as the knowledge of being randomized when completing a web-based questionnaire, may have deterred patients from participating. In addition, the type of intervention may have influenced the participation rate, as the majority of patients did not have problems with emotional adjustment to having cancer and therefore may have been less interested in a self-management intervention. Another explanation may be related to the fact that participation and response rates for health-related research have been declining over the past several years [30,31], and potential participants are faced with an increasing number of requests to participate in studies. This may result in patients refusing to participate in all studies [32].

We further compared the characteristics of RCT participants with those of paper respondents. RCT participants, who completed the web-based questionnaire, were younger, more often men, and more highly educated than the paper respondents, which are similar to the characteristics from previous observational studies within our study group [33,34]. Highly educated patients more often display prosocial behavior than patients with lower levels of education, and therefore the former group may be more likely to participate in an RCT for altruistic reasons [35]. In addition to differences in sociodemographic characteristics, RCT participants reported lower scores related to neuroticism and higher scores related to openness than paper respondents. In addition, information preferences slightly differed between RCT and paper respondents, as RCT participants more often wanted to receive all available information on their disease. RCT participants also more often reported using the internet. To complete a web-based questionnaire, and subsequently be enrolled in a web-based self-management intervention RCT, patients must not only be able to use a computer but also be sufficiently skilled in browsing the internet [33]. Although there seems to be a trend of older individuals becoming more active online [33,36], there is still a subgroup of patients who do not use the internet and thus have no access to a web-based questionnaire or internet-based intervention.

Despite these various differences between RCT participants and paper participants, baseline scores on self-management skills, satisfaction with information provision, and psychological distress appeared to be comparable between these groups, although scores for emotional distress were slightly lower among RCT participants.

Strengths

The strengths of this study include its unique setting. As patients were recruited from the population-based NCR, we had information on sociodemographic and clinical characteristics of both RCT participants and nonparticipants. In addition, as the RCT was embedded in the PROFILES registry, we were able to assess differences between RCT participants and paper respondents on sociodemographic and clinical characteristics, in addition to personality traits, information preferences, and baseline psychological distress, self-management skills, and satisfaction with information provision (ie, RCT outcome variables). This information provided the opportunity to determine both the reach and generalizability of the RCT sample.

Limitations

The current study has some limitations. Although information regarding sociodemographic and clinical characteristics of nonparticipants was available, we did not have information about nonparticipants' reasons for declining participation or their physical and psychological health. Therefore, it remains unclear whether the physical and psychological health of RCT participants is similar to that of nonparticipants. In a previous study that assessed the generalizability of the results of observational research among cancer survivors by comparing characteristics of participants and nonparticipants, sensitivity analysis demonstrated that quality of life might be lower among nonparticipants [34]. As RCT participants may have a systematically higher quality of life or report fewer symptoms compared with nonparticipants, observed outcomes may represent a group of healthier patients with better outcomes. This may lead to circumspection in generalizing the results of an RCT to the target population. It is important to keep this in mind when interpreting RCT results that may only represent a minority of the target population.

Conclusions

The participation rate in the RCT was 25%. RCT participants may be not representative of the target population owing to different sociodemographic and clinical characteristics. RCT results should be considered with caution, as RCT participants represent a minority of the target population, and may actually be those least in need of the intervention.

Acknowledgments

This study was financially supported by the Jonker-Driessen Foundation. The study funder had no role in study design; in the collection, analysis, and interpretation of data; in the writing of the report; or in the decision to submit the paper for publication.

Authors' Contributions

LPJA was responsible for patient recruitment, data collection, data analysis, and drafting the manuscript. SO was responsible for data collection and was a major contributor to drafting the manuscript. EFMP, DEI, MO, RvdG, and MRN were responsible for

data collection and contributed to writing the manuscript. LVvdP-F was project leader and was a major contributor in drafting the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Unhealthy nutrition contributes to the worldwide rising prevalence of noncommunicable diseases. As most adverse reproductive outcomes originate during the periconception period, effective interventions targeting this period are needed. Therefore, we developed the lifestyle intervention Smarter Pregnancy to empower women to adapt a healthy diet prior to conception and during early pregnancy and performed a randomized controlled trial.

Objective: The objectives of this trial were to investigate compliance and effectiveness in women using the Smarter Pregnancy program.

Methods: Women aged between 18 and 45 years who were contemplating pregnancy or <13 weeks pregnant and their male partners living in the urban area of Rotterdam, the Netherlands, were eligible for participation. After baseline screening, the intervention group received personal online coaching based on identified inadequate intakes of vegetables, fruits, and folic acid supplements. The sum of these risk factors was used as a dietary risk score (DRS), ranging from 0 (healthy) to 9 (unhealthy). The control group did not receive coaching. We applied an intention-to-treat principle and used a multivariable linear regression model to evaluate the change in DRS after 24 weeks. Compliance was defined as the percentage of women who completed the screening questionnaire at 24 weeks.

Results: Of women recruited, 81.2% (177/218) completed the program (intervention: 91/218, 83.5%; control: 86/218, 78.9%; *P*=.95). After 24 weeks, the reduction in DRS of women in the intervention group was significantly larger than in the control group (β=.75, 95% CI 0.18-1.34). This reduction was mainly due to increased vegetable intake (β=.55, 95% CI 0.25-0.86).

Conclusions: The high compliance and the larger improvements in nutritional behaviors, especially vegetable intake, in women in the intervention group emphasizes the effectiveness of empowering women by using the lifestyle change intervention Smarter Pregnancy.

KEYWORDS

mHealth; preconception care; nutrition; pregnancy

Introduction

Unhealthy nutrition contributes to the development of noncommunicable diseases (NCDs) such as obesity, diabetes, and cardiovascular and metabolic disease [1-5]. In recent decades, the worldwide prevalence of NCDs and corresponding mortality rates have increased rapidly [6]. Vitamin deficiencies and high caloric intake combined with inadequate physical exercise are key risk factors for metabolic and endocrine derangements that contribute to obesity and a wide spectrum of NCDs [7-9]. These risk factors are also highly prevalent in women and men during the reproductive phase of their life, with significant consequences for fertility, growth, and development of the offspring [10-17]. Moreover, unhealthy nutrition and lifestyle also confer increased transgenerational risks for offspring in developing NCDs in later life [2,5,18-20].

There is increasing evidence for a need for effective interventions to improve nutrition and other modifiable risk factors in women who are contemplating pregnancy, particularly in the periconception period (ie, the period 14 weeks prior to conception up to 10 weeks after conception) [19,21]. As most adverse reproductive and pregnancy outcomes originate during this period, it is considered the earliest window of opportunity for interventions. However, since the periconception period is often neglected in regular health care, with specific periconception care rarely implemented, the prevalence of these modifiable risk factors still remains very high in the population of reproductive age [10,22].

In order to translate the scientific evidence currently available into accessible periconception care, various barriers need to be overcome. These barriers include the lack of intrinsic motivation for changing lifestyle in the target population; low levels of awareness; and a lack of clarity regarding responsibility, organization, and costs [23-26]. One way of overcoming some of these barriers is to make use of recent developments in electronic health (eHealth). These include using the broad range of functions available on mobile phones and handheld devices, with or without internet access, also known as mobile health (mHealth) [27,28]. Indeed, the global use of smartphones has opened new doors for health care delivery: new and innovative approaches in the fields of preventive and personalized medicine can provide patients with both general information and individualized content [27,29,30]. In 2011, we launched a lifestyle change intervention called Smarter Pregnancy that aims to empower women and men to adopt healthy nutrition and lifestyle behaviors before and during pregnancy. This program is based on models for behavior change and existing evidence regarding the impact of nutrition and lifestyle on fertility and maternal pregnancy and birth outcomes and provides individual coaching on five major risk factors: inadequate vegetable, fruit, and folic acid supplement intake and smoking and alcohol consumption [10,12,13,28,31-34]. Since an inadequate daily intake of fruit and vegetables are the most prevalent risk factors for unhealthy nutrition and users appreciate interventions that are as simple as possible, we hypothesized that stimulating the intakes of these healthy food groups would result in a more balanced and healthy diet and lifestyle in general. We designed a randomized controlled trial to determine compliance with the Smarter Pregnancy intervention and investigate whether use of the program empowers women to improve nutrition prior to conception and during early pregnancy.

Methods

Trial Design, Participants, and Recruitment

A detailed study protocol is published elsewhere [34]. In short, women between aged 18 and 45 years were considered eligible for inclusion in this study if they were in possession of a smartphone with internet access, resided in the Netherlands, and were contemplating pregnancy or already pregnant (<13 weeks of pregnancy). We excluded women if they had insufficient knowledge or understanding of the Dutch language, if they were being treated by a dietician to lose weight in the context of fertility treatment, or if they were on a vegan diet. Body mass index (BMI) was not an exclusion criterion. Dutch-speaking male partners with smartphones were also invited to participate unless they were receiving dietary advice or were on a vegan diet.

We performed a single-center, open randomized controlled trial in the urban area of Rotterdam, the Netherlands. There was no blinding of participants, involved health care professionals, or involved researchers. Women eligible for inclusion were invited to participate by a health care professional working in one of the following locations in this area: one academic hospital, four teaching hospitals, four midwifery practices, and several children's daycare and child health centers. After online registration, each woman was contacted by a researcher to verify her eligibility, provide her with more details about the study, answer any questions about the Smarter Pregnancy program, and confirm her inclusion in the study. After the researcher had verified the eligibility of women willing to participate in the study, inclusion occurred by signing an online (ie, digital) patient informed consent form, which was sent by email to the participant through a secure study email account. Participants were asked to print and sign the informed consent form to ensure compliance with the guidelines laid down in the Declaration of Helsinki. Participants were able to resign from the study at any time without having to give a reason. All procedures involving patients were approved by the medical ethical and institutional review board of the Erasmus Medical Center, University Medical Centre, Rotterdam, the Netherlands. Trial was registered at Netherlands Trial Register [NL3927].

Randomization

Randomization was stratified according to the location from which the participants had been recruited. A preprogrammed permuted blocking design (two intervention and two control allocations per block) ensured that the number of women from the different locations was balanced between the two treatment groups and allocation into groups was concealed from the researchers. Men were always assigned the same group as their female partner.

Intervention

The design and development of the lifestyle change intervention led to the availability of two versions that we could use in our study: a full version that included all functionality and

personalized interaction (the intervention), and a modified version that had limited functionality and no personalized interaction, which was used in the control group. Detailed information on the program can be found in the study protocol [34]. Because the focus of this study was on evaluating the change in the intakes of vegetables and fruits, details on the intake of other food groups and cessation of smoking and alcohol consumption are not further addressed.

Men and women in the intervention group received tailored coaching based on their answers of the baseline questionnaire to questions regarding vegetable, fruit, and folic acid supplement intake. Vegetable intake and fruit intake were both subdivided into a risk score of 0, 1.5, or 3, where 0 represented an adequate daily intake (vegetable intake of ≥200 grams per day or a fruit intake of ≥2 pieces per day). A score of 1.5 represented a nearly adequate intake (vegetable intake of 150 to 200 grams per day or a fruit intake of 1.5 to 2 pieces per day). A score of 3 represented an inadequate daily intake (vegetable intake <150 grams per day or a fruit intake of <1.5 pieces per day). Folic acid supplement use was considered adequate (score 0) or inadequate (score 3) based on the international recommended dose of 400 µg per day. The dietary risk score (DRS) was calculated as the sum of the scores for vegetable, fruit, and folic acid supplement intake, thus ranging from 0 to 9 in women, in which 9 was the most unhealthy risk score. In men, the DRS ranged from 0 to 6, as they did not receive any coaching regarding folic acid supplement use.

The tailored coaching comprised a maximum of three emails or text messages per week. These emails and messages contained seasonal recipes, incentives, feedback, recommendations, and additional questions regarding the participant's diet. Progress regarding the adoption of healthy behavior was monitored using online questionnaires at 6, 12, 18, and 24 weeks in the intervention group, while the control group only received these questionnaires at 12 and 24 weeks.

The first follow-up study questionnaire was sent at 36 weeks (ie, 12 weeks after the final screening questionnaire) and contained the same questions on nutrition, lifestyle, and pregnancy status as the other online questionnaires at baseline, 12, and 24 weeks.

All participants were given access to a personal online webpage that provided access to additional modules (ie, apps) that promoted physical activity, a calendar to improve compliance with hospital appointments and taking their folic acid supplements, and a module to monitor the safety of any prescribed medication.

Outcome Measures

The main outcome measures of this study were compliance of all participants, defined as the percentage of participants who completed the online screening at 24 weeks, and degree of improvement in nutrition in women 24 weeks after starting the Smarter Pregnancy program, as reflected by a reduction in the DRS.

Statistical Analysis

We analyzed data from all participants, those who completed the Smarter Pregnancy program and those who resigned prematurely, whereby missing data were handled using the last-observation-carried-forward method.

For all participants, the DRS was calculated at baseline (t=0), 12 weeks (t=12), and 24 (t=24) weeks. In further analyses, we included all women with a DRS>0 at baseline since these women were able to improve unhealthy behaviors and thereby reduce their risk scores. The primary analysis was based on intention to treat. The difference in differences principle was used to analyze the continuous outcome measures used in a multivariable linear regression model, adjusted for the baseline value of the DRS. Bootstrapping was performed on all analyses because residuals of the linear regression analyses were not normally distributed [35]. All analyses were performed using SPSS Statistics for Windows version 21.0 (IBM Corp). The analyzed dataset of this trial will be available from the corresponding author upon reasonable request.

Patient Involvement

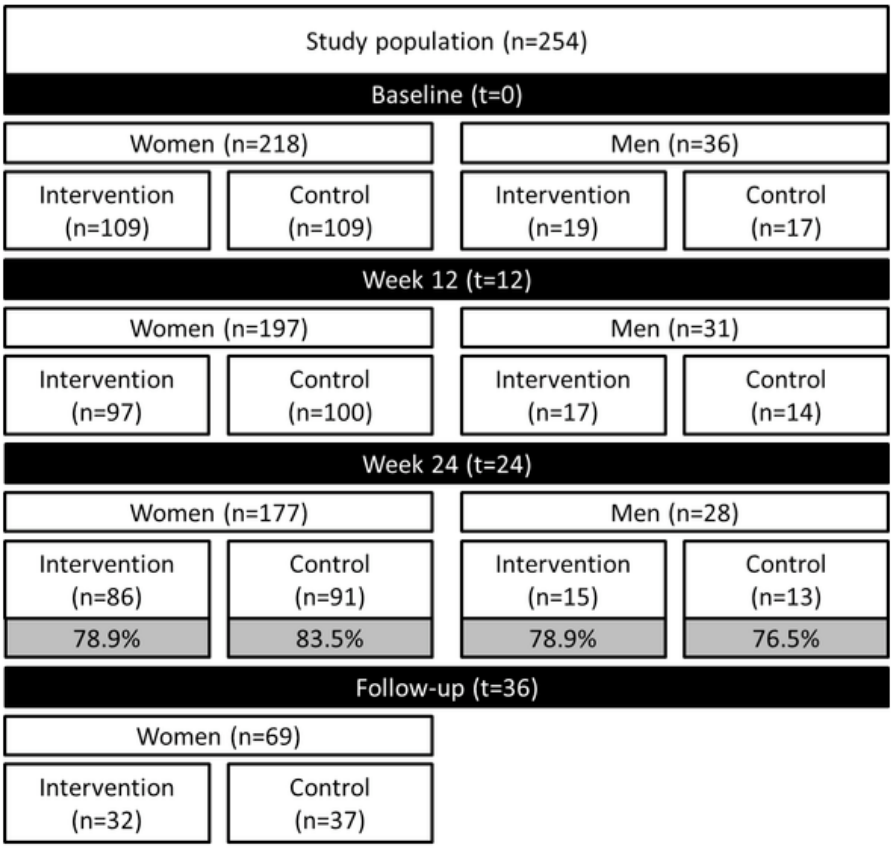
The design of this trial was based partly on patient evaluations obtained during a survey of the Smarter Pregnancy program [12]. During this study, we also received questions and feedback from participants, which we used to optimize trial procedures and improve participant satisfaction.

Results

Participant Characteristics

The study was open from May 2014 until January 2017 and included 218 women and 36 men. After randomization, the intervention group consisted of 109 women and 19 men and the control group of 109 women and 17 men (Figure 1). Baseline characteristics of all women in the study population are shown in Table 1. Median age, median BMI, pregnancy status, and partner participation were similar for women in the intervention and control groups. In our population, the BMI of all participants ranged between 16.3 to 45.9 kg/m^2. In both groups, most women were highly educated and of Dutch origin.

Figure 1. Flowchart of the study population stratified by sex.



Regarding nutrition and lifestyle, in both groups almost two-thirds of women reported an inadequate vegetable intake. Fruit intake was inadequate in about one-third of women in both groups. In both groups, almost 1 in 10 women reported inadequate folic acid supplement use. These figures resulted in a median DRS at baseline of 3 in both groups. The baseline characteristics of the participating men are shown in Multimedia Appendix 1; in both groups, men had a higher DRS and a higher prevalence of smoking compared with women.

Table 1. Baseline characteristics of all women in the intervention and control groups.

Characteristics	Intervention n=109	Control n=109
Age in years, median (IQR[a])	30.6 (5.3)	30.7 (5.7)
Height (cm), median (IQR)	170.0 (9)	170.0 (9)
BMI[b] (kg/m^2), median (IQR)	24.2 (6.0)	23.7 (5.4)
Pregnant at enrollment, n (%)	36 (33.0)	37 (33.9)
Partner participation, n (%)	19 (17.4)	18 (16.5)

[c]DRS: dietary risk score.

Compliance and Dropout

Of women entering the study, compliance was 81.2% (177/208). In the intervention group, compliance was 78.9% (86/109) and in the control group 83.5% (91/109; *P*=.95). In men, overall compliance was 77.8% (28/36), with 78.9% (15/19) in the intervention group and 76.5% (13/17) in the control group (*P*=.59). When we compared the baseline characteristics of all women who completed the program (n=177) with those of women who resigned prematurely (n=41), we observed that women who resigned prematurely had a significantly higher median DRS (*P*=.007) and a significantly lower level of education (*P*=.01; Table 2).

Table 2. Baseline characteristics of all women, stratified by compliance, defined as whether they completed the questionnaire at 24 weeks or resigned before this time point.

Characteristics	Completed n=177	Resigned n=41	*P* value
Age in years, median (IQR[a])	30.8 (6.0)	30.1 (6.0)	.33
Height (cm), median (IQR)	170 (10.0)	169 (8.0)	.86
BMI[b] (kg/m^2), median (IQR)	23.4 (5.8)	25.6 (4.5)	.13
Pregnant at enrollment, n (%)	63 (33.9)	10 (31.3)	.77

Smoking, n (%)	13 (7.0)	4 (12.5)	.28

[a]IQR: interquartile range.

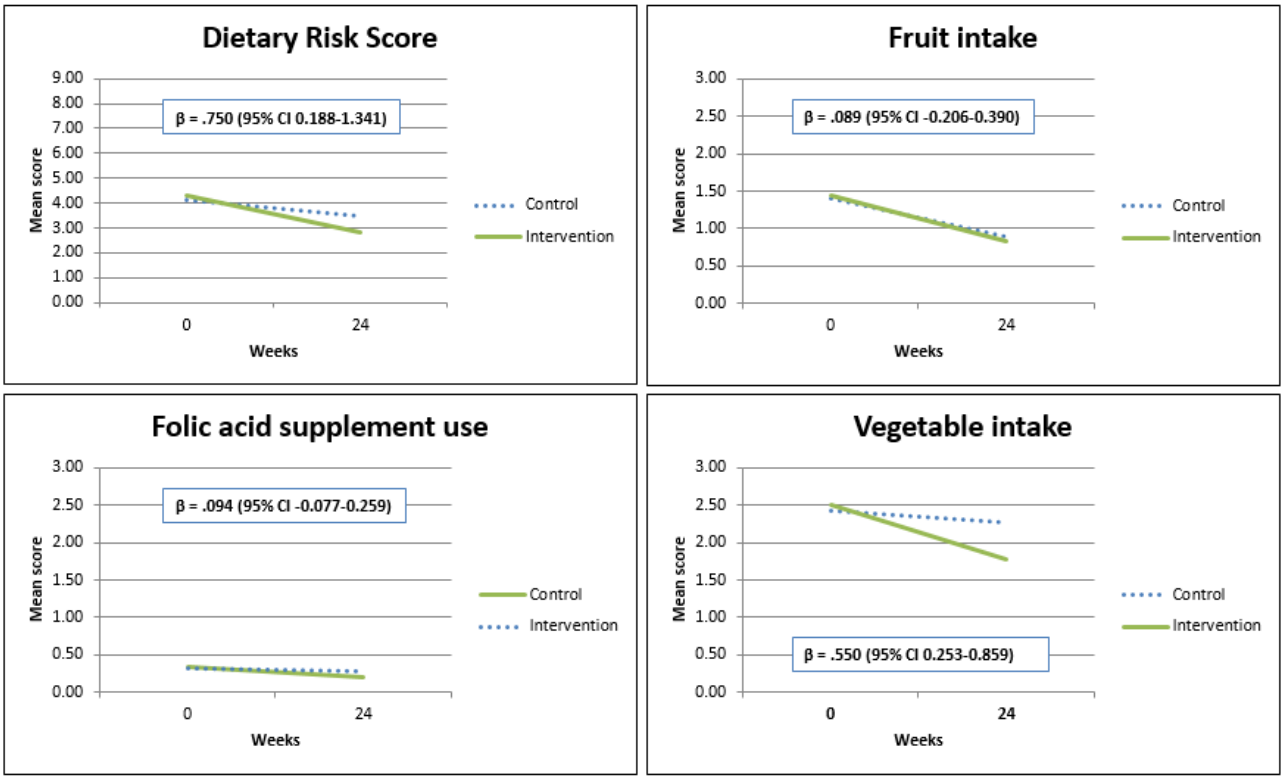
[b]BMI: body mass index.

[c]DRS: dietary risk score.

Dietary Risk Score

The outcomes of the multivariable linear regression model regarding the DRS and separate risk factors are depicted in Figure 2. Compared with participants in the control group, participants in the intervention group showed a significantly larger reduction in the DRS (β=.750; 95% CI 0.188-1.341), in particular for vegetable intake (β=.550; 95% CI 0.253-0.859). There were no significant differences between groups regarding fruit intake and folic acid supplement intake.

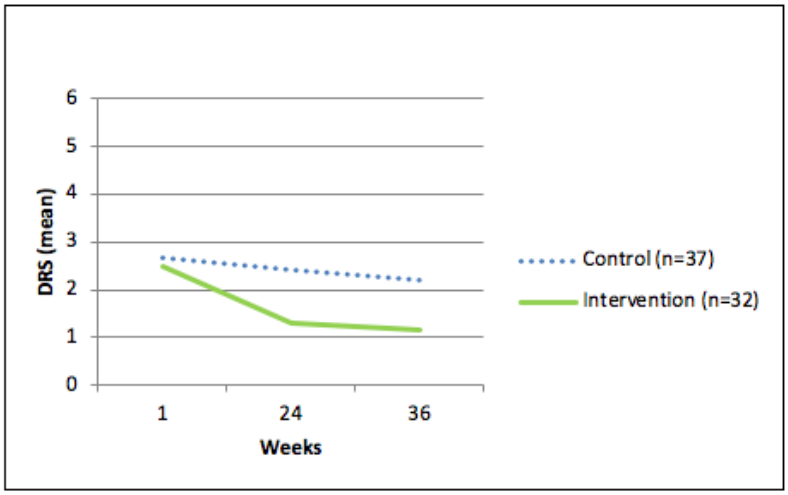
Figure 2. Dietary risk score (DRS) and separate risk factors over time in all women (with a baseline DRS>0) in the intervention and control groups. The linear regression model includes adjustment for baseline DRS and randomization.



Follow-Up

A total of 69 women (27.1%) completed the follow-up questionnaire 36 weeks after randomization. Although women did not receive any coaching during the period between 24 and 36 weeks, the mean DRS appeared to continue to decrease in both the intervention group (n=32) and control group (n=37; Figure 3). All men were lost to follow-up regarding the questionnaire at 36 weeks.

Figure 3. Mean dietary risk score (DRS) over time in all women who completed the follow-up questionnaire at 36 weeks (n=69).



Discussion

Principal Findings

The results of this randomized controlled trial indicate that compliance with the empowering lifestyle change intervention Smarter Pregnancy is high. Our findings also demonstrated that the use of this program improved the intake of vegetables (in particular) in women prior to conception and during early pregnancy. The follow-up results also suggest that this intervention had a positive effect on the continuation of healthier nutrition intake 12 weeks after stopping the intervention.

Strengths and Limitations

Major strengths of this study are the randomized controlled trial design, the fact that we used a standard and light version of the Smarter Pregnancy intervention, and the uniform collection of data in both the intervention and control group at baseline, 12,

24, and 36 weeks. By providing the control group with limited information and interaction, we encouraged participants in this group to adhere to the program, thereby ensuring high compliance and preventing dropout. The high compliance rates observed in both groups support this strategy. A further strength is that a wide range of professionals and non–health care professionals recruited women for the study, as women were approached not only during a scheduled hospital or midwifery visit, but also at children's day care centers, for example. Women who had not been personally invited could also enroll via the website we set up, thereby limiting selection bias. Additional strengths of this study are the longitudinal observations, the fact that male partners also participated, and that we collected additional information regarding lifestyle factors, educational level, geographic origin, and pregnancy status at enrollment.

In terms of weaknesses, we experienced difficulties enrolling a sufficient amount of women in the preconception period, which was the reason we expanded our inclusion criteria to include women up to 13 weeks of pregnancy. This meant that our sample size was limited, which prevented us from carrying out subgroup analyses that would have provided additional quantitative data regarding lifestyle, fertility, pregnancy course and outcome, and cost effectiveness.

We decided to reduce the total number of questionnaires in the control group from 4 to 2 because we expected that further reduction of the number of questionnaires to 1, or even 0, would have led to a higher number of resigning participants. This led to a difference in questionnaire administration, which can be considered a limitation.

A further limitation was that the program Smarter Pregnancy was only available online and in the Dutch language, thereby excluding women who have insufficient knowledge of this language or no internet access from participation in this trial. This might have excluded a high-risk population of women who might have benefitted the most from the program. An English version of this program will be released very soon.

Comparison With Other Studies

To date, there is little scientific evidence for the success of nutrition and lifestyle interventions during the preconception or periconception period. Most studies regarding preconception interventions have focused on micronutrient supplementation or weight gain, for example [36,37], or on specific subgroups and disease-related conditions, such as fertility treatment [38], polycystic ovary syndrome [39], or pre-existing/gestational diabetes [40,41]. Even fewer studies have looked at interventions on the mobile phone specifically focused on the preconception and periconception periods [40,42].

The small amount of scientific evidence regarding mHealth during the periconception period mainly showed comparable results regarding the prevalence of unhealthy nutrition and lifestyle, especially insufficient fruit and vegetable intake and smoking. These and other studies also showed and specifically addressed the relatively high dropout rates among all users [43-46]. There is a clear need for high-quality evidence that intervening in these periods in general is indeed effective, since many studies could also not demonstrate significant effectiveness [45,47,48]. A key problem underlying this lack of evidence is the lack of awareness of the importance of periconception care among both patients and health care professionals, resulting in low adherence and uptake of such care. This was described in 2002 by De Weerd et al [49]. While this barrier is widely acknowledged, and various studies have focused on how to overcome it, unfortunately barriers still remain [24,28,50,51]. It has been suggested that modern marketing campaigns such as those increasingly found online might help to overcome or at least lower this barrier [30]. Taking this into account, together with the wide uptake of mobile devices and online information [52], we believe that our approach—using a personalized intervention on the mobile phone specifically targeted at identifying and improving periconceptional risk factors—can contribute to lowering the unawareness barrier.

Conclusions and Future Perspectives

To our knowledge, Smarter Pregnancy is the first intervention on the mobile phone showing effectiveness in empowering women to improving healthy nutrition before and during early pregnancy. We therefore consider this study a good example of a successful intervention study, of which the findings support the considerable potential of using mobile phone apps. Current awareness among health care professionals of their responsibility to inform their patients about healthy nutrition is very low [53]. However, we assume that the increasing amount of evidence for the importance of nutrition in the periconception period will make health care professionals particularly more aware and make them more likely to recommend evidence-based interventions to their patients. This will contribute to an increase in the general awareness of the importance of the periconception period. As a result, we hope that periconception care will become more easily and more widely accessible, thereby improving reproductive and pregnancy outcomes in both fertile and subfertile couples.

Acknowledgments

This research was funded by the Department of Obstetrics and Gynecology, Erasmus Medical Center, University Medical Centre, Rotterdam, the Netherlands; a grant from the Netherlands Organisation for Health Research and Development (ZonMW) Health Care Efficiency Research program; and the Erasmus Medical Center Mrace Health Care Efficiency Research program. We would like to thank all women and men who participated. We also would like to thank all health care professionals involved in the recruitment of participants at the midwifery practices, hospitals, children's day care centers (KindeRdam), and child health centers in the Rotterdam region. We thank Sally Hill of Scientific Texts for critical review of the manuscript. We would also like to thank Peercode BV, Lukkien, and OGD for their technical support and the AS Watson Group for supplying incentives and vouchers.

We also thank Prof Hans Severens and Prof Hein Raat for their help in applying for funding. The analyzed dataset of this trial is available to all involved researchers and collaborators and can be provided by the corresponding author on reasonable request. To gain data access, requestors will need to sign a data access agreement.

Authors' Contributions

MRVD contributed to the design of the study, data acquisition, and writing of the manuscript. MPHK contributed to data analysis and writing of the manuscript. ECO contributed to data acquisition. SPW wrote the statistical analysis plan. EAPS was responsible for preconceptional care, facilitated the recruitment of participants, and critically reviewed the final version of the manuscript. RPMST initiated and developed the Smarter Pregnancy program and was responsible for all aspects of the study as well as contributing to all versions of the manuscript. All authors critically revised the manuscript for intellectual content and read and approved the final version.

Conflicts of Interest

Since 2016, RPMST has been Chief Executive Officer of eHealth Care Solutions. The other authors declare no competing interests.

Abstract

Background: With the global rise in chronic health conditions, health care is transforming, and patient empowerment is being emphasized to improve treatment outcomes and reduce health care costs. Patient-centered innovations are needed. We focused on patients with chronic myeloid leukemia (CML), a chronic disease with a generally good long-term prognosis because of the advent of tyrosine kinase inhibitors. However, both medication adherence by patients and guideline adherence by physicians are suboptimal, unnecessarily jeopardizing treatment outcomes.

Objective: The aim of this study was to develop a patient-centered innovation for patients with CML using a design thinking methodology.

Methods: The 5 phases of design thinking (ie, empathize, define, ideate, prototype, and test) were completed, and each phase started with the patient. Stakeholders and end users were identified and interviewed, and observations in the care system were made. Using tools in human-centered design, problems were defined and various prototypes of solutions were generated. These were evaluated by patients and stakeholders and then further refined.

Results: The patients desired (1) insights into their own disease; (2) insights into the symptoms experienced, both in terms of knowledge and comprehension; and (3) improvements in the organization of care delivery. A web-based platform, CMyLife, was developed and pilot-tested. It has multiple features, all targeting parts of the bigger solution, including a website with reliable information and a forum, a guideline app, personal medical records with logs of symptoms and laboratory results (including a molecular marker and linked to the guideline app), tailored feedback based on the patients' symptoms and/or results, screen-to-screen consulting, delivery of medication, and the collection of blood samples at home.

Conclusions: The multifeatured innovation, CMyLife, was developed in a multidisciplinary way and with active patient participation. The aim of developing CMyLife was to give patients the tools to monitor their results, interpret these results, and act on them. With this tool, they are provided with the know-how to consider their results in relation to their personal care process. Whether CMyLife achieves its goal and the evaluation of the added value will be the focus of future studies. CML could become the first malignancy for which patients are able to monitor and manage their disease by themselves.

Introduction

Background

In 2002, the World Health Organization reported about expecting dramatic changes in global health because of the rising prevalence of chronic health conditions, underscoring the necessity for innovations in health care to effectively manage long-term health problems [1], which also requires a shift in the traditional roles of physicians and patients. The growing involvement of patients in their own care process and self-management needs to be stimulated [2] as this could improve the health outcomes of treatment and reduce health care costs [3]. Ideally, care for chronic illnesses should be patient-centered, resulting in an increased understanding and awareness of health, treatment options, symptoms, and behaviors [4,5]. This patient-centeredness should be of major focus when facilitating innovation in health care. In other sectors, involving the end user of a product in its development is a common practice, and different kinds of human-centered approaches are available [6]. One of these approaches is *design thinking*. Although a universal definition is missing, the solution-focused methodology is best described as "a discipline that uses the designer's sensibility and methods to match people's needs with what is technologically feasible and what a viable business strategy can convert into customer value and market opportunity" [7]. By engaging the end user from the beginning of the process, solutions are developed bottom-up instead of top-down [8]. Nowadays, design thinking is also gaining ground in the field of health care and health care education [9-13]. Design thinking and user-centered design are quite similar and start from the same standpoint—the user. The steps of both processes are quite comparable. However, design thinking emphasizes the ideation phase and focuses on finding solutions and has a specific set of tools.

Objective

This paper aimed to describe the development and pilot testing of a patient-centered innovation that can change the current model of health care. As starting with small and rapid prototyping is key, we started with changing care for a specific group of patients (ie, patients with chronic myeloid leukemia [CML]). This malignant disease results from a reciprocal translocation between chromosomes 9 and 22, generating an abnormal Philadelphia chromosome. The resulting *BCR-ABL1* fusion gene encodes for a constitutively active tyrosine kinase, which is pivotal in the pathogenesis of CML and can be inhibited by tyrosine kinase inhibitors (TKIs). With the advent of TKIs, CML became a chronic disease rather than an often fatal one [14,15]. As with many chronic diseases, therapy compliance and guideline adherence are challenging. The paramount step in the monitoring of patients with CML is the quantification of *BCR-ABL1* transcripts with a polymerase chain reaction on peripheral blood, which represents disease activity [16]. The recommendations for the monitoring of patients with CML are defined in international guidelines [16,17]. However, guideline adherence by physicians is often suboptimal [18-20], which is associated with a higher risk of progression to an advanced phase of the disease and death [21]. Another challenge in CML care comprises suboptimal adherence to TKIs by patients, which in part relates to the adverse events (AEs) caused by TKIs [18,21-24]. Common AEs are muscle aches and cramps, fatigue, gastrointestinal symptoms, and fluid retention, among others [25,26]. AEs are the main cause of intentional nonadherence. The adequate management of AEs is a necessity, as an adherence rate of ≤90% is clearly related to a lower probability of reaching important treatment goals [22]. Furthermore, physicians tend to underestimate the severity of AEs experienced by patients and overestimate the patients' overall health status [27].

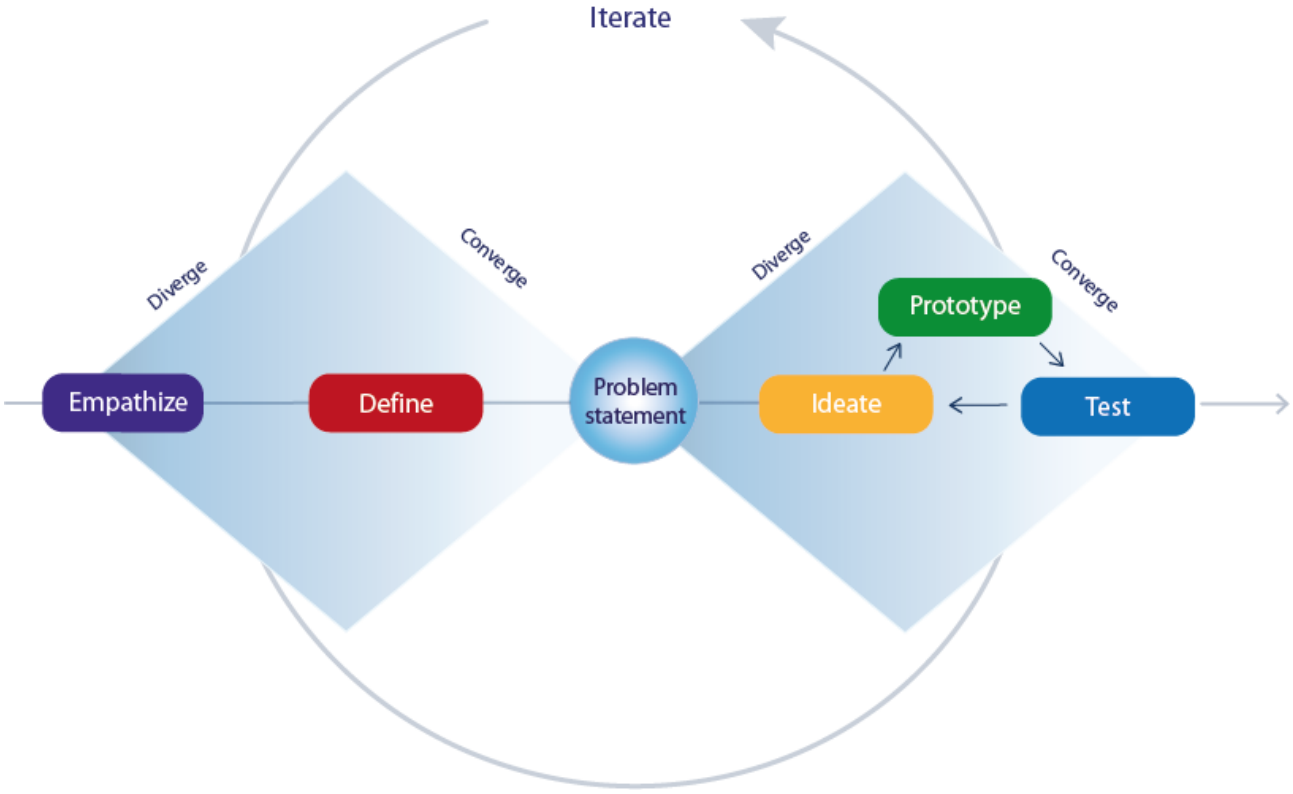
By transforming CML care into a patient-centered care model, the self-management of monitoring and intake of TKI can be stimulated, resulting in improved health outcomes and the involvement of patients in their own care process. Hence, CML is pre-eminently suited for developing an innovative patient-centered care model.

Methods

Overview of the Study Design

The design thinking methodology [28] was used for the development of the innovative patient-centered care model. It comprises the following 5 phases: empathize, define, ideate, prototype, and test. We started with the key element of every phase, ie, the end user, and in our case, the patient. Pilot evaluations of the developed innovation were performed by focus group interviews with patients. Design thinking is a dynamic process where phases can run parallel or in iterative circles based on new insights or feedback. Going back is possible at any moment during the process. Generally, it can be visualized in the shape of 2 diamonds: first diverge in empathizing, then converge and define a problem, then again diverge and converge, generating ideas for a solution and prototyping and testing the right solution, respectively. Figure 1 represents this process and is adapted from an illustration developed by Jasper Liu [29].

Figure 1. The double diamond model depicting the essentials of the design thinking process.



Setting

The project has been established by a collaboration among hematologists at 3 hospitals in the Netherlands, the Dutch hematological patient advocacy group, *Hematon*, and the Reshape and Innovation Center of Radboudumc. A multidisciplinary project team was formed to coordinate the process, comprising patients, health care professionals, designers, developers, and a communication specialist, thereby representing both the participating and the developing parties. The study was approved by the institutional review board of the Radboudumc.

Phase 1: Empathize

The understanding of the end users and their needs, desires, and challenges in everyday life is crucial and should be explored. To do so, we conducted in-depth interviews with patients and hematologists until data saturation was reached. The interviews were conducted by the user-centered designers of the project team. The patients were asked to participate during a national meeting of the patient association *Hematon* or were approached by their hematologists. The hematologists were approached via professional associations. Furthermore, field observations of different parts of the patient's journey in the health care system were made. These observations took place in pharmacies, in waiting rooms, during blood sample collection, and at the outpatient clinics during consultations with the hematologists. A checklist was used to evaluate a certain set of items (eg, providing information on prescription medication, waiting time). Communication science students conducted the observations and were supervised by the project team. All information gathered in this phase was clustered into themes to identify connections. Furthermore, a stakeholder analysis was made, with the aid of stakeholder mapping, to identify all stakeholders.

Phase 2: Define

During this analyzing phase, all information gathered in the *empathizing phase* was translated into a problem statement: an expression of the problem we were aiming to address. The statement had to be human-centered, broad enough for creative freedom and narrow enough to make it manageable [30]. Therefore, tools such as affinity clustering, the 5 whys, frameworks, and creating a point of view were used [31-33]. The statement was defined by the project team in an iterative process until consensus was achieved.

Phase 3: Ideate

Here, the goal was to generate the broadest range of ideas for design as possible, preferably from different stakeholders' perspectives. We started ideating with a selection of the project team comprising at least a designer, patient, developer, and health care professional. Subsequently, the ideas were shared and modified by the entire project team. By asking "how might we" questions, the information gathered in the previous phases was converted into requirements of the innovation. It was key to strive for as many ideas as possible to solve parts of the problems and not just for one idea to solve the whole problem. In this manner innovation concepts could be formed and tested on a small scale.

Phase 4: Prototype

We started with rapid prototyping by developing many low-resolution (quick to make and without much expenses) prototypes, eg, screenshots of possible apps and websites. These were tested early in the process and immediately refined after

feedback from the end users and stakeholders. Feedback was collected during the test sessions with small groups of end users. In addition, meetings were held with the project team, complemented by the representatives of different stakeholders. If additional information was found to be missing or new ideas came up, the previous phases were repeated.

Phase 5: Test

This phase ran partially parallel with the prototype phase where every feature from the mock-up to concept product was tested iteratively with the end users. Eventually, a pilot test was run on a small scale at the Radboudumc (the center where the project team was situated). A stepwise workflow was developed, containing the tasks and requirements that had to be fulfilled at each step and the person who had to fulfill these in the first 12 months. To create awareness of the innovation, a communication plan was developed for both patients and health care professionals. In the prototype phase, the prototypes were tested in small groups of mostly patients (4-6 patients). During the pilot test, focus groups were conducted with the help of a structured interview guide (Multimedia Appendices 1 and 2). They were conducted with groups of patients and hematologists. Participants were approached via the website of the innovation, *Hematon*, and professional associations. The first focus group comprised 4 patients and 1 patient's caregiver (3 males and 2 females, aged 54-72 years). In the subsequent focus group, 7 patients participated. They were interviewed about the introduction to and awareness of the innovation, practical issues in utilizing it, layout, content, and the added value in one's own life. Another focus group was conducted with 13 hematologists, following a CML-focused national working group. The topics were similar to those in the patients' focus groups (see Multimedia Appendix 2 for the interview guide). Quantitative data on the usage of the innovation's website and different mobile features were established at 12 and 16 months using Google Analytics and data from the third parties involved, respectively.

Results

Phase 1: Empathize

Overall, 8 patients (data saturation was reached) were interviewed to understand their experiences and explore their needs and desires. The mean age of these patients was 53 years (range 28-75), and 75% (6/8) were male. Each interview lasted between 60 and 90 min. The patients' strongest wish was to be cured of the disease; however, 3 other wishes were mentioned almost unanimously. First, insights into their disease, with more knowledge and comprehension, were desired (for instance, "Am I doing well or not?" and "Where am I in my disease course?"). Second, they wished for better support in understanding and coping with the symptoms they experienced (eg, "I'm having a hard time summarizing all the symptoms of the past 3 months before consultation" and "How can I explain [to] my family and friends what the impact is on my daily life?"). Finally, they wished for improvements in the organization of care delivery. The journey to the hospital and different appointments (ie, hematologist, nurse specialist, blood sample collection, pharmacy) at different times and multiple locations were considered to be time-consuming, apart from the time spent in a waiting room.

A total of 14 hematologists (9 working at a university hospital and 5 at a nonuniversity hospital) were interviewed, and they mentioned the following desires: to empower the patient, better insight into the patient-reported experiences and outcomes, improvement of guideline adherence, and providing care only when medically needed or when desired by the patient.

In addition, 34 observations (data saturation was reached) in the outpatient clinic, during blood testing, or in the pharmacy were made to fully understand the patients' journey. The observations were not connected to the patients interviewed and took place during different parts of the day. Lengthy waiting times were the biggest issue in almost all observations as well as receiving too little information regarding the prescription medication at the pharmacy. Altogether, the role of the patients was too small in their own care process, and adequate tools to take the lead were lacking.

The following stakeholders were identified: the patients as end users; health care professionals such as hematologists, general practitioners, and, to a lesser extent, pharmacists; molecular biologists; and health insurers.

Phase 2: Define

The objective of the innovation was defined as "to empower patients and facilitate them to take the lead in their own care process." As CML cannot be cured, we could not meet the biggest desire of curing the disease. However, it has recently become clear that it is feasible for patients to achieve a durable remission of the disease after discontinuation of their treatment [34,35]. This is referred to as *treatment-free remission* (TFR) and is considered to represent an *operational cure*. TFR is having a stable, deep molecular response without any ongoing TKI treatment. Patients in chronic phase CML who have maintained a stable and deep molecular response (for at least two years) are considered for TKI discontinuation. In an international consensus statement of patient representatives and doctors, TFR was adopted as a desirable goal of CML therapy in the context of adequate medical and psychological support [36]. It was established that optimizing guideline adherence and therapy compliance are prerequisites for achieving this goal.

Phase 3: Ideate

On the basis of the Define phase, the innovation should provide reliable information and instruments for the patients to gain insights into their own disease course and educate them in the subsequent steps. In addition, the innovation had to support patients when experiencing symptoms, whether disease-related or TKI-related. To reduce logistic struggles such as waiting times and to achieve availability for every patient with CML, the multidisciplinary project team decided that the innovation had to transfer part of the current care from the hospital to the personal environment of the patient.

Owing to the variety in problems, a variety of solutions were proposed, for instance, electronic health (eHealth) technologies to enhance knowledge and comprehension of the disease, provide a way to report and log symptoms, facilitate contact

among patients for both social support and sharing insights, improve the organization of care delivery, and eliminate unnecessary steps, and, in addition, a nurse specialist in both CML and electronic nursing, who can empower and educate patients with the aid of eHealth technologies. The multidisciplinary project team came up with a web-based innovation covering these different solutions to achieve the main goal of empowering the patient and making CML care more patient-centered by improving the quality of life, medication adherence, guideline adherence, treatment outcomes, and reducing organizational burdens of the care process.

Phase 4: Prototype

Low-profile prototypes varying in content and layout were made of various parts of the coordinating solution (eg, different graphs depicting *BCR-ABL1* values to select the most insightful one; Figure 2). Eventually, the iterative testing of the prototypes with the patients' focus groups resulted in the concept of a web-based platform called CMyLife, literally meaning *see my life* and referring to CML. The platform was extended by adding different features, with the patients deciding which features to use in their own care process. It comprised a public website containing reliable information on the disease; treatment (eg, AE profiles per TKI and TFR); other medical issues; the impact on social aspects, eg, sports and financial issues (Figure 3); and a patient-tailored part with additional features in a secure environment. These features have been described as follows.

Figure 2. Four examples of graphs depicting BCR-ABL1 values. Graphs B, C, and D have a colored area under the curve, in contrast to graph A. Furthermore, the percentages on the y-axis differ: graphs A, C, and D have percentages from 100 to ≤0.001, representing the number of BCR-ABL1 transcripts. Graph B has a positive approach with percentages from 9 to ≥99.999, representing the amount of healthy cells.

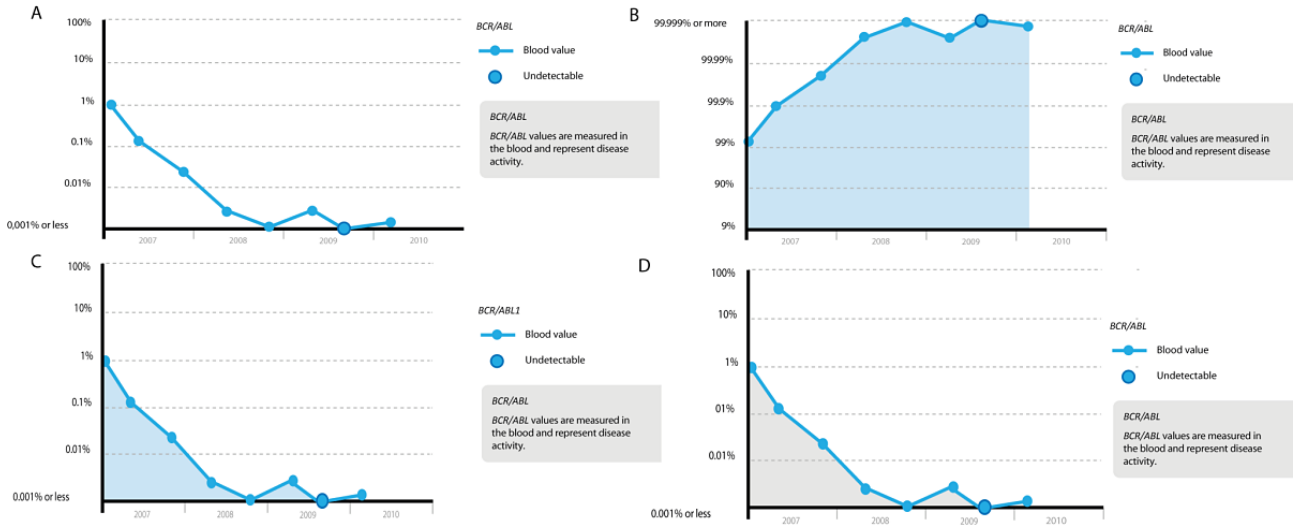


Figure 3. Screenshot of the CMyLife website.

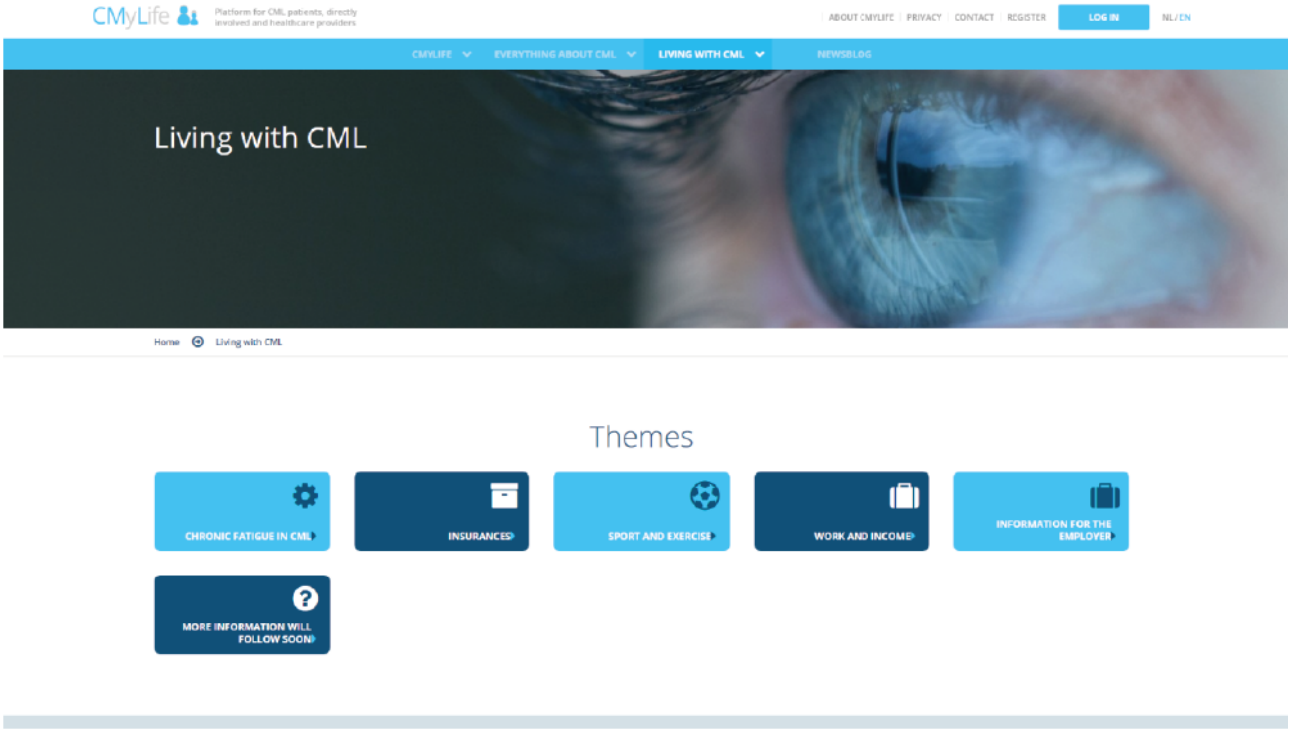

Forum

A forum was developed in a secured part of the platform, where patients could meet other patients and ask questions. It was monitored by 2 patient-experts and the community manager of the project team who can refer the questions to a hematologist, in case of medical questions.

Patients Know Best

Another feature is the Patients Know Best portal [37], where patients are in control of their personal medical record. They can grant access to the medical records to their health care professionals (including professionals other than hematologists) or choose to keep them private. For patients in the pilot hospital, a connection was made between the hospital's eHealth record and the Patients Know Best portal. In this way, laboratory results are uploaded to the Patients Know Best automatically.

MedApp

We reached out to the developers of the mobile phone app, MedApp, aimed at helping patients managing their medications [38]. This resulted in a *CMyLife module* that is linked to a patient's Patients Know Best portal in the app. In this module, patients can rate 10 frequent TKI-related symptoms daily on a 4-point Likert scale, resulting in a weekly or monthly overview. This can be used as a visual representation of the impact of CML on their daily life and can be shared with family and friends. If the patients share their Patients Know Best record with the hematologist, this can result in a more tailored consultation. Preparations are made to develop a feedback loop signaling the nurse specialist to contact the patient in case of grade 3 or 4 AEs.

Disease Activity

To provide insight into an individual's disease course, graphs depicting the molecular marker measured to monitor disease activity (*BCR-ABL1* transcript values) are uploaded in the Patients Know Best record, in collaboration with the local molecular laboratory (Figure 4).

Figure 4. Screenshot of the graph depicting BCR-ABL1 transcript values in a patient's own Patients Know Best record in the CMyLife environment. When a dot is selected, it shows the results and its date.

Guideline Application

The above-mentioned graph (Figure 4) visualizing the molecular marker levels is linked to the guideline app. This app contains an easy to understand stepwise explanation of the Dutch CML guideline for patients with CML in chronic phase using a first-line TKI [39]. On the basis of their last molecular response and moment of testing, patients receive advise, for example:

> *The response is optimal, you should continue with your medication.*
>
> *The response is not optimal. This can be due to medication interactions, skipping medication or progression of disease. Ask your hematologist about it on your next appointment.*

In addition, reminders are sent when patients should be tested again. Expanding the functionalities to second-line treatment and CML in other phases is planned for the near future.

Reducing Hospital Visits

Furthermore, organizational issues were addressed by the following features, all aimed at minimizing hospital visits.

Blood Samples

In collaboration with the Thrombosis Service, a service monitoring anticoagulant therapy in the Netherlands, which draws blood samples at home or nearby for patients with thrombosis using oral anticoagulants, patients with CML can get their blood samples drawn at home.

Pharmacy

TKIs are delivered to the patient's home by the pharmacy. In the MedApp's CMyLife module, patients can request the pharmacy directly for a new delivery when they are almost out of TKIs. Hence, a 12-month valid prescription is supplied by the hematologist.

Screen-to-Screen Consulting

Finally, patients are offered a screen-to-screen consultation with their hematologists. Consultation rooms were provided with the right equipment, and health care professionals were trained. Face-to-face consultations with the hematologist were reduced to once a year unless additional face-to-face physical consultations at the hospital were considered desirable by the patient. Between these visits, patients were supported through screen-to-screen consultations and the other features described above.

Security

All data were secured, and data protection conformed to the national and European privacy regulations (General Data Protection Regulation). The features containing data from the hospital's electronic health record (ie, laboratory results in their personal health record, website, and app) were secured with a password-protected log-in and subsequent token via an SMS text message for authentication. This is in accordance with the Dutch security guideline NEN7510. The forum is password protected.

Before the connection can be made between the hospital's systems and CMyLife, a patient has to register for a personal health record. Subsequently, their identity is checked based on

name, date of birth, postal code, and citizen service number. The personal medical record is International Organization for Standardization/International Electrotechnical Commission 27001:2013 certified.

Phase 5: Test

Focus Groups

Patients had different experiences of how and when CMyLife was introduced to them. Some preferred an introduction by the patient association *Hematon*, others by the hematologist. With regard to the practical issues in its utilization, it turned out that patients had little experience with the platform at this time ("I did not even know it existed"). A few content-specific suggestions were made, such as a small piece of information helping patients explain CML and its impact to others. Screen-to-screen consultations and having blood samples drawn at home received a positive response:

> *I really like the video-consulting, this way I am certain I don't have to waste a half day every 3 months or so.*
>
> *My consultations with my doctor never last longer than 3 minutes. "Everything looks fine, great, bye and see you next time." (...) What am I doing here. There are people who need the hematologist more than I do, especially when I'm doing well. I would prefer video-consulting, it saves time for the both of us.*
>
> *I receive a prescription from my doctor, go to the hospital pharmacy and a few days later I can pick up my TKIs, if I am lucky...And you always have to make a call on forehand to check if your order is ready. It is old-fashioned.*

Insights into individual laboratory results was desirable when combined with an easy-to-understand version of the guidelines ("We do not want our care to be dependent of which doctor is treating you, it should be the same everywhere"). The responses to registering symptoms and medication intake were variable as everyone could not imagine this to be beneficial to their management:

> *It involves extra steps and it can result in more work, though.*
>
> *I understand the advantage, a doctor can prepare the consultation.*

Hematologists were a little more reluctant regarding CMyLife. They could imagine the added value in improving patient empowerment and transferring care to outside the hospital. However, there were concerns regarding time investment, as time is a scarce resource in daily practice:

> *I think it is very important to provide care at home and for a patient to take the lead. The problem is that as a doctor, I don't want to have extra work, so it has to be very well facilitated.*
>
> *I think it can help improving adherence. Of course, patients only experience CML-related symptoms if it went wrong, if patients monitor their own results and see the numbers and decrease in log value, it could be stimulating to be really adherent to their medication.*
>
> *All our patients search the internet for information. What you want as doctors is provision of trustworthy information, I think that is an important goal of such a CMyLife intervention.*
>
> *I see potential; however, I also foresee many technical issues in connecting the CMyLife system to our hospital system.*
>
> *Through a system like this, you can diminish a lot of routine follow-up visits every 3 months, in order to create more time for other things.*

Another topic of concern was the growing development of (commercial) mobile interventions, all specified to just a specific disease and often focused on just one aspect of that disease:

> *An important barrier is the coordination with similar initiatives for other patients than CML patients. One universal solution is desirable. The strength of CMyLife is that it can be regarded as a blueprint that can be used for other diseases.*
>
> *Patients have comorbidities, some patients see a hematologists, cardiologist and other doctors, it would be preferable if CMyLife was not a stand-alone application.*

User Statistics

With regard to the user statistics of the CMyLife website, in the first year (December 2016-December 2017), CMyLife had 6334 unique visitors, with approximately 600 visitors per month for the last 6 months. Unique page views in the last 12 months were 36,300. Per session, 5.17 pages were visited on average, with the page containing the latest blogs and information on AEs having the most visits after the homepage and log-in page. A total of 338 users were registered, who were treated in 62 different hospitals. Per month, the forum was visited on an average of 150 times by 40 users. One-fifth of the visitors were new; 80% comprised returning visitors. A total of 677 users registered for the CMyLife module in MedApp, with 156 active users (ie, monthly use) in the last month.

Running and Expanding the Pilot

The publicly available website and online user forum were launched nationwide during *Hematon*'s information day on CML, on April 23, 2016. Gradually, we extended the other features for patients of the Radboudumc to test and refine CMyLife and prepare for further implementation. The workflow of the electronic consultations has been described hereafter. As the pilot was confined to patients of the Radboudumc, the additional features (ie, except the website and user forum) were separated from the public version of the tool.

Patients received a letter from their hematologist accompanied by a CMyLife information brochure. Extra time was scheduled for their next follow-up visit. This visit comprised 4 parts. First, the hematologist completed the routine follow-up and then explained the changing model of care. If desired, a 12-month valid prescription was written for TKIs to be delivered to the patient's home. Second, an introduction with the nurse specialist

took place, followed by an explanation of the functions and first half of the features of CMyLife (information source and Patients Know Best). Third, the patient visited a member of the project team who showed an explanatory video and installed and activated CMyLife and Patients Know Best (after an identification check). If necessary, instructions were provided by email and telephone. In total, 80 min were reserved for these 3 parts. Finally, the patient visited the pharmacy where the type of medication and the number of pills in possession of the patient were registered in CMyLife. After 3 months, the patient had a routine follow-up scheduled with the hematologist, who could discuss the symptoms reported in CMyLife and TKI adherence. Thereafter, the patient visited the nurse specialist who evaluated the experiences of using CMyLife and explained the second half of the features (ie, video consulting, having blood drawn at home, and scoring symptoms). Both visits lasted for 20 min each. After 6 months, the hematologist proposed the possibility of screen consulting for the next visit, followed by an explanatory visit, including instructions for video consulting with the nurse specialist.

Discussion

Principal Findings

Finally, with the aid of the design thinking methodology, the CMyLife innovation was developed, which is a web-based platform with multiple features such as a website with reliable information and a forum, a guideline app, personal medical records with logs of symptoms and laboratory results (including molecular markers connected to the guideline app), screen-to-screen consulting, and delivery of medication and collection of blood samples at home. Since the beginning of the pilot, 338 users were registered, and the website had 6334 unique visitors. However, it should be noted that CML is a rare disease, with approximately 160 new patients per year in the Netherlands.

Gaining insights into the course of one's disease was most desired by patients. Hence, an easy-to-understand version of the Dutch CML guideline connected to personal laboratory results was developed, which provides patients with the tools to take the lead in their own care process, enhancing patient empowerment and guideline adherence. In daily practice, adherence to guidelines by physicians is often suboptimal [18-20,40,41], which is associated with lower medication adherence and inferior treatment outcomes, including an increased risk of progression to an advanced phase of the disease [19-21,24]. A second feature is the provision of trustworthy information on a variety of subjects related to CML care, based on patients' feedback. Furthermore, by transferring the majority of care outside of the hospital, CML care is centralized digitally. This could be beneficial as adherence to guidelines was found to be the lowest in small centers treating just one or a few newly diagnosed patients with CML [42]. Even for patients who have achieved TFR and discontinued TKI treatment, CMyLife could be of added value. As approximately half of the patients remain in TFR after TKI discontinuation [43-45], optimal monitoring is important.

Another key feature of CMyLife is the personal health record that can be created and filled with patient-reported outcomes (PROs) such as TKI intake, health status, and AEs. In the literature, AEs are frequently reported and are even described as the main reason for skipping TKI doses intentionally [46-49]. These low adherence rates are a serious challenge in CML care [48,50,51], leading to decreased treatment responses and subsequently increased rates of resistance and progression [22,23,47,52]. Obviously, recognition of AEs by the physician is essential to relieve the symptoms or consider switching TKI to enhance adherence. However, physicians tend to rate symptom severity lower than patients and overestimate the adherence of their patients [27,53]. Patients reporting their own outcomes have improved control of symptoms, medication adherence, and patient satisfaction. Furthermore, PROs provide distinct prognostic information, exceeding clinical measurements [54-56].

Naturally, the utilization of human-centered design approaches and the development of mobile health technologies in health care are not new. There are numerous examples of mobile health technologies for patients and their caregivers for various diseases. Even interactive patient portals in breast and lung cancer care, developed with active patient participation, are described in the literature [57,58]. Laboratory result, PRO, and frequently asked question sections are common features of these portals. Other web-based interventions include a previsit communication tool for malignant lymphoma, an online community for adolescents and young adults with cancer, online communities for patients with breast cancer, and a web-based app supporting cancer survivors in self-management by monitoring PROs and acquiring feedback with a summary of personalized supportive care options [59-62]. As such, the individual web-based features of CMyLife are not unique; however, the combined features and the transfer of care from the hospital to the patient's own environment are unique. CMyLife changes the current delivery of care and centralizes it digitally.

Laboratory results, PROs, electronic consulting, and information provision can be considered as generic components of innovative apps for all types of cancer and even for nonmalignant chronic diseases. It is key to the development of such innovations to start at the beginning, ie, with the patients, and tailor the innovation as a solution to the patients' needs. CMyLife in its entirety incorporates a holistic approach, which could serve as an example for innovations for other malignancies.

CML, however, is distinguishable from other malignancies based on the nearly normal survival rates and, above all else, the availability of a molecular marker representing disease activity. Fortunately, survival is nowadays seldom the key issue for patients and the emphasis shifts to the management of AEs, decreasing the disease burden in daily life.

Limitations

Design thinking was an effective method to develop an innovation in a bottom-up approach. However, it is possible that a different product would have been developed if another user-centered method had been used. In addition, our study is limited by the possible bias in patients voluntarily participating

in the development of the innovation. Patients willing to participate in the project could be a more active group, and their needs may not represent the needs of the overall population of patients with CML.

Future Research

The ability of CMyLife to achieve its goal as well as the added value of CMyLife and its features will be the focus of future studies. Pre- and posttest design studies were running at the time of writing this paper. CMyLife will be evaluated on objective criteria (ie, quality of life, cost-effectiveness, adherence rates, etc). In addition, the further development and fine-tuning of CMyLife remains to be a continuous process. During this process, qualitative studies with more focus groups and interviews will be performed.

Enhancing adherence could save health care costs. A Dutch report assessed the potential value of improving both patients' adherence to TKIs and physicians' adherence to guidelines [63]. For each yearly cohort of newly diagnosed patients with CML (160 patients) over a period of 25 years, a cost reduction of approximately US $3.1 million (€2.8 million) and US $1.3 million (€1.2 million) would be possible by improving the patients' adherence and physicians' adherence, respectively, to 100%. For the improvement of every 1% of adherence, cost reduction was established at US $118,460 (€106,560) and US $48,380 (€43.520) per yearly cohort over 25 years, respectively.

Conclusions

The main takeaway of this study is that we have developed a holistic intervention with the aid of active patient participation. We aimed to change the current model of care by using and continuously improving CMyLife. Patients are provided with an easy to understand guideline for the management of CML. In addition, they receive their own laboratory results, including the paramount *BCR-ABL1* values, depicted in a simple yet understandable graph. With the aid of CMyLife, we give patients the tools to monitor their results, interpret these results, and act on them. They are provided with the know-how to consider their results in relation to their personal care process. Patients themselves monitor their treatment and know when it is time to check their values again. After all, physicians proved not to be the most adherent monitors [41]. Of course, the hematologist will not become completely redundant, monitoring is still required, although from a distance. An approximate comparison can be made with a chronic disease such as diabetes mellitus, where patients monitor their own glucose levels and therapy and have, eg, yearly contact with their health care professional. CML would be the first malignancy where patients are able to monitor and manage their disease by themselves.

Historically, CML has been a prototype malignant disease for innovations in medicine: it was the first human cancer in which the causative genetic abnormality was identified (the Philadelphia chromosome) and was the first disease for which a successful targeted anticancer therapy was developed (the TKI imatinib). Perhaps, CML can lead innovation in oncology once again and be the model of change in current health care by redesigning the model of care to be truly centered around the patient, with the patient in full control and ensuring the highest quality and best outcomes.

Acknowledgments

The authors would like to thank all the patients for their contributions to the development of CMyLife.

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

The corresponding author (GE) attests that all listed authors have met authorship criteria and that no others meeting the criteria have been omitted.

Conflicts of Interest

GE, PW, RH, KB, BH, OV, JJ, NB have no conflicts of interests to declare. JJWJ received research support by Novartis and BMS, and honoraria of Abbvie, Novartis, Pfizer and Incyte. He is the president of the Apps for Care and Science Foundation which develops the HematologyApp. This nonprofit foundation is supported by Amgen, Daiichi-Sankyo, Janssen, Incyte, BMS, Servier, Jazz, and Celgene.

Abstract

Background: Although evaluation studies confirm the strong potential of men's electronic health (eHealth) programs, there have been calls to more fully understand acceptability, engagement, and behavior change to guide future work. Relatedly, mapping of behavior changes using health promotion theories including the transtheoretical model (or stages of change) has been recommended to build a translatable empirical base to advance design and evaluation considerations for men's eHealth programs.

Objective: This study aimed to use a benchmark sample as a reference group to map the recent and intended health behavior changes in Canadian men who use the *Don't Change Much* (DCM) eHealth program. The hypothesis being tested was that increased exposure to DCM would be positively associated with men's recent and intended health behavior changes.

Methods: DCM users (n=863) were sampled for demographic data and self-reported recent and intended health behavior changes. Respondents also reported their usage (frequency and duration) for each of the 3 DCM components (web, newsletter, and social media) and were allocated to limited exposure (257/863, 29.8%), low exposure (431/863, 49.9%), and high exposure (175/863, 20.3%) subgroups. A benchmark sample (n=2000), comprising respondents who had not accessed DCM provided a reference group. Bivariate analysis of recent and intended health behavior changes and DCM exposure levels were used to compute the strength of association between the independent variables (exposure levels) and the 10 categorical dependent variables (recent and intended health behavior changes). Binary logistic regression models were computed for each of the 10 recent and intended health behavior changes. Linear regression was used to model the association between the number of recent and intended changes and the level of exposure to DCM.

Results: Compared with the benchmark reference group, DCM high-exposure respondents had significantly increased odds for 9 of the 10 health behavior changes, with the largest effect size observed for Changed diet or Improved eating habits (odds ratio [OR] 5.628, 95% CI 3.932-8.055). High-exposure respondents also had significantly increased odds for 9 intended health changes, with the largest effect sizes observed for Reduce stress level (OR 4.282, 95% CI 3.086-5.941). Moderate effect size (goodness of fit) was observed for increased total number of recent ($F_{12,2850}$=25.52; *P*.001; adjusted R^2=.093) and intended health behavior changes ($F_{12,2850}$=36.30; *P*.001; adjusted R^2=.129) among high-exposure respondents.

Conclusions: DCM respondents contrasted the predominately precontemplative benchmark sample mapping across the contemplative, preparation, and action stages of the transtheoretical health behavior change model. Almost 10% of variation in the recent and 13% of variation in the intended health behavior changes can be explained by DCM exposure and demographic factors, indicating the acceptability of this men's eHealth resource.

KEYWORDS

men's e-Health; men's health behavior change; men's health promotion

Introduction

The case for men's health is often articulated through sex differences research wherein lower life expectancy in men (compared with that of women) is connected to their overall poor self-health practices, including estrangement from professional *in person* health care services [1,2]. The major mortality causes accounting for men's reduced life expectancy include cardiovascular disease, suicide, motor vehicle accidents, liver failure (most often due to alcohol overuse), and infectious diseases (most often HIV) [3]. These (and many other) mortality causes and contributors to morbidities are seemingly amenable to prevention-based interventions, and by virtue of that, tailored health promotion programs have surfaced to garner men's health behavior changes [4-6]. The platforms and mechanisms for promoting men's health, although diverse, have grown exponentially in the electronic health (eHealth) sector over the last two decades [7,8]. That said, empirical insights to the acceptability, engagement levels, and behavior changes reaped through these well-intended men's eHealth programs, while promising, are emergent and drawn from diverse study designs [7,9]. The aim of this study was to use a benchmark sample as a reference group to map the recent and intended health behavior changes in Canadian men who use the *Don't Change Much* (DCM) eHealth program [10]. The hypothesis being tested was that increased DCM exposure levels would be positively associated with men's recent and intended health behavior changes.

Men's lifestyles have attracted health promotion research describing specific risk factors and a range of potential remedies. In terms of risk, unhealthy diets, alcohol overuse, smoking, and sedentary lifestyles have featured as issues warranting tailored behavior change interventions [11]. There is also diversity in the predisposition to the aforementioned behavior risks whereby inequities within social determinants of health (ie, income, employment, education) result in disadvantage to some male subgroups both in terms of their knowledge levels and access to health care services [12,13]. Within this context, men's health risks and the potential for behavior change emerge as somewhat relative, deeply reliant on resources being freely available and easily accessible. By lessening structural barriers and mobilizing men's strength-based efforts for optimizing their health, important behavior changes can occur for men [13]. In this regard, men's eHealth resources have great potential to improve access and meet many health promotion needs for men.

Men's eHealth programs have grown significantly to deliver diverse information and services across ever expansive platforms (ie, web, social media, and email). The wide variety of men's eHealth programs include interventions tailored to address weight loss [14], smoking cessation [15], prenatal health education [16], fathering [17], depression management [7,18], sexual health [19-24], and prostate cancer [25]. Although there are claims that eHealth resources can engage diverse subgroups of men, satiating their preferences for anonymity and self-directed health help-seeking, two significant issues prevail. The first relates to the varied conceptualizations and approaches to evaluating needs analyses (acceptability) and end-user engagement, as well as the lack of conclusive empirical evidence regarding associations between men's eHealth programs and behavior change. For example, needs analysis of men transitioning to fatherhood by Da Costa et al [17] confirmed substantial interest among new and expectant fathers for using internet-delivered strategies to promote their mental health and prepare for parenthood. Within this and similar needs analyses work, the insights drawn from potential end users have affirmed the acceptability of men's eHealth programs in specific contexts and informed tailored content and targeted delivery of the interventions. Evaluations of newly launched and established eHealth programs have tended to focus on men's engagement or linkages to behavior change [16,22]. Examples include a single-group, repeated measures design evaluating the applicability of Man Central (a web and mobile phone intervention for men with depression), which showed significant improvements in depression symptoms, depression risk, externalizing symptoms, and work and social functioning among end users [7]. Pre-post eHealth evaluation studies reported significant improvements in depressive symptoms among a community sample of overweight and obese men with depression [14], whereas Bottorff et al [15] highlighted tobacco reduction and/or cessation for 66% (43) of men who used the QuitNowMen resource. Klein et al's [24] quasi-experimental, 2-arm study evaluated *Real Talk* (an eHealth harm reduction intervention targeting black men who have sex with men) reported end user's HIV knowledge gains (although there were no significant differences between *Real Talk* and the control participant's actual condom use or other risk reduction strategies). Although the aforementioned and many other men's eHealth evaluation studies have been limited by small samples, attrition, and/or a lack of control groups, the results are encouraging [25,26]. In sum, acceptability and evaluation studies confirm the strong potential of men's eHealth programs amid calls for more evidence to efficiently guide future work and confidently claim sustained health behavior change effects.

The second issue relates to incorporating theory to map men's health behavior changes and their relationships to tailored eHealth programs. Simoni et al [26] argued the need for health promotion theory in men's eHealth to build a translatable

empirical base and advance the design and evaluation of gender-sensitized interventions. Among many health promotion theories, the transtheoretical (or stages of change) model [27,28] has guided eHealth program designs and helped contextualize barriers and facilitators to men's health behavior changes in a range of contexts [29-31]. Comprising precontemplative, contemplative, preparation, action, and maintenance, these interconnected and recursive stages of change characterize the transtheoretical model, underpinned by processes reliant on men's access, self-efficacy and recognition of, and commitment to the benefits of sustained modifications. Program design, acceptability, engagement, and behavior change evaluations of men's eHealth resources can, and many argue should, interface with the transtheoretical model (or similar) to map men's progress and adjust intervention content and/or delivery accordingly [29-31]. In line with this recommendation, and reflecting our commitment to fully integrating the transtheoretical model, this study adds to methodological approaches by using a benchmark sample as a reference group to map men's eHealth engagement and behavior change, in making recommendations for DCM, and, more broadly, the burgeoning field of men's eHealth.

Methods

Overview

Following university ethics approvals, demographic and self-reported recent and intended health behavior change data were collected via survey questionnaires from two Canadian male cohorts: (1) benchmark (reference group), comprising respondents who had not accessed DCM, and (2) DCM users. Data collection details and cross-sectional findings from the benchmark sample have been reported elsewhere [6,32]. Briefly, the 5083 respondents recruited via web-based panel provider to complete a Canadian men's health survey were reduced to 2000, stratified by age and location to be close to the most recent Canadian census data. The 15-min web benchmark survey was administered from April 20, 2017, to April 28, 2017.

The second cohort comprised DCM users recruited via the DCM website and email newsletter recipient list, and these respondents were incentivized with the option to enter a prize draw to win Can $500 (US $377.60) cash. By way of background, the DCM eHealth program was purpose-built in 2014 by the Canadian Men's Health Foundation, a national nonprofit organization, with the goal of inspiring men and their families to lead healthier lives. Reliable information and easily accessible tips are developed based on focus group interviews with Canadian men and reviews of the men's health literature, and by drawing from the expertise of global thought leaders. The DCM information shared through testimonials, text, video, and audio is brief, often times humorous, and always easy to access with a focus on practical strategies to improve diet, exercise, sleep, and stress management as well as reduce alcohol use and/or smoking. A range of strategies are offered in point form recognizing that end users are diverse in their contexts, needs, and alignments to the transtheoretical stages of change (ie, precontemplative, contemplative, preparation, action, and maintenance). In addition to providing a framework for evaluating DCM, the program content was developed drawing on the transtheoretical model. Specifically, DCM's strength-based approach and wide-reaching materials were purpose-built to engage men at diverse levels of readiness to change and progress points. In essence, the interconnected stages characterizing the transtheoretical model guided the DCM content design to work with men at whatever point they were at, to advance their self-health.

The DCM demographic and survey questionnaire data were collected between January 1, 2018, and March 31, 2018; the data collection tools were identical to those of the benchmark survey but also included questions about the respondent's usage (duration and frequency) of the three DCM components (web, newsletter, and social media). Of the 1743 respondents who went to the DCM survey introduction page, 94.8% (1653) opted in. This sample was reduced to 1034 Canadian male DCM users by removing incomplete surveys (n=459), female respondents (n=90), speeding and/or straight lining responses (n=60), respondents from outside of Canada (n=7), and those under the age of 19 years (n=3). Some demographics were asked at the end of the survey (education, household income, and ethnicity), making it impossible to accurately evaluate and report the demographic characteristics for the 459 incomplete surveys. Speeding was assigned to respondents who completed the survey in 5 min or less (less than one-third of the median completion time), and straight lining comprised respondents inputting the same numerical response to all Likert items on 2 or more consecutive survey pages. The final sample of 863 DCM users was obtained through listwise removal of an additional 171 respondents who answered *not sure* to questions regarding their use (duration and frequency) of the 3 DCM components, as a numerical code could not be assigned to classify those respondents' DCM exposure level.

Measures

Demographic data, including age, employment, living arrangements (lives alone; children younger than 19 years living at home), education, visible minority, sexual orientation, and household income (before taxes) were collected. *Visible minority* is the terminology used by Statistics Canada, and based on that classification system, we used the term in our postcoding. In addition to being a Canadian resident, respondents were asked: *Do you belong to any distinct ethnic or cultural group?* with response options: *Yes (please specify)* or *No (Prefer not to say)*. Responses from those who answered *Yes (please specify)* were postcoded using Statistics Canada 2016 Census definitions. Regards sexual orientation, respondents were asked the following: *Do you consider yourself to be: Select one: Heterosexual or straight, Gay or lesbian, Bisexual, Not sure or questioning, or Other (please specify)*. Responses were coded as a dichotomous variable (0=heterosexual or straight, 1=other).

Respondents in both cohorts were also asked about the recent and intended changes to improve their health. The first question asked, *In the past 12-months, have you made any changes that would improve your health?* inviting respondents to select all that applied from the following 10 items: (1) changed diet or improved eating habits, (2) made an effort to sit less and walk more, (3) increased exercise, sports or physical activity, (4) I haven't made any changes, (5) drink less alcohol, (6) had a

routine check-up or visit to doctor, (7) improved consistent sleep quality, (8) lost weight, (9) reduced stress level, and (10) quit or reduced smoking. Intended changes were collected through soliciting responses to the same 10 options, with the stem question, *In the next month (30-days), do you intend to make any changes that would improve your health? Select all that apply*.

The 863 DCM respondents had access to three DCM eHealth components: (1) the website, (2) email newsletter, and (3) social media accounts (Facebook, Instagram, and Twitter). Respondents checked yes, no or not sure options for each of the three DCM components in answering the question, *Have you ever used, or subscribed to, any of the following DCM resources?* Respondents who checked *Not sure* responses were excluded. *No* responses were allocated a zero value and assigned to the limited exposure subgroup. *Yes* responses were used to subsequently populate DCM items (website, newsletter, and social media) in asking 2 additional questions to score each respondent's DCM usage (duration and frequency) and calculating exposure levels [33]. The work of Quinn and Chaudoir [33] guided the assignment of numerical codes to participant's single-item frequency and duration responses for the DCM components that they had used.

1. *When did you FIRST use, or subscribe to, the following resources?* Response options: never before, in the past month, 1-6 months ago, 7-12 months ago, 13-24 months ago, more than 2 years ago, and not sure. Participants checked the duration level based on their first use for the DCM resources. The categorical measure was converted to a continuous measure representing the duration as follows: *never before*=0.0, *in the past month*=0.5, *1-6 months ago*=3.5, *7-12 months ago*=9.5, *13-24 months ago*=18.5, *more than 2 years ago*=24.0, and not sure (excluded).
2. *How often do you use or access the following resources?* Response options were as follows: several times a day, once a day, several times a week, once a week, several times a month, once a month, several times a year, once a year, less often, do not use, and not sure. To calculate frequency, the checked categorical measure was converted into a continuous measure: *several times a day*=1095, *once a day*=365, *several times a week*=156, once a week=52, several times a month=36, *once a month*=12, *several times a year*=3, *once a year*=1, *less often* =0.5, *do not use*=0, and not sure (excluded).

DCM user classifications were based on the sum of the product of duration and frequency for each of the three DCM components, to calculate respondent exposure scores. Duration responses were converted to numerical scores that represented the number of months since accessing DCM. Frequency responses were converted to numerical scores proportional to the number of times each DCM component was used. To illustrate, respondents who completed the survey questionnaire but indicated a duration of *Never before* and a frequency of *Do not use* for all three DCM components received a summed score of 0 and were classified to the limited-exposure group (257/863, 29.8%). A user who engaged one DCM resource for a duration of *In the past month* (0.5) at a frequency of *Less often* (0.5) received a total summed score of 0.25 and was classified to the low-exposure subgroup (431/863, 49.9%; range 0.25-680). A respondent who used two DCM programs, both for a duration of *7-12 months ago* (9.5) at a frequency of *Several times a month* (36), received a total summed score of 684 and was classified as high exposure (175/863, 20.3%; range 684-9048). Through these classifications, three DCM user subgroups, limited, low, and high exposure, were delineated.

Data Analysis

Bivariate analyses were conducted to assess the magnitude of differences in demographic factors between benchmark respondents and DCM users. The chi-square test was used to assess whether there was an association between the two categorical variables. Cohen *d* was used to calculate effect size. When the means of three or more independent groups were compared, Cohen *d* was obtained by computing partial eta-squared (another type of effect size) and then converting partial eta-squared to Cohen *d* using formulae in the study by Cohen [34]. Cramer's V was used to calculate an effect size for the strength of association between the two categorical variables, with values ranging from 0 to 1 (inclusive) [35].

Regression analysis included logistic regression to model the association between the dependent variables recent and intended health behavior changes, and independent variable, level of exposure to DCM. R-squared values were used to measure the proportion of variance in a dependent variable that can be explained by the independent variable in the regression models [34]. For models analyzing recent changes, the dependent variable was whether the user made the specified behavior change (eg, *Increased exercise, sports or physical activity*) in the past 12 months or not. Similarly, for models analyzing intended changes, the dependent variable was whether the user intended to make the specified behavior change (eg, *Change diet or improve eating habits*) in the next month (30 days) or not. Linear regression was used to model the association between the number of recent and intended changes and the level of exposure to DCM. In total, two linear regression models were computed, with the first model having the number of recent changes as the dependent variable, and the second model having the number of intended changes as the dependent variable. The DCM users were classified into 1 of 3 categories, limited, low, or high exposure. Benchmark respondents, classified as no exposure, were the reference group. All logistic and linear regression models controlled for the following covariates: age, employment, living arrangements (lives with partner; children younger than 19 years living at home), education, visible minority, sexual orientation, and household income (before taxes). Odds ratios are effect sizes and were used to indicate the strength of association between predictor variables and dichotomous outcome variables [36]. Variance inflation factors (VIFs) were computed as a collinearity diagnostic check.

Results

Benchmark respondents had not used DCM and served as a reference group to assess the effect of DCM program exposures on recent and intended health behavior changes. Assessment of the magnitude of differences in demographic factors between

benchmark respondents and DCM users revealed small to negligible effect sizes for the 8 demographic factors (see Table 1). Most respondents in both cohorts reported being employed, living with a partner, not living with children younger than 19 years, not having graduated from university, and identifying as heterosexual. There were no statistically significant differences in age between the two cohorts. Compared with benchmark respondents, a higher proportion of DCM users reported having a household income of Can $120,000 (US $92,307.69) or more, although household income and the two cohorts were weakly associated as a whole.

For the DCM group, all recent health behavior changes had significant associations with increased levels of exposure to DCM. Moderate effect sizes were observed in *Changed diet or improved eating habits* (χ^2_3=210; *P*<.001; Cramer's V=0.271) and *Made an effort to sit less and walk more* (χ^2_3=167; *P*<.001; Cramer's V=0.242). All intended health behavior changes had significant associations with increased DCM exposure. Moderate effect sizes were observed for the following seven intended health behavior changes: (1) *Improve consistent sleep quality* (χ^2_3=207; *P*<.001; Cramer's V=0.269), (2) *Changed diet or improved eating habits* (χ^2_3=181; *P*<.001; Cramer's V=0.252), (3) *Increase exercise, sports or physical activity* (χ^2_3=169; *P*<.001; Cramer's V=0.243), (4) *Make an effort to sit less and walk more* (χ^2_3=168; *P*<.001; Cramer's V=0.242), (5) *I don't intend to make any changes* (χ^2_3=148; *P*<.001; Cramer's V=0.227), (6) *Reduce stress levels* (χ^2_3=129; *P*<.001; Cramer's V=0.212), and (7) *Lose weight* (χ^2_3=119; *P*<.001; Cramer's V=0.205). There was a significant association between the total number of recent health changes and increased DCM exposure levels (ranging no exposure 2.39 to 4.23 high exposure), with a large effect size observed (*P*<.001; *d*=0.818). There was a significant association between the total number of intended health changes and increased DCM exposure levels (ranging no exposure 2.09 to 3.92 high exposure), with a very large effect size observed (*P*<.001; *d*=1.018). Following Bonferroni-adjusted Dunn pairwise tests, with the no-exposure benchmark cohort, all recent and intended changes in the limited-, low-, and high-exposure DCM subgroups were statistically significant (*P*<.001). Recent changes were also statistically significant for DCM limited- and high-exposure subgroups (*P*<.001), as well as for the DCM low- and high-exposure subgroups (*P*=.01).

Table 1. Benchmark versus Don't Change Much users' sample profile.

Demographics and baseline characteristics	Benchmark (n=2000)	DCM[a] users (n=863)	Chi square (*df*)	*P* value	Cramer's V

[a]DCM: Don't Change Much.

[b]As a ratio variable, the test performed was a *t* test for this characteristic.

[c]As a ratio variable, the test performed was a Cohen *d* for this characteristic.

[d]N/A: not applicable.

Compared with the benchmark no-exposure respondents, high-exposure respondents had significantly increased odds for all recent health behavior changes except *Quit or reduced smoking* (OR 0.820, 95% CI 0.461-1.458) and significantly decreased odds for *I haven't made any changes* (OR 0.140, 95% CI 0.065-0.301) while holding other predictor variables constant. Moderate effect sizes were observed for *Changed diet or improved eating habits* (OR 5.628, 95% CI 3.932-8.055), *Increased exercise, sports or physical activity* (OR 3.439, 95% CI 2.444-4.839), and *I haven't made any changes* (OR 0.140, 95% CI 0.065-0.301) [36]. Of the controlled predictor variables, age, employment, lives with children, education, and income were statistically significant with small effect sizes for some of the recent health behavior changes (see Table 2; full table in Multimedia Appendix 1).

Table 2. Logistic regressions between statistically significant demographics and recent health changes (separate multiple logistic regressions were conducted for each outcome variable with all predictor variables entered on the same step).

Dependent variables (recent health change)	Predictor variables, odds ratio (95% CI)							
	Don't Change Much level of exposure (ref=benchmark no exposure)			Age (years)	Employment	Education	Household income (ref=Can $60,000-$119,999; US $46,153.86–$92,306.92)

[a]$P<.05$.

[b]$P<.01$.

[c]$P<.001$.

Compared with the no-exposure respondents, high-exposure respondents had significantly increased odds for all intended health changes except *Quit or reduce amount smoked* (OR 1.043, 95% CI 0.559-1.946), while holding other predictor variables constant. Moderate effect sizes were observed for *Reduce stress level* (OR 4.282, 95% CI 3.086-5.941), *Improve consistent sleep quality* (OR 4.019, 95% CI 2.911-4.547), *Increase exercise, sports or physical activity* (OR 3.649, 95% CI 2.565-5.191), and *I don't intend to make any changes* (OR 0.162, 95% CI 0.082-0.321; see Table 3; full table in Multimedia Appendix 2).

A linear regression was, then, conducted. Compared with the no-exposure respondents, high-exposure respondents had significantly increased total number of recent and intended health changes, while holding other predictor variables constant. Moderate effect size (goodness of fit) was observed for both total number of recent health behavior changes ($F_{12,2850}$=25.52; $P<.001$; adjusted R^2=.093) and intended health behavior changes ($F_{12,2850}$=36.30; $P<.001$; adjusted R^2 =.129). The VIF criterion was within the acceptable range, and there was no indication of multicollinearity.

Table 3. Logistic regressions between statistically significant demographics and intended health changes (separate multiple logistic regressions were conducted for each outcome variable with all predictor variables entered on the same step).

Dependent variables (intended health change)	Predictor variables, odds ratio (95% CI)

Discussion

Principal Findings and Comparison With Previous Work

This study's findings confirm the potential of men's eHealth programs as previously described in a range of contexts and diverse studies [7,14-25]. Adding to the literature focused on understanding men's eHealth acceptability, engagement, and behavior change, this study contributes some important empirical insights and supports calls for future research to more fully investigate dose-response relationships with randomized controlled trials [25,26]. Although careful not to overstate the current findings or imply attribution, some explanations and potential implications for the statistically significant associations between men's DCM exposure levels and their recent and intended health behavior changes are offered as a means to scoping adjustments for DCM, and making broader recommendations for the men's eHealth field. Our hypothesis—increased DCM exposure levels would be

positively associated with men's recent and intended health behavior changes—was supported by the study results. These findings corroborate broader acceptability claims and previous reports [7,14-16] about the compatibility of diverse eHealth resources with some men's help-seeking preferences and practices. Also reinforced are assertions about the associations between engagement (based on self-reported duration and frequency of use) and men's recent and intended health behavior changes [22]. That these findings held when controlling for key demographics synonymous with social determinants of health (ie, income, employment, education) might be interpreted as reflecting the wide reach, accessibility, and engagement potential of DCM for men from diverse backgrounds. In essence, the DCM content and dissemination strategies seem to be acceptable to, and engaging of men from an array of circumstances, with the net result that the DCM components can support health behavior changes in wide-ranging end users. Future work might use structural equation modeling to investigate statistically significant predictor variables including age, education, employment, and household income to distil their mediation and moderating effects. That said, it is also important to acknowledge the possibility, within the context of this study, that motivation to make health behavior changes actually caused some men to engage with DCM.

In further breaking down this study's findings, questions emerge about if (and if so—how?) to act on some recent and intended health behavior change results to adjust the DCM content. Central here are the determinations for integrating specialist resources to DCM as a means to engaging more men with specific health behavior changes. For example, tobacco reduction and smoking cessation (TRSC) demand specialist resources (beyond the rhetoric messaging that *smoking is bad for you*) [15], and this study's findings regarding low recent and intended changes for *Quit or reduce smoking* likely reflect the relatively small number of male smokers in Canada (compared with the overall population), as well as the lack of dedicated DCM resources focused on men's TRSC. In essence, TRSC messaging was relevant to fewer end users (ie, smokers) and that relatively small subset of respondents were unlikely to have accessed DCM with the sole focus of reducing or quitting smoking. Similarly, that *Reduce stress* and *Improve consistent sleep quality* featured prominently as the most intended health behavior changes with fewer end users reporting recent changes in those health behaviors might indicate the need to adjust and/or integrate additional tailored DCM stress reduction and sleep aiding resources. Building on this point, Yardley et al [37] has argued the value of promoting effective engagement (defined empirically as sufficient engagement with the intervention to achieve intended outcomes) rather than simply more engagement. This is salient advice both in planning to adjust, add, and/or replace some DCM content and evaluating end users' experiences through triangulating time-based exposure data with qualitative interviews as a means to more fully contextualizing men's engagement. In addition, it is clear that longitudinal research is required to map content and end-user behavior changes over time and empirically guide ongoing adjustments to men's eHealth programs.

Although acknowledging the inherent complexities to accounting for human behaviors and health behavior change in men more specifically [38], this study's findings, consistent with findings from previous work [27,31], were mapped to the transtheoretical model (or stages of change). DCM respondents (contrasting the benchmark cohort) were clearly nestled across the contemplative, preparation, and action stages. That almost 10% and 13% of the variation in respondents' recent and intended health behaviour changes, respectively, were explained by DCM exposure levels and demographic variables, confirms the acceptability of, and engagement with DCM as well as the end users' readiness to change. Herein, DCM users can be broadly characterized as planning to make, as well as investing actions toward some health behavior changes. This finding confirms the DCM end users as a distinct subset of the male Canadian population, and although challenges remain for advancing more men past the precontemplative stage (toward DCM or similar), the DCM end users offer unique opportunities for building engagement, and by extension, aiding some men's efforts to maintain their health behavior changes.

Limitations

A methodological limitation suggesting caution for interpreting the results of this study is the high potential for familywise errors as a byproduct of conducting 22 separate regression analyses. Self-report biases, both in relation to respondents recalling their DCM usage and disclosing recent and intended health behavior changes are also limitations. In particular, social desirability especially pertaining to exercise and healthy eating may have influenced men's responses [39]. Reliance on quantitative measures limits the understanding about the diverse contexts that can influence men's health practices including their eHealth help-seeking. In addition, that respondents were Canadian reduces the generalizability of the findings to other men living elsewhere. Further acknowledged is that the benchmark sample was not stratified by race or ethnicity because defining stratification quotas by race/ethnicity in addition to gender, age, and location would have created too many interlocking stratification variables to administer and lead to sparse data within certain strata. This study, although purposefully differentiating acceptability and engagement, was also limited by its elementary conceptualization and formal evaluation of the acceptability of DCM [40]. Some of these limitations can, however, be addressed in future work by triangulating data collection to qualitatively build understandings about what constitutes and counts as engagement from end-user perspectives and more fully evaluating the multifaceted concept of acceptability [40], comparing men from other countries who visit DCM, and/or the use of larger sample sizes with noninterlocking strata for race/ethnicity. Although the hypothesis that increased DCM exposure levels were positively associated with men's recent and intended health behavior changes was supported by this study's findings, RCTs and control group comparisons are needed to make dose-response and attributions claims to advance the men's eHealth field. The inclusion of an economic analysis and specific behavior change techniques to consider cost would also strengthen future DCM studies [41].

Implications and Conclusions

Men's eHealth programs operate across a continuum of working to replace, augment, and connect men to professional *in person* health care services. This study, although focused on DCM in reporting men's recent and intended health behavior changes, confirms the potential of eHealth programs for aiding health behavior changes. Also offered are important empirical insights and approaches to designing content and evaluating men's eHealth resources, and mapping end-user outcomes with the transtheoretical model. Taken together, this study design and findings offer some methodological guidance and empirical weight to advance the men's eHealth field.

Acknowledgments

The Canadian Men's Health Foundation DCM eHealth program and DCM evaluation was supported with funding from the Public Health Agency of Canada. The DCM evaluation was subcontracted to, and completed by Intensions Consulting; The American Urologic Association, Research Scholar Award supported the involvement of RF.

Abstract

Background: The efficacy of a highly tailored digital intervention to support medication adherence and feasibility to support clinical effectiveness as an adjunct to the primary care setting has not been evaluated.

Objective: This trial aimed to assess the behavioral efficacy of a highly tailored digital intervention to support medication adherence and to evaluate the feasibility of its clinical effectiveness, in patients with either or both hypertension and type 2 diabetes. We also examined quality of life and mechanisms of behavior change. Intervention fidelity, engagement, and satisfaction were also explored.

Methods: This was a multicenter, individually randomized controlled trial of 2 parallel groups: an intervention group that received a highly tailored text message and interactive voice response intervention for 12 weeks, and a control group that received usual care. Medication adherence was measured using self-reports and assessor-blinded practice records of a repeat prescription. Systolic blood pressure and glucose levels were assessed by nurses blinded to group allocation during practice visits at 3 months follow-up. Questionnaires obtained data to assess intervention mechanisms of action and satisfaction and digital log files captured data to evaluate fidelity and engagement.

Results: A total of 135 nonadherent patients (62/135, 46% female; 122/135, 90.3%; aged above 50 years) were randomly allocated in the intervention (n=79) or in the control group (n=56); of whom 13% (18/135) were lost at follow-up. Medication adherence was significantly improved in the intervention group compared with the control group (t_{116}=2.27; *P*=.02, 2-tailed). Systolic blood pressure was 0.6 mmHg (95% CI −7.423 to 6.301), and hemoglobin A_{1c} was 4.5 mmol/mol (95% CI −13.099 to 4.710) lower in the intervention group compared with the control group. Changes in intentional nonadherence and nonintentional nonadherence explained the improvements in medication adherence in the intervention group (beta=.074, SE=0.464; *P*=.04), but not in the control group (beta=.00, SE 1.35; *P*=.37). The intervention had 100% fidelity, a median of 12 days of engagement, and 76% overall satisfaction.

Conclusions: Our trial is the first that has been conducted in the United Kingdom and showed that among nonadherent patients with either or both hypertension and type 2 diabetes, a highly tailored digital intervention was effective at improving treatment adherence and feasible to obtain clinically meaningful outcomes. Changes in intentional and nonintentional nonadherence predicted the improvements in medication adherence. The intervention had high fidelity, engagement, and satisfaction. Future research using a rigorous design is needed to evaluate the clinical effectiveness and cost-effectiveness of the intervention in primary care.

KEYWORDS

medication adherence; hypertension; type 2 diabetes; text messaging; interactive voice response

Introduction

Background

The clinical management of cardio-metabolic conditions, like hypertension and type 2 diabetes mellitus, is one of the most common consultations in primary care [1,2] and pharmacotherapy is an essential part of effective management of these conditions [3]. However, many patients do not adhere to their prescribed medication regimen [4], leading to reduced treatment efficacy, increased risk of complications, additional consultations, and hospital admissions [5,6]. Medication adherence can significantly reduce these risks and prevent health complications [7,8]. It could also result in health care savings, with estimates from the United Kingdom of approximately US $115.4 million preventable cost being spent annually, due to only nonadherence to antihypertensive medications [9].

Setting

Primary health care providers can facilitate treatment adherence, but their time is limited and expensive. Given the growing prevalence of hypertension, the associated comorbidities, and the aging population, it is likely that there will be an increased need for health care resources to support medication adherence. Digital interventions are promising strategies to support adherence [10,11] and can be highly tailored and acceptable adjunct to primary care consultations [12]. Telephone-based interventions that deliver text and voice messages may have a wider reach as they can be delivered to any device, even in places of low network coverage, and are accessible to people from all socioeconomic backgrounds and age groups. We have therefore developed the Medication Adherence for Patient's Support intervention, a behavioral intervention that uses text and voice messages, to support medication adherence in patients with either or both hypertension and type 2 diabetes as an adjunct to primary care consultations.

Aims and Objectives

This study aimed to assess if patients with either or both hypertension and type 2 diabetes, who used the intervention for 3 months in addition to usual care, had improved medication adherence and if they differed in terms of systolic blood pressure or hemoglobin A_{1c}, and quality of life at 3 months follow-up. We have also assessed intervention mechanisms of action, as well as intervention fidelity, engagement and satisfaction. However, this feasibility trial primarily aimed to attain evidence about the feasibility of obtaining medication-related clinical outcomes to inform a larger effectiveness and cost-effectiveness trial in primary care.

Methods

Study Design

We used an individually randomized controlled trial of unequal 3:2 allocation ratio with a 3-month follow-up. We used unequal allocation ratio to increase the information obtained about the intervention. Intervention group patients received highly tailored and interactive text and voice recognition messages for 12 weeks, as an adjunct to usual care. The control group received usual care only [13].

Study Setting

Participants were recruited over 7 months, from March to September 2018, from 8 primary care practices in the East of England. We selected a wide range of primary care practices from different areas of deprivation (based on Index of Multiple Deprivation), and at least 50% in highly deprived areas, to obtain information about the reach and implementation of the intervention in different sites, and to increase the scalability of the intervention to a larger trial. Follow-up data collection was conducted between May 2018 and February 2019.

Participant Recruitment and Eligibility Criteria

A member of the practice staff screened medical databases against the inclusion criteria to identify eligible patients. Patients were eligible when they met all the following criteria: (1) were 18 years or older, (2) had a diagnosis of hypertension, type 2 diabetes mellitus, or both health conditions; (3) had been prescribed at least 1 antihypertensive medication or glucose lowering medication as documented in practice records for a period of 3 to 6 months before recruitment; and (4) had either or both poorly controlled blood pressure (controlled by age group) and glucose levels as logged in their medical records, or had gaps in collecting repeat prescriptions during the 6 months before the study invitation. When possible, patients' digital literacy was screened for inclusion.

A general practitioner screened the generated list of potentially eligible patients against the exclusion criteria to confirm eligibility. Patients were excluded when they met any of the following criteria: (1) were taking part in another medication adherence or digital intervention or (2) had a health condition that could impair their participation in the study.

Eligible patients were invited to the study by the primary care practices using text messages, postal invitations, and follow-up calls to postage invitations, or were recruited opportunistically during usual care consultations (eg, blood pressure checks and medication reviews) by health care providers.

Study Procedures

Interested patients were invited and attended baseline consultations with a health care provider (a practice nurse or a health care facilitator), where they were screened for eligibility (eg, digital literacy) and asked to provide informed consent. Baseline consultations involved the completion of a baseline questionnaire, measuring medication adherence, quality of life, and theoretical determinants associated with intentional nonadherence and nonintentional nonadherence (eg, necessity beliefs about medication taking and self-efficacy) and were facilitated by the health care provider. Responses to the baseline questionnaire were included in a webpage (which consisted of the tailoring algorithm, the intervention schedule, the intervention messages, and the inbound calls) to further inform the tailored intervention to those allocated to receive the digital intervention.

After the end of the consultations, patients were randomized to intervention or control groups and were sent a text message or a letter with information about which group they are allocated in. Further, intervention group patients completed information (on a webpage or verbally during phone calls; depending on their digital literacy) about their preferred times and frequency to receive the intervention messages. They were also provided with more information on how to use the digital delivery modes. All patients were provided with additional information about the trial procedures. Baseline consultation was conducted few days before each patient's repeat prescription was due for collection.

Intervention

Intervention group patients received highly tailored and interactive text and voice recognition messages for 12 weeks, initiated the day their repeat prescription was due for collection. The intervention development was guided by the theoretical framework that distinguishes between intentional and nonintentional nonadherence [14], previous evidence [11,12,15], and included behavior change techniques and strategies mapped onto either or both intentional and nonintentional nonadherence. Nonintentional nonadherence refers to patients not taking their medications as prescribed because they forget or misunderstand the recommendations. Intentional nonadherence refers to patients not taking their medications as prescribed because they decide to take less medication or miss a dose or a day of their medications. The intervention aimed to improve medication adherence by employing behavior change strategies to modify either or both intentional and nonintentional nonadherence.

The interactive element of the intervention was utilized for dynamic tailoring: patients could record a personalized implementation intention plan to further tailor intervention content and be grouped to receive more habit formation or self-monitoring advice based on records and responses obtained during the intervention. We have also adopted a flexible approach to intervention delivery, providing participants with functions to change delivery options (eg, decrease or increase the frequency of messages or stop the messages). Details of the intervention development are published elsewhere [12].

Outcomes

This trial aimed to assess the behavioral efficacy of a highly tailored digital intervention to support medication adherence in patients with either or both hypertension and type 2 diabetes, and its feasibility to support medication-related clinical outcomes. We also examined mechanisms of action. Recruitment and attrition rate and intervention fidelity, engagement, and satisfaction were also reported.

Primary outcomes were the efficacy of the intervention to support medication adherence and the feasibility of its clinical effectiveness at a 3-month follow-up (T2). Secondary outcomes included the mechanisms by which the intervention supported medication adherence, as well as intervention engagement and satisfaction.

Efficacy was measured using 2 self-reported items of adherence (ie, days of adherence during the past week and percentage of adherence during the past month) at T2, and repeat prescription claims during the last 2 intervention months before T2. A subsample of patients (n=9 intervention and n=2 control group) were randomly selected and invited to use a Medication Event Monitoring System caps for a duration of 7 consecutive days after T2. Medication Event Monitoring System is an electronic pill-bottle cap that registers the date and time of bottle opening [16]. Patients were provided with information about how to use the Medication Event Monitoring System and the number and specific medications to include in the container during follow-up consultations (see Multimedia Appendix 1). Practice records raw data (ie, dates of prescription claims) were extracted by a member of the practice staff from medical records and Medication Event Monitoring System data were extracted by a member of the research team; both nursing and research team staff were blinded to group allocation.

Clinical outcomes were measured at T2 by nurses blinded to group allocation during practice visits. Blood pressure was measured in patients prescribed antihypertensive medications and hemoglobin A_{1c} from those prescribed glucose-lowering medications. Blood pressure was measured 3 times with 1-minute intervals using calibrated blood pressure digital monitor devices (eg, Omron). The last 2 readings were included in the analysis. Blood samples were anonymized and sent to the Addenbrookes Hospital Pathology laboratory for analysis of hemoglobin A_{1c}.

Quality of life was measured using the 5-level EQ-5D [17]. Medication Adherence Rating Scale [18] was used to measure intentional nonadherence (4-items) and nonintentional nonadherence (1-item). Feasibility was assessed by the recruitment and attrition rate (percentage of people who responded to the invitation and those randomized and the percentage of people who attended consultations at follow up).

Intervention fidelity was measured by calculating the proportion of messages received out of those messages scheduled per patient, for the duration of the 12 weeks intervention. Intervention engagement was calculated using the median number of days patients interacted with the intervention during the 12-week intervention period. Data were captured objectively

by digital log files and extracted by a member of the research team.

Sample Size

The sample was selected to obtain evidence about the feasibility to implement a cost-effectiveness trial in primary care. It aimed to provide evidence about the potential effectiveness of the intervention, and the values needed to estimate clinically meaningful outcomes (eg, mean and CIs for systolic blood pressure and hemoglobin A_{1c}). We included more participants in the intervention group, to obtain more information about the mechanisms by which the intervention supported medication adherence, and about the intervention engagement and satisfaction.

Randomization and Blinding

Block randomization (4 blocks, each of size of 25) was conducted to ensure random group allocation. The random sequence was generated by a centralized Web-based service [19] and was stratified in 2 important confounders: treatment adherence, as measured by the Medication Adherence Rating Scale, and burden of pills. Medication Adherence Rating Scale threshold of 24 was selected to indicate low (<24) or high (≥24) adherence. A burden of pills ratio of 10:6 (10 tablets: 6 different health conditions) was selected to indicate low (<10:6) or high (≥10:6) burden of pills; and the ratio was based on our pilot studies [12].

Data to calculate the burden of pills ratio were extracted from medical records, and Medication Adherence Rating Scale was self-reported. Both measures were entered into the randomization webpage by a member of the research team, after the completion of baseline consultations.

Health care providers were blinded to group allocation during baseline consultations. Participants were partly blinded during the baseline consultations as the purpose of the study was explained to them (trial videos in Multimedia Appendix 1).

Data Analysis

The analysis was performed based on complete cases at follow-up, excluding missing data. That is, only participants who completed the outcome measures at follow-up were included in the analysis. Histograms were used to explore continuous variables' distribution, and the Levene test was used to assess the assumption of equality of variance between groups. A *t*-test was used to investigate the differences between independent groups, and when its assumptions were not met, a nonparametric Mann-Whitney test for independent samples was conducted. Descriptive statistics (eg, means, SD, and percentages) was used for comparisons between groups, and for describing fidelity, engagement, and satisfaction with the intervention. A subgroup analysis was performed to explore differences in outcomes due to missing data: we compared if there were statistically significant differences between responders and nonresponders at each of the baseline and follow-up outcome measures. Subgroup analyses were performed on the total sample size. Multivariable regression analysis was performed to explore the mechanisms by which the intervention supported behavior change and control of medication-related clinical outcomes. The analysis was conducted in December 2019 using STATA.

Ethical Consideration

The study protocol was approved by the Ethics Committee of East of England, Essex Research Ethics Committee (REC Reference number 17/EE/0203) and Health Research Authority. Written informed consent was obtained from all study participants.

Results

Recruitment

A total of 4468 eligible patients were invited to the study. From those, 256 expressed interest to participate (a 5.7% response to the invitation), 140 were invited and attended consultations, and 135 were deemed eligible and randomized to the intervention (n=79) or control (n=56) group.

Randomization

The groups were very similar on baseline variables used for minimization and for most other variables. The majority (122/135, 90.3%) of patients were above 50 years of age (Table 1). Intervention group patients self-reported taking more pills per day compared with usual care group patients. This variable was not accounted for minimization, because an objective measure of burden of pills was selected (eg, burden of pills ratio extracted from medical records) instead of self-reports.

Table 1. Patients characteristics at baseline.

Variables[a]	Intervention group (n=79)	Usual care group (n=56)	*P* value
Index of multiple deprivation, n (%)			**N/A[b]**
20-30(most deprived)	9 (11.4)	6 (10.7)	
30-40	46 (58.3)	31 (55.3)	
40-50	0 (0)	0 (0)	
50-60	6 (7.6)	4 (7.2)	
60-70	6 (7.6)	8 (14.3)	
70-80 (least deprived)	12 (15.1)	7 (12.5)	
Age (years), n (%)			**.37**

Full-time	22 (27.8)	10 (17.8)	
Part-time	12 (15.2)	3 (5.4)	
Unemployed	1 (1.2)	1 (1.8)	
Unable to work due to disease	3 (3.8)	7 (12.5)	
Retired	41 (52)	35 (62.5)	
Number of pills prescribed to take per day, self-reported, mean (SD)	8.13 (6.21)	5.95 (5.14)	.03
Number of different pills prescribed to take per day, self-reported, mean (SD)	5.74 (3.67)	4.57 (3.52)	.06
Health condition, n (%)			**N/A**
Hypertension	42 (53.2)	38 (67.9)	
Type 2 diabetes	32 (40.5)	16 (28.6)	
Comorbidities of hypertension, type 2 diabetes, and cholesterol	5 (6.3)	2 (3.5)	
Medication adherence, mean (SD)			
Number of days of adherence, last week	6.46 (1.23)	6.38 (1.29)	.73
Percentage of adherence, last month	91.19 (13.11)	93.98 (33.32)	.49
Medication Adherence Rating Scale	22.78 (2.81)	23.25 (2.32)	.30
Repeat prescription	0.97 (0.20)	0.95 (0.26)	.64
Quality of life, mean (SD)			
EQ-5D[c], 5-items	1.71 (0.76)	1.74 (0.75)	.86
EQ-5D, total health	76.01 (19.68)	47.83 (21.56)	.74

[a]Data are reported as means (SD) or number (percentage). Health condition: main comorbidities were extracted from prescription data. Index of Multiple Deprivation was calculated based on general practice postcode; 10: low Index of Multiple Deprivation to 100: high Index of Multiple Deprivation. Repeat prescription was defined and calculated: supply of medication claimed by the patients, excluding the next prescription day the medication was claimed, and divided by the number of days of assessment period. Assessment period at baseline refers to the supply claimed by each patient before the

start of the study (ie, consent process). Assessment period at follow-up refers to the last 2 months of the study. Ratio was calculated per patient due to different denominators (eg, supply prescribed to be issued every 28 or 56 days). The overall adherence value was calculated by averaging each patient's ratio and dividing by the total number of patients.

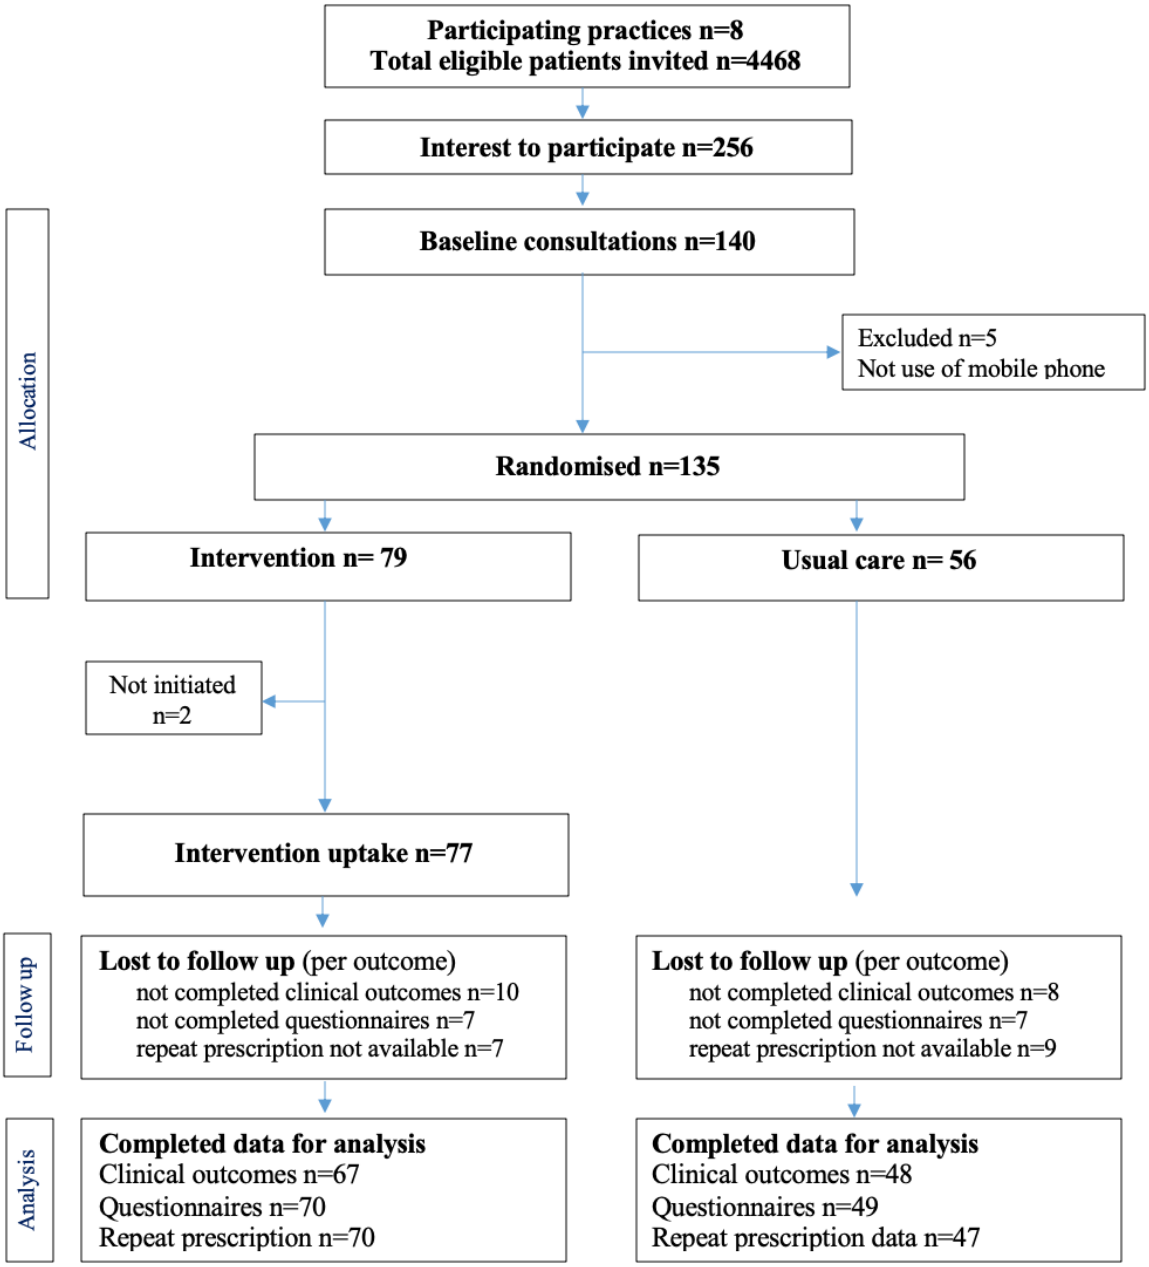
[b]N/A: not applicable.

[c]EQ-5D-5L: descriptive system of health-related quality of life states consisting of five dimension (mobility, self-care, usual activities, pain/discomfort, anxiety/depression) each of which can take one of five responses. The response record five levels of severity (no problems/slight problems/moderate problems/ severe problems/ extreme problems) within a particular EQ-5D dimension.

Attrition Rate

At 3 months follow-up, 88% (119/135) of participants completed the self-reported questionnaires and 85% (115/135) completed practice visits and provided clinical outcomes. Repeat prescription data were obtained for 87% (117/135) of the recruited patients (Figure 1).

Figure 1. Trial CONSORT patients flow diagram.



Intervention Retention Rate

Of those randomized to the intervention group, 97% (77/79) initiated the intervention: intervention uptake was defined by the number of participants who responded to the intervention messages during the first week of the intervention. Reported reasons for not initiating the intervention after group allocation was hospitalization. Intervention drop out was 2.5%, defined as the number of participants requesting to stop the intervention; and all drop out was captured during the first 4 weeks of the intervention.

Outcomes

The analysis found statistically significant difference in the repeat prescription adherence (t_{116}=2.27; *P*=.02; mean 0.99 [SD 0.11] for the intervention group vs 0.92 [SD 0.21] for the control group), days of adherence (t_{112}=2.37; *P*=.02; mean 6.85 [SD 0.47] vs 6.36 [SD 1.59]), Medication Event Monitoring System (t_{10}=4.04; *P*<.001; mean 6.05 [SD 2.29] vs 3.5 [SD 4.94]), and percentage of adherence (t_{112}=1.69; *P*=.05; mean 96.64 [SD 5.60] vs 91.89 [SD 18.60]) between groups, suggesting improvements in the intervention group. Nonstatistically significant differences in Medication Adherence Rating Scale (t_{104}=−0.24; *P*=.98; mean 23.66 [SD 1.99] vs 23.67 [SD 2.33]) between groups were found (Table 2).

Systolic blood pressure was lower (mean difference −0.6 mmHg, 95% CI −7.423 to 6.301) in the intervention group (137.8 mmHg) compared with the usual care group (138.4 mmHg). Similarly, hemoglobin A_{1c} was lower (a mean difference of −4.53 mmol/l, 95% CI −13.099 to 4.710) in the intervention group (57.2 mmol/l) in comparison to the usual care group (61.7 mmol/l), but for both of these clinical outcomes, this study was not intended to be powered to detect significant between-group differences. No statistically significant differences were found in quality of life between groups (t_{112}=0.524; *P*=.60; 2-tailed).

Subgroup analysis found no differences between the respondents and the nonrespondents of each of the above-mentioned outcomes.

Table 2. Difference between intervention and usual care group in medication adherence at 3 months follow-up.

Outcome[a]	Intervention group	Usual care group	Test statistic (*df*)	*P* value (2-tailed)	Mean difference	95% CI
Medication adherence						
Days adherence	6.85 (0.47)	6.36 (1.59)	2.37 (112)	.02	0.49	0.08 to 0.87
Percentage adherence	96.64 (5.60)	91.89 (18.59)	1.7 (112)	.05	4.74	−0.29 to 9.52
Repeat prescription	0.99 (0.11)	0.92 (0.21)	2.27 (116)	.02	0.07	0.00 to 0.12

[a]Figures per complete case analysis. Data are reported as means (SD) and are not adjusted for any baseline characteristics. The numbers present the difference between the intervention and the comparator group in outcomes at 3 months follow-up. Positive numbers present outcomes that were larger among the intervention group than the comparator group, and negative numbers present outcomes that were smaller among the intervention group than the comparator group.

Intervention Mechanism of Action

Multivariable regression analysis found that between-group differences in days of medication adherence was explained by changes in intentional and nonintentional nonadherence for the intervention group (beta.=074, SE=0.464; *P*=.04), but not for the control group (beta=.00, SE=1.35; *P*=.37); suggesting that changes in intentional and nonintentional nonadherence explained the improvements in medication adherence for the intervention group.

Further multivariable regression analysis revealed that better control of clinical outcomes (blood pressure <140/90mmHg or hemoglobin A_{1c} <42mmol/mol) was predicted by more days of medication adherence and positive beliefs about taking medication for the intervention group (beta=3.57, *P*=.03), but not for the control group (beta=.795, *P*=.46).

Intervention Fidelity, Engagement, and Satisfaction

Intervention fidelity was 100% for the total duration of the intervention, suggesting that all messages were delivered as scheduled. Most (56/77, 73%) intervention group patients selected to receive 1 intervention message per day and some (21/77, 27%) selected to receive 2 messages per day. The majority of patients selected to receive intervention messages around the time they used to take their medications.

Total intervention engagement was 12 days, suggesting that patients interacted with the digital intervention and potentially engaged with the medication adherence intervention.

The majority of the participants found the intervention easy to use (51/70, 73%), liked the automated voice delivering the voice messages (44/70, 62.5%), the content of the messages (50/70, 71.5%), and the availability to call and ask questions when needed (36/70, 51.6%). Overall, patients were satisfied with the experience with the intervention (53/70, 76%), and they would recommend it to other people who take medications for a long-term health condition (46/70, 65%; Multimedia Appendix 2).

Discussion

Principal Findings

Among those patients with either or both high blood pressure and high glucose levels recruited from primary care practices, patients who used the digital intervention improved their adherence to medication at 3 months by an average of 2 days (intervention effect size Cohen d=0.42), compared with those continuing with their usual care only. Taking into consideration that adherence declines during the first month following usual care consultations [20], our trial suggests that the intervention can support treatment adherence to nonadherent patient.

The attrition rate was low, and the end of intervention clinical outcomes found that the intervention group patients had lower blood pressure and lower glucose levels, compared with those allocated in the control group. Although the study was not powered to assess effectiveness in clinical outcomes, considering the impact of medication nonadherence on uncontrolled blood pressure [21] and uncontrolled hemoglobin A_{1c} [22,23], these results provide us with confidence that the intervention is feasible and could potentially be an effective adjunct to primary care consultation.

The intervention effectively improved medication adherence by modifying patients' intentional and nonintentional nonadherence, which proves the importance of the highly tailored intervention to support health behavior change. This result proves that this highly tailored intervention can effectively support the processes of behavioral change and in turn the health behavioral outcomes.

It was also found that patients interacted with the digital intervention for 12 days, which provides us with confidence that patients engaged with the medication adherence intervention [24], a prerequisite to achieve behavior change and clinically meaningful outcomes at least in the short term.

Strengths and Limitations

This trial provides evidence about the efficacy of the intervention to improve medication adherence based on self-reports, which might over estimate adherence levels. Nevertheless, the proxy measure of adherence, that is, the repeat prescription claims, was statistically significant, which provides us with confidence about the efficacy of the intervention; although both these measures do not directly reflect medication-taking behavior.

Another strength of the study is the recruitment of patients from a range of primary care practices, most in highly deprived areas. Considering the challenges with recruitment in a primary care setting [25], the recruitment rate provided us with confidence that the interventions can be scaled up to a wider range of practices and reach patients of different socioeconomic backgrounds.

A limitation of this study is that we could not reliably identify the patterns of nonadherent behavior (eg, frequency and sequence of nonadherent behavior) when patients were enrolled in the study. Similarly, we could not reliably identify the frequency of changes in prescribed medications, as well as the reasons for these changes (eg, therapeutic thresholds reported by patients or clinicians) [26]. Nevertheless, we decided to enroll all patients, regardless of the patterns or reasons of past nonadherence, to obtain more information about the intervention engagement and mechanism of action.

Possible Mechanisms and Implications for Clinicians or Policymakers

The results of this study suggest that the intervention was effective at improving medication adherence by supporting intentional and nonintentional nonadherence, had good engagement and satisfaction, and low attrition rate. In view of the demographics of the participants, who had more experience with and possibly expectation of patient-clinician interactions, and the recruitment setting of the study [25], these findings prove that the digital intervention is a feasible and acceptable adjunct to primary care consultation.

The baseline face-to-face consultation lasted on average 30 min and involved the completion of study procedures and signposting patients to the digital intervention, in addition to usual care (eg, addressing patients' concerns and side effects). From those patients allocated to the digital intervention, only 1% requested additional human support regarding the use of this technology, and requests involved changes to the time of the message delivery, or the dose or the name of the medication when a change in the prescribed tablet was recommended by their health care providers. Moreover, the low attrition rate suggests that the intervention is highly acceptable as an adjunct to usual care. Given that the cost to deliver the digital intervention is very little (monthly cost of £0.029 per patient), and there were no adverse events or additional consultations recorded during the 3 months, it is likely that the intervention is inexpensive for the primary care.

Future Directions

Improved medication adherence has been associated with decrease in all-cause mortality and morbidity, and digital interventions can be a solution to rapidly evolve the provision of health care [10]. Future research of larger sample sizes and objective outcome measures for medication adherence (eg, urine analysis for detection of antihypertensive medication) is needed to provide evidence about the effectiveness and cost-effectiveness of the intervention to support treatment adherence and clinical outcomes.

Conclusions

This is the first trial that has been conducted in the primary care setting in the United Kingdom. The finding of this feasibility trial suggests that the intervention is a feasible adjunct to primary care consultations and effective in improving medication adherence and process of care to patients nonadherent to either or both antihypertensive and antiglycaemic medications. The intervention is scalable and low cost. More research is needed to evaluate its effectiveness and cost effectiveness.

Acknowledgments

This paper presents independent research funded by the National Institute for Health Research (NIHR) under the Research for Patient Benefit program [grant number PB-PG-0215-36032]. The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care. Authors AK, VM, JB, SE, SG, TP, and SS were funded by the grant PB-PG-0215-36032 and EM from NIHR Research Capability Funding. No financial disclosures were reported by the authors of this paper.

The authors would like to acknowledge Vikki Houghton for assisting in data collection. We would also like to thank the following GP practices in East of England for taking part in this trial: the Breckland Alliance (Grove Surgery, Watton Medical Practice and School Lane Surgery), the Cornerstone Practice, the Little St Jones Street Surgery, the Mattishal Surgery, the New Queen Street Surgery and the Stanground Surgery, the Orchard Surgery Dereham, the Riverside Practice, and the Wansford Surgery.

Authors' Contributions

AK and SS have developed the intervention. JB and SE developed the digital platforms to facilitate intervention delivery in collaboration with AK. SG provided clinical advice and TP statistical advice during the design of this trial. EM provided statistical advice during data analysis. AK led the implementation and evaluation of this trial in the primary care, and VM assisted in data collection. AK conducted the analysis and drafted this publication. SS advised AK during the above mentioned processes. The paper's contents have not been previously presented elsewhere. All authors have read and approved this manuscript for publication and report no financial disclosures. Primary data are available upon request to AK.

Abstract

Background: The internet-based stepped-care intervention iCAN-DO, used in the multicenter randomized controlled trial *AdultCan*, was developed for adult patients undergoing treatment for cancer and concurrently experiencing anxiety or depressive symptoms. iCAN-DO aimed to decrease symptoms of anxiety or depression. Step 1 comprises access to a library with psychoeducational material and a peer-support section, as well as the possibility to pose questions to a nurse. Step 2 of the intervention offers treatment consisting of internet-based cognitive behavioral therapy (iCBT) to participants still experiencing anxiety or depression at 1, 4, or 7 months after inclusion.

Objective: The study aimed to explore user experiences of delivery, design, and structure of iCAN-DO from the perspective of people with cancer.

Methods: We studied user experiences by interviewing 15 informants individually: 10 women with breast cancer (67%), 4 men with prostate cancer (27%), and 1 man with colorectal cancer (7%) with a mean age 58.9 years (SD 8.9). The interviews focused on informants' perceptions of ease of use and of system design and structure. Informants had been included in iCAN-DO for at least 7 months. They were purposefully selected based on activity in Step 1, participation in iCBT (ie, Step 2), gender, and diagnosis.

Results: Of the 15 informants, 6 had been offered iCBT (40%). All informants used the internet on a daily basis, but 2 (13%) described themselves as very inexperienced computer users. The analysis revealed three subthemes, concerning how user experiences were affected by disease-specific factors and side effects (User experience in the context of cancer), technical problems (Technical struggles require patience and troubleshooting), and the structure and design of iCAN-DO (Appealing and usable, but rather simple).

Conclusions: The results indicate that user experiences were affected by informants' life situations, the technical aspects and the design of iCAN-DO, and informants' preferences. The results have generated some developments feasible to launch during the ongoing study, but if iCAN-DO is to be used beyond research interest, a greater level of tailoring of information, features, and design may be needed to improve user experiences. The use of recurrent questionnaires during the treatment period may highlight an individual's health, but also function as a motivator showing improvements over time.

KEYWORDS

interactive web portal; stepped care; user experience; cancer; interviews

Introduction

Today, many people with cancer are cared for as outpatients during cancer treatment [1], leaving limited occasions for meeting health care personnel. People with cancer may experience multiple symptoms from the disease and treatment [2] and might need information and advice for self-care of these symptoms [3]. Many patients have questions, especially during ongoing treatment, and would need information and advice, but there is a risk that these questions remain unanswered and patients live with unmet needs [4-6].

One option is to have patients access information and support functions via the internet. Internet-based support can provide relevant quality-assured information with just-in-time access, and can be combined with packages for enhanced social support and behavior change [7]. One advantage with this is that people can use such support when they feel ready for it or have time to access a computer or mobile device.

Internet-based support for people with cancer could be a way of providing information and support that may improve self-management of symptoms and thereby relieve distress and unmet needs. Further, it seems that improved access to information via the internet can stimulate engagement and empowerment [8]. In *AdultCan* [9], which is a multicenter randomized controlled trial (RCT), an internet-based stepped-care intervention, iCAN-DO, has been evaluated regarding its effects on anxiety and depressive symptoms in people with breast, colorectal, or prostate cancer with these symptoms.

If iCAN-DO is effective in reducing symptoms, the step toward clinical implementation is not far ahead. However, before implementing internet-based support into clinical care, the experience must be carefully explored from the user perspective. Important user-experience aspects to explore may be ease of use, navigation in the system, and perceptions of the design and structure [10].

This paper aims at exploring user experiences of delivery, design, and structure of the internet-based stepped-care intervention iCAN-DO used in *AdultCan* from the perspective of individuals with cancer who have symptoms of anxiety or depression.

Methods

Design

This was a qualitative study with an inductive approach using data collected through semistructured individual interviews.

Setting

The Uppsala University Psychosocial Care Program and the Web Portal

We recruited the informants in this study from *AdultCan* (ClinicalTrials.gov Identifier: NCT-01630681), an RCT within the Uppsala University Psychosocial Care Program (U-CARE) [11]. U-CARE is a strategic research venture supported by the Swedish government and has a multidisciplinary composition involving caring science, psychology, and information systems. All U-CARE research projects deliver interventions and collect patient-reported data via a web portal (ie, *the portal*) developed within the U-CARE program.

At the time of the start of *AdultCan* in 2013, end users could access the portal using a two-step verification: (1) via username and password and (2) with a code sent by SMS. Most of the participant views employed the Bootstrap framework.

The AdultCan Trial

AdultCan targeted individuals with breast, colorectal, or prostate cancer with symptoms of anxiety or depression. Screening regarding symptoms of anxiety and depression was performed using the Hospital Anxiety and Depression Scale (HADS) [12]; participants with a score of more than 7 on either of the two subscales were randomized to the iCAN-DO or standard care groups.

We developed the structure and content of iCAN-DO in collaboration with team members in clinical cancer care, system developers, and end users [13]. Step 1 of the intervention was accessible for 24 months and comprised a nurse-led interactive support program based on Orem's Self-Care Deficit Theory and the concept of psychoeducation [14] and social cognitive theory [15]. A key part in this support program was an information library with materials and self-care advice concerning common problems surrounding cancer, such as pain, nausea, and sleeping problems (see Figures 1-4). Figure 1 illustrates the start page in the portal while the subsequent figures illustrate visual and written information on diagnosis (see Figure 2), treatment (see Figure 3), and advice for symptom management (see Figure 4).

Figure 1. The start page of the portal (in Swedish).

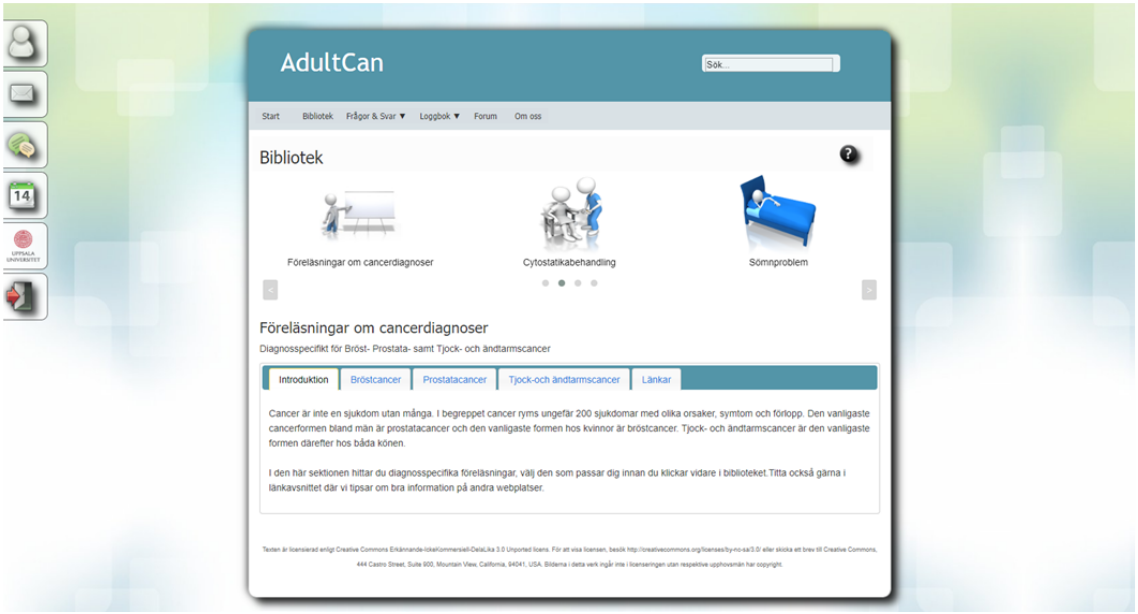

Figure 2. Diagnoses, with information on pathophysiology, prevalence, incidence, and prognosis (in Swedish).

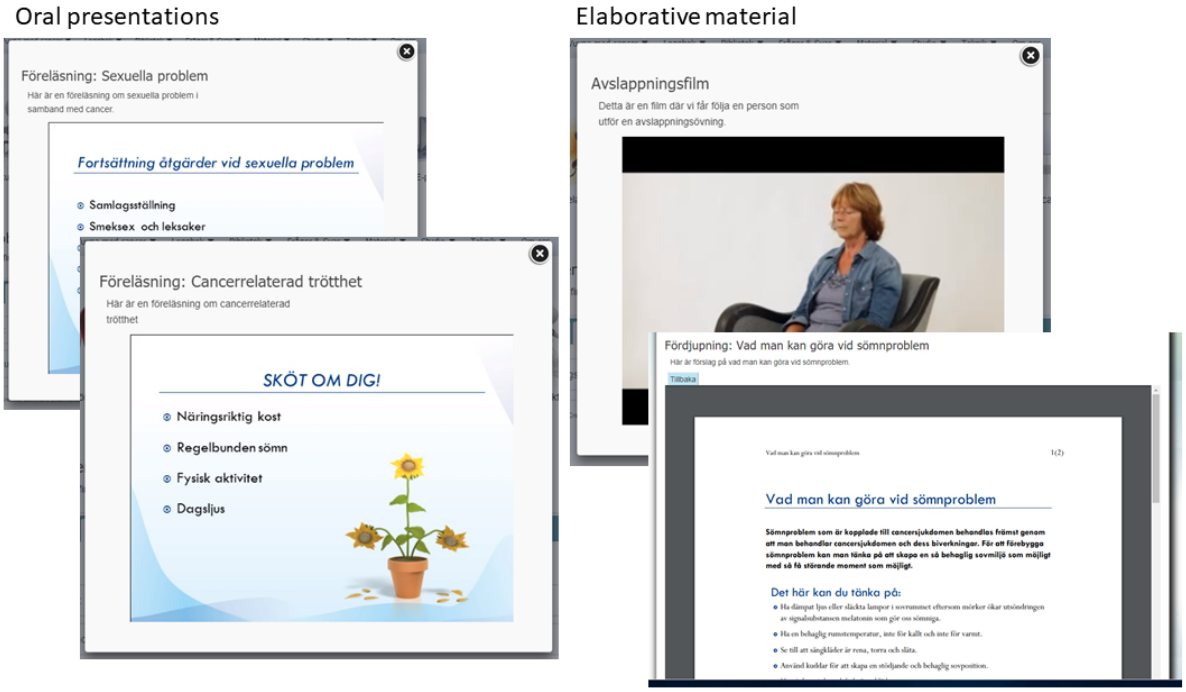
Figure 3. Oncological treatments: why and how (in Swedish).

Figure 4. Symptoms and consequences of anxiety and depression as well as advice for self-care (in Swedish).

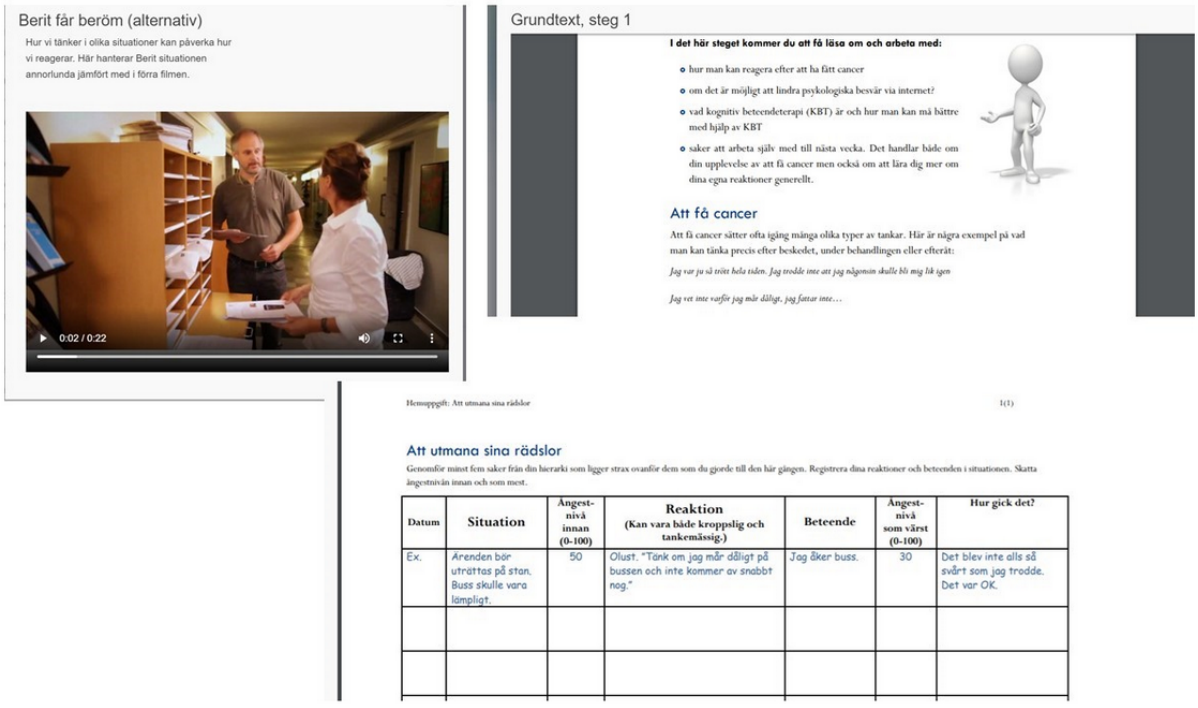


Information was available in text, audiovisual presentations, slideshows, and video clips. All contents were visible to all users, though some parts of the information concerned a specific diagnosis. Step 1 also contained a forum, a chat function, and a frequently asked questions (FAQ) section, alongside the feature *Ask an expert*, where users could pose questions (see Figure 5). In order to strengthen the therapeutic alliance, the nurses (Step 1) and psychologist (Step 2) were presented with a photo and a brief description [16].

Figure 5. Frequently asked questions (FAQ), *Ask an expert*, and chat function (in Swedish).

Step 2 in iCAN-DO constituted a 10-week internet-based cognitive behavioral therapy (iCBT) program [17] managed by a psychologist. iCBT was offered once and only to participants with prevailing symptoms of anxiety or depression (ie, score >7 on either HADS subscale) at 1, 4, or 7 months after inclusion. The treatment comprised 15 modules with written text, audiovisual presentations, and video clips covering a range of problem areas that were relevant for this population, including worry, fatigue, and depressed mood [18]. See Figure 6 for examples of a video clip, text, and homework assignment in iCBT.

Figure 6. Examples of a video clip, text, and homework assignment in internet-based cognitive behavioral therapy (iCBT; in Swedish).



All participants accepting iCBT were offered an introductory module, after which they were free to choose the most relevant modules to work with over 10 weeks. A psychologist guided the participants by monitoring their work, answering any questions, and delivering weekly feedback. All communication took place in the form of written messages via the portal.

Informants

To be included, informants had to have had access to iCAN-DO for at least 7 months. In order to obtain variation among informants, a purposive selection was performed, mainly regarding activity in Step 1 and whether they participated in iCBT or not, but also regarding age, gender, and general online activity. A total of 20 individuals were approached, of whom 2 declined to participate and 3 were unreachable. In total, 15 informants were interviewed (see Table 1) in 2016 and 2017. All informants used the internet on a daily basis, but their general online activity varied. A total of 2 informants (13%) described themselves as very inexperienced computer users.

Procedure

A letter was sent to potential informants with study information. They were informed that they would receive a phone call from research personnel within a couple of days asking about willingness to participate. If they did not want to receive this phone call, they could contact the person responsible for *AdultCan*; no one used that option. When a person consented to participate, a time and place for an interview were booked. All informants were treated with confidentiality and had time to consider their participation after getting written and verbal information. All provided signed informed consent. The study was approved by the regional committee for research ethics in Sweden, Uppsala county (Dnr 2012/003/9).

Data Collection

Questionnaires and Log Data

Background information on informants was retrieved from self-reported questionnaires. All informants' activity in iCAN-DO was logged in the portal. Information about general online activity was retrieved at the time of the interviews.

Interviews

The second author (AH) was the interviewer. AH is a registered specialist nurse with experience in palliative cancer care. AH has been involved in some parts of the development and delivery of the stepped-care intervention, but has no overall responsibility in the program. An interview guide with open-ended questions was used, containing questions regarding participants' user experiences of iCAN-DO. Follow-up questions were based on each informant's responses and were used to acquire more thorough descriptions of experiences [19]. Questions such as "How did that feel?" or "How did you use that?" were used, as well as probing and interpreting questions. One test interview was performed to explore the design and understanding of questions, but no adjustments to the interview guide were needed. Informants were offered the option to have iCAN-DO open during the interview, if they wanted to. The interviews were performed in a place chosen by the informant; some informants chose their place of work, some wanted to meet in their home, and a few chose the hospital. The interviews were tape-recorded and lasted between 45 and 120 minutes.

Data Analysis

Interviews were transcribed verbatim by AH, and latent content analysis [20] was used to analyze the interviews. The text was read several times and the manifest content (ie, what is explicit and obvious in the text) of each interview was divided into meaning units and condensed meaning units. Each condensed meaning unit was then given a code to describe the key message, and codes with similar content were allocated to the same category (see Table 2). An interpretation of the latent content (ie, the underlying meaning of the text) was made by abstracting the underlying implicit aspects of the manifest and explicit content. Thus, when several categories were identified as containing similar, repeating ideas, a subtheme was formed. The implicit underlying meaning of all subthemes was then abstracted to one overarching theme. AH and HI were mainly responsible for the analysis, but the group of authors—mainly HI, AH, BJ, and SA—discussed and considered the results on several occasions. The quotes presented in the paper were translated by the first author (HI), AH, and Linnea Holmén at Calyptic.

Table 1. Informants' characteristics at time of inclusion in the randomized controlled trial (RCT) AdultCan.

Characteristic	Value (N=15)

Meaning unit	Condensed meaning unit	Code	Category
That you can sit at home, in peace and quiet, when you feel like it and something comes up. You seldom come to think of things when you have the possibility to ask questions, at the hospital.	Studying the material when the questions arise	Available when the need arises	A web portal provides high availability and accessibility
The disease means that it's hard for me to get going, I feel best in the evening and that's when I can gather information in the portal.	Being able to gather information when I feel well	Availability tailored for my health	A web portal provides high availability and accessibility

Results

Overview

In the analysis, 10 categories were derived concerning user experiences and perceptions of delivery, design, and structure of iCAN-DO. The categories were abstracted into three subthemes with the overarching main theme *The cancer disease and its treatment place high demands on accessibility and user experience* (see Table 3).

Subtheme 1: User Experience in the Context of Cancer

The personal situation and consequences of illness, both somatic and cognitive, were mentioned by all informants as factors that in various ways affected their ability to make use of iCAN-DO. Symptoms of fatigue and pain could require being in a comfortable position when listening or reading. Some informants considered it facilitating to be able to use iCAN-DO on tablets as well as on a computer, even though the design was not optimized for mobile devices. Furthermore, having direct access to iCAN-DO was perceived as beneficial by those experiencing a lot of time constraints in everyday life. They could use iCAN-DO when it suited them and when they had the time.

The information in Step 1 was provided in different formats, and informants had varying preferences in regard to the material. Some assimilated the contents best by reading, others by listening to audio clips or watching video clips, and others by using some combination of these formats. Some printed all the material and read it on paper. Though video facilitated immersion in the material, in some cases video clips were considered too long or had poor audio quality, which hampered the informants' ability to pay attention. Furthermore, informants stated that answering questionnaires evoked both negative and positive feelings, but also made them reflect on their health. They felt questionnaires could be a part of health care, for example, as preparation ahead of a visit to oncology care.

Subtheme 2: Technical Struggles Require Patience and Troubleshooting

Many of the informants described the multistep log-in as an overly difficult way to log in, and an option of using Mobile BankID, an electronic identification application, would have been preferred by most. Some of the informants described how having different log-in codes caused problems. The multistep log-in also reduced spontaneous visits. The informants also described other technical struggles, such as the need for separate add-ons to make the page work and a perceived instability, for example, being involuntarily logged out and difficulties when communicating with the psychologist. Some of these problems were described as transient and occurring only in the initial phase, while others were seen as persistent. Perceived technical difficulties were described as a factor that caused negative feelings, lack of motivation, and a postponing behavior.

The prevalence of technical problems required a lot of problem solving. The informants described different ways of handling problems. Some informants described solving problems themselves by installing new software or requesting a new password. Others enlisted the help of relatives or friends. The importance of technical support was highlighted and those who contacted information technology (IT) support were satisfied with the help they got. Some preferred calling and others sent an email or direct message via the portal. Technical support was described as crucial for not giving up.

The informants also had suggestions for improvements to the interface. An aspect described as important was to receive a confirmation that a written message had reached the help desk when awaiting an answer.

Subtheme 3: Appealing and Usable, but Rather Simple

iCAN-DO was experienced as easier to use than many other systems, and getting access to the contents was seen as more important than getting an advanced system. Some informants had the perception of an intuitive interface that was easy to understand and navigate, while others perceived the same simplicity as a shortcoming. The graphical design was described by some as simple and serving its purpose, while others found it dull or overly intricate. The experiences varied between informants who were experienced everyday internet users with high interest in social media and those who were more inexperienced with little or no use of social media.

When participants had questionnaires to answer in the portal, repeated reminders were sent via SMS. Informants described the reminders as a trigger for accessing the supporting material as well, as it meant they logged in. The informants also came up with ideas regarding functions that could improve iCAN-DO, such as better layout of questionnaires, adding news coverage, and adding graphical displays of self-reports.

Table 3. The results of qualitative content analysis—subthemes, categories, and quotes—for the theme The cancer disease and its treatment place high demands on accessibility and user experience.

Subtheme and categories	Quotes
User experience in the context of cancer	
My health status and environment affect how I use the portal	"The tablet is light and the computer is heavy...so if my body is hurting in every fiber, I don't want to have something heavy in my lap, so I used the tablet almost all the time..." [Informant #3]
Multiple delivery modes enable assimilation of the content	"The mini lectures have been good, maybe they could have been a bit shorter...because it's been tough when you're sick to listen for such a long time." [Informant #13]
A web portal provides high availability and accessibility	"Like, when you are on a bus or train you might want to use the time to check something, you have to be able to do that. Right now, I use my smartphone more than my computer; I only use the computer when I really have to." [Informant #7]
Questionnaires make you reflect on your health	"I could feel a little...well, blue, afterwards. You think...Should I feel like that too?" [Informant #2]
	"...even just answering the questions has been therapeutic. I noticed a difference myself too. At the start I indicated how bad I felt and I noticed that it did actually get better." [Informant #12]
Technical struggles require patience and troubleshooting	
Complicated multistep log-in procedure	"It was awfully tricky, and I should really be able to do it, because I've worked a bit with VPN [virtual private network] connections, but this one crashed several times for me; it didn't work..." [Informant #3]
Annoying technical problems reduce motivation to use the portal	"You get a response within the response itself and then I have an inbox as well, where it ended up. So you have it in two places and even though I have read the response, it still looks unread in the inbox." [Informant #9]
	"Technical hassles are not good, it's very annoying...and once you postpone your visit it might never happen." [Informant #10]
Troubleshooting and the importance of support	"Because otherwise, if you don't get help, you feel like you don't give a damn...When there are technical difficulties on the site you postpone your visits, I will log in later...but then you never do it. But then at the end I got information [from the help desk] so..." [Informant #1]
Appealing and usable, but rather simple	
Intuitive but unstable interface	"I thought it was easy to see what it was about, what they had...if there was something that appealed to you, then it was easy to access and I could see what it said. I'm not a computer person, really, but I managed pretty well, I think, and that's a good sign." [Informant #4]
Appealing, yet simple graphical design	"For people in general, it's probably pretty good that it is so simple. Because then it will be used." [Informant #14]
	"I am into Instagram, Facebook, and all those places, you know, so I felt this was...a bit boring. I am sorry to say that, but that's just me. It doesn't give me the kind of input and variety I need." [Informant #11]
Technology that creates motivation and innovation	"It was good to have the reminders, because sometimes you maybe don't have the energy the first time, you're having a bad day, but then maybe you can manage it after the second or third reminder...I have often looked around a bit at other things when I was logged in on the portal anyway." [Informant #11]
	"In that part, you would want a graphical...like a curve so that you can see it yourself...Another thing that I've thought about is that there could be like a news function, things that are going on within oncology care, like in all of Sweden, maybe." [Informant #12]

Discussion

Principal Findings

According to the informants, the user experience of iCAN-DO was affected by physical and cognitive symptoms, as well as time constraints in everyday life, which all highlighted the importance of 24-hour access, a responsive design, and a well-functioning system providing access to technical support.

Both health-related problems and external circumstances may constitute barriers for making contact with health care in the daytime or during working hours. By using iCAN-DO, informants could study information at a time suitable to their situation and health, and could review the information as many times as needed. The delivery of content in different formats also stood out as a positive feature, as informants reported such varied preferences in this regard. In the developmental phase, the use of different information formats was suggested as highly important by patient representatives, who had their own experiences of fatigue or other debilitating symptoms. Further, the participants underlined the benefit of the contents being accessible via different devices, such as computer, tablet, or mobile phone. In the trial, a responsive design was later

incorporated into the software in order to adapt the portal to mobile devices, including smartphones and tablets. Regardless of which functions are incorporated and what devices are used, it is important to include functions for recording portal activity and usage, to secure internal validity [21].

Informants also described various aspects of filling out questionnaires. Some reported that the questionnaires reminded them of their situation in a negative way, but others perceived the questionnaires as enlightening and providing them with feedback on their own health over time. Other studies have reported promising results on individual tailoring of content depending on diagnosis, treatment, and even tracking of symptoms [22], given that the individual does not feel distress at such monitoring [23]. To motivate patients and professionals to use patient-reported symptoms, it is important to underline the aim of this use and to clearly state which professionals have the responsibility to review and discuss the results [24].

Various aspects of technical struggles were revealed in the interviews. Before launching iCAN-DO in *AdultCan*, user-experience testing was performed in various settings, by both professionals and patient representatives. Still, informants in this study described difficulties, and technical support was crucial for not giving up. Experiencing difficulties when attempting to use a program has been described to influence perceptions of its value as a whole. However, training and technical support can make users feel more capable over time [25,26]. This is in line with the Technology Acceptance Model [27], which posits the predictive power of the person's perceived usefulness of the system and ease of use. Though the informants in this study mentioned perceived benefits from the 24/7 access and the multifaceted information, the technical problems when logging in or filling out questionnaires were described as hampering use. Some problems were transitional and could be solved. The possibility to contact a support desk was crucial, suggesting that a highly accessible support function may be very important for new web portals. A take-home message is that electronic health (eHealth) initiatives, to a higher extent, should look into how to provide more user support using technology. For instance, in multiple fields of practice, there is an increasing use of chatbots (ie, text-based conversational interface) to provide customers with support. Such technologies have also been considered in the health care setting when it comes to medical counseling (eg, in oncology care [28]), but could be extended to include technical support to (1) provide a better user experience and (2) increase the scalability of eHealth solutions by reducing the need for support desk staff.

Since iCAN-DO was part of an RCT, an authorization procedure was necessary for control and internal validity. However, many informants perceived the multistep log-in procedure as burdensome, which has also been recognized in similar platforms [29]. After this set of interviews, access to iCAN-DO has been facilitated by the incorporation of Mobile BankID, which drastically reduced the need for support regarding log-in matters. BankID is the leading electronic identification solution in Sweden and has around 8 million active users out of the total population of 10 million people. Even though this particular solution is not available in all countries, we want to stress the need to investigate and adopt electronic identification solutions that are prevalent in the national care provision context and that are well known to the users.

The experiences of the design and the user experience of iCAN-DO varied between the informants who were experienced internet users with a high interest in social media and those with little or no use of social media. As stated earlier, patient representatives from the three diagnostic groups participated in the development of iCAN-DO to increase the relevance of the internet-based stepped care. This group of patient representatives was a quite homogenous group with regard to their opinions about the graphical design, stressing the need for simplicity. It is worth highlighting that more computer experience has been reported to be associated with increased use in another web-based intervention for patients with cancer [30]. In a review of patient web portals for primary and secondary prevention, sociodemographic factors, such as belonging to a racial and ethnic minority, having less education, and having lower health literacy, have been found to be associated with less system use [31]. Thus, when designing future web-based interventions, efforts should be made to do a user analysis and to include patient representatives with varied experience of social media, internet use, education, health literacy, and ethnicity. Furthermore, future web portals not restricted to research projects may benefit from updating the content at regular intervals [28] and incorporating features with news and statistics.

Methodological Considerations

The aim of this study was to evaluate the user experiences of iCAN-DO used in *AdultCan*; thus, the only people available for inclusion were participants in the ongoing trial, which might lower the transferability to other people and contexts. The sample also had a predominance of female informants with breast cancer, reflecting the total sample in the RCT. The majority of the informants were well educated, which may act as a confounder for both perceived usefulness and user experiences of the portal and its material. Beyond differences in diagnoses and education, informants in this study varied in other aspects, such as general online activity and age. Even though the results relate only to this particular portal and web-based support, the take-home message regarding accessibility, delivery mode, technical matters, and design aspects is one that researchers and designers of other web-based support might benefit from. Future studies should consider the user experience in light of not only age, gender, and diagnosis but also factors such as ethnic background, education, and health literacy.

Conclusions

The high accessibility and variety of delivery modes provided by iCAN-DO were important, but consequences of illness, as well as individual situations and preferences, placed high demands on user experience. Technical struggles decrease motivation and usage, which highlights the importance of a support function. Users' internet activity, computer experience, and interactions in social media are aspects that seem to impact on the perception of the interface and graphical design. Future web portals would gain from tailoring both content and design to individual preferences.

Acknowledgments

The study was funded by grants from Forte and the Swedish Cancer Society.

Abstract

Background: People living with cancer face numerous psychosocial challenges, including cancer-related fatigue, fear of recurrence, and depression. There is a lack of digital interventions tailored to the needs of people living with all types of cancer. We developed a 6-week, digital, peer-delivered, self-management program: iHOPE (Help to Overcome Problems Effectively; where 'i' indicates the digital version of the program). The program is underpinned by positive psychology and cognitive behavioral therapy to meet these psychosocial challenges.

Objective: This study aimed to assess the feasibility of the iHOPE program among people living with cancer. Program adherence and satisfaction along with changes in psychological distress and positive well-being were measured.

Methods: A pre-post, acceptability, and feasibility design was used. People living with cancer (N=114) were recruited via a national cancer charity in the United Kingdom and were given access to the iHOPE program. Demographic and other participant characteristics were recorded. Participants completed digital measures at baseline and the end of the 6-week program for depression, anxiety, cancer-related fatigue, cancer *worry* or fear of cancer recurrence, positive mental well-being, hope, gratitude, and health status. The website's system recorded data on the usage of the program. Satisfaction with the program was also measured.

Results: A total of 114 participants completed the baseline questionnaires. Of these, 70 people (61.4%) participated in all 6 sessions. The mean number of sessions undertaken was 5.0 (SD 1.5). Moreover, 44.7% (51/114) of participants completed at least three sessions and end-of-program outcome measures. A total of 59 participants completed the satisfaction questionnaire, where ≥90% (54/58) of participants reported that the program was easy to navigate and was well managed by the peer facilitators, and that they found the social networking tools useful. Preliminary efficacy testing among the 51 participants who completed baseline and postprogram outcome measures showed that postprogram scores decreased for depression, anxiety, cancer-related

fatigue, and fear of recurrence (all $P<.001$) and increased for positive mental well-being ($P<.001$), hope (both $P<.001$), and gratitude ($P=.02$).

Conclusions: The feasibility evidence is promising, showing that the peer-delivered digital iHOPE program is acceptable and practical. Implementation of the iHOPE program on a wider scale will incorporate further research and development to maximize the completion rates of the measures. Initial effectiveness data suggest positive impacts on important cancer-related quality of life and mental well-being outcomes. A randomized controlled trial design with a longer follow-up is needed to confirm the potential of the iHOPE program for improving mental and physical health outcomes for cancer survivors.

Introduction

Background

Globally, there were an estimated 18.1 million new cases of cancer in 2018 [1]. The worldwide incidence of cancer is predicted to rise by 75% over the next two decades [2], leading to a world cancer burden of around 25 million cases by 2030 [3]. Globally, there are around 43.8 million people living 5 years beyond their diagnosis [1]. On the basis of the most recently collected national datasets in the United Kingdom, 4.7 million new cases of cancer were detected in 2018, with 13.5 million people living 5 years beyond their diagnosis [4]. The number of cancer survivors in the United Kingdom alone is projected to increase by approximately 1 million per decade from 2010 to 2040 [5]. Combined with effective treatments, this leads to a growing population of cancer survivors, many with unmet needs, and experiencing psychosocial and physical difficulties.

Cancer survivors face a number of challenges following primary treatment, including fatigue, pain, sexual problems, cognitive functioning, fear of cancer recurrence, depression, anxiety, social isolation, and financial issues [6-8]. A substantial number of studies report such difficulties in the long term, particularly when treatment ends and contact with health care professionals diminishes, patients often report feeling abandoned, vulnerable, and as if they have lost the *safety net* they felt they had during treatment [7]. Clinically significant cancer-related fatigue is common [9,10]. Research suggests that after treatment has ended, a significant proportion of cancer patients experience fear of recurrence [11], with potential long-term negative impacts on quality of life and mental health, including hypervigilance, anxiety, posttraumatic stress, and depression [11-16]. Support for fear of cancer recurrence is an unmet need for between 22% and 90% of cancer survivors [12]. Overall, 12% to 20% of survivors of cancer meet diagnostic criteria for major depression and 18% to 40% for an anxiety disorder in the first 2 years following diagnosis [15,16]. Although these problems are frequently encountered in clinical practice, no clear consensus exists on the best management strategies to support people experiencing anxiety and depression posttreatment.

In the United Kingdom, the National Health Service (NHS) national health care strategy has identified the important role that technology can play in supporting patients with long-term conditions to be better able to self-manage their health [17,18]. This builds on the UK National Cancer Survivorship Initiative, which highlighted the need for a greater focus on recovery, health, and well-being after cancer treatment [19]. Digital self-management interventions are then a central feature of future plans to support cancer survivors.

Self-management interventions have been found to improve outcomes, including quality of life and health care utilization in long-term conditions [20]. Although there are substantial issues concerning intervention fidelity and content, implementation, and scaling and reach of intervention delivery, findings from a review and meta-analysis of digital self-management interventions for cancer survivors found generally positive, support for this approach [21]. A recent systematic review of all cancer self-management interventions highlighted the enormous diversity in intervention content, rendering it difficult to draw conclusions about their effectiveness, and found that there was very poor sustainability of interventions [22]. Furthermore, it is vital to note that many of these research-based interventions are not openly available to the public, with poor implementation observed [23]; indeed, there are very few self-management programs actually available in the United Kingdom [24]. Partnering with implementation stakeholders at an early stage in intervention development is advised to address this challenge [25].

In response to the shortage of available, tailored self-management support programs for cancer survivors, we worked with cancer survivors, clinicians, and other experts to develop a group-based, face-to-face self-management program: Help to Overcome Problems Effectively, known as the *HOPE* program, for survivors of all types of cancer. A recent systematic review of self-management interventions showed that content was largely based on expert opinions or previous models of self‐management or chronic care, with patient input into the design reported in only about 10% of the studies [26]. Therefore, the involvement of cancer survivors in the development, testing, and facilitation of the HOPE program is a particular strength of the intervention compared with other cancer self-management programs. Furthermore, the HOPE program is novel and distinct from many other cancer self-management programs because of its roots in positive psychology [27-29] and its unique focus on hope and gratitude to create an upward spiral of positivity [30] to improve well-being and coping. Fredrickson [31] shows that increasing positive emotions broadens attention, thinking, and action, which enables people to develop more creative thought and action pathways (eg, expanding coping skills), and thus

develop crucial personal and social resources for self-management.

Hope theory [32,33] is similar to self-efficacy theory, but the latter focuses on specific goals and behaviors, whereas hope theory recognizes enduring cross-situational goals and behaviors, and as such, hope theory is better suited to the complexity of managing the diverse impact of long-term conditions. Goals are fundamental in hope theory, which encompasses a cognitive set that is based on both agency (goal-directed determination) and pathways (planning ways of achieving goals).

Gratitude has been shown to improve psychological well-being and increase positive emotions [34,35], with some interventions showing that increasing gratitude is linked to improvements in depression [36]. A gratitude activity is a weekly feature in the HOPE program and is designed to increase participants' positive emotions. The HOPE program also includes other evidence-based cognitive behavioral therapy and positive psychological activities such as identifying personal strengths, scheduling pleasant activities, mindfulness, relaxation training, and reviewing successes.

Group curative factors of instilling hope, universality, and altruism [37] are embedded within the HOPE program content, where participants observe their peers overcoming challenges and achieving goals (*instillation of hope*), share experiences (*universality*), and provide informational and emotional support for each other (*altruism*). Thus, drawing on the principles of positive psychology, the hope theory and gratitude, and embedding group curative factors, the HOPE program provides participants with a novel toolkit to develop skills and resources to improve their well-being and quality of life during and beyond treatment.

Objectives

The HOPE program recognizes the common challenges and unmet needs across all types of cancer, including fatigue, fear of recurrence, and psychological distress [6-16]. The HOPE program was co-designed with service users and stakeholders from one of the United Kingdom's leading cancer charities, Macmillan Cancer Support (MCS) [38,39]. It has been delivered face-to-face to breast cancer survivors and in community settings for all cancer types [38,40]. Initial evaluations demonstrate that cancer survivors participating in the face-to-face program feel more confident and hopeful and valued the peer support element of the program, which made them feel less alone with their problems [38].

MCS experienced difficulties recruiting cancer survivors to the face-to-face program in some regions of the United Kingdom. This mirrors the national and international self-management experience [41]. Digital delivery of interventions can improve access and increase user choice for those who may be unable to physically attend face-to-face programs and those who may prefer a remote, digital intervention [42].

It is unclear if digital interventions can offer the same active intervention ingredients, known as group curative factors [37], that participating in a face-to-face group provides. The growth in social networking potentially offers a strong sense of community, a place for sharing experiences of cancer, and a useful platform for self-management and support [43]. Evidence shows that digital interventions have a positive impact on the quality of life and other health, self-management, and behavioral outcomes in cancer survivors and other long-term conditions [44,45]. Digital interventions also appear to address barriers to participation [46] (eg, physical, psychological, cognitive, economic, social, and cultural factors) in existing face-to-face programs [47]. Therefore, we adapted the existing face-to-face format of the HOPE program to create the digital iHOPE (Help to Overcome Problems Effectively; where the 'i' indicates the digital version to distinguish it from the face-to-face HOPE program) program. In this study, we aimed to explore the feasibility of the digital version of the program available for people living with all types of cancer. As a feasibility study, the specific aims were to examine the following aspects:

- Implementation: recruitment rates, completion rates of measures, and adherence rates to the program (ie, number of participants who participated in the sessions)
- Acceptability: satisfaction ratings, ratings of appropriateness and potential usefulness of the program, and indications of positive and negative effects on participants
- Practicality: feedback on the ability to complete activities in terms of time constraints and other personal commitments
- Preliminary efficacy testing: outcomes and effect size estimation [48-50].

Methods

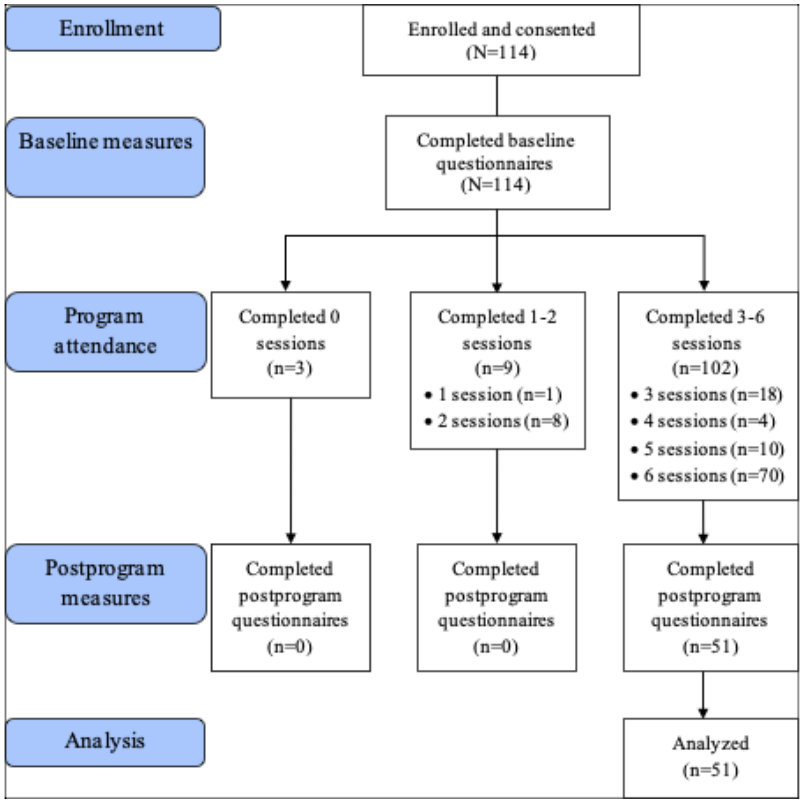
Informed Consent

The study was approved by the Coventry University Ethics Committee (P21296). All participants provided informed consent before participation in the study.

Participants and Recruitment

A convenience sample of cancer survivors recruited to 5 iHOPE programs over 10 months was used (n=114). Eligible study participants were adults (≥18 years), living in the United Kingdom, coming to the end of cancer treatment or surgery, or having recently completed treatment, able to read and understand English, and with access to the internet and an email account. Participants were recruited through advertisement of the program on the MCS Facebook page, Twitter, and Macmillan's *LearnZone* area on their website. Participants were allocated a place on the program on a first-come, first-served basis. In light of previous digital intervention research showing that participants who completed a minimum of 50% of sessions had a reliable change in outcome measures [51], we categorized participants as having completed the course if they completed three or more of the 6 sessions (n=102). All participants completed the baseline questionnaires (n=114), but only those who also completed the postprogram questionnaires were included in the analysis (n=51). Of the remaining 63 participants who did not complete the postprogram questionnaires, 3 participants did not use the program at all, 9 participants completed 1 or 2 sessions, and 51 participants completed between 3 and 6 sessions (see Figure 1).

Figure 1. Participant flow.



Program Development

Full details of the development of the HOPE program have been published elsewhere [38-40,52,53]. The HOPE program has been taxonomized using the taxonomy of self-management support [54]. The adaptation to the digital iHOPE program was undertaken in consultation with people who had attended, delivered, and commissioned the delivery of the face-to-face HOPE program. A user-centered, iterative approach was undertaken [55], as detailed below. A set of design requirements and a design brief were drawn up in consultation with end users and stakeholders. It was specified that the digital version (iHOPE) should replicate the process and content of the group-based HOPE course to ensure that the marketing and recruitment of both versions of the course would be consistent and that cross-training of face-to-face facilitators to deliver iHOPE would be kept to a minimum. The initial digital version of HOPE went through a number of iterative testing sessions, with improvements made to usability after each iteration. It was intended through these iterations to develop a system that was usable and accepted by the intended user group to increase the likelihood of uptake and continued usage, and ensure the technology did not prove a barrier to engagement and participation.

Iteration 1

We conducted usability testing of iHOPE with stakeholders, including MCS staff, trainers, and cancer survivors. A link to the course was circulated to past participants and facilitators of the face-to-face program. They were asked to work through the web-based material and provide feedback to specific questions via email. This study aimed to explore if the core components of HOPE were integrated effectively.

Iteration 2

The iHOPE web-based course was then reviewed by a wider audience and demonstrated to delegates at the National Cancer Voices conference in November 2013. This round of feedback focused on the acceptability of the translation of face-to-face course features into a web format.

Iteration 3

MCS and Coventry University researchers held a workshop with the web design team and experienced HOPE facilitators to collect feedback on iHOPE design, usability, and content. User and facilitator feedback led to further revisions to improve usability and course experience.

Iteration 4

The final iterative feedback was undertaken as part of the iHOPE evaluation, and 5 cohorts reviewed the system while they were enrolled in the program.

Content

The iHOPE program content comprises text, images, downloadable documents, and links to external websites, for example, activities and media related to cancer-related fatigue and developing character strengths. The content delivered is configured into interactive activities (eg, quizzes, self-monitoring tools, and diaries) that can be used by participants to learn and consolidate program content (Table 1 gives details of iHOPE program content and activities, and Figure 2 shows screenshots of user dashboards). The iHOPE program uses forums and messaging facilities that act as a conduit for communication between participants and facilitators.

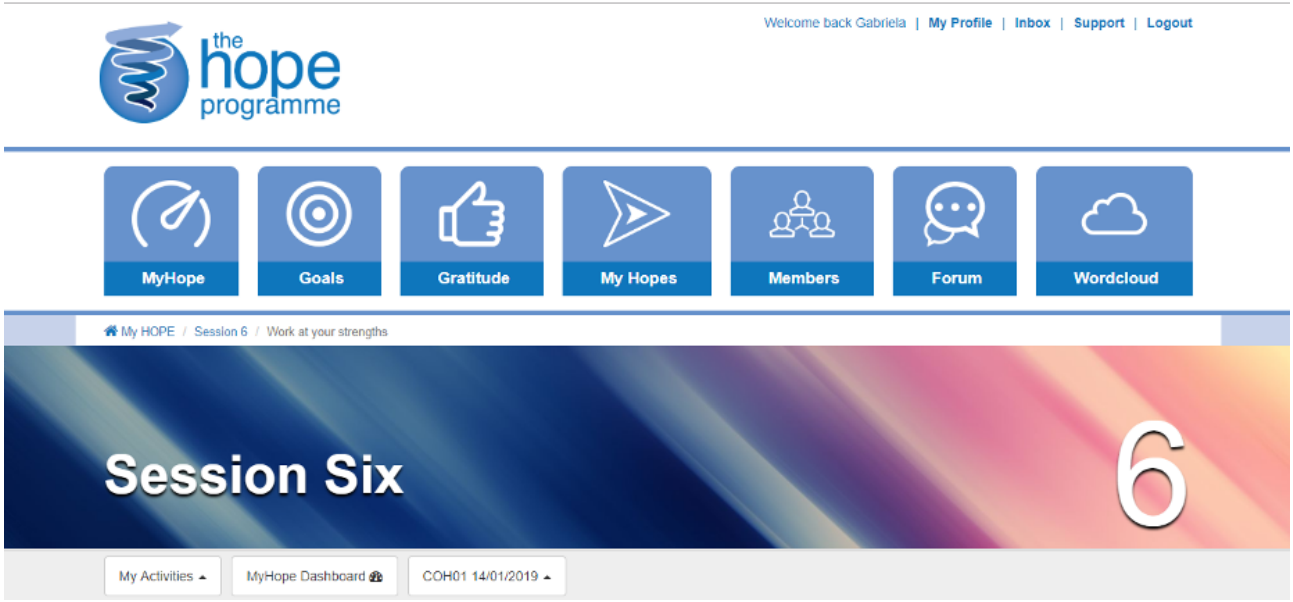
Table 1. Weekly topics, content, exercises, and activities included in the 6-week Help to Overcome Problems Effectively (where 'i' indicates digital version) program.

Session	Examples of content	Examples of exercises and activities (self-management tools)
Week 1: Introduction/instilling hope	• Aims of the program • User guide to navigating the platform and setting up a profile • Introduction to self-management • The benefits of positive emotions • Video: positive emotions for a flourishing life • The power of gratitude • Personalized goal setting • Video: how to set achievable goals • Forum topic: reasons for joining the program • Further resources and links (eg, videos, podcasts, and websites) to gratitude, positivity, and goal setting	• Interactive gratitude diary • SMARTER[a] goal setting • Assessment: positivity ratio test and positive and negative emotions test
Week 2: Stress management	• Understanding stress • Managing stress • Videos: how to manage stress and how to make stress your friend • Coping with unhelpful thinking patterns • Mindfulness for stress management and meditation • Self-compassion and acceptance • Video: how to be kind to yourself • Forum topic: how do you deal with cancer-related stress? • Further resources and links (eg, videos, podcasts, and websites) to self-compassion, mindfulness, and stress management	• Interactive gratitude diary • SMARTER goal setting and goal feedback • Guided relaxation and meditation exercise (podcasts) • How to cope with unhelpful thoughts (worksheet)
Week 3: Managing fatigue	• Understanding the boom and bust cycle • Using the 3 Ps (prioritizing, planning, and pacing) for managing fatigue • Video: tips for managing fatigue • Sleeping better; podcast: tips to improve sleep • Forum topic: coping with fatigue • Further resources and links (eg, videos, podcasts, and websites) to sleeping better	• Interactive gratitude diary • SMARTER goal setting and goal feedback • Fatigue and pacing diaries (worksheets) • Quiz: What are the main challenges faced by cancer survivors?
Week 4: Body image and communication	• Body image • Video: body image and cancer • Sexuality and intimacy • Video: Cancer as a passport to emotional intimacy • Communication skills and tips for talking with the health care team and family • Forum topic: experiences of coping with body changes and experiences of communicating with the health care team • Further resources and links (eg, videos, podcasts, and websites) to sexuality, intimacy, and relationships	• Interactive gratitude diary • SMARTER goal setting and goal feedback
Week 5: Physical activity and fear of recurrence	• Coping with fear of recurrence • Videos: Moving forward while being worried about cancer returning and the regrets of those who are dying • Hopes and dreams for the future • Video: Before I die project • The benefits of physical activity • Video: Tips for becoming and staying active • Forum topic: Concerns about cancer coming back • Further resources and links (eg, videos, podcasts, and websites) to managing concerns about cancer coming back and getting more active	• Interactive gratitude diary • SMARTER goal setting and goal feedback

Session	Examples of content	Examples of exercises and activities (self-management tools)
Week 6: Character strengths and happiness	• Understanding how using your strengths can lead to a more fulfilling life • Video: The science of character strengths • Tips for authentic happiness; managing setbacks and keeping going • Forum topic: Learning from the program • Further resources and links (eg, videos, podcasts, and websites) to Macmillan Cancer Support online communities and happiness resources	• Interactive gratitude diary • SMARTER goal setting and goal feedback • Assessment: positivity ratio test and positive and negative emotions test and character strengths • Quiz: What contributes to happiness?

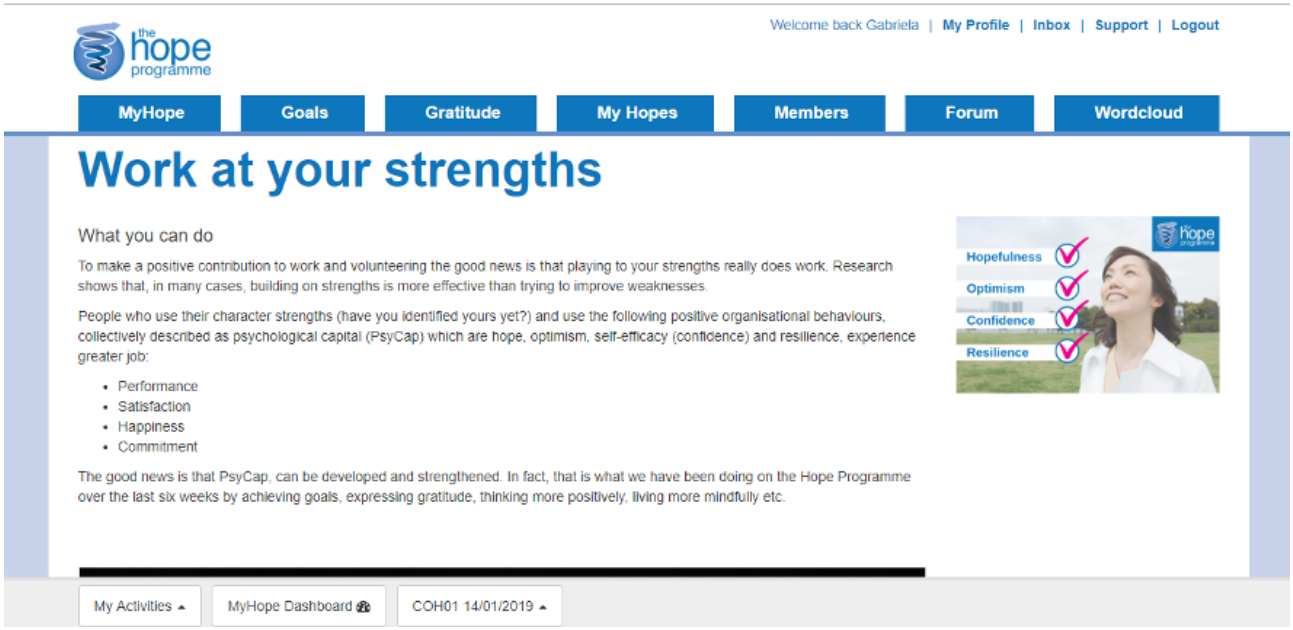
[a]SMARTER: SMARTER is an acronym used by many organizations for goal setting, and stands for: Specific, Measurable, Achievable, Relevant, Time-bound, Enjoyable, Reward.

Figure 2. Help to Overcome Problems Effectively user dashboard.



The theory underpinning the HOPE program is described elsewhere [38,53]. Briefly, the iHOPE program aims to enhance well-being by fostering positive emotions and stimulating positive functioning. A parallel goal is to reduce depressive symptoms. The iHOPE program is based on principles derived from positive psychology and focuses on positive experiences, strengths, and personal competencies rather than mental health problems such as anxiety and depression. It incorporates evidence-based exercises based on positive psychology, in addition to elements stemming from mindfulness, cognitive behavioral therapy, and problem-solving therapy (Figure 3 gives an example of personal strength exercises). The use of positive psychology interventions in cancer survivorship has, to date, been limited; however, a systematic review has supported their impact on well-being and quality of life [56].

Figure 3. Help to Overcome Problems Effectively personal strengths exercise.



Delivery

The maximum group size for each program delivery was set at 20 participants, following consultation with the iHOPE program facilitators and a beta test involving 33 participants. The iHOPE program content is released weekly over 6 weeks, thus mirroring the delivery model of the group-based face-to-face HOPE program. The iHOPE program is an asynchronous program that does not require real-time attendance. On the same day each week, new content is released, whereas previous content remains available. Participants are encouraged to log on for approximately 2.5 hours per week and use a range of behavior change techniques, including weekly goal setting, action planning, and self-monitoring. Peer support and interaction is facilitated through social networking tools and shared interactive activities where all participants' comments appear. Weekly topics and activities are provided in Table 1.

Goal setting and gratitude activities are recurring weekly features, and participants are encouraged to post a goal or something they may feel grateful for on the *online walls* for everyone to see and comment on. Each week, a number of questions are set as discussion topics that are featured in weekly forums. These questions are related to the program content for each week. There is also a weekly forum (Hope Lounge) where participants can start a discussion about either their experience of living with and beyond cancer or a noncancer related topic.

The iHOPE program is moderated by 2 trained peer facilitators who are affected by cancer in some way. The facilitators received training from MCS and followed a delivery protocol. The facilitator's role is to offer encouragement to participants, stimulate discussion in social networking forums by inviting participants to respond with comments to specific questions, or respond to questions/comments posted by participants. Facilitators also monitor daily social networking posts for safety and report any technical problems to the research team. Facilitators spent 2 hours each per session, supporting the participants.

Procedure

One week before each group's iHOPE program start date, participants were sent a link to a web-based survey to access an introductory letter that explained the purpose of the study, the research participant information sheet, consent form, demographic questionnaire, and outcome measures (ie, baseline questionnaires). Participants completed these and then went on to access the iHOPE program. At the end of the 6-week program, participants were emailed the survey link to complete the outcome measures again (ie, postprogram questionnaires) and complete a usability questionnaire.

Data Collection

Data collection was designed to address each of the feasibility testing research aims. Demographic data were collected at baseline on participants' age, sex, ethnicity, marital status, employment status, changes in work hours because of cancer, educational level, and cancer site.

Implementation

Recruitment, retention, and completion rates of the measures were recorded. The iHOPE program system captured basic adherence data, in terms of how many participants accessed the program and the number of sessions they accessed. Furthermore, detailed usage data were captured by the number of times participants carried out key program activities, such as goal setting and gratitude diaries.

Acceptability and Practicality

We created our own bespoke questionnaire to derive satisfaction scores with specific elements of interest for program development purposes, such as navigation, presentation, the usefulness of specific program elements, and support from the program facilitators. As previous literature shows that the optimal number of potential responses on a scale is between 4 and 7 [45], we presented participants with a choice of 4 responses (ie, strongly disagree, disagree, agree, and strongly agree) in an effort to reduce participant response burden. In

addition, as these responses were used to inform program development and changes to future versions, the inclusion of a *neutral* response on the scale would be uninformative. Satisfaction with the program was assessed using a 4-point scale [57] anchored at strongly agree and strongly disagree. The 13 questions (summarized in the Results section and Multimedia Appendix 1) were derived from published research examining the usability of digital self-management interventions [58-60].

Outcome Measures for Preliminary Efficacy Testing

All of the following outcome measures were administered at baseline and again at the end of the iHOPE program.

The quality of life in adult cancer survivors scale (QLACS) [61] is a validated questionnaire comprising 47 items across 12 domains, where 7 domains measure the generic quality of life and 5 domains measure the cancer-specific QLACS. In this study, we used 2 subscales of the QLACS that specifically address frequently cited unmet needs for survivors: cancer-related fatigue and cancer-related concern or fear of recurrence. Fatigue is assessed using the following 4 items: *In the past four weeks... (1) you had the energy to do the things you wanted to do [note that this item was reverse-scored]; (2) you felt fatigued; (3) you did not have energy to do the things you wanted to do; and (4) you felt tired a lot*. Fear of cancer recurrence is measured by the following 4 items: *In the past four weeks… (1) you worried about dying from cancer; (2) you worried about cancer coming back; (3) whenever you felt a pain, you worried that it might be cancer again; and (4) you were preoccupied with concerns about cancer*. Each item in these 4-item subscales is scored from 1 to 7 (1=never, 2=seldom, 3=sometimes, 4=about as often as not, 5=frequently, 6=very often, and 7=always). Items are summed to give an overall score of 4 to 28 for each of the 2 subscales (ie, fatigue and fear of recurrence), with higher scores indicating greater difficulties.

The patient health questionnaire-9 [62] is a 9-item measure that assesses the frequency of experience of the symptoms of depression, for example, *Over the past two weeks, how often have you been bothered by any of the following problems... (1) little interest or pleasure in doing things; (2) feeling down, depressed, or hopeless; and (3) poor appetite or overeating*. Responses to each of the 9 items range from 0 to 3 (0=not at all, 1=several days, 2=more than half the days, and 3=nearly every day), leading to a summed score between 0 and 27, with higher scores indicating greater severity of depression. Scores of 10 or more are presumed to be above the clinical range, and so, scores of less than 10 are classified as *cases* of depression. Recovery rates were calculated as those patients who scored ≥10 (cases) before treatment and scored <10 posttreatment.

The generalized anxiety disorder scale [63] is a 7-item scale measuring symptoms of generalized anxiety disorder, for example, *Over the past two weeks, how often have you been bothered by the following problems… (1) feeling nervous, anxious, or on edge; (2) trouble relaxing; and (3) becoming easily annoyed or irritable*. Responses to all 7 items range from 0 to 3 (0=not at all, 1=several days, 2=more than half the days, and 3=nearly every day), providing a total score of 0 to 21, with higher scores indicating greater anxiety. Scores ≥8 are classified as *cases* of generalized anxiety disorder. Recovery rates were calculated for those patients who score ≥8 (cases) before treatment and <8 post-treatment.

The Warwick Edinburgh mental well-being scale [64] is a scale of 14 positively worded feelings and thoughts, used to assess mental well-being within the adult population. The scale includes measures of positive affect, satisfying interpersonal relationships, and positive functioning, for example, *Below are some statements about feelings and thoughts. Please tick the box that best describes your experience of each over the last two weeks… (1) I have been feeling optimistic about the future; (2) I have been thinking clearly; and (3) I have been feeling love*. Participants rated each of the 14 items on a scale of 1 to 5 (1=none of the time, 2=rarely, 3=some of the time, 4=often, and 5=all of the time), providing a total positive mental well-being score ranging from 14 to 70, with higher scores representing greater positive mental well-being. A change of three or more is seen as clinically *meaningful* change [65].

Hope was measured using the 6-item adult state hope scale [66], which assesses goal-directed thinking in any given situation. The scale has 3 agency items, for example, *At the present time, I am energetically pursuing my goals*, and 3 pathway items, for example, *I can think of many ways to reach my current goals*. Participants indicated the extent to which they agree with each of the 6 statements, in accordance with how they feel at the present moment, on a scale of 1 to 8 (1=definitely false, 2=mostly false, 3=somewhat false, 4=slightly false, 5=slightly true, 6=somewhat true, 7=mostly true, and 8=definitely true). Total hope scores range from 6 to 48, with higher scores indicating higher levels of hopeful thinking.

The gratitude questionnaire-6-item form [67] is a self-report measure of disposition to experience gratitude in everyday life. It is a 6-item scale, comprising items such as *(1) I have so much in life to be thankful for, (2) I am grateful to a wide variety of people, and (3) when I look at the world, I do not see much to be grateful for [note that this item is reverse-scored]*. Participants scored each item from 1 to 7 (1=strongly disagree, 2=disagree, 3=slightly disagree, 4=neutral, 5=slightly agree, 6=agree, 7=strongly agree), giving a total score of 6 to 42, where a higher score indicates more gratitude shown [67].

Analysis

All statistical data analyses were conducted using IBM SPSS Statistics 25 (IBM Corp Released 2017. IBM SPSS Statistics for Windows, Version 25.0). The sample was not powered to detect significance in the outcome measures; nevertheless, we present changes in the scores to aid understanding of the potential effect of the program and to provide data on which to base a power calculation for a larger study of efficacy. The level of statistical significance was set at $P<.05$. Owing to some deviations from the normal distribution in follow-up gratitude, anxiety, and depression scores, all variables were analyzed using Wilcoxon signed-ranks for paired samples. We report the means with SDs and medians with a range of scores. As recommended for nonparametric paired data, we report r as the effect size estimates ($r=z/\sqrt{n}$), where z is calculated through the Wilcoxon test and n is the number of observations (n=102) [68]. Recommended boundaries for r were used to determine small (0.1), moderate (0.3), and large effect sizes (0.5) [69].

Results

Descriptive Data

A total of 114 participants completed the baseline questionnaires, and those who also completed the postprogram questionnaires were included in the analysis (n=51). Participant characteristics are shown in Table 2. Participants were predominately female, white ethnicity, married, with educational qualifications, and employed. The majority had cut work hours because of their cancer, and 38.6% (44/114) had breast cancer; however, data on cancer site was incomplete as participants did not always share this. There were no significant differences between these subgroups of participants on any of the demographic variables.

Examining baseline depression, anxiety, well-being, quality of life, cancer-related fatigue and worry, hope, and gratitude scores between those who did and did not complete postprogram questionnaires revealed no significant differences (scores are summarized in Multimedia Appendix 2).

Table 2. Participant demographic information at enrolment, baseline, and postprogram.

Characteristics	Sample at enrolment (N=114)	Completed baseline questionnaire only (n=63)	Completed baseline and postprogram questionnaire (n=51)
Age, mean (SD)	51.3 (9.6)[a]	47.4 (8.8)[b]	53.6 (9.4)[c]
Female, n (%)	102 (89.5)	56 (89)	46 (90)
White ethnicity, n (%)	111 (97.4)	61 (97)	50 (98)
Married or living with partner, n (%)	86 (75.4)	46 (73)	40 (78)
Employed, n (%)	68 (59.6)	36 (57)	32 (63)
Cut work hours because of cancer, n (%)	73 (64.0)	43 (68)	30 (59)
Possessed postschool qualifications, n (%)	110 (96.5)	60 (95)	50 (98)
Cancer type, n (%)			
Breast	44 (38.6)	22 (35)	22 (43)
Gynecological	13 (11.4)	6 (10)	7 (14)
Other	36 (31.6)	21 (33)	15 (29)
Not reported	21 (18.4)	14 (22)	7 (14)

[a]n=75 because of missing data.

[b]n=27 because of missing data.

[c]n=48 because of missing data.

Implementation

A total of 114 people were recruited to the program, of which 102 participants completed 3 or more sessions (89.4% completion of the program). The mean number of sessions was 5.0 (SD 1.5), and 61.4% (70/114) of participants attended all 6 sessions. Half of those who completed 3 or more sessions of the program (n=51) went on to complete the outcome measures, giving a 50% response rate to questionnaires at the end of the program.

Acceptability and Practicality

The 59 participant responses to the satisfaction questionnaire are detailed in Multimedia Appendix 2. The overwhelming majority of participants *strongly agreed* or *agreed* that the program and its delivery were positive and activities in the program were useful.

Preliminary Efficacy Testing

Table 3 provides a summary of all outcome measures for the 51 participants who completed baseline and postprogram questionnaires.

Table 3. Baseline and postprogram outcome scores (n=51).

Outcome measure[a,b]	Baseline scores, mean (SD)	Baseline scores, median (range)	Postprogram scores, mean (SD)	Postprogram scores, median (range)	*P* value[c]	*r* value[d]
Depression	8.9 (5.2)	9 (0-20)	6.1 (4.9)	5 (0-25)	<.001	−0.46
Anxiety	6.8 (4.9)	5 (0-20)	4.1 (4.1)	3 (0-18)	<.001	−0.35
Positive mental well-being	42.2 (9.3)	43 (21-63)	49.9 (7.5)	51 (25-67)	<.001	−0.50
Fatigue	18.1 (5.7)	19 (5-28)	14.4 (6.4)	13 (4-27)	<.001	−0.44
Fear of recurrence	15.9 (6.3)	13 (8-28)	13.2 (6.0)	12 (4-28)	<.001	−0.37
Hope	28.0 (10.0)	28 (8-47)	35.3 (7.4)	36 (11-46)	<.001	−0.51
Gratitude	34.8 (5.3)	36 (16-42)	36.7 (5.1)	38 (14-42)	.02	−0.24

[a]For depression, anxiety, fatigue, and fear of recurrence measures, decreasing scores indicate improvement.

[b]For positive mental well-being, hope, and gratitude measures, increasing scores indicate improvement.

[c]*P* value based on Wilcoxon signed-ranks.

[d]Effect size of change.

Psychological Distress

At the end of the iHOPE program, participants reported statistically significant improvements in depression and anxiety, with moderate effect sizes. Before the program, 47% (24/51) of participants exceeded the clinical cutoff scores for depression, and 43% (22/51) of participants exceeded the clinical cutoff scores for anxiety. At the end of the program, 31% (16/51) and 29% (15/51) of participants had scores that indicated a *recovery* from depression (z=−4.607; P<.001; r=−0.46) and anxiety (z=−3.534; P<.001; r=−0.35), respectively (ie, their scores were no longer above the threshold for clinical levels of distress).

Quality of Life for Cancer-Related Concerns

At the end of the iHOPE program, participants reported statistically significant improvements in cancer-related fatigue (z=−4.421; P<.001; r=−0.44) and *worry* or fear of recurrence (z=−3.765; P<.001; r=−0.37), with moderate effect sizes.

Positive Well-Being, Gratitude, and Hope

At the end of the iHOPE program, participants reported statistically significant improvements in positive mental well-being (z=−5.075; P<.001; r=−0.50) and hope (z=−5.113; P<.001; r=−0.51), with a moderate effect size for well-being and a large effect size for hope. Participants also reported statistically significant improvements in gratitude (z=−2.422; P=.015; r=−0.24), but with a small effect size (Table 3).

Discussion

Principal Findings

This study aimed to describe the development, evaluation, and feasibility of a digital self-management program for people who are living with, or have survived, all types of cancer. The program was well attended, with 114 participants at enrolment and 102 participants (89.5%) completing at least three of the six sessions. Feedback from the participants who completed the satisfaction questionnaire was overwhelmingly positive for many aspects of the content and design. Preliminary efficacy testing had positive results, with generally moderate-sized effects in the expected direction.

The majority of the participants were female, white, married, employed, and educated. Although this may present a limitation in terms of generalizing the study results to other demographic groups (eg, genders, cancer sites, ethnicities, and socioeconomic groups), a recent systematic review has reported that the majority of participants in self-management cancer programs are indeed women [26], and so, this study is representative in this respect. A low attendance rate for men is common in self-management and is linked to their reluctance to seek help [70]. Men are more likely to respond to marketing and recruitment messages that emphasize stoicism, independence, and control [70] and where marketing and recruitment materials contain images of men [71]. Our research group has begun looking at the self-management priorities of men diagnosed with cancer and the types of digital support they prefer [72,73]. It will be vital to conduct further development work to explore how to reach males, members of other ethnic groups, unemployed, and people with lower educational attainment. Ensuring that recruitment materials contain images and messages that appeal to multiple audiences and that recruitment and advertising take place in areas and locations frequented by people of all ages, ethnicities, genders, and income groups has been shown to widen participation in other studies [71]. These recruitment strategies will be suggested to MCS for future recruitment to the digital iHOPE program, as recommendations to reduce inequalities in care provision and recruitment bias.

Reporting rates of cancer sites were suboptimal, and data collection procedures should be improved, perhaps with a user-friendly checklist of cancer sites. Furthermore, collection of data on time since diagnosis and/or stage of treatment will allow us to verify in future studies if those recently diagnosed with cancer will show the same postprogram improvements in outcome measures as those who have survived cancer (or are coming to the end of treatment). Of those providing data, the largest group was breast cancer, reflecting national data. Gynecological cancers were reported by 11.4% of participants, which is greater than the estimated 5% of the population incidence [74]. However, the iHOPE program recognizes commonalities across types of cancer in the challenges faced and in unmet psychosocial needs; therefore, the majority of the

content is relevant to all cancer survivors regardless of the type of cancer. This pragmatic approach is a particular strength of the iHOPE program, especially as some patients may have cancer in more than one primary cancer site. Nevertheless, there are some elements of the iHOPE program content that may be more or less applicable to certain groups. In future cohorts, the iHOPE program could be offered to patients at all stages of treatment and/or with the same type of cancer. Another option is to adapt the program for some of the most common types of cancers, so that depending on the users' profile, personalized content is delivered. For example, in the body image session, prostate cancer and breast cancer users are provided with information, case studies, and other materials specific to their needs. Research has shown that personalized content improves engagement and retention.

The implementation of the program had positive results—89% of the participants completed the program (ie, attended 3 or more sessions) [51], and the average number of sessions attended was 5. Overall, 61% completed all 6 sessions, which is in line with rates of full program completion in other digital interventions, where a median of 56% of participants completed the full program [51,75].

There is a distinction between *dropout attrition* where participants do not fill in questionnaires (ie, 50% in this study) and *nonusage attrition* where participants stopped using the program (ie, only 11% completed <3 sessions in this study) [76]. High rates of nonusage attrition [76], are common and of concern in digitally delivered interventions. Reporting and analyzing the data at the level of session completion is crude, and a more useful and nuanced understanding of engagement and attrition is being developed, but still in its infancy. Researchers are beginning to use a variety of tools such as visualization and log data analysis, which provide evidence of features and content usage over time and detect usability issues. This type of analysis has the potential to improve user experience and improve engagement and outcomes. It is worth noting that some studies have not shown a linear relationship between time spent, the number of sessions completed, and outcomes [51]. It is possible that the *nonusage* participants in this study may be *e-attainers* (as described in [77]), where these participants may have left the program before completion but achieved what they needed from the program, such as learning about goal setting and stress management or obtaining reassurance and relief that their challenges and concerns are shared by others [37]. A higher rate of noncompletion of postprogram measures was observed in this digital delivery of iHOPE (ie, 50%) than the response rate in a face-to-face trial of the cancer HOPE program (88%, unpublished data). We suggest that the high noncompletion rate in this study was partly because of the timing of the research—data collection occurred around the Christmas period. Avoiding holiday times [78], using behavioral prompts [79], and reducing the number of outcome measures to reduce respondent burden [80] could improve data completion rates in future studies assessing the feasibility and practicality of digital cancer self-management programs.

The program was acceptable and appears to be practical, with positive feedback on program activities. The program uses peer support features and is supported by a facilitator with personal experience of cancer. There is a growing evidence base showing that trained peers can respond safely and therapeutically to distressing issues that often arise during self-management programs [81]. This study suggests the potential for the web environment to also provide peer support benefits to cancer survivors. The outcomes we measured capture important challenges for cancer survivors. Several activities in the iHOPE program directly address fatigue and worry, with a fatigue management session comprising video material and pacing and fatigue diaries, in addition to sessions on relaxation and mindfulness [82].

Acknowledging the significant limitations owing to the 50% completion rate of postprogram questionnaires, the findings show that scores for depression, anxiety, well-being, cancer-related fatigue and worry, hope, and gratitude were improved postprogram for those who completed the questionnaires. Moderate effect size improvements were achieved for most of the outcomes, which is consistent with other self-management research for long-term conditions involving self-selecting participants [83]. The fact that some of these improvements were evident in such a short period (6 weeks for postprogram outcomes) is extremely encouraging and consistent with early improvements found in brief self-management programs [84]. The variables likely to be used as clinical outcome variables (depression, anxiety, well-being, fatigue, and worry) all achieved moderate effect sizes in our uncontrolled pre-post study. Considering a future randomized controlled trial and taking into account the limitations of this study, a generic sample size calculation for moderate effect size (power 0.95, comparing 2 groups over 2 time points) would lead to a required total sample size of 132 (66 in each arm) [85].

The need for better care for comorbid depression in cancer survivors has been called for [14,19]. Many participants exceeded clinical cutoff values for depression (47%) and anxiety (43%) when they started the program. This indicates a high rate of clinical depression and anxiety among this population, therefore supporting the need for, and provision of, programs such as iHOPE. Further resources are needed to provide a range of interventions across the NHS for people with depression and anxiety following cancer. These resources could include a digital self-management program as part of a comprehensive stepped care package, particularly as the provision of expert mental health care across Europe remains limited [86].

By the end of the iHOPE program, the scores indicated that nearly one-third (16/51, 31%) had *recovered* from depression and over a quarter (15/51, 29%) had *recovered* from anxiety. These results are encouraging, compare well with general data on short-term psychological interventions [87], and suggest that further research investigating the effectiveness of the iHOPE program is imperative. The improved scores in gratitude and hope are reassuring, as this program is based on these core positive psychology concepts. Gratitude is linked to fewer health complaints, feeling more attentive, more energetic, more determined, more satisfied with life, more optimistic, having more feelings of connection to others, and being more likely to give and use social support [88]. The iHOPE program aims to increase hope among participants by encouraging participants to set and achieve weekly goals. Weekly goal setting and

feedback are important factors in initiating behavior change [89]. To date, there are very few hope-based, goal setting interventions that have been evaluated among cancer survivors [56], supporting the need for further development of the iHOPE program. An important next step is to formally explore if changes in hope and gratitude are important mechanisms of change for depression, anxiety, quality of life, and positive mental well-being.

Limitations

Our findings from this study are limited by the lack of a control group; lack of longer-term follow-up; small sample size; and a sample mainly of white, married women with a high level of education. Participants were recruited via the MCS charity website, Facebook, and other social media sites. This is likely to have attracted highly motivated cancer survivors, with good health and digital literacy skills, compared with cancer survivors who do not access health websites. Further studies of the feasibility and acceptability of the iHOPE program could utilize recruitment strategies aimed at widening participation for male cancer survivors [72,73] and participants from ethnic minorities and low-income backgrounds [71]. Further research is required to understand what drives some participants toward a digital intervention and to work with those with cancers in other sites to ensure that there are no barriers to accessing the iHOPE program.

There was a low response to the postprogram questionnaire. It is possible that there is a bias in responding to those who did find the program useful. The results of this study should be considered with caution, particularly in relation to the generalization of data. However, this feasibility testing suggests there is acceptability and practicality to our program, but there is a further requirement to support retention to complete research measures in future programs. This study used a crude usage attrition assessment. Future studies would benefit from using more sophisticated tracking tools and data analysis to reduce usage attrition and improve engagement and outcomes. Future research should now be a randomized controlled trial, powered to detect significant changes, a longer follow-up, and continued measurement of health and well-being related outcomes, satisfaction, and program usage.

Conclusions

We have shown that a digital self-management program, iHOPE, has the potential to improve several common and pressing unmet needs of cancer survivors, including fatigue and worry, depression, and anxiety. These improvements need to be further tested using a more robust research design involving a much larger sample over a longer time frame within a randomized controlled trial.

Acknowledgments

The authors would like to thank the individuals who took part in the initial usability testing of the iHOPE program and all those who participated in the study and completed the outcome measures. The authors would also like to thank the facilitators, Ian Cockerham, Lisa Larkin, Vicky Harker, and Stephen Wilkinson, who moderated the iHOPE program, and Macmillan Cancer Support, who funded the study.

Conflicts of Interest

AT is the coinventor of the HOPE program and iHOPE. WC, BW, GP, FM, LM, HW, and MM declare that they have no conflicts of interest.

Abstract

Background: Hypertension is one of the leading risk factors for ischemic heart diseases, and high rates of hypertension prevalence have either remained the same or increased in developing countries in recent years. Unfortunately, about 20% to 50% of patients with chronic diseases have been nonadherent to their drug therapy. SMS text messaging and pharmacy student–led consultations have the potential to help patients manage their blood pressure (BP).

Objective: The aim of this study was to assess the effectiveness, feasibility, and acceptability of SMS text messaging and consultation to manage the BP of Chinese patients with hypertension.

Methods: We conducted a two-arm cluster randomized controlled trial among patients with hypertension in Xi'an City, Shaanxi Province, China, and recruited 384 patients from 8 community health care centers. Patients were randomized into an intervention group to receive SMS text messages and consultations or into a control group to receive usual care for 3 months. We sent SMS text messages at 3-day intervals and collected data at baseline (including demographics, clinical outcomes, medication complexity, side effects, patient behavior, knowledge about hypertension, BP, and medication adherence) and the 3-month follow-up (including BP, medication adherence, and knowledge about hypertension).

Results: We assessed 445 patients with hypertension and excluded 61 patients who were not eligible or who had not filled out their questionnaires. The mean age of the patients was 68.5 (SD 7.9) years in the intervention group and 69.4 (SD 9.7) years in the control group, and the sample was primarily female (265/384, 69.0%). Patients in the intervention group showed significant improvements in systolic BP (SBP; mean 134.5 mm Hg, SD 15.5 mm Hg vs mean 140.7 mm Hg, SD 15.2 mm Hg; *P*=.001), medication adherence (mean 7.4, SD 1.2 vs mean 7.0, SD 1.3; *P*=.04), and knowledge about hypertension (mean 6.3, SD 0.9 vs mean 5.9, SD 1.2; *P*=.004) compared with those in the control group. In measures of diastolic BP (DBP), the two arms showed nonsignificant improvements (mean 78.2 mm Hg, SD 9.0 mm Hg vs mean 77.2 mm Hg, SD 10.3 mm Hg; *P*=.06). In total, 176 patients had controlled BP at the 3-month follow-up (98 patients in the intervention group vs 78 patients in the control group), but it was nonsignificant (*P*=.08).

Conclusions: The use of SMS text messaging and consultation to manage SBP and improve medication adherence is effective, feasible, and acceptable among Chinese patients with hypertension, although a significant difference was not observed with regard to DBP. It is important to maximize the potential of SMS text messaging and consultation by increasing the feasibility and acceptance of mobile interventions and conduct a cost-effectiveness analysis on this method.

Introduction

Background

Hypertension is regarded as one of the leading risk factors for ischemic heart diseases, affecting more than 1.4 billion people globally [1,2]. In the United States alone, over 100 million people are living with hypertension, according to a recent report of the American Heart Association [3]. Hypertension has also greatly amplified the rate of deaths, for example, every year nearly 9.4 million deaths are attributed to hypertension worldwide [4]. High rates of hypertension prevalence have either remained the same or increased in developing countries in recent years [5]. A study conducted in China from 2012 to 2015 concluded that the prevalence of hypertension in China was 27.9% [6], increased by 48.4% compared with the previous study conducted in 2002 [7].

The risk of ischemic heart diseases could be reduced by up to 50% via lowering the systolic blood pressure (SBP) by 20 mm Hg or diastolic blood pressure (DBP) by 10 mm Hg, thus preventing the rate of mortality and morbidity [8]. In the People's Republic of China, hypertension, with its several life-threatening complications, including stroke, heart attack, heart failure, renal failure, and coma, has seriously challenged the financial health care delivery system [9].

The management of hypertension is based on drug therapy coupled with lifestyle modifications. Better control of hypertension is possible by improving adherence to antihypertensive medications, which could further minimize its complications [10]. Unfortunately, adherence to the prescribed medications is always considered as a problem in patients with chronic diseases [11]. For example, a study reported that 20% to 50% of patients with chronic disorders have been nonadherent toward their drug therapy [12-14]. Similarly, patients with hypertension have also struggled to comply with the guidelines of their health care providers [15-17].

A large number of interventions and strategies have been proposed to improve adherence to the treatment plan among patients despite inconsistent results [18]. One such approach is the use of SMS text messaging via mobile technology, which has the potential to tailor patients' behavior to support their treatment adherence [19,20]. The use of customized SMS text messages offers several advantages, including cost-efficiency, wide coverage, ease in accessibility, and timely delivery of useful medical information [21-23].

Pharmacists are an integral part of the health care system, and their role in overcoming poor medication adherence is evident in the literature [24]. Owing to the limited number of qualified pharmacists in developing counties and the lack of proper education and counseling to patients [25,26], patients are struggling to cope with the problem of poor adherence. To address this issue, consultations by pharmacy students could be another alternative that is already in use in different health care settings of the United States and Kenya [27,28]. Meanwhile, as future pharmacists, pharmacy students can expand the scope of pharmacists' practices by holding patient consultations in their early stages. A study highlighted that 89% of patients had a better understanding of their medications when counseled by pharmacy students and residents in a discharge counseling program [28]. Furthermore, a 5-min pharmacy student–led counseling session offered to 198 participants greatly improved the rates of vaccination as well as reduced medication errors and costs in acute health care settings [23].

Objectives

A systematic review concluded that an intervention needs to reduce costs and expand outreach, and more studies from resource-limited settings, especially in Africa and Asia, are needed [29]. Moreover, a greater number of studies have been conducted to determine the effect of SMS text messaging on adherence among patients with heart diseases, mental diseases, and HIV. The literature is lacking in studies investigating the impact of SMS text message reminders sent by pharmacy students on patients with hypertension [30-33]. Thus, we conducted a two-arm cluster randomized controlled trial among patients with hypertension to assess the effectiveness, feasibility and acceptability of SMS text messaging and consultation to manage blood pressure (BP) among Chinese patients with hypertension.

Methods

Study Design

From October 2018 to May 2019, we completed the randomized controlled trial testing the efficacy of SMS text messages and personal consultation to improve adherence among patients with hypertension. The study was reviewed and approved by the Research Ethics Committee of Health Science Center, Xi'an Jiaotong University (Number: 2018531), and all patients provided written informed consent before enrollment. We conducted this study in 8 community health care centers (CHCs) in Xi'an City, Shaanxi Province, China. The full details of the trial design were published previously [34]; however, key elements are summarized subsequently. This study compared medication adherence and clinical outcomes, including SBP and DBP, between the intervention and control groups. The 8 CHCs, located in different geographic and socioeconomic areas, were randomized in a ratio of 1:1 to the intervention or control group using a random number generated by the computer. The study is reported according to the Consolidated Standards of Reporting Trials of Electronic and Mobile HEalth Applications and onLine TeleHealth V1.6.1 (Multimedia Appendix 1) [35].

Participants

To be eligible for enrollment, patients had to be adults (aged over 18 years) meeting the following criteria: diagnosed with hypertension and currently using antihypertensive medications,

BP <220/120 mm Hg at enrollment, and with health records at CHCs included in the study. Participants also had to have a mobile phone capable of receiving SMS text messages or access to a mobile phone and be able to read and complete informed consent. We excluded patients who had dementia, depression, and serious heart, lung, and kidney diseases and who were pregnant or in their lactation period.

Patient Recruitment

Participants were recruited during the process of physical examination or physician consultation. Potential patients were screened and approached by the clinic staff and a trained research assistant. Eligible patients in both groups completed a baseline survey comprising demographics, clinical outcomes, medication complexity, side effects, patient behavior, knowledge about hypertension, and medication adherence. Medication adherence was measured by using a validated 8-item Morisky Medication Adherence Scale (MMAS-8) [36]. The 8 items of MMAS-8 were designed to detect patients who are nonadherent to their medications and the reasons for such behavior, such as forgetfulness, insufficient knowledge, inconvenience, and side effects. The score of MMAS-8 ranges from 0 to 8, with a score of <6 indicating low adherence, 6 to <8 indicating medium adherence, and 8 indicating high adherence. The knowledge questionnaire included 7 questions, and the score ranges from 0 to 7, with a high score indicating a high knowledge level.

Intervention

The intervention program comprised 2 components. The first component comprised personal consultations by trained pharmacy students. The second component was SMS text messages sent at 3-day intervals. Patients randomized into the intervention group were given a personal consultation that lasted about 5 min to identify the reasons for medication nonadherence. For patients with poor memory for taking medication, we suggested setting an alarm on their phones as well as keeping medications near their beds or drinking glasses. Regarding patients with poor knowledge, we helped them understand the need to take antihypertensive medications throughout their lives to decrease BP fluctuation as well as the chances of serious complications, and we told them to modify their lifestyles, for example, reducing salt intake or stopping tobacco or alcohol consumption. Pharmacy students certified by Professor Morisky took personal consultations. Professor Morisky and the research group trained pharmacy students on July 20 and 21, 2018. The training comprised 3 parts: interactive discussion on measurements of medication adherence and their advantages and disadvantages, Morisky Training Test, and use of the Morisky Widget. Professor Morisky trained the students on how to use MMAS-8 appropriately to detect patients with low medication adherence and identify the reasons behind it so that we could offer advice to overcome medication nonadherence on an individual basis. The students were asked to finish a test assessment after the first day's training, and the students who failed the test were excluded from further training. In addition, we conducted a role-playing process to simulate the real scenario when faced with patients. Professor Morisky evaluated the process and offered general and individual feedback. Only those students who passed the test assessment and role-playing evaluation were given certification by Professor Morisky. The details of the training sessions were discussed in our earlier study [34].

After a personal consultation, we told patients to read the SMS text messages sent by our research group. SMS text messages were unidirectional and sent at 3-day intervals at 7 AM. The content of the SMS text messages was developed by researchers, a nurse coordinator, and a cardiologist with regard to helpful suggestions on the management of risk factors and motivation based on previous references [10,20,37]. SMS text messages were incorporated into 3 parts: knowledge about hypertension, lifestyle modifications and additional information on physical activity, dietary sodium reduction, normal BP, complications of hypertension, healthy diet, smoking cessation, weight reduction, and strategies to cope with emotions [34], and suggestions of measures to improve medication adherence. SMS text messages were sent to patients via an open website. During the 3-month program, patients in the intervention group received a total of 30 SMS text messages. The examples of SMS text messages are shown in Table 1.

Table 1. Text message contents.

Category classification	Example of content
Knowledge about hypertension	Please remember to take your antihypertensive medications every day. Hypertension is defined as systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg. Hypertension can cause cardiovascular disease, stroke, and kidney failure. Please keep an eye on your blood pressure and seek medical assistance if you have any abnormalities
Lifestyle modifications	Please remember to take your antihypertensive medications every day. Please reduce salt intake and pay attention to the intake of hidden salt (sausage, canned food, soy sauce, and pickles). The maximum of daily salt intake is a beer bottle cap (about 6 grams). Please keep an eye on your blood pressure and seek medical assistance if you have any abnormalities
Measures to improve medication adherence	Please remember to take your antihypertensive medications every day. Put medications around your toothbrush or drinking glass to remind yourself of taking them daily. Please keep an eye on your blood pressure and seek medical assistance if you have any abnormalities

Control Group

Patients in the control group received a welcome SMS text message and an end-of-trial SMS text message, but they did not receive a personal consultation. Besides, both patients in the intervention group and control group were given standard pharmaceutical care according to the Guidelines for Good Pharmacy Practice (GPP) [38]. GPP require pharmacists to provide medications along with pharmacy practice, which is a patient-centered, outcomes-oriented service to cooperate with

physicians and nurses to promote health, prevent and manage disease, and assess, monitor, initiate, and modify the medication regimen. Finally, patients' health-related quality of life can be optimized.

Follow-Up Assessment

Follow-up assessments were performed in both study arms at month 3, based on the intention-to-treat principles. In this case, outcomes were evaluated in all randomized participants, including those in the intervention arm who did not read SMS text messages. The study assessment also evaluated medication adherence, BP, and patient knowledge about hypertension at month 3.

Outcomes

The primary outcomes were a mean change of BP, measured by using the OMRON BP cuff (HEM-7200, OMRON Corporation) by clinical staff and trained research coordinators, as well as medication adherence and knowledge about hypertension at baseline and month 3. Two BP readings were collected after the patients sat and rested for 5 min [39]. A third reading was taken if the difference between the previous two readings was ≥5 mm Hg, and the final BP reading was the average of the two closest BP readings [39]. The secondary outcome was whether patients had controlled BP, defined as SBP<140 mm Hg and DBP<90 mm Hg for patients without diabetes mellitus or chronic kidney disease, SBP<130 mm Hg and DBP<80 mm Hg for patients with diabetes mellitus or chronic kidney disease, and SBP<150 mm Hg and DBP<90 mm Hg for patients aged over 80 years.

Sample Size

We sought to enroll 384 patients to have 90% power to detect a 5-mm Hg difference in BP between the intervention and control groups, with an alpha of .05, a 15% attrition rate, or an SD of up to 14.1 mm Hg [40].

Statistical Analysis

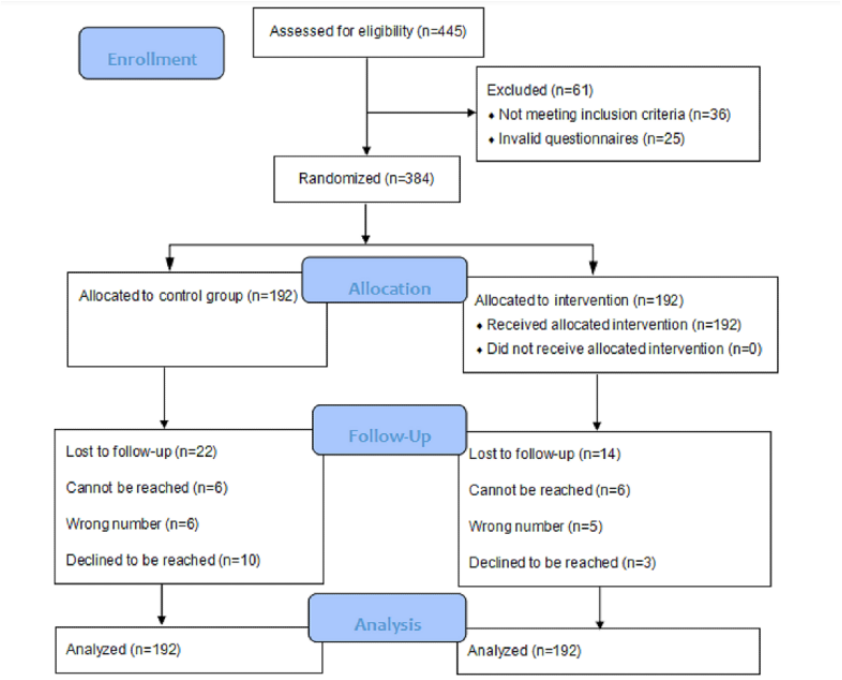
We conducted our analyses using intention-to-treat principles. Frequencies and percentages or means and SDs were presented in descriptive statistics. An independent-samples 2-tailed *t* test was used for continuous variables, and the chi-square test was used for categorical variables. A univariate linear regression model was used to analyze factors associated with medication adherence and SBP. The primary outcomes were analyzed using a mixed effect model to produce a difference in mean change, 95% CIs, and *P* values from baseline to follow-up. The model considered time, treatment group, and group-by-time interactions as fixed effects and incorporated random effects for individuals across time. The secondary outcome was analyzed using a mixed effect logistic model. All analyses were performed using SPSS Version 18.0 (SPSS Inc), and a two-sided *P* value of <.05 was considered statistically significant.

Results

Study Population

We assessed 445 patients with hypertension and excluded 61 patients who were not eligible or who had not filled their questionnaires. A total of 384 patients were randomly allocated to either the intervention group (n=192) or the control group (n=192). Figure 1 shows study enrollment and retention flow. A total of 14 and 22 patients were lost to follow-up in the intervention and control groups, respectively. In the final analysis, we included 384 patients in the mixed models based on the intention-to-treat analysis.

Figure 1. Flow diagram.



Baseline Characteristics

The mean age was 68.5 (SD 7.9) years in the intervention group and 69.4 (SD 9.7) years in the control group. The sample was primarily female (265/384, 69.0%), with 64.6% (124/192) of patients in the intervention group and 73.4% (141/192) in the control group. More than one-third (146/384, 38.0%) of the patients had attained junior high school education, and most of the patients did not smoke (343/384, 89.3%) or drink (340/384, 88.5%). A total of 83.1% (319/384) of the participants were living with family members; of them, 166 (52.0%) patients were in the intervention group, and 153 (48.0%) patients were in the control group. The mean BMI was 25.2 kg/m^2 and 24.8 kg/m^2 in the intervention group and control group, respectively. Their mean SBP and DBP were 147.9 mm Hg and 78.9 mm Hg, respectively, with a mean score of 5.6 in the knowledge part. The mean score of MMAS-8 was similar in both groups (mean 6.9, SD 1.5 in the intervention group and mean 6.8, SD 1.3 in the control group). Sociodemographic variables between the randomized groups were well balanced, and these are shown in Table 2.

Table 2. Baseline characteristics of participants (N=384).

Variables	Intervention group (n=192)	Control group (n=192)	*P* value
Age (years), mean (SD)	68.5 (7.9)	69.4 (9.7)	.32
Gender, n (%)			.08
Male	68 (35.4)	51 (26.6)	
Female	124 (64.6)	141 (73.4)

8-item Morisky Medication Adherence Scale score, mean (SD)	6.9 (1.5)	6.8 (1.3)	.67
Knowledge score, mean (SD)	5.7 (1.3)	5.6 (1.2)	.34

Factors Associated With Medication Adherence and Systolic Blood Pressure

The determinants of medication adherence and SBP are presented in Tables 3 and 4, respectively. Age and frequency of BP measurements were found to have significant associations with medication adherence by the linear regression model. For age, beta was 0.19 (95% CI 0.01 to 0.05; *P*=.001), and patients with older age tended to be less likely to be medication nonadherent. For the frequency of BP measurements, patients with a higher frequency of BP measurements were more likely to be medication adherent (beta=.19; 95% CI 0.05 to 0.18; *P*<.001). With a linear regression model, age, gender, education, and DBP were found to be significantly associated with SBP. For age, young patients were likely to have optimal SBP (beta=.28; 95% CI 0.41 to 0.87; *P*<.001). Patients who were female tended to have higher SBP than their male counterparts (beta=.12; 95% CI 0.42 to 9.88; *P*=.03). Those with a bachelor's degree or above (beta=−.12; 95% CI −3.90 to −0.33; *P*=.02) and low DBP (beta=.48; 95% CI 0.72 to 1.08; *P*<.001) were likely to have low SBP.

Table 3. Factors associated with medication adherence.

Variables	Beta (95% CI)	*P* value[a]
Age (years)	0.19 (0.01 to 0.05)	.001
Gender	0.02 (−0.32 to 0.44)	.75
Education	0.01 (−0.13 to 0.16)	.87
Smoking	0.02 (−0.46 to 0.62)	.77
Drinking	0.06 (−0.23 to 0.79)	.28
Living arrangements	0.05 (−0.21 to 0.56)	.38
BMI (kg/m^2)	0.05 (−0.02 to 0.07)	.33

[a]Linear regression model.

Primary Outcomes and Secondary Outcome

Table 5 shows the primary outcomes measured at baseline and follow-up and changes in these outcomes between the intervention and control groups. The mean (95% CI and *P* value) difference change in SBP between the two groups was −6.86 mm Hg (−10.37 to −3.34 and *P*=.001). Both intervention and control groups had an improved MMAS-8 score (mean 7.4, SD 1.2 and mean 7.0, SD 1.3, respectively) and a knowledge score (mean 6.3, SD 0.9 and mean 5.9, SD 1.2, respectively) at follow-up, and intervention patients experienced significant mean improvements in these two outcomes compared with the control group (*P*=.04 and *P*=.004). However, negligible improvements in DBP were noted (mean 78.2 mm Hg, SD 9.0 mm Hg and mean 77.2 mm Hg, SD 10.3 mm Hg, respectively) with no significant difference found between the two groups

(*P*=.06). The proportion of participants achieving controlled BP was 55.7% (98/176) and 44.3% (78/176) in the intervention group and control group, respectively, at the follow-up (Table 6), and the improvements in BP control did not have a significant difference between the two arms (*P*=.08).

Table 5. Baseline and changes in systolic blood pressure, diastolic blood pressure, 8-item Morisky Medication Adherence Scale score, and knowledge score at each assessment point using the missing data method.

Variables	Intervention group, mean (SD)	Control group, mean (SD)	Difference in mean change (95% CI)	*P* value[a]
Systolic blood pressure				.001
Baseline	146.0 (18.1)	149.9 (21.7)	N/A[b]	
3 months	134.5 (15.5)	140.7 (15.2)	−6.86 (−10.37 to −3.34)	
Diastolic blood pressure				.06
Baseline	77.9 (10.7)	79.9 (10.6)	N/A	
3 months	78.2 (9.0)	77.2 (10.3)	−0.95 (−1.09 to 2.98)	
8-item Morisky Medication Adherence Scale score				.04
Baseline	6.9 (1.5)	6.8 (1.3)	N/A	
3 months	7.4 (1.2)	7.0 (1.3)	0.39 (0.12 to 0.65)	
Knowledge score				.004
Baseline	5.7 (1.3)	5.6 (1.2)	N/A	
3 months	6.3 (0.9)	5.9 (1.2)	0.44 (0.22 to 0.66)

Variable - Blood pressure control[a]	Intervention group, n (%)	Control group, n (%)
Baseline	70 (54.3)	59 (45.7)
3 months	98 (55.7)	78 (44.3)

[a]Mixed effect logistic regression model showed a *P* value of .08.

Text Acceptability

We sent 5760 SMS text messages to participants in the intervention group and 384 SMS text messages to those in the control group, and all SMS text messages were sent successfully. In the intervention group, 68.0% (121/178) of the patients reported reading the messages sent by our research group, and 32.0% (57/178) of the patients reported having not read the messages as they did not have the habit of reading messages (34/57, 60%) and they could not see messages clearly because of old age (18/57, 32%), and some of them declared that they were too busy to read messages (5/57, 9%). A total of 69.7% (124/178) of participants in the intervention group reported having improved satisfaction about their BP, whereas 53 (29.8%) and 1 (0.6%) of them reported having the same satisfaction and decreased satisfaction, respectively, compared with the baseline study at month 3. The details are presented in Table 7.

Table 7. Text acceptability after the 3-month intervention (n=178).

Variables	Value, n (%)
How many SMS text messages that were sent by our research group did you read?	
0	57 (32.0)
1-10	55 (30.9)
10-20	29 (16.3)
20-30	37 (20.8)
What is the reason for not reading SMS text messages?	
I do not have the habit of reading messages	34 (59.6)
I cannot see messages clearly because of old age	18 (31.6)
I am too busy to read messages	5 (8.8)
Has your satisfaction with blood pressure control changed after participating in this study?	
Yes, my satisfaction increased over the process	124 (69.7)
No, my satisfaction remained the same	53 (29.8)
Yes, my satisfaction decreased over the process	1 (0.6)

Discussion

Principal Findings

In this randomized controlled trial of SMS text messaging and consultation, we found significant improvements in both medication adherence and SBP over 3 months of follow-up in the intervention group compared with the control group in a general population of patients with hypertension. Using an inexpensive means of communication and consultation, there was a relative increase of 0.5 in the MMAS-8 score and a decrease of 11.5 mm Hg in SBP in the intervention group. The secondary outcome of the trial focusing on patients having controlled BP showed a promising trend toward improved BP control even though the difference was insignificant.

There was no evidence of differences in the intervention effectiveness in DBP; however, compared with DBP, elevated SBP is the main target of antihypertensive therapy. Epidemiological studies indicated that hypertension is undertreated, especially SBP, which should be the primary target of antihypertensive treatment [41].

During the study period, patients reported high acceptability of SMS text messaging and consultation. They said that it helped them to understand how to manage hypertension through medication treatment and lifestyle modifications in their daily lives. However, there were participants (32.0%) who did not read their messages. Studies showed that improved patient-provider communication could help patients commit to lifestyle adaptations [42]. In future studies, we can call patients every month to confirm whether they read the SMS text messages. If they did not, we can remind them and ask about their interests in the context of SMS text messaging. In this way, patients are more engaged and involved in the process, so they will likely be more committed to the study.

A large number of previous studies based on SMS text messaging and student consultation have shown a significant improvement in medication adherence [33,43,44]. A meta-analysis of 16 randomized trials involving 2742 patients with chronic diseases, such as asthma, cardiovascular diseases, and HIV, has shown twice the improvement in the odds of medication adherence [43]. This improvement of medication adherence translated into adherence rates from 50% to 67.8%, with an absolute increase of 17.8%, suggesting that SMS text messaging interventions have the potential to improve medication adherence in patients with chronic diseases [43]. Moreover, a study conducted in Santiago, Chile, among 314 patients with hypertension with <6 months of antihypertensive treatment, found a boost in adherence levels from 49.0% to 62.3% in the SMS text messages–led intervention group [44]. Abughosh et al [33] evaluated the impact of an intervention based on motivational interviewing conducted by 11 pharmacy students on 743 patients with diabetes and hypertension. This intervention also resulted in a significant improvement in the patient's adherence to medication treatment.

Strengths and Limitations

However, there are a few limitations inherent in this study. First, we hypothesized that medication adherence and SBP have a significant association, but the hypothesized interaction was not found in the baseline survey. This finding contrasts with studies that have observed better BP control in those with better adherence [45]. Medication adherence was measured by a self-reported measure, which has social desirability bias and may overestimate true adherence [46]. Furthermore, patients were recruited with the help of nurses and physicians; therefore, patients may have been more likely to report being adherent to please the medical staff. Moreover, those with high baseline SBP and DBP were excluded in this study, which could influence the ability to discover the relationship between them. However, this study is not designed to observe the relationship between medication adherence and BP. Second, we used 3 months as our intervention period, which is inconsistent with our protocol. Taking time, cost, and seasonal factors into account, we decided to intervene in 3 months rather than 6 months, as patients' BP is lower in summer compared with

winter, because of which this study's results might be biased. Moreover, in a meta-analysis, the median intervention duration is 3 months, and response fatigue may be the feature of long-duration interventions [43]. In addition, the results in this study might be interpreted with caution because 69.0% of the participants were female, which might create a bias for this study's results. Finally, we used one-way communication in this study, and future studies on two-way SMS text messaging are suggested. According to a meta-analysis of 8 randomized trials [47], two-way SMS text messaging is related to substantially improved medication adherence compared with one-way SMS text messaging. Interactive SMS text messaging requires further inquiry and provides an opportunity for patients to get support from health care providers about healthy lifestyles, which can be translated into a long-term behavior change.

Despite these caveats, to our knowledge, this was the first study to evaluate the combined effect of SMS text messaging and consultation on patients with hypertension in the People's Republic of China. Given the rapidly changing lifestyle, characterized by high-salt and high-fat diets as well as low levels of physical activity, the prevalence of hypertension will continue to increase in China [48], and this study provides evidence to help manage the situation. The strength of this study is the combined intervention, randomized design, and use of SMS text messaging, which is convenient, inexpensive, and has a high penetration rate in society. Moreover, this study was conducted in CHCs, which represent the real-world setting; therefore, the results of this study can be used on a large scale.

Conclusions

We found significant improvements in medication adherence, SBP, and knowledge about hypertension but no difference in DBP between the intervention and control groups. The results of this study provided valuable insight and evidence on the design of intervention studies in developing countries and demonstrated that it is possible to improve BP control in community settings by using our intervention model. It is important to maximize the potential of SMS text messaging and consultation by increasing the feasibility and acceptance of mobile interventions, and future studies aimed at a cost-effectiveness analysis of this intervention model can also be conducted.

Abstract

Background: Behavior change methods involving new ambulatory technologies may improve lifestyle and cardiovascular disease outcomes.

Objective: This study aimed to provide proof-of-concept analyses of an intervention aiming to increase (1) behavioral flexibility, (2) lifestyle change, and (3) quality of life. The feasibility and patient acceptance of the intervention were also evaluated.

Methods: Patients with cardiovascular disease (N=149; mean age 63.57, SD 8.30 years; 50/149, 33.5% women) were recruited in the *Do Cardiac Health Advanced New Generation Ecosystem (Do CHANGE)* trial and randomized to the *Do CHANGE* intervention or *care as usual* (CAU). The intervention involved a 3-month behavioral program in combination with ecological momentary assessment and intervention technologies.

Results: The intervention was perceived to be feasible and useful. A significant increase in lifestyle scores over time was found for both groups ($F_{2,146.6}$=9.99; P<.001), which was similar for CAU and the intervention group ($F_{1,149.9}$=0.09; P=.77). Quality of life improved more in the intervention group (mean 1.11, SD 0.11) than CAU (mean −1.47, SD 0.11) immediately following the intervention (3 months), but this benefit was not sustained at the 6-month follow-up (interaction: P=.02). No significant treatment effects were observed for behavioral flexibility ($F_{1,149.0}$=0.48; P=.07).

Conclusions: The Do CHANGE 1 intervention was perceived as useful and easy to use. However, no long-term treatment effects were found on the outcome measures. More research is warranted to examine which components of behavioral interventions are effective in producing long-term behavior change.

cardiovascular diseases; lifestyle; habits; eHealth; mHealth

Introduction

The elimination of modifiable behavioral risk factors for cardiovascular disease (eg, smoking and physical inactivity) in the general population could prevent 80% of adverse clinical outcomes [1]. In patients diagnosed with cardiovascular disease, a modest reduction in risk behaviors can decrease the mortality rates by approximately 50% [2]. However, recommended targets (eg, lifestyle and medication adherence) for secondary prevention are rarely reached [3]. To achieve sustained health behavior change, active interventions that go beyond patient education are needed [4].

Sustainable behavior changes can be enhanced by implementing a personalized patient-tailored approach [5,6]. New ambulatory technologies can now be used to provide personalized support in a low threshold, nonobtrusive, and ecologically valid manner. These devices can be used to provide feedback about ambulatory health behaviors (eg, physical activity levels), but they are not sufficient to produce long-term behavior change [7,8]. In the setting of cardiac rehabilitation, telemonitoring guidance for patients' physical activity levels was found to be feasible in the FIT@Home study, and this intervention resulted in higher patient satisfaction and trends toward lower health care costs, but not in better improvements in fitness or physical activity levels relative to standard center-based rehabilitation [8]. The impact of this intervention could potentially have been further improved if a more patient-tailored approach were added. Another study found initial support that an app using persuasive design techniques can improve biological and psychological factors in patients after cardiac rehabilitation [9]. It is therefore plausible that ambulatory assessments are likely to have better therapeutic effects when combined with prompts that promote health-related behaviors (ie, ecological momentary interventions). These new methodologies also require a deeper knowledge about patients' needs and preferences [10].

This trial (*Do Cardiac Health Advanced New Generation Ecosystem*, Do CHANGE) was specifically designed to examine this multidisciplinary approach to behavior change [11]. What is unique to this trial is that patients received the behavior change program, *Do Something Different* (DSD), which has been previously developed to change unhealthy habits through the increase of behavioral flexibility [11]. Behavioral flexibility is associated with a broad range of the behavioral repertoire, making people more open to experience and the adoption of new behaviors [12]. DSD has been evaluated in other patient samples and has shown promising results by producing health behavior change [13]. For this study, the program was adapted to meet the needs of patients with cardiovascular disease (coronary artery disease, CAD; heart failure, HF; and hypertension, HT). Hence, the aim of this study was to provide proof of concept for the behavioral intervention aiming to address (1) behavioral flexibility, (2) lifestyle change, and (3) quality of life. The feasibility and patient acceptance of the intervention were also evaluated.

Methods

Design

The Do CHANGE trial is an international (the Netherlands and Spain), multicenter, randomized controlled trial, designed to enhance lifestyle changes in patients with cardiac disease (NCT02946281). The trial findings described in this paper are the first (proof of concept and feasibility) phase of the Do CHANGE project (phase 1) and will serve as input for further development of a second phase of this randomized controlled trial (Do CHANGE, phase 2; NCT03178305). A detailed description of both phases of the Do CHANGE trial has been published previously [11]. As this trial was developed to provide information about proof of concept and feasibility, an a priori sample size calculation was not performed. For this phase, we aimed to include 150 patients across 2 countries, which is considered sufficient to give information about proof of concept and feasibility of the intervention.

Study Sample

Patients diagnosed with CAD (having experienced a myocardial infarction, percutaneous coronary intervention, angina pectoris, or coronary artery bypass graft surgery), symptomatic HF (New York Heart Association class I-IV), and HT were included in the study. HT was defined as systolic blood pressure ≥140 mm Hg and/or diastolic blood pressure ≥90 mm Hg on two different measurements spaced 1 to 2 min apart and after 3 to 5 min in a sitting position. The values of the second measure were used. HF patients were included if they had a diagnosis of systolic or diastolic HF and the presence of HF symptoms.

Patients were recruited at Badalona Serveis Assistencials (Badalona, Spain) and Elisabeth-TweeSteden Hospital (Tilburg, the Netherlands). The study was approved by the medical ethics committees of the participating hospitals and was conducted in accordance with the Helsinki Declaration.

The inclusion criteria were as follows: (1) a primary diagnosis of CAD, HF, or HT; (2) aged 18 to 75 years; (3) having ≥2 of the following risk factors: positive family history, increased cholesterol, smoking, diabetes, sedentary lifestyle, and/or psychosocial risk factors; (4) sufficient knowledge of the country's native language; (5) access to the internet at home; and (6) having a smartphone compatible with the apps used in the study.

The exclusion criteria were as follows: (1) life expectancy <1 year, (2) life-threatening comorbidities (eg, malignancy), (3) history of psychiatric illness other than anxiety and/or depression, (4) significant cognitive impairments (eg, dementia), and (5) on the waiting list for heart transplantation.

Procedure

Patients meeting the inclusion criteria were approached for participation by a cardiologist or cardiac nurse. If interested, patients received information about the study in writing and orally. After 10 days, patients were contacted to inquire about their participation. If the patient indicated that they wanted to participate, a face-to-face appointment was scheduled at the hospital. Patients were asked to sign an informed consent

document and were provided with the first set of questionnaires (baseline). After filling in the questionnaires, patients were randomized. Patients in the intervention group received information about the intervention and the use of associated devices (see the *Intervention* section). The following day, patients in the intervention group were contacted by telephone to check that the devices were installed correctly and that the system was functional.

Patients received the intervention for 3 months. Follow-up questionnaires were sent at 3 and 6 months. Patients returned the devices after completion of the intervention (ie, after 3 months).

Randomization and Blinding

Patients were randomized (1:1) after completing the baseline questionnaires. Randomization sequences were computer generated and individually sealed before recruitment started. After completing the questionnaires, one sealed envelope was drawn by the research assistant containing the group allocation. Owing to the nature of the behavioral monitoring aspects of the study, blinding health care providers or participants to the treatment condition was not possible, whereas the initial analyses of the study outcomes were analyzed without knowledge of the treatment allocation.

Intervention

Do Cardiac Health Advanced New Generated Ecosystem Intervention Versus Care as Usual

Behavior Change Technique

Patients randomized to the intervention group received a 3-month behavior change program, *DSD*, which was provided via text messages on patients' mobile phones. The DSD program that was used aims to change unhealthy habits through the increase of behavioral flexibility [12]. This is achieved by disrupting patients' daily behavioral routine for a short period (few seconds) with behavioral prompts, which are referred to as *Do's* (eg, "EXPLORE MORE DAY. Today instead of going the same old way, take a different route. Look around, spot 10 things you wouldn't see on your usual journey") and are provided through patients' mobile phones. These messages challenge patients to do something different and get out of their comfort zone. They have been developed by a multidisciplinary team, including cardiologists and psychologists, to make sure that the Do's apply to the patient population and are thus related to their daily behaviors/needs. Patients received a total of 32 Do's during the 3-month intervention period (2-3 Do's every week). DSD has been evaluated in other patient samples and has shown promising results with respect to behavior change [13]. For this trial, the program was adapted to the cardiac population with slight differences in the program depending on patients' primary diagnosis (eg, CAD, HF, HT), as the preferred health behaviors may vary depending on the diagnosis. For example, because of disease-specific symptoms, advice regarding fluid intake was taken into account within the program only for patients with HF. More details regarding the DSD program are provided in the previously published design paper of this project [11].

Technological Tools

In addition to the DSD program, to obtain objective measures on patients' physical functioning, all patients received a blood pressure monitor, the Moves app (ProtoGeo, Helsinki; to register the GPS location), and the CarePortal (Docobo Ltd, Leatherhead; eg, a home monitoring device measuring daily symptoms and electrocardiogram). Owing to the disease-specific reasons, patients diagnosed with HF also received a weight scale, as daily weight monitoring is of importance in this subgroup. Data obtained from these devices will not be included in this analysis. This manuscript will focus on the primary outcome measures related to lifestyle parameters and patient-reported outcomes, which were derived from validated questionnaires (see the study by Habibović et al [11] for a description of primary and secondary outcomes).

Control Group

Patients randomized to the care as usual (CAU) group received the treatment as usual and were only provided with the validated questionnaires at baseline and at 3 and 6 months. These patients did not receive devices for ambulatory monitoring measures.

Measures

Questionnaires

Primary outcomes

Behavioral Flexibility

Behavioral flexibility was measured using the *DSD* questionnaire from scale items designed for this study [11]. This scale contains 30 different descriptions of behavior coupled in 15 pairs of opposites (Multimedia Appendix 1). Patients were asked at each measurement point to select the behaviors that best describe them (eg, *gentle* or *firm*). On the basis of a formula, the behavioral flexibility for each participant at each time point was calculated as outlined below.

Every addition of behavior raises the score as well as when both of a pair of opposite behaviors are added. For example, definite, systematic, trusting, predictable, and unpredictable are selected. All these selected behaviors raise the flexibility score. However, because predictable and unpredictable are each other's opposites, these are added to the formula again and increase the flexibility score even more. The model interprets this seemingly contradictory behavior as evidence of flexibility: based on what a given situation demands, the person can use different reactions and thus be more flexible. The total score can range from 0 to 100. The internal consistency in this sample was considered acceptable (Cronbach alpha=.67 to .76).

Lifestyle

The Health-Promoting Lifestyle Profile questionnaire was administered to assess health-promoting lifestyle habits [14]. This survey evaluates whether the subjective perception of patients regarding their lifestyle is changed and consists of 52 items (eg, "Eat 6-11 servings of bread, cereal, rice, and pasta each day") in total. Each item can be answered on a 4-point Likert scale, ranging from 1 (never) to 4 (routinely). The total

score can therefore range from 52 to 208, with a higher score indicating a better lifestyle. Furthermore, the questionnaire includes 6 different subscales that each cover a health promotion lifestyle domain (ie, Physical Activity, Spiritual Growth, Health Responsibility, Interpersonal Relationships, Nutrition, and Stress Management). The internal consistency was considered as excellent in this sample (Cronbach alpha=.88 to .90).

Quality of Life

To administer changes in the quality of life, participants completed the World Health Organization Quality of Life—BREF (WHOQOL-BREF) [15]. The WHOQOL-BREF is considered a reliable, generic multidimensional quality of life measure and consists of 26 items in total. Two items refer to the facet's overall quality of life and general health, whereas the abiding 24 items reflect 4 different domains (ie, physical health, psychological health, social relationships, and environment). The internal consistency in this sample was excellent (Cronbach alpha=.89 to .90).

Perceived Usefulness and Acceptance

The Unified Theory of Acceptance 2 (UTAUT2) scale [16] was administered to assess the perceived usefulness and acceptance of the tools that were used in the intervention. Mean scores on 8 subscales are provided, namely, (1) Performance Expectancy, (2) Effort Expectancy, (3) Social Influence, (4) Facilitating Conditions, (5) Hedonic Motivation, (6) Habit, and (7) Behavioral Intention. The initial subscale, *Price Value*, of the UTAUT2 was not included, as the cost per individual for the intervention could not be estimated. The total score per subscale can range from 4 to 20, with a higher score indicating higher usefulness and acceptance [16]. The internal consistency in this sample was excellent (Cronbach alpha=.89).

Client Satisfaction Questionnaire

To assess the satisfaction of the patients about the ecosystem, the 8-item Client Satisfaction Questionnaire [17] was used. This self-administered questionnaire is a general scale that consists of 8 Likert scale items (eg, "To what extent has our program met your needs?") ranging from 0 to 4, with response descriptors that vary. The overall score can range from 8 to 32, with a higher score indicating a higher satisfaction. The internal consistency was rated as excellent (Cronbach alpha=.92) [17].

Other Questionnaires Included in the Model

Type D Scale (Distress Scale-14)

Type D personality was assessed using the Type D scale (Distress Scale-14) [18]. This 14-item questionnaire consists of 2 subscales with seven 5-point Likert scale items each, ranging from 0 (false) to 4 (true). Total scores on both subscales range from 0 to 28. The 2 subscales represent the characteristics of negative affectivity (NA; eg, the tendency to experience negative emotions across time and situations) and social inhibition (SI; eg, the tendency not to express feelings). When scoring ≥10 on both subscales, patients were classified as Type D. With a reported Cronbach alpha value of .86 and .88, respectively, the internal consistency of SI and NA are considered as satisfactory [18].

The 7-Item Generalized Anxiety Disorder Scale

To gauge self-administered symptoms of anxiety, the 7-item Generalized Anxiety Disorder scale was administered [19]. The questionnaire is comprised of 7 items (eg, "Feeling afraid as if something terrible might happen") that can be answered on a 4-point Likert scale, ranging from 0 (not at all) to 3 (almost every day). To get an indication of anxiety symptom severity, the total score (range from 0 to 21) can be used. A higher score implies higher levels of anxiety. The internal consistency was considered excellent (Cronbach alpha=.92) [19].

Nine-Item Patient Health Questionnaire

Depressive symptoms were administered at each time point by using the 9-item Patient Health Questionnaire (PHQ-9) [20]. This self-report questionnaire consists of 9 items in total (eg, *feeling down*, *depressed*, or *hopeless*), each evaluated on a 4-point Likert scale (ie, not at all, several days, and nearly every day). The total score ranges from 0 to 27, with a higher score as an indication of worse depression symptom severity. The internal consistency was considered excellent (Cronbach alpha=.90) [21].

Demographic and Clinical Data

Demographic characteristics (eg, age, sex, marital status, working status, level of education, and smoking behavior) were obtained by patients' self-report. Clinical data (eg, comorbidities; prescribed cardiac medication; prescribed psychotropic medication; left ventricular ejection fraction; history of coronary artery bypass grafting; history of percutaneous coronary intervention; and resting heart rate and systolic and diastolic blood pressure measured at the most recent outpatient visit) were obtained from the medical record.

Statistical Analyses

Categorical variables were compared using chi-square tests, and continuous variables were compared using a two-tailed *t* test for independent samples. To evaluate the treatment effectiveness, based on intention-to-treat, a univariate and multivariate Linear Mixed Model analysis was performed. Multivariable analyses were adjusted for age, sex, education, site of inclusion (Badalona Serveis Assistencials [BSA] or Elisabeth-TweeSteden Hospital [ETZ]), primary diagnosis, Charlson comorbidity index scores, Type D personality, baseline anxiety scores, and baseline depression scores. *F* values with two-sided *P* values were reported for main and interaction effects (group×time). For the estimated fixed effects, beta coefficients with two-sided *P* values were reported. Data were analyzed using the SPSS software package (version 24).

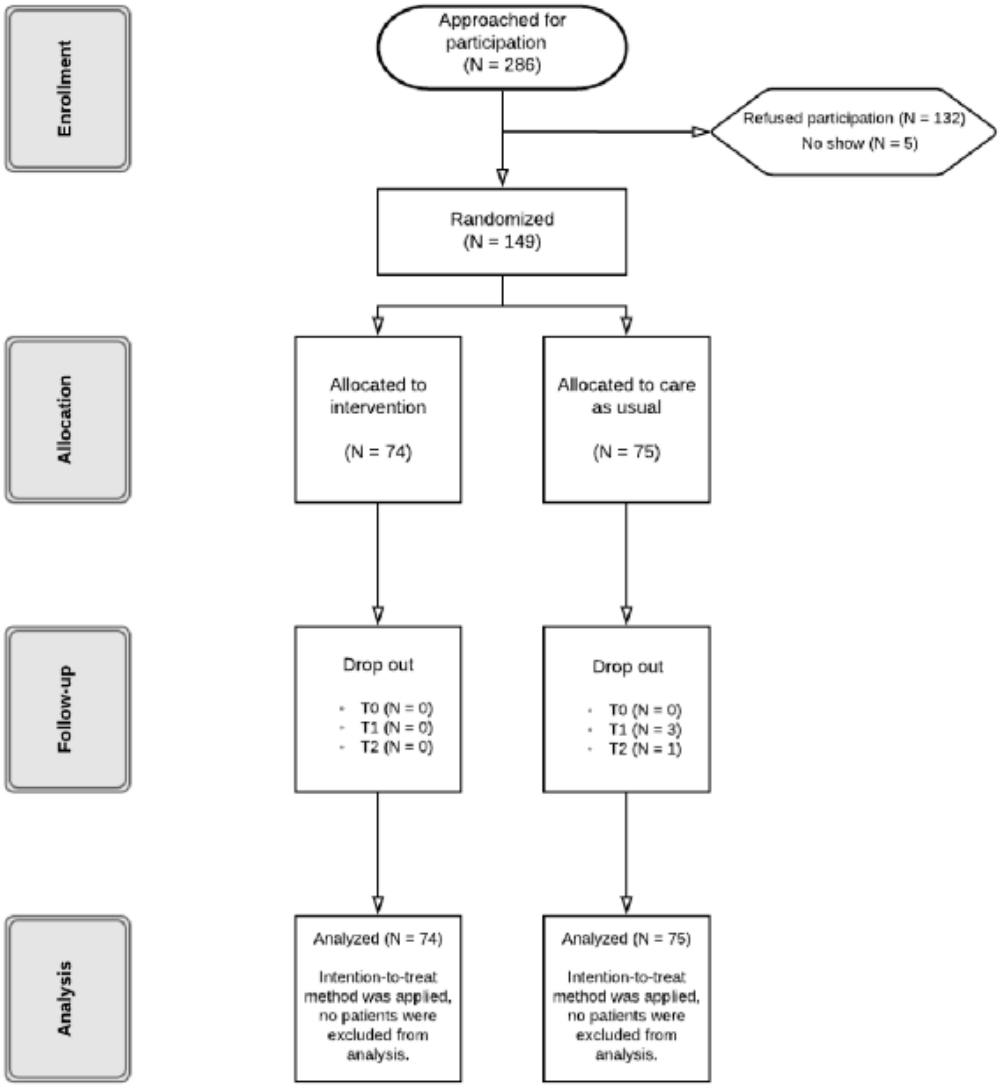
Results

Sample

The data collection took place between January 2017 and September 2017. In total, 286 eligible patients were approached for participation, of which 132/286 (46.1%) patients refused to participate. An additional 5/286 (1.7%) participants did not show up or declined participation. The reasons for refusal included that it would be too time consuming, they did not want to be confronted about their heart disease every day, and they

were reluctant to use technology. A total of 149 (response rate: 149/286; 52.0%) patients were enrolled. Enrollment per study site was as follows: BSA randomized a total of 74 (intervention: n=37 and CAU: n=37) patients; ETZ randomized 75 patients (intervention: n = 37 and CAU: n=38). Of the total sample, 4 participants within the CAU condition dropped out, as they did not receive the intervention and were therefore not willing to continue. Of the patients randomized to the intervention condition, 82% (61/74) reported having completed the entire 3-month program. Overall, 97.3% (145/149) of the participants completed the follow-up assessments. Figure 1 presents the flowchart of patient recruitment.

Figure 1. Flow diagram of patient recruitment.



Baseline Characteristics

The mean age of the total sample was 63.6 (SD 8.3) years, and 66% (99/149) were men. There were significant differences observed in mean completed education in years between the intervention group (mean 14.3, SD 6.2) and the CAU group (mean 11.8, SD 7.9; *P*=.03). This means that patients in the intervention group completed more years of education than those in the CAU group. Furthermore, a significant difference between the 2 groups was found on the mean PHQ-9 baseline scores, with a higher mean score on depressive symptoms in the CAU group (mean 3.61, SD 3.6 vs mean 5.56, SD 4.17; *P*=.003). No other differences were found between the intervention and CAU groups. Table 1 presents an overview of the baseline characteristics of this sample.

Intervention Effects

Behavioral Flexibility

The univariate analysis on behavioral flexibility scores (including group, time, and group×time) revealed no significant main effects for group ($F_{1,148.93}$=3.42; *P*=.07) or time ($F_{2,146.82}$=1.69; *P*=.18) and group×time interaction ($F_{2,146.82}$=1.09; *P*=.34). After adjusting for covariates (as previously described), main effects for time ($F_{1,146.81}$=1.74; *P*=.18), group ($F_{1,149.00}$=0.48; *P*=.07), and group×time ($F_{2,146.81}$=1.13; *P*=.33) remained nonsignificant (Figure 2). These findings indicate that behavioral flexibility scores did not significantly change over time, and that there were no differences between the 2 groups. With regard to covariates included in the model, the estimated fixed effects of HT (β=−6.07; *P*=.01) and CAD (β=−5.57; *P*=.02) were significantly associated with lower levels of behavioral flexibility scores (across all time points). In addition, the site of recruitment was associated with behavioral flexibility scores, with only patients from Spain showing an increase in behavioral flexibility over time (β=6.31; *P*<.01) when compared with those in the Netherlands (see Table 2).

[a]Compared with the main diagnosis of heart failure.

Lifestyle

A univariate analysis showed no significant effect for group ($F_{1,434.91}$=0.91; *P*=.34) or group×time ($F_{2,282.73}$=0.39; *P*=.68). These findings present that, without the addition of possible confounding variables, the intervention and CAU group did not differ. In addition, no interaction effect between allocation to group and time was found. However, a significant improvement for both groups on overall reported lifestyle behavior was found ($F_{2,282.73}$=4.28; *P*=.02). When adjusting for covariates in the multivariable analysis, this improvement remained significant ($F_{2,146.63}$=9.99; *P*<.001). As shown in Figure 2, both groups reported improvements in lifestyle behavior over time. The effects of interaction ($F_{2,147.02}$=1.36; *P*=.26) and allocation to group ($F_{1,149.90}$=0.09; *P*=.77) remained nonsignificant in the adjusted models. This indicated that no effect of the intervention on healthy lifestyle behavior was found. The estimated fixed effect of depression (β=−4.17; *P*=.03) was negatively associated with lifestyle promoting behavior, indicating that patients who score higher on the depression scale report lower healthy lifestyle behaviors. Patients from Spain showed an increase in lifestyle behavior (β=12.86; *P*<.01), in comparison with those in the Netherlands (see Table 2).

Quality of Life

The results of the univariate analysis of the quality of life total scores showed an interaction effect between time and group ($F_{2,146.40}$=4.22; *P*=.02). This finding indicates that the mean scores on quality of life of the intervention and CAU groups have different slopes over time: the intervention group showed a small improvement in the quality of life after 3 months, whereas the CAU group reported a small decline in the quality of life (mean improvement 1.11, SD .11 vs mean −1.47, SD .11). Both groups stabilized to baseline level after 6 months. The interaction effect remained significant after adding the covariates in the multilevel analysis ($F_{2,146.52}$=4.29; *P*=.02; Figure 2), suggesting a significant, positive effect of the intervention on self-reported quality of life in the first 3 months. The estimated fixed effects of higher levels of education (β=.25; *P*=.02) and being recruited in Spain (β=4.62; *P*=.008) compared with those in the Netherlands were significantly associated with higher scores on quality of life. Lower scores were predicted by higher CCI scores (β=−1.76; *P*=.05) anxiety (β=-0.90; *P*=.03), and depression (β=−3.63; *P*<.01; see Table 2). Examining subscales of the WHOQOL revealed no specific subscale differences regarding response patterns to the intervention.

Acceptability and Satisfaction

Overall, patients in the intervention group indicated being satisfied with the intervention (mean 26.22, SD 4.82). The intervention was perceived to be useful (mean 13.88, SD 3.96) and easy to use (mean 17.07, SD 2.57). Patients did not feel social pressure to use the devices from the intervention (mean 9.85, SD 3.63) and reported to be quite satisfied with the possibilities to receive support (mean 15.44, SD 2.43) and had a neutral opinion regarding the pleasure in using the devices offered in the intervention (mean 10.63, SD 2.44). Furthermore, the intervention was integrated relatively well in patients' lives (mean 11.71, SD 3.05). However, patients indicated that they were neutral regarding the intention to use the ecosystem in the future (mean 8.40, SD 3.34).

Discussion

Principal Findings

This study aimed to provide proof of concept for the Do CHANGE behavioral intervention targeting behavioral flexibility, lifestyle change, and quality of life in cardiac patients. No significant differences between the groups were observed on behavioral flexibility and lifestyle. However, a small increase in quality of life at 3 months was observed in the intervention group, but at 6 months, no significant difference between the groups was observed. With respect to the usefulness and feasibility of the intervention, the findings of this study revealed that the ecosystem is experienced as useful, easy to use, and integrated well into the daily life of the patients. It made the participants more aware of the fact that they must undertake activities themselves to feel better. Patients also reported feeling more *safe* because health care professionals were watching along. Nonadherence is a common issue in Web-based interventions for promoting health-related behavior, and the average study results in only 50% of participants adhering to the intended intervention [22]. However, 82.4% of the patients participating in this Do CHANGE intervention condition completed the intervention, which may further indicate that the intervention was not perceived as demanding.

The findings of the study are not completely in line with previous studies in other patient populations [13]. An explanation for this discrepancy could be the fact that this was the first study implementing the concept of behavioral flexibility and thus the core Do's of the DSD program in the cardiac population. In addition, the Do's might not have been tailored enough to the patients' needs that the timing of the Do's might not have been optimal. For example, one would want a patient to receive a distractive Do at the time when the *unwanted* behavior occurs. In this trial, patients from 2 different cultures (Spain and the Netherlands) and diagnosed with different cardiac disorders (ie, HT, HF, or CAD) were enrolled. This reflects the heterogeneity of the sample, which may have affected the results. Another important area for future research is the exploration of the mediating factors that drive the interplay between behavioral flexibility, lifestyle factors, and quality of life in the setting to electronic health (eHealth) interventions.

Enrollment in the study may have increased the general awareness of lifestyle change in both groups. This awareness could unknowingly lead to the adaptation of a lifestyle, independent of the allocation to a group. Previous research in cardiac patients affirms that there is a relationship between general knowledge about cardiac risk factors and self-reported lifestyle changes in the short term [23]. Furthermore, although lifestyle change is crucial in the treatment of cardiovascular disease, there is a lack of emphasis on lifestyle change and self-care of the patient in the current health care systems [24]. Addressing self-care and lifestyle change in clinical practice is therefore warranted. The Do CHANGE trial provides (longitudinal and momentary) knowledge that can be used in the further development of personalized interventions that will help patients reach recommended lifestyle goals.

Behavioral flexibility is an important construct on which behavioral change can possibly be initiated. However, the results of this study may indicate the need for a better measurement tool, as the questionnaire that is used might not be sensitive enough to reveal significant alteration in patients' behavioral flexibility over time.

The findings on quality of life, on the other hand, are not entirely in line with previous studies in cardiac samples, which have shown that there is a decline in quality of life and generally a slight increase in anxiety and depression scores within the 3 months postcardiac event [25]. This could be explained by patients having to adapt to new behaviors after visiting the hospital and being reminded of the fact that they have a chronic illness. In this study, the intervention group received the behavioral program, which could have contributed to first an increase in their quality of life, with a slight decrease after 3 months, sustaining their baseline quality of life. After the behavioral intervention ends, the quality of life in the intervention group also goes down as the additional *support* is no longer provided.

The findings of this study must be interpreted in light of a few limitations. At baseline, the intervention group and CAU group showed some differences in mean years of completed education and mean scores on depressive symptoms. The CAU group scored significantly higher on both variables. Another limitation of this study was that the sample was rather small, in relatively good health, and clinically heterogeneous, which may have limited the possibility to find substantial effects. Although the intervention was positively evaluated by participants, half of the approached patients did refuse participation. Therefore, it can be concluded that eHealth interventions similar to those described in this study are appealing for certain subgroups of patients. Future research should focus on eHealth interventions within the cardiac population based on a larger sample with significant power that is assessed over a prolonged follow-up duration (eg, beyond 6 months) to draw firm conclusions on sustainable behavior change. The results of this study showed that depression was associated with negative behavioral and psychological outcomes, which is in line with previous findings [26]. Depressive symptoms are common in patients with cardiovascular disease [27-29] and are related to various behavioral risk factors (eg, sedentary lifestyle, unhealthy diet, alcohol overconsumption, and smoking) [30,31]; this may explain the relation between depression and lower lifestyle behavior scores. Hence, future research is needed to examine which psychological and clinical factors contributing to health behavior change and potentially address these factors during the intervention.

For clinical practice, it is important to acknowledge that technology and eHealth solutions might be the feasible way forward in meeting patient needs and initiated health behavior change. However, the findings of this study underline the importance of a personalized approach that includes the assessment of a patient's demographic, clinical, and psychological profile.

Conclusions

In conclusion, the Do CHANGE 1 intervention was perceived as useful and easy to use. However, no main effects were found on behavioral flexibility, lifestyle behavior, and quality of life. More research is warranted to examine which components of behavioral interventions, and in which patients, are effective in producing long-term behavior change.

Acknowledgments

The authors would like to thank all the patients for participating and the health care professionals in the participating hospitals for making this work possible. In addition, the authors would like to thank all the students/research assistants for their help with the patient recruitment and data management. Finally, the authors want to thank the consortium members of the Do CHANGE project. This study was funded by the European Commission's Horizon 2020 program (grant number: 463735). For this project, the Do CHANGE team received funding for research and innovation from the European Union. One startup (Onmi) and 2 small- and medium-sized enterprises (DSD, Docobo Ltd) are supported financially to develop their products.

Abstract

Background: Office workers face workplace-related health issues, including stress and back pain, resulting in considerable cost to businesses and health care systems. Workplace health promotion attempts to prevent these health issues, and the internet can be used to deliver workplace health promotion interventions to office workers. Data were provided by Fitbase GmbH, a German company, which specializes in workplace health promotion via the internet (Web-based health). The Web-based health intervention allowed workers to focus on different health categories by using information modules (reading health information) and/or completing practical exercises (guided, interactive health tutorials).

Objective: This study aimed to identify the extent to which office workers have workplace-related health issues, assess whether office workers who differ in their health focus also differ in their improved well-being, and assess whether completing practical exercises is associated with improved well-being compared with reading information modules.

Methods: Fitbase GmbH collected data for the period of February 2016 to May 2017 from health insurance employees undergoing Web-based health training in Hamburg, Germany. The data consisted of a needs assessment examining health issues faced by office workers, a wellness questionnaire regarding one's perception of the Web-based health intervention, and activity logs of information modules and practical exercises completed. Through logistic regression, we determined associations between improved well-being from Web-based health training and differences in a worker's health focus and a worker's preferred intervention method.

Results: Nearly half of the office workers had chronic back pain (1532/3354) and felt tense or irritated (1680/3348). Over four-fifth (645/766) of the office workers indicated that the Web-based health training improved their well-being (P<.001). Office workers who preferred practical exercises compared with information modules had 2.22 times greater odds of reporting improved well-being from the Web-based health intervention (P=.01; 95% CI 1.20-4.11). Office workers with a focus on practical exercises for back health had higher odds of improved well-being compared with other health foci. Office workers focused on practical exercises for back pain had at least two times the odds of having their well-being improved from the Web-based health intervention compared with those focused on stress management (P<.001), mindfulness (P=.02), stress management/mindfulness (P=.005), and eye health (P=.003). No particular health focus was associated with improved well-being for the information modules.

Conclusions: Office workers frequently report having back pain and stress. A focus on Web-based health training via practical exercises and practical exercises for back health predict an improvement in office workers' reported well-being.

Introduction

Background

Office workers face a multitude of health issues, including back pain [1], stress [2,3], eye problems [4], and upper limb pain [1]. Internationally, costs from back pain [5] and stress in the workplace [6] are extensive. Eye problems decrease the productivity of office workers [7], and upper extremity injuries result in long absences from work and are a financial burden to businesses [8]. All of these health afflictions can have a significant financial toll through loss of work and increased health care expenses.

Workplace health promotion can be used to prevent many workplace-related health concerns and can include a range of information delivery systems. These systems include intervention programs, disease management programs, print materials, health education classes, fitness facilities on worksites, health fairs, and interventions for diet and fitness, among other methods [9]. Web-based electronic health interventions (Web-based health) are also available, which can be used to address the stated health issues. Web-based health interventions have been shown to decrease back pain [10], help manage stress [9,11], and provide improvements to nutritional and physical activity habits [9,12]. Addressing health issues via Web-based health techniques is favorable given that they can be personalized, highly structured, visually stimulating, and readily available to workers [13]. Furthermore, internet-based interventions have been shown to dramatically restore work capacity [14], have more favorable changes in health behavior and knowledge compared with non–Web-based interventions [15], and improve worker well-being [16].

Self-reported well-being and self-reported health have been beneficial predictors for decreased sick days, decreased costs to the health care system, and increased productivity [17-20]. There is also evidence that well-being is negatively associated with spinal pain [21], stress [22], eye problems [23], and mortality [24]. Thus, self-reported well-being as an outcome of Web-based health training can be an important measure. If a worker's reported well-being differs from his or her health concern (such as stress management or back pain) is an important question. Although there is literature documenting the effects of Web-based health interventions on worker well-being (through measures of stress, psychological distress, depression scores, etc) [16], we found little literature documenting the effect of Web-based health interventions on a worker directly reporting that their well-being had been improved from an intervention (defined in this work as *self-reported well-being*). Furthermore, many Web-based health interventions to our knowledge aim to improve a worker's psychological well-being through cognitive therapies and stress management [16], not via physical health improvement (ie, back health).

Web-based health promotion interventions primarily aim to change health behaviors through education and may involve the worker passively reading or listening to health information without engaging workers in practical, hands-on exercises designed to improve health. The effectiveness of practical, hands-on exercises (as opposed to simply reading information modules) in Web-based interventions is undocumented in the literature to the best of our knowledge. Also, information on self-perceived health issues (related to back pain, stress, etc) for office workers goes largely unreported.

Objectives

Our study was designed to address these two gaps in the literature. This study has the following research objectives: (1) identify the extent to which office workers have health issues related to repetitive strain injury (RSI, ie, upper limb pain associated with computer work), back pain, resilience, mindfulness, nutrition, stress, and eye health; (2) to assess if office workers who differ in their health focus also differ in their self-reported well-being; and (3) evaluate if completing practical exercises influences the self-reported well-being of office workers more than reading information modules.

Methods

Data

Data regarding health insurance employees in Hamburg, Germany, undergoing Web-based health training for the period of February 2016 to May 2017, was sourced from Fitbase GmbH, a German company based out of Hamburg, Germany, specializing in Web-based health training for companies and individuals. Their Web-based health training intervention consists of reading educational information modules (with health categories in back pain, stress management, nutrition, mindfulness, eye health, RSI, and resilience), and practical exercises (with health categories in back pain, stress management, mindfulness, eye health, and RSI). The information modules educate workers on maintaining a healthy lifestyle, and the practical exercises are guided health tutorials for activities related to healthy behavior. The data included responses to a needs assessment, a questionnaire, and practical exercise and information module logs of the employees. For privacy reasons, no employee demographic information was made available.

The total number of employees enrolled in the Web-based health training was 5694. The needs assessment was administered before beginning the Web-based health training and consisted of statements associated with RSI, back pain, resilience, mindfulness, nutrition, stress management, and eye health. These statements were, respectively: (1) "After intensive PC (personal computer) work, I feel pain, tingling or numbness in my hands or arms"; (2) "I have upper and lower back pain"; (3) "I basically assume that I can overcome difficulties in life"; (4) "I notice that I'm lost in thought about the future or the past"; (5) "I crave fast food"; (6) "I feel tense or irritated"; and (7) "My eyes hurt after work." Responses to these statements were *never*, *rarely*, *sometimes*, *frequently*, and *constantly*. Questionnaires regarding perceptions of the Web-based health training were administered during training at roughly 3, 6, and 9 weeks and were completed voluntarily. The last questionnaire completed was used for all analyses to best capture an individual's perception at the end of training. The statement of interest on the questionnaire was "Online training improves my well-being," answered by a worker as *strongly disagree*,

disagree, *agree*, or *strongly agree*. The University of Saskatchewan Research Ethics Board waived the need for ethics approval based on secondary analyses of the data.

Variables

Outcome Variable

Those who responded *strongly disagree* or *disagree* to the statement on the questionnaire "Online training improves my well-being" were coded as *disagree*, and those who responded *agree* or *strongly agree* were coded as *agree*, creating a binary outcome variable. These responses were combined due to a small sample size.

Independent Variables: Preferred Type of Intervention, Practical Exercise Health Focus, and Information Health Focus

The practical exercises completed and information modules read throughout the Web-based health training were recorded per user. On the basis of these logs, we computed the total numbers of practical exercises completed, and information modules read per health category. From these totals, we computed per individual the grand total of practical exercises completed and the grand total of the information modules read. We then defined a user's *preferred type of intervention* as the intervention associated with the greater of these two grand totals; if these grand totals were not different, the workers *preferred type of intervention* was set to be *no preference*. For example, if a worker completed statistically more practical exercises than information modules, they were assigned a *practical exercises* preference.

A user's *practical exercise health focus* was defined to be the practical exercise health category associated with the maximum total of the practical exercise-related health categories. For example, if a worker completed most of their practical exercises in stress management, they were assigned a *stress management* focus. A user's *information health focus* was derived similarly. If two health categories were completed most frequently, a tie was assigned to the worker. The number of ties was negligible (each combination <1%) except for workers completing both stress and mindfulness, and both back pain and RSI practical exercises. Consequently, we respectively labeled their *practical exercise health focus* as *stress and mindfulness* and *back and RSI*, and we excluded the data for individuals with all other ties.

Analyses

To address our first research objective (which was to identify the extent office workers experience health issues such as RSI, back pain, resilience, mindfulness, nutrition, stress, and eye health), we summarized the frequencies of the needs assessment data. From these frequencies we found the proportion of office workers who responded as *never*, *rarely*, *sometimes*, *frequently*, and *constantly* to the questions/statements: (1) "After intensive PC work, I feel pain, tingling or numbness in my hands or arms" (n=3354); (2) "I have upper and lower back pain" (n=3354); (3) "I basically assume that I can overcome difficulties in life" (n=3348); (4) "I notice that I'm lost in thought about the future or the past" (n=3354); (5) "I crave fast food" (n=3354); (6) "I feel tense or irritated" (n=3348); and (7) "My eyes hurt after work" (n=3348).

To address our second and third objectives, we developed a logistic regression model that predicted the well-being of workers from the Web-based health training. Those who completed at least two practical exercises, two information modules, and a questionnaire were included for the logistic regression analysis (n=779). The response to the statement, "Online training improves my well-being," was used as the outcome variable. Independent variables included the derived variables *practical exercise health focus*, *information health focus*, and *preferred type of intervention*. Office workers with an *RSI* categorized *information health focus* (n=7) and with a *back and RSI* categorized *practical exercise health focus* (n=6) were removed due to the extremely small sample size and were not included in the final model (n=766). Due to insufficient sample size, interactions between variables were not considered in the model.

Bivariate analyses of the independent variables with the outcome variable having $P<.20$ were to be included in the model, and all subsequent analyses were completed at the alpha=.05 level. All variance inflation factor scores were below 1.7, indicating a negligible influence of multicollinearity. All statistical analyses were conducted using SAS version 9.4.

Results

User Statistics

Of the 934 workers who completed a questionnaire, 765 (81.9%) indicated that the Web-based health training improved their well-being whereas 169 (18.1%) indicated the Web-based health training had not improved their well-being ($P<.001$).

Of the workers who completed two or more practical exercises, 29.69% (1057/3560) focused on back pain, 21.94% (781/3560) focused on stress management, 18.93% (674/3560) focused on mindfulness, 13.88% (494/3560) focused on stress and mindfulness equally, 10.81% (385/3560) focused on eye health, and 2.70% (96/3560) focused on RSI (Table 1).

Of the workers who completed two or more information modules, 46.07% (2415/5242) focused on back pain, 18.41% (965/5242) focused on stress management, 17.89% (938/5242) focused on nutrition, 7.34% (385/5242) focused on mindfulness, 5.32% (279/5242) focused on eye health, 2.61% (137/5242) focused on RSI, and 2.35% (123/5242) focused on resilience (Table 2). Among the workers who completed a questionnaire and did two or more information modules and practical exercises, 84.2% (645/766) reported that the Web-based training had improved their well-being ($P<.001$; Table 3).

Table 1. Number of office workers categorized in each practical exercise health focus who completed at least two practical exercises (n=3560), and the number of office workers categorized in each practical exercise health focus who completed at least two practical exercises, at least two information modules, and a questionnaire (n=779).

Health focus	Office workers categorized in each practical exercise health focus who completed practical exercises (N=3560), n (%)	Office workers categorized in each practical exercise health focus who completed information modules, practical exercises, and a questionnaire (N=779), n (%)
Back pain	1057 (29.69)	226 (29.0)

Research Objective 1

Our first research objective was to identify the extent to which office workers have health issues related to different health categories. Our results related to this are the distributions of the responses to the needs assessment questions as illustrated in Table 4. Over 42.60% (1429/3354) never felt pain, tingling, or numbness in their hands or arms after intensive PC work. Nearly half of the office workers (1532/3354) chronically had back pain. About three-fourth (2554/3348) believed they can consistently overcome difficulties in life. Half of the office workers (1680/3348) felt chronically tense or irritated. About one-fifth of office workers (643/3348) had eye pain after work frequently or more often.

Research Objectives 2 and 3

The results of the logistic regression model, including *P* values, odds ratios (ORs), and 95% CIs, could be found in Table 5. For our second research objective, which was to assess if office workers who differ in their health focus differ in their self-reported well-being, we found one's *practical exercise health focus* to be statistically significant (Wald chi-square value, χ^2_5=14.5; *P*=.01) with a worker's improved well-being from the Web-based health training. For our third research objective, which was to evaluate if completing practical exercises influence self-reported well-being more than information modules, we found one's *preferred type of intervention* to also be statistically significant (Wald chi-square value, χ^2_2=6.7; *P*=.03) with a worker's improved well-being from the Web-based health training.

Table 4. Needs assessment frequency data of office workers in Germany. Number (%) represents the office workers and their responses to needs assessment statements (n=3354).

Needs assessment statements	Never, n (%)	Rarely, n (%)	Sometimes, n (%)	Frequently, n (%)	Constantly, n (%)	Missing, n (%)
"I basically assume I can overcome difficulties in life."	15 (0.45)	147 (4.38)	632 (18.84)	1655 (49.34)	899 (26.80)	6 (0.18)
"I notice that I'm lost in thought about the future or the past."	392 (11.69)	936 (27.91)	1025 (30.56)	787 (23.46)	214 (6.38)	0 (0.00)
"After intensive PC work, I feel pain, tingling or numbness in my hands or arms."	1429 (42.61)	880 (26.24)	671 (20.01)	325 (9.69)	49 (1.46)	0 (0.00)

Resilience	1.979 (0.419-9.359)	0.505	.39

[a]OR: odds ratio.

[b]1/OR: reciprocal of the odds ratio.

[c]*P* value estimated from a Type III Analysis of Effects via a Wald χ^2 test.

[d]N/A: not applicable.

[e]RSI: repetitive strain injury.

Compared with workers focused on practical exercises for back pain, workers focused on eye health, mindfulness, stress management, and stress/mindfulness statistically differed (refer to Table 5 for the respective *P* values). Those workers with a focus on practical exercises for back pain had 3.11 times the odds greater than those focused on stress management (*P*<.001), 2.28 times the odds greater than those focused on mindfulness (*P*=.02), 3.14 times the odds greater than those focused on stress/mindfulness (*P*=.005), and 3.44 times the odds greater than those focused in eye health practical exercises (*P*=.003) of having their well-being improved.

Among office workers whose preferred intervention was practical exercises, the odds were 2.22 times greater to report improved well-being from the Web-based health training than those who preferred information modules (*P*=.01).

Discussion

Principal Findings

This study sought to examine the level of importance in which office workers perceived health issues, and examined possible differences in improved well-being from Web-based health training. We were interested in if there are differences in the associations for a worker's well-being based on specific health categories and if completing guided practical exercises or reading educational information modules had a different impact on improving an office worker's well-being.

In our exploration of office worker work-related health issues, back pain and stress management were most important; mindfulness and nutrition were moderately important; and RSI, resiliency, and eye health were of least concern to office workers. Back pain and stressful demands from work are common among office workers [25]. This aligns with the popularity of these two health categories in our study, as they were the most popular practical exercises and information modules completed by workers. Studies have reported a wide range of back pain prevalence (ranging from 23% to 56%) in office workers [1,26-29]. This is consistent with our finding that workers frequently focused on back pain when completing both practical exercises and information modules (29.69% and 46.07%, respectively).

Office workers may suffer from stress [2,3], and our study cohort was no different. Half of the office workers in this study felt chronically tense or irritated. However, over three-quarters of office workers in our study stated that they frequently or constantly could overcome life difficulties, suggesting our study participants are intrinsically confident in their abilities to overcome stressors. This indicates an apparent dichotomy between a worker experiencing stress and their resilience.

Oha et al [27] found that 7% of computer workers reported frequent wrist/hand or shoulder pain. Other studies report varying results; the prevalence of upper limb symptoms as low as 10% and as high as 52% have been documented in office workers [1,27-30]. Our findings support that workers experience varying degrees of pain after PC work, whereas most studies simply report if workers experience upper limb pain in a dichotomous fashion [1,28-31]. In fact, those responding *constantly feeling pain after PC work* might have disabling pain or worse [32]. In our study, 11.15% of workers chronically felt pain in their hands or arms after PC work, compared with 68.84% of workers reporting rarely or never. These estimates are considerably different from the literature, which estimates a higher prevalence of RSI pain [29]. Only 19.21% of our office workers reported routinely feeling eye pain after work. Another study identifying health issues in data processing office workers report a 26% prevalence of sore eyes from work [28].

Our logistic regression model yielded that well-being was influenced by different health categories. Workers focused on practical exercises for back pain had higher odds of having their well-being improved compared with almost all health categories. Prior literature has demonstrated that Web-based back pain interventions for office workers improves their quality of life [10], possibly consistent with our findings. Our logistic regression model also yielded that well-being was influenced by if office workers completed more practical exercises or more information modules. In general, completing practical exercises improved a worker's odds of having their well-being improved. Our findings suggest that completing practical exercises can be more effective in improving well-being as opposed to passively reading information modules, thus suggesting a need for hands-on, instructional, do-it-yourself exercises in Web-based health promotion for the office workplace.

Furthermore, participation rates in Web-based health promotion activities are typically low and hence a major concern [33]. Evidence suggests that guided Web-based health programs promote worker retention [16]. Our finding that office workers have increased odds of improved well-being when utilizing guided, follow-along exercises might reflect this. Available literature shows exercise-driven back pain interventions can decrease pain and improve back function [34,35]. Our study suggests back health might be in greatest demand by office workers; this makes sense, given that many different occupations are linked with back pain [36]. For groups with limited resources, their worker's health might benefit the most from focusing on back health.

Overall, an emphasis on practical exercises for back pain might benefit a workplace to the greatest extent when focusing on a worker population's well-being. For our office worker population, we found that back pain was the most popular health focus and was perceived as a persistent health issue (although those who focused on practical exercises for back pain had higher odds of having their well-being improved). It is possible that different working populations have different health needs. Our work may suggest that workers should address their primary health concern with practical exercises for maximal improvement in their perceived well-being.

To the best of our knowledge, our findings are the first demonstrating that completing Web-based health training is associated with improved self-reported well-being in office workers and that completing practical exercises rather than simply receiving Web-based health information may improve well-being. Our work supports that practical exercises for Web-based health interventions are beneficial to Web-based health promotion as a whole, regardless of a specific health

focus, in office workers. With respect to Web-based health promotion in the workplace, our work suggests that actively engaging workers to take part in their health is more beneficial than passively engaging workers. The data suggests that Web-based health interventions for an office-workplace should tailor resources toward promoting back health and in general, exercise-intensive health promotion strategies.

Given the potential cost benefits of reported well-being, employers and health insurers could benefit from incorporating practical back health exercises into Web-based health promotion efforts. As there is a shift in employment to many sedentary and office-confined occupations [37] and the internet is widely used globally [38], our findings might be applicable to a wider spectrum of occupations.

Limitations

As only those who completed a questionnaire, practical exercises, and information modules were included in our logistic regression modeling, there is potential selection bias. The absence of demographic information on the office workers prevented us from controlling for socio-demographic confounding factors. The findings were centered on German office workers and therefore may not generalize to other countries. Health categories, from which workers chose, were not exhaustive; there are likely other important concerns that were not included in this study, such as physical activity [39]. Future studies should identify objective measures (blood pressure, cortisol levels, etc) and a way to compare the perceived quality of the practical exercises to information modules.

Conclusions

Our finding suggests that a Web-based health promotion intervention using hands-on activities can be an effective method for addressing workplace-related health concerns and general worker well-being. We recommend future Web-based health promotion workplace interventions should focus on the main health issues experienced by workers and to include guided practical exercises for those who are wanting to improve their health. As technology becomes more mainstream in the workforce and jobs continue to shift toward seated computer work, Web-based health promotion will become increasingly more important.

Acknowledgments

The authors thank Fitbase GmbH and all of their employees for collecting and making data available, as well as the DAAD Research Internships in Science and Engineering professional program and the Dr James Rossiter Master's of Public Health Practicum Award for financial support.

Conflicts of Interest

DT was a former intern at Fitbase GmbH, but this work was completed after DT's internship, and DT has no financial incentives. Fitbase had no role in the design, practice, or analysis of this study.

Abstract

Background: While eMental health interventions can have many potential benefits for mental health care, implementation outcomes are often disappointing. In order to improve these outcomes, there is a need for a better understanding of complex, dynamic interactions between a broad range of implementation-related factors. These interactions and processes should be studied holistically, paying attention to factors related to context, technology, and people.

Objective: The main objective of this mixed-method study was to holistically evaluate the implementation strategies and outcomes of an eMental health intervention in an organization for forensic mental health care.

Methods: First, desk research was performed on 18 documents on the implementation process. Second, the intervention's use by 721 patients and 172 therapists was analyzed via log data. Third, semistructured interviews were conducted with all 18 therapists of one outpatient clinic to identify broad factors that influence implementation outcomes. The interviews were analyzed via a combination of deductive analysis using the nonadoption, abandonment, scale-up, spread, and sustainability framework and inductive, open coding.

Results: The timeline generated via desk research showed that implementation strategies focused on technical skills training of therapists. Log data analyses demonstrated that 1019 modules were started, and 18.65% (721/3865) of patients of the forensic hospital started at least one module. Of these patients, 18.0% (130/721) completed at least one module. Of the therapists using the module, 54.1% (93/172 sent at least one feedback message to a patient. The median number of feedback messages sent per therapist was 1, with a minimum of 0 and a maximum of 460. Interviews showed that therapists did not always introduce the intervention to patients and using the intervention was not part of their daily routine. Also, therapists indicated patients often did not have the required conscientiousness and literacy levels. Furthermore, they had mixed opinions about the design of the intervention. Important organization-related factors were the need for more support and better integration in organizational structures. Finally, therapists stated that despite its current low use, the intervention had the potential to improve the quality of treatment.

Conclusions: Synthesis of different types of data showed that implementation outcomes were mostly disappointing. Implementation strategies focused on technical training of therapists, while little attention was paid to changes in the organization, design of the technology, and patient awareness. A more holistic approach toward implementation strategies—with more attention to the organization, patients, technology, and training therapists—might have resulted in better implementation outcomes. Overall, adaptivity appears to be an important concept in eHealth implementation: a technology should be easily adaptable to an individual

patient, therapists should be trained to deal flexibly with an eMental health intervention in their treatment, and organizations should adapt their implementation strategies and structures to embed a new eHealth intervention.

KEYWORDS

eHealth; blended care; implementation; log data; forensic mental health care

Introduction

Mental health issues cause an increasing number of personal, social, and financial burdens [1] and form a growing challenge for health care systems [2,3]. Technology can be used to address this challenge by supporting treatment of mental health problems in an efficient manner [3,4], while maintaining comparable clinical outcomes as standard in-person treatment [5-7]. The application of technology in mental health care is often referred to as eMental health: the use of technology for treating or preventing mental health disorders [8]. Multiple types of technology can be used. Multimodal web-based interventions based on cognitive behavioral therapies have been studied most often; other examples are mobile apps or virtual reality [8-11]. eMental health technologies can be used as a stand-alone tool, used individually by a person, but often they are integrated within in-person treatment, delivered by one or more therapists. The combination of offline, in-person treatment and online technologies in mental health care is referred to as blended care [12]. Blended care can offer various advantages. Among other things, it has the potential to increase patient engagement and sense of ownership for their treatment, reduce barriers toward receiving mental health care, offer treatment in a more standardized, evidence-based manner, and save time and decrease costs; it can also be personalized to optimally fit patients [4,8,13-15]. However, while eMental health has a broad range of potential benefits, most are not observed in practice [8,16].

An important reason for this gap between the potential and the current situation can be found in issues related to implementation. Implementation of eHealth (electronic health) refers to the strategies that are undertaken to realize the adoption, dissemination, and integration of eHealth innovation into care [17,18]. Examples of such implementation strategies are training and education of stakeholders, changing an organization's infrastructure, using evaluative strategies, or supporting clinicians in using the intervention [19]. Ideally, these implementation strategies have a positive impact on implementation outcomes, defined in Table 1 [20,21]. However, studies show a broad range of issues with implementation outcomes for eMental health interventions, including acceptance by therapists and patients [22], therapists' lack of knowledge on how to optimally combine eMental health and in-person treatment [14], a suboptimal fit with existing technologies such as electronic patient records, and practical barriers such as continuous maintenance of the technology or good internet access [16]. Consequently, to further actualize the benefits that eMental health can offer, implementation strategies should be improved. In order to identify relevant points of improvement, a recent review of eHealth implementation recommended that there is a need for more studies that critically analyze implementation strategies and outcomes of eMental health technologies in practice [23].

Table 1. Implementation outcomes and their definitions, adapted from Proctor et al [21].

Implementation outcome	Definition
Acceptability	Intervention is agreeable, palatable, or satisfactory among implementation stakeholders
Adoption	Intention, initial decision, or action to try or employ an intervention by a care provider or organization
Appropriateness	Perceived fit, relevance, or compatibility of the intervention for a given practice setting, provider, or consumer and/or perceived fit of the innovation to address a particular issue or problem
Cost	Cost impact of an implementation effort, dependent on the costs of the intervention, implementation strategy used, and location of service delivery
Feasibility	Extent to which a new intervention can be successfully used or carried out within a given setting
Fidelity	Degree to which an intervention was implemented as it was prescribed in the original protocol or as it was intended by the program developers
Penetration	Integration of an intervention within a service setting and its subsystems
Sustainability	Extent to which a newly implemented intervention is maintained or institutionalized within a service setting's ongoing, stable operations

Several studies have focused on this issue and identified barriers and facilitators for the use of eMental health in practice [14,24-26]. However, as a recent review pointed out, most of the studies that analyze implementation of eMental health focus on one level (eg, factors related to patients) [16]. In order to get a good grasp of implementation of eMental health, attention needs to be paid to other levels as well (eg, organizational [16] or policy levels [13]). These recommendations on eMental health are in line with more general implementation models and literature: implementation should be seen as a multilevel and

complex process [27] that requires a holistic approach [28,29]. Implementation models like the consolidated framework for implementation research (CFIR) [30] and the nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework [31] account for the dynamic interaction between different factors and emphasize the interrelationship between characteristics and perspectives of users, organizations, and the intervention itself. Consequently, analyzing and integrating characteristics and perspectives of users; the context in which the eHealth intervention will be used; and the content, design, and use of the technology itself is expected to result in a complete, realistic picture of the implementation process and outcomes [20,28-32].

In order to apply such a holistic approach to eHealth implementation, a combination of different types of data that provide insight into the different aspects of eHealth implementation is necessary. Collecting multiple types of data does justice to the dynamic, complex interaction between factors that influence implementation, as opposed to analyzing these factors separately [33]. Also, from a holistic point of view, implementation should be studied from multiple angles and perspectives to gain in-depth insight into the technology, context, and people involved [18,28]. To illustrate: if only quantitative data from questionnaires are used to analyze implementation, an in-depth understanding of the reasons for the use of eMental health might be lacking [24]. However, when only using qualitative methods like interviews, information might not be as reliable or objective as is necessary for a thorough analysis of implementation [34]. Consequently, a mixed-methods approach where different types of quantitative and qualitative data are triangulated does justice to the complex integration of factors related to people, technology, and context. This is required for wielding a holistic approach toward the evaluation of eHealth implementation [35-38].

This study applied a mixed-methods approach to the holistic evaluation of the implementation process and outcomes of a blended eMental health intervention introduced in routine care by an organization for forensic mental health care. This setting provides an interesting context to study implementation in practice. First, the evaluation of implementation processes of eMental health technologies that have been implemented in routine care by an organization is expected to result in more ecologically valid results, as opposed to technologies that are being used because of research-initiated studies [20,35]. Second, our study focused on the implementation of an online eMental health platform with multiple modules that has been used for over 4 years in an organization that offers forensic mental health care to both in- and outpatients, which is expected to provide novel insights into long-term implementation processes in practice. Third, forensic mental health care is a branch of mental health care that focuses on treatment of a broad range of in- and outpatients who have committed or were on the verge of committing an aggressive or sexual offense, partly caused by one or more psychiatric disorders [39]. Because of the complex nature of this type of mental health care, and because not much is known about implementation in this type of setting [40], forensic mental health care offers an interesting setting to study implementation strategies and outcomes. Consequently, the goal of our study was to apply a mixed-methods approach to the holistic evaluation of the implementation strategies and outcomes of an eMental health intervention in an organization that offers forensic mental health care. The main research questions are as follows:

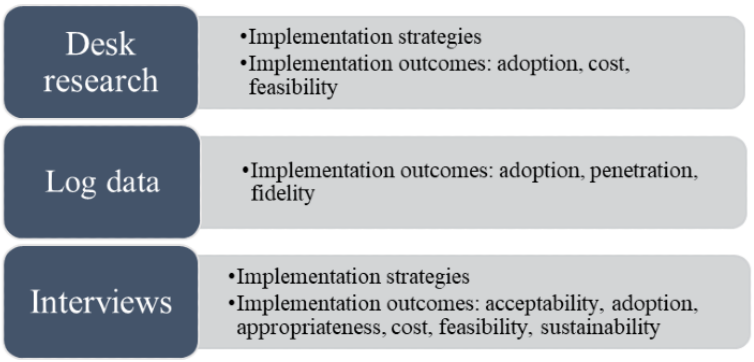
- Which implementation strategies were employed by the organization?
- What are the implementation outcomes in terms of adoption, fidelity, and penetration of the eMental health intervention?
- How do therapists perceive and explain implementation strategies and outcomes in terms of factors related to context, technology, and people?

Methods

Design

This mixed-methods study has evaluated the long-term use of a web-based application from multiple perspectives. A convergent parallel mixed-methods design was used [41] in which qualitative and quantitative data were collected in parallel, analyzed separately, and then merged. First, qualitative desk research was used to describe implementation strategies of the organization. Second, quantitative log data were used to analyze the objective use of an eMental health intervention by therapists and patients to gain insight into implementation outcomes. Third, interviews with therapists were conducted to gain more insight into implementation strategies and outcomes and analyze how they perceive and explain these strategies and outcomes. The purpose of this design is complementary [42]: the qualitative results are used to explain, illustrate, and provide more depth to the results from the quantitative log data, and the quantitative log data are used to enhance and illustrate the qualitative results in order to improve the interpretation of these findings and substantiate conclusions [43]. In order to answer the research questions, results were synthesized in the discussion by means of the aforementioned implementation strategies and outcomes. In Figure 1, an overview of this mixed-method study is provided.

Figure 1. Overview of methods used in this study with types of outcomes seen in each method.



Setting

Organization

This study focused on the implementation strategies and outcomes of implementation of an eMental health intervention within one forensic mental health care organization. This organization started a pilot with the intervention in 2012 and gradually implemented the intervention in the entire organization around the beginning of 2014. The Dutch organization in which this study took place offers forensic mental health care to both in- and outpatients. From January 1, 2014, until May 30, 2019, 3865 in- and outpatients were treated at one of the locations of the forensic hospital. The hospital has two main outpatient clinics, where approximately 85% of patients are treated, and three main inpatient clinics, where the remaining 15% are treated. A total of 252 therapists worked at the hospital between 2014 and 2019.

Electronic patient records show that from January 1, 2014, until May 30, 2019, 2076 patients were treated in the outpatient clinic where the interview study took place, which is 54% of the total patient population of the forensic hospital. According to electronic patient records, 23.27% (483/2076) of the patients had a level of education of primary school or none at all, 22.74% (472/2076) attended secondary school, mostly vocational, 16.33% (339/2076) completed vocational secondary education, 3.32% (69/2076) completed higher secondary education at (applied) universities, and for 34.49% (716/2076), no information was available. Comorbidity was high in this patient population, and there was a broad range of diagnoses for psychiatric disorders (eg, personality, attention deficit, sexual, anxiety, depression, schizophrenia, and substance use disorders).

Online Intervention

The eMental health intervention that is the topic of this study is a website containing a collection of different types of modules. The intervention is suitable for all types of mental health care, not just forensic mental health care. The intervention was designed by a commercial company, and organizations that want to use it must pay for a subscription. In total, 234 modules were available in May 2019. These modules cover a broad range of topics including attention deficit hyperactivity disorder (ADHD), autism, social skills, mindfulness, personality disorders, trauma, addiction, and relaxation. The intervention also contains 6 modules specifically developed for forensic mental health care. These modules focus on creating offense chains and prevention plans, patient recovery, positive self-image, and leading a meaningful life. However, since forensic patients suffer from a broad range of psychiatric disorders and psychosocial problems, other, nonforensic modules are often suitable as well. Therapists must choose which module they find most fitting for their patient; they are able to assign any of the 234 modules. If a therapist does not assign a module, a patient is not able to use the intervention.

Each module consists of multiple sessions provided in a fixed order and accessed via a browser. These sessions consist of a combination of elements (eg, written information about the topic, a story from a peer (in video or text), written assignments derived from cognitive behavioral therapy, and videos to provide additional information about the topic of the session). The underlying assumption is that a patient must complete all sessions in order to be adherent to a module. In our study, the intervention is used as part of blended care, which means that the patient is asked to complete assignments in each session on which the therapist provides written feedback. The patient can only continue with the module once the therapist has provided feedback on a session.

Desk Research

In order to identify the implementation strategies employed by the organization, desk research was conducted. In total, 18 documents describing the pilot project and implementation of the eMental health intervention were obtained from a policy advisor of the forensic organization who has been involved in the implementation of the intervention from the start. Examples of included documents are reports on the planning, progress, and outcomes of the pilot; communication with management; and brief research reports. In order to summarize the implementation process, a timeline with a chronological description of decisions, products, and events was distilled.

Log Data Analysis

Log data from the entire organization from December 2013 until May 2019 were collected and analyzed. These data were analyzed to gain insight into the following implementation outcomes: adoption by therapists and patients, fidelity, and penetration of the eMental health intervention in the organization. Log data refers to anonymous records containing information of every action performed by every user [36]. To be able to analyze the log data, several files with anonymized log data were retrieved from the platform. First, multiple files with information on modules assigned to patients and sessions

completed were downloaded. The raw data were combined and organized into an overview of modules and accompanying lessons by means of a macro in Excel (Microsoft Inc). Second, a file with the monthly number of feedback messages sent by individual therapists was retrieved. All log data were stored and processed anonymously and in line with privacy regulations relevant at that point in time. Ethical approval (No. 18408) was obtained from the ethics committee of the Faculty of Behavioral, Management, and Social Sciences from the University of Twente.

Interview Study

Participants

In order to gain a deeper insight into how therapists perceive and explain implementation strategies and outcomes, interviews were conducted with therapists working at one outpatient clinic of the forensic hospital. In this clinic, therapists were expected to use the eMental health intervention. Therapists were interviewed because of their key role in implementation: if they did not introduce the intervention to the patients, patients could not participate. The attitudes and actions of health care professionals appear to have an essential role in eHealth implementation [44]. At the time of the interviews, 20 therapists were working at the outpatient clinic. All therapists were invited to participate by the manager of the outpatient clinic, but two of them were excluded because they did not receive training and had no experience with the eMental health intervention.

Materials and Procedure

The main goal of the interview study was to identify factors which, according to therapists, are related to the use and nonuse of the eMental health intervention. These factors provide insight into implementation strategies and outcomes. In order to achieve this, semistructured interviews with the 18 therapists were conducted in April and May 2018 by two researchers (KR & NtC) at the outpatient clinic. The interviews were audiorecorded and took between 21 and 61 minutes, with an average of 41 (SD 10) minutes. Ethical approval (No. 18239) for the interview study was given by the ethics committee of the Faculty of Behavioral, Management, and Social Sciences of the University of Twente.

The interview started with a brief explanation of the goal and content of the study. After that, informed consent was signed. The interview scheme consisted of 6 main categories with accompanying open questions. First, sociodemographic questions were asked. Second, experiences with the introduction of the eMental health intervention were discussed. Third, the participant was asked to describe in what way, how often, and with which patients he or she used the eMental health intervention. Reasons for nonadherence were also discussed. The fourth part contained questions on the potential and experienced added value of the eMental health intervention for the therapist, patient, and organization. Fifth, participant was asked to describe what the ideal situation with regard to the use of the eMental health intervention would look like. In the sixth part, barriers for using the intervention were discussed. These questions were divided into 5 topics, loosely based on 5 relevant domains of the NASSS framework [31]: barriers related to patients, therapists, and the forensic health care organization; the wider context; and characteristics of the eMental health intervention. The NASSS framework was used because its holistic nature, in which attention is paid to different types of factors and their interrelationships, fits the research goal of this study. The interview's final question focused on what should be done to overcome these barriers and optimize benefits.

Analysis

The interviews were transcribed verbatim. In order to answer the research questions, deductive, top-down coding via the NASSS framework was combined with an inductive, bottom-up analysis of all fragments belonging to a domain of the NASSS framework. First, all relevant fragments were analyzed deductively by categorizing them into 1 of the 7 domains of the NASSS framework. This deductive analysis ensured a clear main structure of the results in line with the holistic focus of the research goals. The NASSS framework was used to structure the analysis because of its focus on technology in health care and holistic approach [31]. After deductive analysis using domains of the NASSS framework, fragments within each domain were analyzed inductively to look for more specific factors important for the use of the technology according to the interviewed therapists. A coding scheme was iteratively created based on all fragments of the first 5 interviews by one researcher (HK) via the method of constant comparison [45]. Using this coding scheme, the 165 fragments of these first 5 interviews were independently analyzed by a second researcher (FS) to determine interrater reliability of the coding scheme. The joint probability of agreement was 89%. After deliberation of the fragments that were assessed differently by the researchers, agreement was reached on all fragments, and several definitions of the code scheme were fine-tuned. No further adaptations to the underlying structure of the code scheme were required. Because of the high interrater reliability, one researcher (HK) coded the remaining 572 fragments and discussed them with the other researcher (FS) in case of doubt. Again, definitions of codes were adapted throughout the process.

Synthesis

In this mixed-methods study, results were synthesized via the implementation strategies and outcomes. Figure 1 shows which method was used to provide information for which implementation outcome. To synthesize the results, implementation strategies were summarized using all three methods. Also, the most important findings per implementation outcome were described and supported by outcomes of desk research, log data analyses, and codes that arose from the inductive analysis of the interviews.

Results

Desk Research

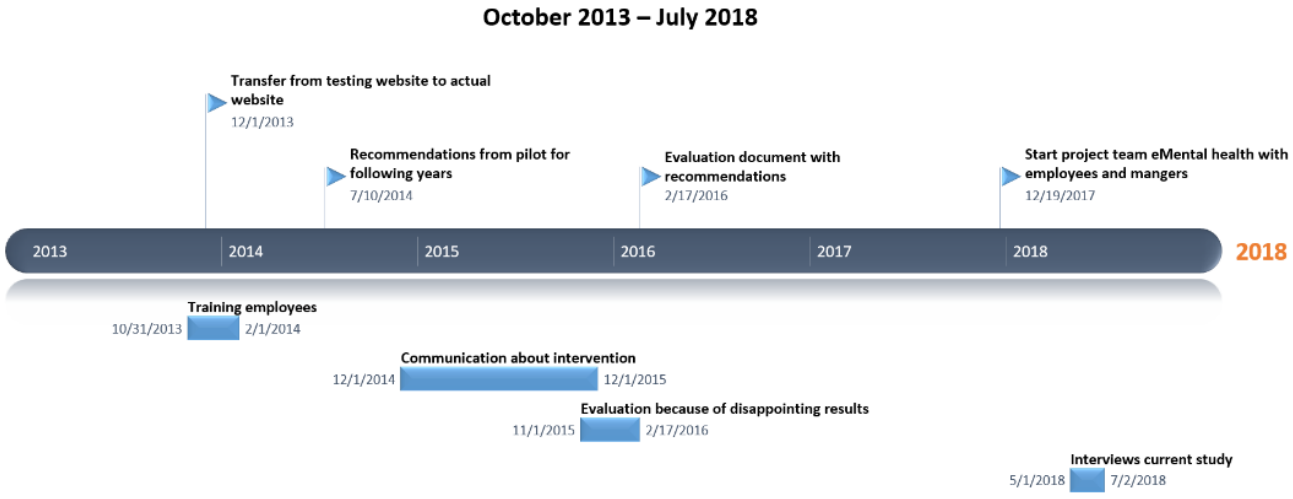
In order to describe the implementation strategies, desk research was conducted with documents generated by the organization. Before the online intervention was disseminated throughout the organization, a pilot was conducted in which the intervention was used on a small scale. This pilot was coordinated by a project team consisting of therapists and policy advisors, and

its timeline is visualized in Figure 2. The goal of the pilot was to improve the content and usability of the intervention and develop a good strategy regarding communication about the eMental health intervention to the organization. The pilot started with an exploratory phase, after which 90 employees were trained and instructed to use the intervention for several months. Desk research did not show how many therapists and patients participated in the pilot. The experiences of the pilot were used to create a strategy and recommendation for implementation of the intervention in the organization. Example of recommendations that arose from the pilot were to provide all employees with the training that participants of the pilot received and write guidelines on how to embed the intervention's modules in existing care programs.

Figure 2. Timeline of the pilot phase of the online intervention.

After the pilot, the online intervention was introduced to all therapists of the organization. An overview of the timeline, until July 2018 when the interview study of this paper was finalized, is provided in Figure 3. The main goal of the implementation was to fully integrate the eMental Health intervention in all primary and supportive processes. Consequently, all therapists received training and were expected to use the intervention. However, because use in practice was not as high as expected, an evaluation was conducted in 2016 that resulted in several recommendations, including that management should improve communication about targets of the eMental health intervention to therapists, a clear overview of useful modules should be created, some skilled therapists should be appointed as champions who can support colleagues in using the intervention, and therapists should motivate patients more by, for example, calling them if they did not use the intervention. When the recommendations did not lead to any major improvements, a new project team to installed to improve implementation in 2017; that team initiated this study.

Figure 3. Timeline of implementation strategies for the online intervention.



Log Data Analysis

Patients

In order to gain insight into implementation outcomes, log data that provide insight into patient use of the intervention were analyzed. From December 2013 until May 2019, 721 unique patients were assigned to at least one module of the eMental health intervention by their therapist. In total, 1019 modules were assigned to these 721 patients. Most patients (514/721, 71.3%) were assigned 1 module, 16.8% (121/721) were assigned 2 modules, 6.4% (46/721) were assigned 3 modules, and 2.5% (18/721) worked on 4 modules. The remaining 2.8% (20/721) worked on 5 to 10 modules. Finally, there were 2 patients who worked on many different modules: one patient worked on 23 modules and another patient on 28. Of the patients, 18.0% (130/721) fully completed at least 1 module, 50.6% (365/721) completed 1 or more lessons but did not complete at least 1 module, and 30.0% (216/721) patients did not complete any lessons at all.

In total, 98 different modules were assigned to patients. The median number of patients assigned to an individual module was 4. The offense script and prevention plan module was assigned to the most patients (104/721), and 18 modules were assigned to only 1 patient. Table 2 provides an overview of all modules that were assigned to at least 10 patients, including an overview of how many patients completed all lessons of the module, completed 1 or more lessons, or did not complete any lessons. When looking at all modules and patients, 180 of the 1019 modules (17.66%) were completed, meaning that all lessons were finished. For 448 of the 1019 modules (43.96%) at least 1 lesson was finished, but not the entire module. On average, when a module was started but not completed, 43.17% (2155/4992) of the modules' lessons were completed. When looking at the longer modules containing 10 to 26 lessons, 44.43% (1994/4488) of the lessons were completed. Of the shorter modules with 9 or fewer lessons, 40.28% (203/504) of the lessons were completed. Finally, in 412 of the 1019 modules (40.43%), no lesson was finished.

Table 2. Overview of the total and relative number of patients that completed, didn't complete, or partially completed modules that were assigned to at least 10 patients.

Topic of module	# lessons	Module completed, n (%)	Module not completed, ≥1 lesson finished, n (%)	Module not completed, no lessons finished, n (%)
Offense script and prevention plan (n=104)	25	14 (13)	71 (68)	19 (18)
Aggression (n=94)	14	7 (7)	48 (51)	39 (41)
Autism psychoeducation (n=76)	10	12 (16)	36 (47)	28 (37)
Substance abuse problems (n=63)	15	5 (8)	37 (59)	21 (33)
Mindfulness (n=59)	9	6 (10)	32 (54)	21 (36)
Offense script and prevention plan (short version; n=55)	17	12 (22)	34 (62)	9 (16)
Expert of yourself (n=53)	10	11 (21)	26 (48)	16 (30)
ADHD[a] (adults): understand your ADHD (n=40)	3	11 (28)	9 (23)	20 (50)
Thought scheme (n=29)	2	9 (31)	10 (34)	10 (34)
Skills for mild intellectual disorders (n=22)	9	3 (14)	11 (50)	8 (36)
Loved ones of patients (n=20)	9	3 (15)	11 (55)	6 (30)
Forensic: positive self-image (n=18)	4	9 (50)	3 (17)	6 (33)
Social skills (n=17)	1	5 (29)	5 (29)	7 (41)
Social skills: saying no (n=15)	2	6 (40)	5 (33)	4 (27)
Information on psychotic disorders (n=14)	9	5 (36)	7 (50)	2 (14)
Psychoeducation for personality disorders (n=14)	4	3 (21)	2 (14)	9 (64)
Generalized anxiety (n=12)	9	2 (17)	7 (58)	3 (25)
ADHD (adults): I want to think before I act (n=11)	9	6 (55)	0 (0)	5 (45)
ADHD (adults): I want to clear my mind more (n=10)	1	2 (20)	0 (0)	8 (80)
Aggression in your relationship (n=10)	14	0 (0)	7 (70)	3 (30)

[a]ADHD: attention deficit hyperactivity disorder.

Therapists

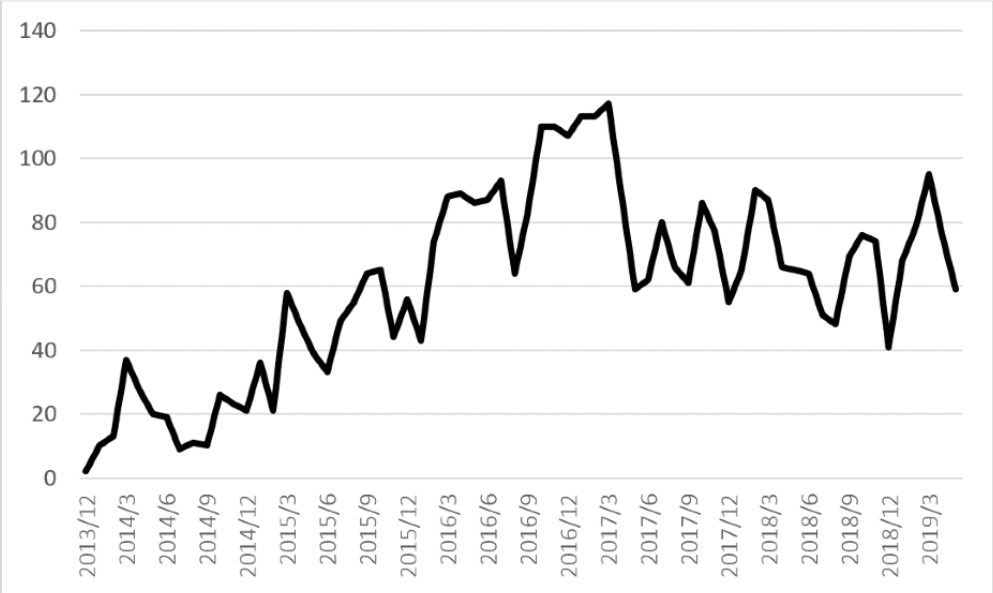
Therapists' use of the intervention was analyzed as well to gain insight into implementation outcomes. A main task of the therapist in using the eMental health intervention was to give feedback on patient assignments. A patient could only continue with the next lesson once the therapist provided feedback, and all lessons required feedback. In total, 172 therapists had accounts, which means they could use the intervention and provide feedback. The median number of feedback messages sent per therapist was 1, with a minimum of 0 and maximum of 460. Of the 54.1% (93/172) of therapists who gave feedback from January 2014 to May 2019, 25.0% (43/172) gave feedback 1 to 5 times, 25.0% (43/172) gave feedback 6 to 19 times, 25.0% (43/172) gave feedback 20 to 50 times, and 25.0% (43/172) gave feedback 51 to 460 times. Table 3 shows how many therapists sent how many feedback messages, showing one major outlier who gave feedback 460 times. The therapist who gave the second highest amount of feedback sent 251 messages.

Table 3. Number of feedback messages sent by therapists.

Messages sent	Number of therapists
0-35	144
35-70	12
70-105	7
105-140	2
140-175	0
175-210	4
210-245	1
245-280	1
280-315	0
315-350	0
350-385	0
385-420	0
420-455	0
455-490	1

Finally, Figure 4 shows the total number of feedback messages that were sent over time, from the introduction of the eMental health intervention until May 2019. The figure shows an increase in sent feedback messages with a peak in 2016, after which the number of messages decreased and seemed to stabilize at approximately 60 messages per month.

Figure 4. Number of feedback messages sent by therapists over time.



Interviews

Participants

In order to gain insight into factors related to implementation outcomes, 18 therapists from one outpatient clinic were interviewed. The therapists had different occupations: 8 psychologists, 6 social workers, 2 system therapists, 1 trauma therapist, and 1 forensic nurse were interviewed. Participants had an average age of 42.5 (SD 10.46) years with a range of 28 to 60 years, and 10 were female. At the time of interviewing, they had been working in forensic care for an average 13.18 (SD 8.68) years with a range from 8 months to 29 years.

First Impressions, Introduction, and Subjective Use of the Intervention

When asked about their first impression of the eMental health intervention and its introduction by the organization, most therapists were positive, as can be seen in Table 4.

Table 4. Therapist responses to survey questions.

Survey question	Very bad	Bad	Neutral	Good	Very good
First impression of the intervention	0	0	6	11	1
Introduction to the organization	0	1	5	10	2

When asked about use of the intervention, 4 therapists indicated that they received training but never used the intervention with a patient. The other 14 therapists had used the intervention with on average 8 patients, with a minimum of 2 and a maximum of 15. Therapists used the intervention in different ways in their in-person sessions with patients. Some discussed the assignments completed by patients very irregularly or never, whereas others discussed them structurally in each session. All therapists saw the intervention as an addition to treatment and used it in a blended manner, where in-person contact was seen as more important. Almost all therapists indicated that most patients did not finish modules and it was hard to keep them motivated.

Coding Schemes

Overview of Codes

The NASSS framework was used to structure the interview scheme and guide the coding process. Consequently, the main codes that were identified in the interviews are mostly aligned with the domains of the NASSS framework, as can be seen in Table 5. However, since a combination of deductive and inductive coding was used, there are several differences between the codes and domains of the NASSS framework. First of all, the adopter domain was split into a therapist and patient code. Integrating all these subcodes into one main adopter code would not have done justice to the differences between these types of factors. Furthermore, the embedding and adaptation over time domain of the NASSS model was not identified in interviews because therapists had difficulties providing a long-term vision on the technology and organization.

Table 5. Main codes, their definitions, number of interviews quote was mentioned (Nint), and number of times code was mentioned (Ntot).

Main code	Definition	N_{int}	N_{tot}
Adopters–therapists	Characteristics, cognitions, or behaviors of therapists that influence the use of technology in treatment	18	203
Adopters–patients	Characteristics, cognitions, or behaviors of patients that, according to therapists, influence the use of technology in treatment	18	194
Value proposition	The (desired) added value that a technology has or should have for treatment, according to therapists	18	121
Technology	Influence of the technology's features on use by therapists and patients	18	104
Organization	Characteristics, culture, and activities of the organization that influence use of technology by therapists	18	94
Wider system	Influence of activities by the broader context on use of technology by organizations and therapists	11	7
Condition	Extent to which the nature of the patient's condition (or disorder) influences use of technology, according to therapists	3	4

Adopters–Therapists

This main code was mentioned most often and refers to characteristics, cognitions, or behaviors of therapists that influence the use of eHealth in treatment. This code was found in all interviews, and 203 fragments belonging to this main code were identified. The subcodes are reported, defined, and illustrated with one or two quotes in Table 6. As can be seen in the table, therapists discussed a broad range of factors related to themselves that could influence the intervention's use. The most mentioned code referred to them not putting in enough time or effort to start or keep using the intervention. This could result in a lack of knowledge and skills to optimally use the intervention. The perceived lack of time was partly attributed to high workload but also to lack of enthusiasm to use the intervention. Among other things, not all participants were keen to work with technology in general. Several therapists believed that the intervention did not have enough benefits for their patients, and some felt that the technology was not easy to embed within standard treatment. Related to this, many therapists indicated that using the intervention was not in their system: while they often were willing to try it, most of the time they simply forgot about it because it was not part of their treatment routine. Consequently, many therapists did not introduce the intervention to their patients or did not motivate them enough to keep using it. Because the intervention was often not on the top of their minds, therapists indicated that they hardly discussed it with their colleagues. Finally, according to several participants, an important reason for successful use was having experienced benefits of the intervention for the patient: if the intervention fits an individual patient's skills and problems, chances on successful use were said to be higher.

Table 6. Subcodes of the main code "adopters–therapists," their definitions, illustrative quote, number of interviews the quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Investing effort and time	Effort and time the therapist is able and/or willing to invest in getting acquainted with and structurally using the technology	• *You have to know what happens in the module, what it contains. And then you have to check which assignments have been completed, and then give feedback on it. That costs extra time. Perhaps that's why people are hesitant. (pp. 13)* • *It can't be like you saying: "Hey, just fill it in, but I'll never look at it again." You have to make time to thoroughly look into it and to familiarize yourself with it. (pp. 4)*	18	48
Supporting patients	Extent to which a therapist actively introduces the technology to patients and/or tries to motivate and support patients to keep using it	• *Sometimes I know in advance: "This one will not use it," and maybe that's a self-fulfilling prophecy, that might be. But still, I'm not really inclined to start then. (pp. 7)* • *Because I've tried a lot of times to start with a certain module with patients who are not passionate about it. [...] But I notice it with myself: because the passion is there I can often make it work. So that's very necessary. (pp. 12)*	17	37
Integration of technology in routines	Extent to which the technology is integrated in the therapist's routine and/or whether they automatically think of using the technology	• *Yeah, I don't know what's the reason, I cannot really explain it, but despite that I like the modules, it's not on the top of my mind. So there is something that's stopping me from diving into my computer to find out which module fits with a patient. And I don't really know why it doesn't come up. (pp. 15)* • *Well, I agreed with a patient that they would hand it in next week Tuesday. Well ok, but then I didn't receive it and I forgot about it myself. The patient stopped doing it and well, it kind of disappears into the background. I now resolved it by planning appointments in my calendar, so that I'll be reminded to send reminders to patients. (pp. 6)*	16	36
Knowledge and skills	Therapist's level of knowledge about the technology and skills to appropriately use it in treatment	• *I also find it difficult to figure out which module fits which patient. [...] And I think that in my case, I'd just have to know which modules exist. And then I can just say "This fits you nicely, I'd like to recommend this, see if it's possible" and then get to work. (pp. 7)*	13	34
Attitude toward the technology	Therapist's opinion on and feelings toward using technology in treatment	• *I think it depends on in which generation you've grown up, I think younger colleagues have more feeling with it. [...] and that asks for a considerable adjustment, transformation, also for a number of older colleagues. (pp. 1)* • *And working with people, I still like doing that. Except for all that technical fuss, computers mean nothing to me, and also smartphones... I don't have any feeling with that and experience it as a burden. (pp. 2)*	12	28
Discussing technology with colleagues	Technology as a topic of conversation among therapists inside and outside of official meetings	• *Then I'll say in our team: "I'm hearing this and this and this," and sometimes someone in the team says: "Hey, eMental Health is something." I think that if people in our team say "Maybe eMental health is an option" more often... And if that rhythm isn't there, that's the reason why there is very little eMental health. Or at least within our team. (pp. 12)*	10	21
Experienced benefits	Extent to which a therapist perceives that the technology has positive effects on the patient's treatment outcomes	• *So then we try to shape the treatment in another way, instead of continuing with something [the module] of which you have the idea that it doesn't have that much effect. (pp. 3)*	2	4

Adopters–Patients

The main code "adopters–patients" was mentioned by all 18 therapists and refers to characteristics, cognitions, or behaviors of patients that influence the use of eHealth in their treatment. In total, 8 subcodes, presented in Table 7, and 194 fragments related to this main code were found. Therapists discussed multiple types of patient-related factors that, according to them, could influence the use of the intervention. It was frequently mentioned that many forensic psychiatric patients are often not motivated to start or keep working on the intervention. Therapists indicated that this was in line with low motivation for their treatment in general, which is partly due to the often obligatory nature of these patients' treatment. Furthermore, therapists stated that a large share of the patient population has cognitive impairments due to psychiatric disorders—such as problems with focusing—or received very little education (eg, having finished only primary school). According to the therapists, this can cause problems with patients understanding the mostly text-based intervention, completing written assignments, being able to individually reflect on their behavior, and having the required technological skills to be able to practically use the intervention. Furthermore, patients have to work in the intervention individually in their own time, which some therapists compared with homework. Therapists stated that many patients have difficulty with this: a large share of the patient population was not seen as conscientious enough to independently work on the intervention. For example, patients

often do not stick to agreements about when assignments were to be completed. Furthermore, therapists indicated that forensic psychiatric patients often have multiple psychiatric disorders and problems within their social environment, which might negatively influence their use of the intervention. When severe psychosocial issues occur, patients might be too preoccupied with these issues to use the intervention. Furthermore, not all patients have access to a computer or laptop, or they do not have a quiet place where they can comfortably work on the intervention.

Table 7. Subcodes of the main code "adopters—patients," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Motivation	Extent to which patient is motivated, enthusiastic, or open toward working with the technology in their treatment	• *I kind of think that, I think I've mentioned before that if that motivation is present, if they have the feeling that eMental Health fits their problems. And that has to be the case. They don't have to think: "Well, what about the problems I have...." They do have to see the connection to be motivated. (pp. 4)* • *Because very demotivated patients who don't want to be here anyhow... See, it's easier to not work on eMental Health at home, then not attending a face-to-face appointment. They'd earlier drop the eMental health then not coming here. (pp. 9)*	14	40
Conscientiousness	Extent to which patient is diligent in working on the technology and fulfills commitments regarding the use of the technology outside of treatment	• *Reading comprehension, making assignments, those kinds of things. If you're not used to doing homework, if you've never done homework in your life—eMental Health is actually homework. So that's a skill in itself. They have to be able to do it. (pp. 9)* • *Next, we open the module and then it seems to go well for about 1 or 2 sessions. But then there's always an "appointment forgotten" or "not finished" or those kind of things. After 3 months someone has stopped filling in the assignments, and only completed two sessions. (pp. 11)*	14	27
Literacy and educational level	Patient's ability to write, read, and understand treatment-related information in the technology	• *But I noticed that it wasn't really working. We've done it a couple of times, but there were a lot of difficult words. And if I explain the words, he'll forget what it means after that. (pp. 4)*	14	22
Experienced benefits	The extent to which a patient experiences a positive influence on his or her treatment because of the use of the technology	• *And whether the module fits the treatment and problems of the patient. [...] If you, for example, have a module on autism, and someone recognizes himself in that, in a module on psychoeducation for example. Then it can actually be useful in their daily lives. (pp. 6)* • *And also what I said earlier, that a module fits the needs of a patient. So if you use a sleeping module on someone with sleeping problems, chances are higher that he will continue with it. (pp. 16)*	14	22
Psychosocial situation	Level of stability of patient's personal life and/or mental state that is required to use a technology	• *I don't really think about it with people who are in a crisis situation. Because in my experience, they really don't have the need to discuss [the intervention]. You have to be in clearer waters, before they at least... Yes, that's my experience, before you can make a connection with someone who's overwhelmed by stress. If you, for example, have trouble about your social security benefit, or trouble with the neighbors, or trouble with your spouse, then it doesn't really work for those people anymore. (pp. 10)* • *Patients who are very prone to psychiatric crisis [...] or have so many psychosocial problems, well, then it won't work. Then you're only trying to stabilize them and you cannot use eMental health. (pp. 9)*	13	28
Technological skills	Level of practical skills required for successfully using information and communication technologies such as computers or smartphones	• *And I also notice that with eMental Health, the problem is that if a patient doesn't know anything about the computer, who isn't focused on that, you won't be able to make it work. You can jump high or low, but you won't get it done. (pp. 12)*	12	17
Availability of technological resources	Patient's access to necessary preconditions to use the intervention: technological device, appropriate working area, and good internet connection	• *I think that in their own environment, where they like doing it. They have to be able to do it privately, not that there's someone around the entire time. So privacy is important for them, I think. We can't facilitate that; they have to arrange that themselves. Or we'd have to offer them a place to work here, so they can sit behind a computer here. (pp. 7)* • *But I have had several people who were pretty positive about it, but who didn't have a computer, or their computer broke. (pp. 8)*	11	18

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Reflective skills	Patient's ability to independently write about and reflect on emotions, cognitions, and behaviors in the technology	• *I'm dealing with a lot of patients that find it really difficult to put their emotions and feelings on paper. They don't talk about those things regularly, like conflicts with their wife. Those people just didn't learn that. And yeah, if that's already difficult in a conversation to tell what you feel, what you want, or what you want differently, it's even more difficult to type it if you're alone, sitting behind a computer. That's on another level. (pp. 10)* • *Because the simplest question—he understands them, but he said to me: "I simply cannot put it into words." And if you have to do such assignments, and answer things... The fact that he hardly gives an answer, that partly has to do with him not being able to visualize and verbalize. (pp. 1)*	11	21

Value Proposition

The main code "value proposition" refers to the added value that a technology has or should have for treatment, according to the therapists. It was mentioned by all 18 therapists, 5 subcodes were identified, and 121 fragments were found in all interviews. As can be seen in the previous tables, not all therapists were positive about the intervention and did not use it often, but they were able to identify a broad range of potential and actual advantages of the eMental health intervention. These focused, among other things, on the content of the treatment: the intervention was said to have the potential to improve the quality of treatment by, for example, providing more structure to the treatment. Also, because therapists often also read the text of the intervention, several participants indicated that using the intervention might further improve or deepen existing knowledge about disorders. The intervention can also support patients in gaining new knowledge and skills (eg, new insights about a psychiatric disorder or an improvement of reflective or coping skills). Furthermore, several therapists explained that because patients must work on the intervention individually, their feeling of responsibility for their own treatment might increase, and they might ascribe positive changes more to themselves instead of their therapists. Moreover, several practical advantages were mentioned, among which saving time of therapists and patients because of less traveling time and replacing part of in-person treatment with the intervention, an increase of patients' access to care because they can individually work on their treatment at their own pace, and providing a new way of delivering treatment to patients. The subcodes are presented in Table 8.

Table 8. Subcodes of the main code "value proposition," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Improving treatment	Possibility of technology to improve quality of and further structure of face-to-face treatment	• *It does help you to focus the treatment on what someone needs. And it helps to not get bogged down in other, less relevant matters that people bring up, where it actually shouldn't be about. Someone has a treatment goal and the program fits that goal and that is what you will be doing. So it really helps to frame your therapy. (pp. 11)* • *Often, there are also things in there that I don't have on the top of my mind. And sometimes it's pretty nice to work via a protocol, that you encounter things of which you think: "Hey, I didn't think about that at all!" (pp. 2)*	14	39
Practical benefits	Benefits for patients, therapists, and the organization related to practical matters such as time and money	• *Well, I think it's very nice that you can put patients to work at a time which suits you, and that they can work whenever it suits them. So planning appointments is less of a hassle. And it's just like communication via WhatsApp or email: you all do it in your own time, so in that sense it's easier insertable in everyone's schedule. (pp. 16)* • *Well, the patient can work on it at home. He'd have to come here less often, face-to-face. So you'd have to plan an appointment less often, which can enable you to see more other patients. (pp. 5)*	14	26
Increase of knowledge and skills	Possibility for the patient or therapist to acquire new insights and skills into the patient or the disorder	• *An advantage for a patient with whom I have done the aggression module is that he did really gain more self-insight and came a little closer to himself. With the other patients I didn't really have a hallelujah experience, but with him it seemed like the penny has dropped. (pp. 15)* • *What I like about that is that you also go through the content yourself. [...] And I really like that of the modules, that you learn things from it yourself, and him as well. (pp. 12)*	13	22
Increase in patient independence	Enabling patients to work more independently and feel more ownership for their treatment	• *Well, the fact that someone does it himself with the module, that they are prouder at themselves because they've achieved something. That it wasn't the therapist who helped you, but that you've done it yourself. (pp. 16)* • *If they're in my room, I often have a fairly high pace, I am pulling and pushing them. But with the intervention, they're in a calm environment and can think calmly. (pp. 2)*	13	19
More options for treatment	Possibility of technology to offer a broader range and different types of treatment to patients	• *Well, for example, if a patient is working on the offense chain, you might notice that he has the need to practice more skills. Or wants to read a bit more about certain relaxation exercises. And if we're not there yet in the module, I move these topics forward, so that we can work on those at that point in time. Or I check in another module if there's something there, that they can work on a topic in between. [...] Then I think: "This fits well at this point in time," and then we can continue with the treatment. (pp. 9)*	11	17

Technology

This main code was mentioned in all 18 interviews and focuses on the influences of the technology's features on use by therapists and patients. In total, 3 subcodes and 104 fragments were identified, as can be seen in Table 9. Usability of the technology was often mentioned by therapists. While a few were fairly positive, most found the technology not easy to use for themselves or for patients: it did not fit their preferences and way of working. Furthermore, while most therapists were relatively positive about the intervention's look and feel, it was mentioned that the way the content was presented was not very suitable for many patients, for example, due to a lot of text or too many sessions within modules.

Table 9. Subcodes of the main code "technology," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Ease of use	Extent to which therapists find use of the technology intuitive, clear, and structured	• *I feel that the eMental health intervention is too big, or too fuzzy. As I just mentioned, all these modules, I know a few, but I think that there are a lot, also specified on other diagnoses. But I find it tricky to find these things. So I don't think it's very well arranged. (pp. 9)* • *I'd see that as tiles in [the electronic patient record] which we are using currently. In User you have multiple tiles and the patient record, and it should also have a tile of [the intervention], on which you click and then you can start. [...] If there would be a block of [the intervention], it would be really easy to go to it. I think that would be more user friendly than when you have to go to the website yourself to log in, because then you have taken multiple additional steps. (pp. 7)*	16	68
Presentation of content	Therapist's opinion on the ways in which the treatment-related content of the technology is presented to the patients	• *The module itself should be shorter. Both the individual sessions and the number of sessions in a specific module I'd make shorter. I feel that certain explanations are too difficult for some patients. So I think there is not enough supply for people with a low intelligence, and a large number of our people has a lower than average intelligence. (pp. 18)*	8	21
Appearance	Therapist's opinion on the overall look and feel of the design of the technology	• *Because I think those modules are really cool. I'm thinking "Wow, the person that came up with this has it right!" But it's just fresh, I'd almost say happy, but also friendly, and user-friendly. And if you can have these things together in a module text, with some videos and some other things and some explanation, that's just amazing! (pp. 12)* • *With regard to the design, with videos and images, it's stimulating and appealing. It's not a boring booklet that you hand out. (pp. 4)*	7	10

Organization

This main code refers to the characteristics, culture, and activities of the organization that influence the use of technology by therapists, and was mentioned in all 18 interviews. In total, 94 fragments for 4 subcodes were identified, which are explained in Table 10. Almost all interviewed therapists explained that the intervention was introduced to them by means of a course in which they gained practical skills to use it. According to therapists, the organization did not pay a lot of attention to the intervention after this course. Multiple therapists indicated that the intervention was often not discussed in official meetings. This was viewed as a partial explanation for therapists not remembering to use the intervention on a regular basis. Also, several therapists indicated that they did not experience enough support for questions about the content of the intervention or the way they could embed it in treatment. To illustrate, some therapists required more support when working with unmotivated patients or had questions about how to integrate assignments of the intervention in their in-person treatment sessions. Besides content-related support, therapists also mentioned several practical barriers that the organization should address, such as a slow internet connection.

Table 10. Subcodes of the main code "organization," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Introduction of technology to therapists	Activities that the organization undertook to introduce the technology and train therapists' necessary skills and knowledge, according to therapists	• *Hmm, much less, because, I think I had a course once, just in the beginning, and there's not really a follow-up. (pp. 10)* • *We've received a very clear explanation, I believe an entire day and you just started practicing. And I liked that. But now I'm thinking, if I'd have to use it with a patient, I'd really have to ask with the people who gave the course. He'd have to quickly explain to me how it works. That knowledge has faded. (pp. 1)*	17	27
Providing support for therapists	Ways in which the organization offers content-related support to therapists for using the technology in treatment	• *I just think that, well, for the long term the organization has to pay more attention to it, for the team. And I also think that you have to implement the trainer-trainer idea. That you pick a couple of people who work well with it or are a bit better in it, that they are appointed as a source of information, and that other people know about that. (pp. 9)* • *Currently I'm trying to figure it out myself, but how do you really shape a blended treatment? If there would be education about that! Also about the more challenging cases, if there is very little motivation. (pp. 4)*	14	34
Integration in organizational structures	Extent to which a technology is structurally featured in activities or products for which the organization is responsible, such as meetings, treatment protocols, targets, or performance reviews	• *But it doesn't get indicated a lot in the intake or in meetings. Often the one who's done the intake has to bring it up themselves, but it's not something that other people in the meeting bring up or come up with, that that's also an option. My personal experience. If I bring it up, they say "Oh yeah it's a good idea," but if I say nothing, they hardly ever come up with it. (pp. 18)* • *So that management says: "eMental health guys, don't forget about that!" (pp. 6)*	11	21
Providing necessary conditions for use	Extent to which the organization ensures boundary conditions such as availability of sufficient technological resources and time for therapists	• *Internet is often slow. Then you've planned half an hour, and you think, I'm going to do it. Well, it doesn't work. It's also a technical issue. From the division around it, the internet, that's so slow. And if you have to start a program such as [the intervention], well, you can do something else in that time... Then you constantly have to wait, well, then I drop out. (pp. 2)* • *And that time is actually scheduled for people. You have to really work on it, so it cannot disappear in the other activities, because you will forget it. If you really have an hour to only work on eMental health, it will remove some barriers and other arguments. (pp. 18)*	7	10

Wider System

This main code refers to the influence of activities by the broader context on use of technology by organizations and therapists and consists of 2 subcodes, which can be found in Table 11. This code was identified 17 times in 11 interviews. Therapists discussed the wider system less often than previous codes. Several participants briefly mentioned health insurance companies and government but did not elaborate on the role of the wider system.

Table 11. Subcodes of the main code "wider system," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
Demands of health insurance companies	Therapist perception about financial incentives for using the technology offered by health insurance companies	• *I don't know, that's something from the health insurer, that they say that we have to do something with [the intervention]. That's a bit how it feels. That we received that assignment because we have to meet the numbers. (pp. 7)*	9	12
Encouragement of government	Extent to which use of a technology is encouraged by the government	• *First, they should make a statement as an organization, together with other organizations, to say: "Yeah it's all good and you can want it in this way but we're going higher to the government and say to the government: this is not ok." There are so many administrative tasks that don't... If you do something and you have to account for this it's fine, but it can be a lot easier. (pp. 12)*	4	4

Condition

This code refers to the extent to which the nature of the patient's condition (or psychiatric disorder) influences use of the technology according to therapists. The subcode was mentioned 4 times in 3 interviews, as can be seen in Table 12. Therapists often did not discuss their patients' diagnoses as a separate factor that directly influences the intervention's use.

Table 12. Subcodes of the main code "condition," their definitions, illustrative quote, number of interviews quote was mentioned (N_{int}), and number of times code was mentioned (N_{tot}).

Subcode	Definition	Illustrative quote	N_{int}	N_{tot}
ADHD[a]	Impact of (symptoms of) ADHD on patient's use of the technology	• *So I cannot really... I do know that those ADHD patients, that it takes too long for them. They're too easily distracted, or find a question too difficult. It's not that everyone has that. (pp 2)*	3	4

[a]ADHD: attention deficit hyperactivity disorder.

Synthesis

When looking at the implementation strategies described by Waltz et al [19], desk research and interviews showed that in this study, most attention was paid to training of therapists, as mostly becomes clear in the subcode *introduction of the technologyto therapists* of the main code "organization." However, little to no strategies related to changes in the organizations' infrastructure, engagement of patients, and adaptation of technology to the context were conducted. This is further illustrated by all subcodes of the main code "organization," but also by the therapist- and patient-related subcodes *integration of technology in routines*, *knowledge and skills*, *discussing technology with colleagues*, and *motivation*. Furthermore, desk research showed that support and assistance for therapists was available, but most interviewed therapists did not experience this as such, which becomes most clear in the "organization"-related subcode *providing support for therapists*. Desk research showed that besides training, several relatively minor evaluation strategies were conducted by the organization itself, during and shortly after the pilot. However, the outcomes of these evaluations did not lead to major changes to the implementation strategies, so no lasting improvements in the use of the intervention were observed in the log data. This is visualized in Figure 4; a short peak in sent messages can be observed during the time of the evaluation, but this increase in sent messages only lasted several months. To conclude, implementation strategies were mostly focused on training of therapists, but little attention was paid to adaptiveness of the technology, changes in the organization, and patient awareness.

The results of the desk research, log data analysis, and interviews were used to assess the implementation outcomes described by Proctor et al [21] from a holistic perspective, structured via the NASSS framework [31]. First, the interviews showed that acceptability of the intervention was relatively high, with therapists being positive about the intervention and able to identify its added value. This fairly high acceptability is illustrated in Table 4, which shows overall good first impressions of the intervention, and is further supported by the main code "values," which points out that therapists are able to mention a broad range of potential and actual advantages. However, despite the fairly positive acceptability, log data analyses and interviews clearly showed that adoption was low; a large share of therapists and patients did not use the intervention at all. Furthermore, the intervention's penetration in the organization was low; log data showed that only a small fraction of therapists and patients used the intervention. Only 54% of the eligible therapists actually used the intervention, and Figure 4 shows that the largest share those who did use it, did not use it a lot. When the intervention was used, fidelity was often low, as can be seen in Table 2. Only 18% of the modules were fully completed, and of the remaining 82%, modules were either not started or not fully completed, implying that they were not used as intended. An explanation for this can be found in the appropriateness of the intervention. Log data showed that several modules were completed, and several therapists indicated that they were able to successfully use the module with some patients. However, therapists indicated that the intervention did not optimally fit most patients' skills and preferences. This is illustrated by the patient-related subcodes *conscientiousness*, *literacy and education level*, *technological skills*, and *reflective skills*. The mismatch between patient characteristics and the intervention also becomes clear in the main code "technology," which shows that usability, design, and content are not optimally tailored to the forensic psychiatric patient population. Furthermore, the intervention also seems not to be appropriate for many therapists, who indicated that they prefer in-person contact and often felt not fully equipped to integrate the intervention in their treatment. This means that currently, the intervention's costs in terms of finances and time investment seem to be higher than the benefits. Also, sustainability was low: therapists stated that the intervention was often not discussed in meetings and was not integrated in electronic patient records they used. While this theme appears in multiple codes, it becomes especially clear in the organizational subcode *integration in organizational structures*. Consequently, therapists often did not even think of the possibility to use the intervention in treatment, which is represented by the therapist-related subcode *integration of technology in routines*. Currently, the feasibility of the intervention is low because of a suboptimal fit between the features of the technology; needs, wishes, and skills of therapists and patients; and characteristics and activities of the organization. It appears that since the implementation strategies were not conducted from a holistic perspective but mainly focused on training the therapists, the implementation outcomes are disappointing.

Discussion

Principal Findings

Main Outcomes

This mixed-method study evaluated the implementation strategies and outcomes of an eMental health intervention in forensic mental health care from a holistic perspective, where attention is paid to factors related to people, organizational context, and technology. Triangulation of the outcomes of desk research, log data analyses, and interviews with therapists

showed that the technology did not optimally fit the therapists, patients, and organization. Furthermore, the implementation process was mostly focused on skill training of therapists and not executed from a holistic perspective; not enough attention was paid to changes in the organization, patients, and other required changes in therapists. The results of this mixed-methods study will be discussed in more detail structured by the main elements of the holistic approach that was applied: the people using the eMental health intervention, the organization in which it was used, and the technology.

Therapists

The interviews and log data showed that although several therapists were active users of the intervention, most of them only tried it once or twice, and a relatively large share of the therapists did not even use the intervention at all. Nevertheless, almost all interviewed therapists were fairly positive about the intervention and able to identify its added value. This shows that cognitions, intentions, and feelings of users are not fully predictive of successful use. Nevertheless, models that focus on individual factors predicting technology acceptance, such as the technology acceptance model (TAM) [46] or the unified theory of acceptance and use of technology [47], are still used regularly to analyze or plan implementation. While these types of models are useful to create an overview of individual beliefs and attitudes that influence a person's intention to use a technology [48], they pay little to no attention to influences of the context, characteristics of the technology, and interrelationships between them [48,49]. Consequently, implementation models or frameworks that apply such a holistic approach like CFIR [30] or the NASSS framework [31] seem to be more useful in this context because of their focus on a broad range of contextual and (inter)personal factors and not merely individual factors of end users.

Despite the fact that all therapists in the organization had received training, only a relatively small proportion actively used the intervention. This implies that skills training only did not suffice for successful implementation: more than just a how-to instruction seems to be necessary to fully equip therapists to embed the intervention in their treatment sessions. Among other things, therapists also need to know how to persuade patients to start with the intervention, they need to be able to keep motivating patients to complete exercises, and they must embed the content of the intervention and the patient's answers in treatment [14,50,51]. This implicates that the use of eMental health might also change the role of the (forensic) mental health professional [51]. In this new way of working, patients might be more in the lead and supported by professionals, and the structure and content of treatment may not be determined only by the professional but also by the intervention. Such a technology-induced role change in domains where communication previously only took place between persons requires changes on a multitude of levels, like management, education, or government [52], and not merely a skills training of therapists. More research on the nature of this role change and implications for implementation strategies is required.

When looking at implementation strategies, it might also be useful to conduct more research on the need to better tailor these strategies to different types of therapists. In this study, there appeared to be a lot of differences in therapists regarding their subjective attitudes and objective use of the intervention. This is in line with a recent study that showed that therapists differ in the types of drivers and barriers they perceive with regard to the use of eMental health [24]. This might imply that different types of therapists benefit from different types of implementation strategies. For example, therapists with a low level of enthusiasm and skills might need to receive a different type of training than enthusiastic and tech-savvy therapists. In line with this, multiple researchers stated that one-size-fits-all interventions are not very suitable for forensic mental health care and that tailoring is advised [40,53-57]. This argument can be extended to professionals: adaptive implementation strategies that fit different types or subgroups of therapists' needs, skills, and attitudes might be beneficial for implementation outcomes. Subsequent research might focus on the identification of different subgroups of therapists, for example, in terms of attitude or eHealth literacy and tailoring implementation strategies to these characteristics. Also, researchers should assess whether tailoring implementation strategies to different types of professionals actually results in better implementation outcomes.

Patients

Therapists indicated that the eMental health intervention requires a relatively high level of reading and writing skills, cognitive reflection, and conscientiousness. However, according to desk research and other literature, forensic psychiatric patients often have low education levels [58,59], which might explain the low number of patients that completed modules. This shows that there seems to be a poor fit between most users' skills and the content of the eHealth technology, which might be a major cause for nonuse or nonadherence [60,61]. Several solutions might address this issue: therapists can support patients more in working on difficult elements of the intervention, or texts and assignments can be shortened and made easier. However, it might also be possible that the studied eMental health intervention is not very suitable for this context and another type of technology would be a better fit for most patients. For example, multiple recent studies point out the potential of interactive virtual reality interventions for forensic mental health care [62-66], among other things because they allows patients to actually practice with behavior instead of talking or writing about it. Another possibility is wearables, which can be used to collect physiological data associated with aggressive outbursts or as electronic momentary assessment devices to gather information about a patient's emotional state [67,68]. This study underlines the importance of adaptability of eMental health to optimally fit the needs and characteristics of individual patients.

Organization

As was mentioned before, the organization focused implementation strategies mostly on skills training of therapists but did not pay much attention to the implementation of the intervention on other levels. The disappointing implementation outcomes show the importance of the use of multiple types of implementation strategies to ensure that an eMental Health intervention is thoroughly embedded in a forensic organization's

infrastructure [40,50]. This is in line with literature on eHealth implementation in general, which emphasizes the importance of integrating technologies in existing organizational structures or even changing the way care is delivered or organized [28,29,32,33,69]. One way to achieve this in the studied organization is by ensuring that therapists structurally discuss the possibility of using an eMental health intervention at predetermined moments in treatment (eg, during a patient's intake). This can be done by means of the existing "fit for blended care" instrument [12], which aims to support therapists in shaping their blended treatment in cooperation with the patient. This instrument can be adapted to fit the specific forensic mental health organization by means of the patient-related factors identified in this study. Furthermore, the eMental health intervention might need to become a permanent item on the agenda of team meetings to ensure that it is discussed regularly [50]. Moreover, therapists indicated that they hardly discussed the intervention with colleagues, as opposed to other parts of their treatment, so peer-coaching sessions to discuss the use of the intervention might be organized [50]. It is important that research is conducted to determine whether these types of strategies actually boost implementation outcomes [23]. Generating more knowledge on suitable and successful implementation strategies will support other organizations in planning implementation and prevent them from reinventing the wheel, which will eventually save time and money.

Technology

One reason for the low use of the intervention was that not all therapists were positive about the user-friendliness of the intervention's design: among other things, they indicated that the website did not give them a clear overview of suitable modules for specific patients. Log data indeed showed that only a fraction of modules were used frequently. Adding more persuasive elements to the intervention might support therapists in using the intervention. An example is tunneling: the system can guide the therapist through the process of selecting suitable modules for a patient [70]. Additional research can be conducted to evaluate and improve the persuasiveness of the intervention (eg, by means of the Perceived Persuasiveness Questionnaire [71]), which might increase its use [72].

A characteristic of the intervention that might have hindered use is the lack of possibilities for personalization. As was mentioned before, the technology does not seem to fit most patients according to therapists: there were too many sessions within a module, there was too much text, and the subject matter was too complex for most patients. Therapists expressed the need for multiple versions of the modules in order to personalize the intervention. Examples are the possibility to choose between videos or text or the option to select texts with different levels of difficulty. Studies on eHealth in general have stated that personalization can increase adherence [73-75], so a more personalized version of the intervention might result in better implementation outcomes. However, more research is necessary on what elements should be personalized, how this should be done, and if this actually positively impacts use and adherence. Ideally, this redesign of the technology should be done in close cooperation with end users to ensure that it better fits their needs [29,64], since cocreation can also have a positive influence on implementation outcomes [28,76].

Strengths and Limitations

This study took place at one forensic psychiatric hospital in the Netherlands, which might raise questions about the generalizability of the results. However, other studies on eHealth in forensic care have identified similar types of implementation issues [50,53,56,63,77]. On top of that, many of the identified issues have been reported for eHealth in general (eg, lack of enthusiasm in therapists, low adherence by patients, or lack of integration of a technology in an organization's structure [32,33,69]). This implies that, on an abstract level, our findings are relevant for other types of (mental) health care as well. A related strength of this study is that all therapists working at the outpatient clinic could be interviewed, which prevented a self-selection bias from occurring.

Furthermore, while use of the NASSS framework to structure the qualitative analysis was a strength of this study, several issues arose during the coding process. A chief example of this is the domain "condition." As opposed to a patient population that suffers from one disorder (eg, depression or diabetes), the forensic psychiatric population is not characterized by one condition: comorbidity is very common among forensic patients, and patients have committed a broad range of offenses [78-80]. This raises the question on how to characterize certain behaviors or cognitions: as part of a patient's personality or as a symptom of a disorder. To illustrate: if a patient has trouble focusing, which hinders the use of an eHealth intervention, should this be viewed as a consequence of the patient's ADHD or as a part of their personality? We therefore recommend that more studies apply the NASSS framework to evaluation of implementation and report on its applicability and suitability, which might lead to possible revisions or fine-tuning of the framework.

Finally, a strength of this study was the combination of different types of data to evaluate the implementation process. By using a mixed-methods approach, objective and more subjective data were combined, which proved to be valuable for gaining insight into a multilevel and elaborate implementation process. It was decided to not interview patients and management, since therapists were asked about the patient perspective and desk research provided insight into the strategies of management. Including these perspectives in interviews would probably not have produced much new information, but it is possible that factors were overlooked. Further research could focus on analyzing the patient perspective in implementation and investigate whether there are any discrepancies between therapist perspectives on patients and the patients' own perceptions. Finally, desk research was combined with interviews to provide a full picture of the implementation strategies, but not all information could be retrieved from the desk research (eg, number of participating therapists in the pilot). This shows the importance of carefully and fully documenting relevant information about implementation strategies from the start.

Conclusion

This study showed that the fit between the characteristics and needs of the therapists and patients, the organization, and the

technology was suboptimal, which has led to suboptimal implementation outcomes. An explanation for this could be the lack of a holistic approach in implementation: the implementation strategies mainly focused on training therapists' technical skills, while more attention should have been paid to necessary changes in the organization, an attitude change in therapists, and design of the technology. Here, adaptivity appears to be an important concept: a technology should be easily adaptable to an individual patient, therapists should be trained to be able to deal with an eMental health intervention in their treatment in a flexible way, and organizations must adapt their implementation strategies and structures to embed a new eHealth intervention. Consequently, in implementation, the holistic nature of eHealth and ensuring adaptivity on multiple levels appear to be pivotal.

Acknowledgments

Funding for this study was provided by Stichting Vrienden van Oldenkotte. We would like to thank Karen Rienks and Nathalie ten Cate, who conducted and transcribed the interviews, and Dirk Dijkslag for his help with the desk research and log data retrieval.

Abstract

Background: Evidence-based best practices are the cornerstone to guide optimal cardiopulmonary arrest resuscitation care. Adherence to the American Heart Association (AHA) guidelines for cardiopulmonary resuscitation (CPR) optimizes the management of critically ill patients and increases their chances of survival after cardiac arrest. Despite advances in resuscitation science and survival improvement over the last decades, only approximately 38% of children survive to hospital discharge after in-hospital cardiac arrest and only 6%-20% after out-of-hospital cardiac arrest.

Objective: We investigated whether a mobile app developed as a guide to support and drive CPR providers in real time through interactive pediatric advanced life support (PALS) algorithms would increase adherence to AHA guidelines and reduce the time to initiation of critical life-saving maneuvers compared to the use of PALS pocket reference cards.

Methods: This study was a randomized controlled trial conducted during a simulation-based pediatric cardiac arrest scenario caused by pulseless ventricular tachycardia (pVT). A total of 26 pediatric residents were randomized into two groups. The primary outcome was the elapsed time in seconds in each allocation group from the onset of pVT to the first defibrillation attempt. Secondary outcomes were time elapsed to (1) initiation of chest compression, (2) subsequent defibrillation attempts, and (3) administration of drugs, including the time intervals between defibrillation attempts and drug doses, shock doses, and the number of shocks. All outcomes were assessed for deviation from AHA guidelines.

Results: Mean time to the first defibrillation attempt (121.4 sec, 95% CI 105.3-137.5) was significantly reduced among residents using the app compared to those using PALS pocket cards (211.5 sec, 95% CI 162.5-260.6, *P*<.001). With the app, 11 out of 13 (85%) residents initiated chest compressions within 60 seconds from the onset of pVT and 12 out of 13 (92%) successfully defibrillated within 180 seconds. Time to all other defibrillation attempts was reduced with the app. Adherence to the 2018 AHA pVT algorithm improved by approximately 70% (*P*=.001) when using the app following all CPR sequences of action in a stepwise fashion until return of spontaneous circulation. The pVT rhythm was recognized correctly in 51 out of 52 (98%) opportunities among residents using the app compared to only 19 out of 52 (37%) among those using PALS cards (*P*<.001). Time to epinephrine injection was similar. Among a total of 78 opportunities, incorrect shock or drug doses occurred in 14% (11/78) of cases among those using the cards. These errors were reduced to 1% (1/78, *P*=.005) when using the app.

Conclusions: Use of the mobile app was associated with a shorter time to first and subsequent defibrillation attempts, fewer medication and defibrillation dose errors, and improved adherence to AHA recommendations compared with the use of PALS pocket cards.

Introduction

Pediatric cardiac arrest is a high-risk, low-frequency event associated with death or severe neurological sequelae in survivors. It requires immediate recognition and care by skilled health providers. Recent studies show that pediatric in-hospital cardiac arrest (p-IHCA) affects 7100-8300 children per year in the United States [1], of which 14% occur in pediatric emergency departments (PEDs) [2]. Pediatric out-of-hospital cardiac arrest (p-OHCA) accounts for a further 7037 children brought to US PEDs by emergency medical services each year [3]. Despite advances in resuscitation science and survival improvement over the last decades, survival remains low, with only approximately 38% of children surviving to hospital discharge after p-IHCA, and 6%-20% after p-OHCA [3,4]. Evidence-based best practices are the cornerstone for the guidance of optimal cardiopulmonary arrest resuscitation care. High-quality cardiopulmonary resuscitation (CPR), according to the American Heart Association (AHA) life-support guidelines, is associated with a successful return of spontaneous circulation (ROSC), improved survival after hospital discharge, and good neurological outcomes [5]. Deviation from recommended procedures is associated with a reduced likelihood of survival from cardiac arrest [6].

While adherence to AHA guidelines in emergency departments has been described for adults, there are limited data for PEDs [7]. Reference tools for pediatric emergency physicians to handle pediatric CPR according to AHA guidelines are available on reference pocket cards. Unfortunately, health care providers frequently do not perform resuscitation according to guidelines, despite cognitive aids [8] and AHA life-support training courses, such as basic life support (BLS) and pediatric advanced life support (PALS). Suboptimal quality of CPR is still commonly encountered for both adult and pediatric patients [9].

New resuscitation strategies using information technologies and devices aiming to improve both in- and out-of-hospital CPR have been assessed to ensure adherence to AHA guidelines [10-16]. Nevertheless, research in this area remains scarce, especially in pediatrics, and studies assessing the impact of information technology on p-IHCA management and improved pediatric CPR outcomes are necessary. In a previous randomized trial, we found that adherence to PALS algorithms when adapted on Google Glass was improved with a significant reduction of errors and deviations in defibrillation doses by 53% when compared to the use of pocket reference cards [17]. However, time to the first defibrillation attempt and adherence to AHA guidelines to other critical resuscitation endpoints in terms of time and drug-dose delivery were not improved using the glasses. The complexity of interacting while wearing glasses, as well as the limits of the system to situate the current action in the whole resuscitation process and their small size, were major limitations to their potential use in p-IHCA. Thus, we have developed a new mobile app—the Guiding Pad app—from the ground up and dedicated it to tablets. It is intended as a guide to support and drive CPR providers in real-time conditions through interactive PALS algorithms enhanced with patient-centered cognitive aids.

Our objective was to investigate, in a simulated model, whether this app would increase adherence to AHA guidelines by reducing deviation and time to initiation of critical life-saving maneuvers during pediatric CPR compared to the use of PALS pocket reference cards.

Methods

Study Design

We conducted a prospective, randomized controlled trial in a tertiary PED (>33,000 consultations/year) with two parallel groups of voluntary pediatric residents. We compared time to the first defibrillation attempt and other critical resuscitation endpoints using a tablet app (Guiding Pad, group A) or AHA PALS conventional pocket reference cards (group B) during a standardized simulation-based pediatric cardiac arrest scenario. No changes were made to the app during the study.

The trial received a declaration of *no objection* by Swissethics and the Geneva Cantonal Ethics Committee, as the purpose of the study was to examine the effect of the intervention on health care providers. For the same reason, and according to the International Committee of Medical Journal Editors, a trial registration number was not required. The trial was conducted according to the principles of the Declaration of Helsinki and Good Clinical Practice guidelines, and in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online TeleHealth) guidelines (see Multimedia Appendix 1) [18] and the Reporting Guidelines for Health Care Simulation Research [19].

Participants

Any physician performing a residency in pediatrics was eligible. Shift-working residents were randomly recruited on the day of the study using an alphabetical list to avoid preparation bias. Included participants benefited from a standardized 5-minute introduction course on the use of the tablet app. As BLS training is a requirement for residents at our institution, all participants had previously completed this course prior to study entry. Participation in a simulation in the past month was an exclusion criterion to avoid a recent training effect. Study participants

were not involved in the study design, choice of outcome measures, or the execution of the study. No participant was asked for advice on the interpretation or writing of the study results. Participants were informed of the results after completion of the study.

Randomization and Blinding

Residents were randomized using a single constant 1:1 allocation ratio determined with the web-based randomization software Sealed Envelope [20]. Written informed consent was obtained from each participant after full information disclosure prior to study participation. Blinding to the purpose of the study was maintained during recruitment to minimize preparation bias. Allocation concealment was managed with the software and was not released until the participant started the scenario.

The Guiding Pad App

Unlike adults, cardiac arrest in children without prior cardiac disease is mainly due to asystole (40%) and pulseless electrical activity (24%) [2]. As ventricular fibrillation and pulseless ventricular tachycardia (pVT), namely shockable rhythms, have been identified in 27% of p-IHCA cases [21], we decided to use the pVT algorithm, as we considered that it would offer a greater opportunity to assess the multiple-step resuscitative skills set out in the AHA guidelines. The app was developed at Geneva University Hospitals using Angular, version 8, a development framework created by Google to build mobile and web apps. The AHA PALS algorithms were adapted for tablets following a user-centered and ergonomic-driven approach by computer scientists, senior pediatric emergency physicians, and ergonomists. The numerous steps of AHA PALS algorithms were split into stages. Each stage transposed to the tablet paralleled the informational content of a resuscitation step from the original algorithm. The algorithms thus obtained were set up in a manner similar to the PALS pocket references regarding the progression and sequence of actions along the original algorithms' sequences. For instance, the complete pVT algorithm was designed to be as concise as possible without hindering proper progression along the algorithm. After completing a quick pediatric assessment triangle as the first step to recognize cardiac arrest and initiate CPR, including information on the weight or age of the patient, the app displays an initial statement about whether the pulse is present or not and the subsequent cardiac arrhythmias. Once selected, the screen then splits into two main sections.

The first section on the left-hand side of the screen displays an entire algorithm overview, thus allowing users to situate the stepwise resuscitation progress in real time along that algorithm. The current step of the resuscitation process is surrounded by a blinking red line that allows an immediate understanding of the current position within the algorithm. Each action already performed turns grey. However, the app provides the possibility for users to navigate back and forth through the algorithm at any time in order to select one of the resuscitation steps if needed.

The second section on the right-hand side of the screen displays the following elements:

1. A color-coded title allowing direct identification of each step in progress.
2. Cognitive aids helping with decision making, such as a distinctive illustration of cardiac rhythms (see Figure 1) or the shock dose to deliver with a picture of a manual defibrillator (Philips HeartStart MRx Biphasic Defibrillator, Philips Medical Systems) (see Figure 2).
3. A detailed and clickable list of actions to perform in a stepwise manner.
4. A footer to preview the next step.

Each action prompts the provider either to perform a choice (ie, choose the correct arrhythmia among several propositions) or to validate an action to be executed (eg, a drug-dose administration), which is brought to the attention of the provider by a red-box warning (see Figure 3). Weight-based drug doses are automatically calculated by an in-built engine already used in another evidence-based app that was assessed in a multicenter randomized controlled trial for in-hospital emergency drug delivery [22]. Shock doses using Philips HeartStart MRx Biphasic Defibrillator are automatically calculated based on patients' weights or ages. Each cycle of chest compression-ventilation is timed by a countdown clock displayed on the screen. In the case of rhythm change, the user can easily navigate across the multiple PALS algorithms (bradycardia, supraventricular tachycardia with poor perfusion, etc) at any time. All actions performed by the provider are automatically saved in log files to preserve information that can be retrieved at any time for debriefing or medicolegal purposes.

Figure 1. A screenshot of the Guiding Pad app. The left-hand side of the screen displays the American Heart Association (AHA) pediatric advanced life support (PALS) ventricular fibrillation (VF) and pulseless ventricular tachycardia (pVT) cardiac arrest algorithm. The current step (eg, determining the shockable status of the arrhythmia) of the resuscitation process is surrounded by a blinking red line. Past actions already accomplished are shown as shaded. At the top right-hand side of the screen, a color-coded title depicts the current step in progress. Below, four pulseless dysrhythmias are displayed; the provider selects the right one under consideration. At the bottom right-hand side, a footer helps to anticipate the next cardiopulmonary resuscitation (CPR) step. IO: intraosseous; IV: intravenous.

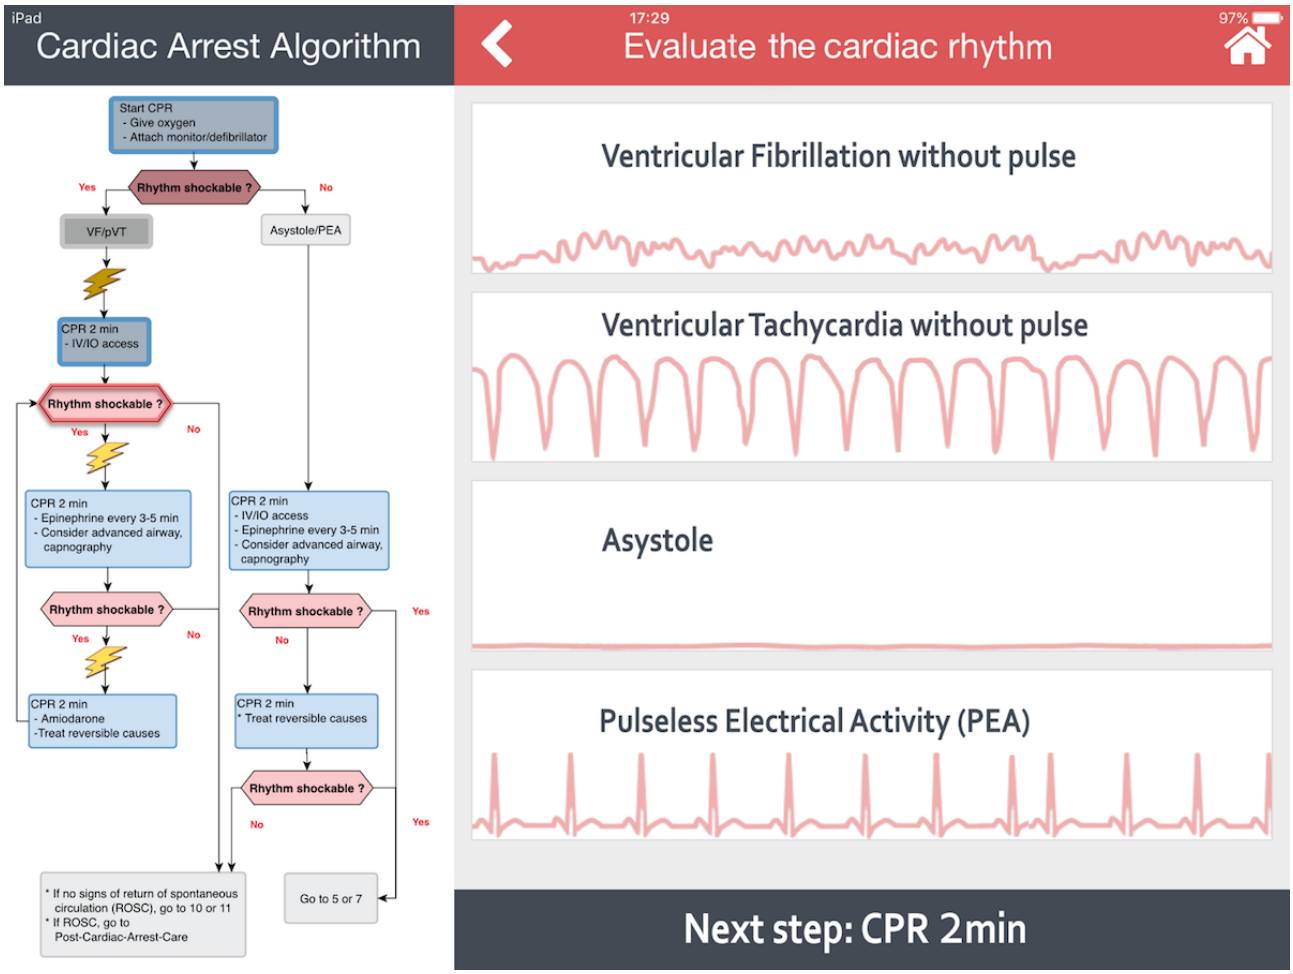

Figure 2. Screenshot of the Guiding Pad app. The left-hand side of the screen displays the American Heart Association (AHA) pediatric advanced life support (PALS) ventricular fibrillation (VF) and pulseless ventricular tachycardia (pVT) cardiac arrest algorithm. The current step (eg, defibrillation) of the resuscitation process is displayed with a red lightning bolt. Past actions already accomplished are shown as shaded. On the right-hand side of the screen, the weight-based shock dose to deliver is displayed with a picture of a manual defibrillator (Philips HeartStart MRx Biphasic Defibrillator). Once delivered, clicking the "Shock delivered" button validates the action and allows the user to proceed to the next step. At the bottom right-hand side, a footer helps to anticipate the next compression:ventilation step. CPR: cardiopulmonary resuscitation; IO: intraosseous; IV: intravenous; PEA: pulseless electrical activity.

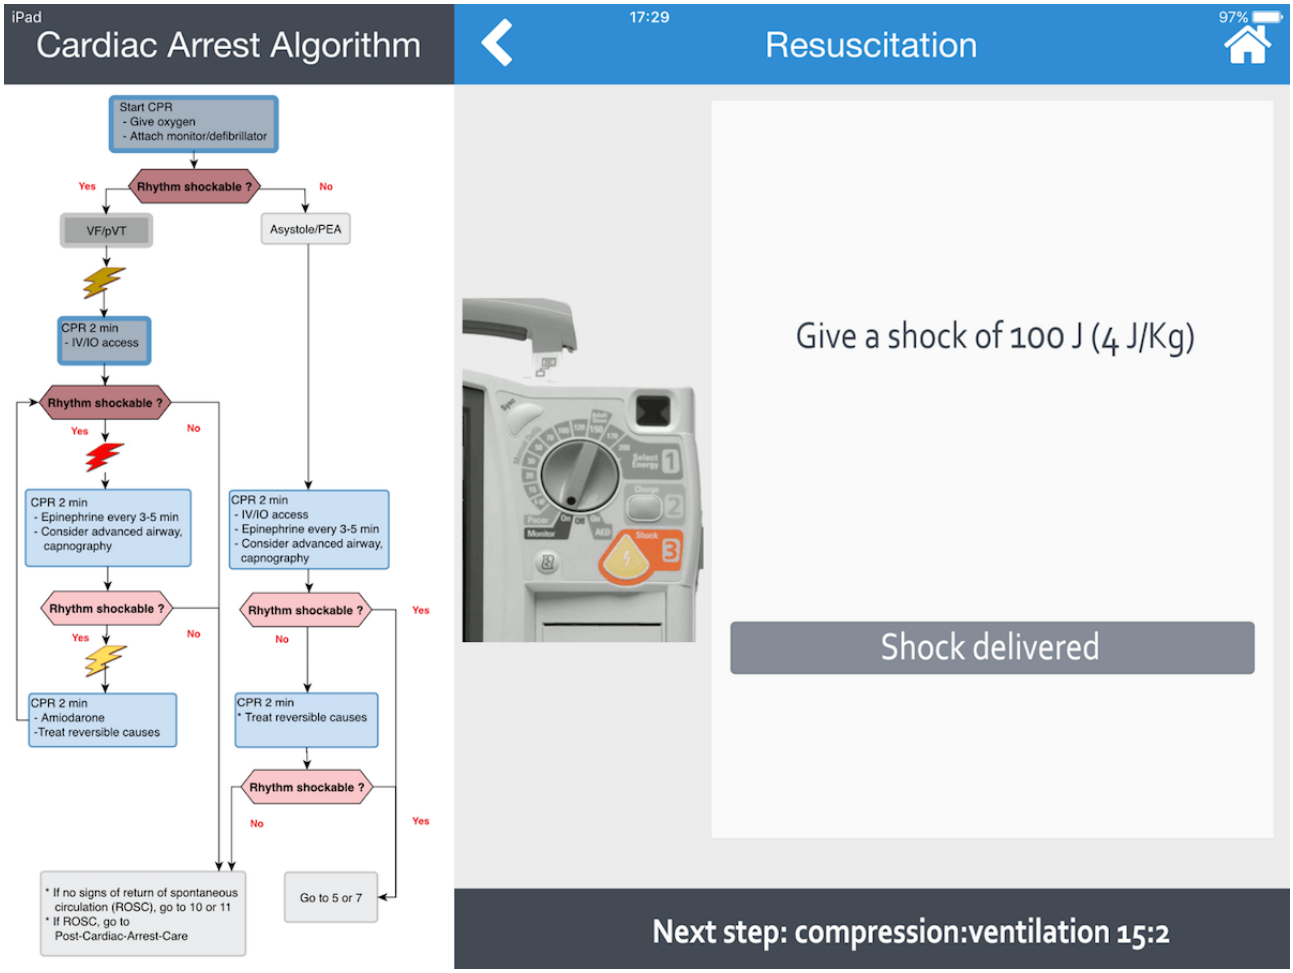

Figure 3. Screenshot of the Guiding Pad app. The left-hand side of the screen displays the American Heart Association (AHA) pediatric advanced life support (PALS) ventricular fibrillation (VF) and pulseless ventricular tachycardia (pVT) cardiac arrest algorithm. On the right-hand side of the screen, the sequence of actions to be taken are displayed in a stepwise manner to facilitate accurate progression along the algorithm. The current action (eg, to resume compression and ventilation) is brought to the attention of the provider by a red-box warning and requires validation by a simple click. Once completed, the next action will be to deliver the weight-based epinephrine dose automatically calculated by the app and then to prepare amiodarone. The next step shown at the bottom right-hand side will be to check the pulse. CPR: cardiopulmonary resuscitation; IO: intraosseous; IV: intravenous; PEA: pulseless electrical activity.

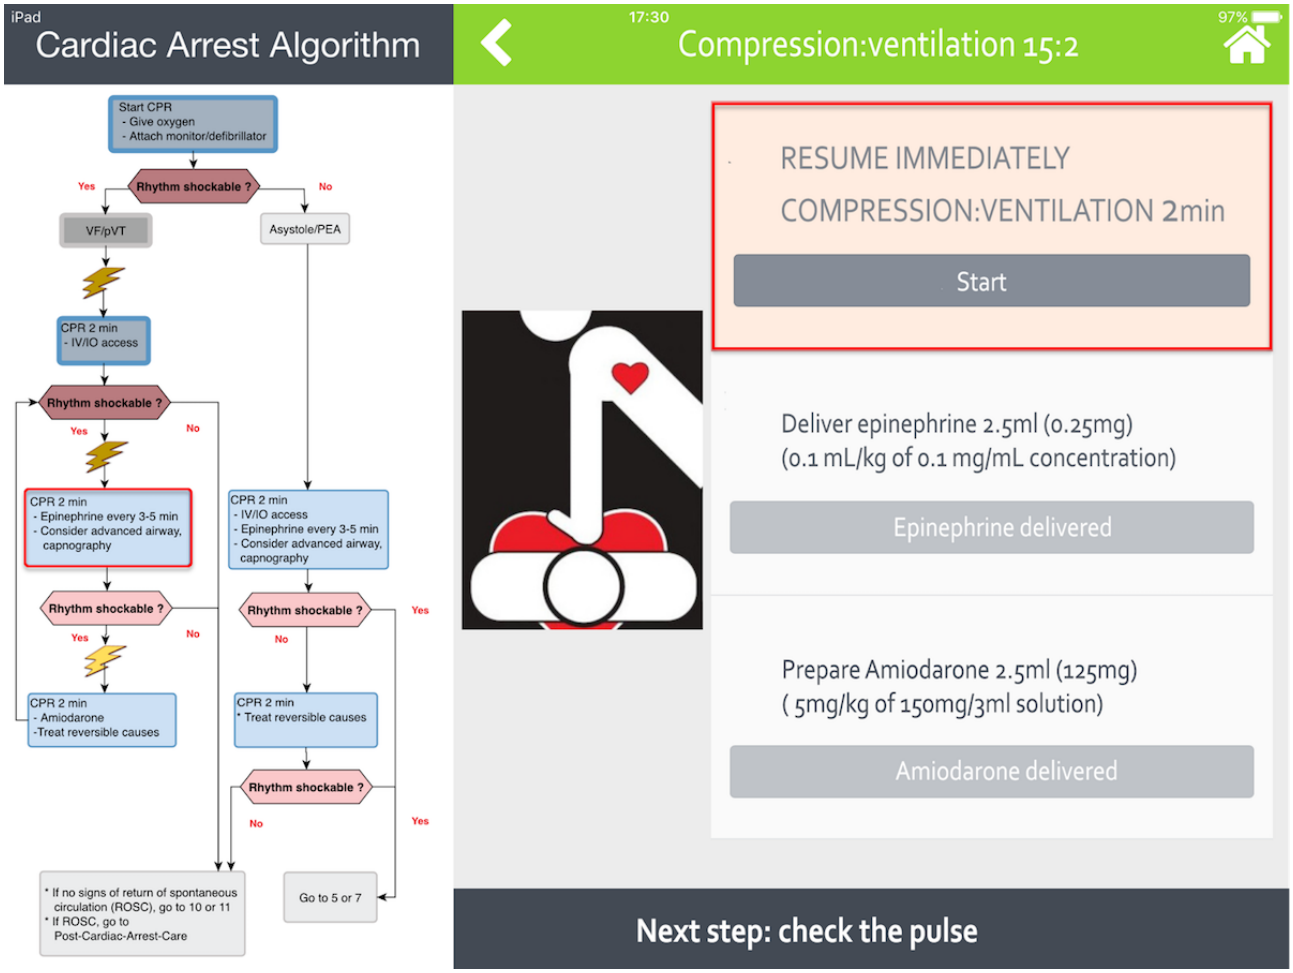

Procedures

On the day of participation, each resident completed an anonymous survey on basic demographic information, professional length of clinical experience, and PALS training. After random allocation, each participant received a standardized 5-minute training session on how to use the app. Participants were then asked to perform a 15-minute, highly realistic, scripted CPR scenario on a high-fidelity manikin (SimJunior; Laerdal Medical). The scenario was standardized to strictly follow the 2018 AHA pediatric pVT algorithm (see Figure 4) and was performed on the same high-fidelity manikin already primed with vital signs appropriate for the scenario (see Multimedia Appendix 2). It was conducted in situ in the PED shock room to increase realism, thus allowing participants to make use of real resources in the actual environment where they were expected to handle cardiac arrest. All participants in group B were offered the possibility to hold PALS pocket reference cards in their hands throughout the entire scenario. Whether they referred to them or not was left to their discretion, similar to real-life settings. No interactions occurred between participants and investigators. The simulation involved the participating resident and a resuscitation team comprising three study team members (ie, a PED registered nurse and two medical students) to assist with resuscitation through drug preparation, chest compression, and bag-valve-mask ventilation. Study team members had no role in decision making to achieve ROSC. A PALS instructor (ie, a pediatric emergency physician) who was not a member of the resuscitation team operated the simulator. To be consistent with the 2018 AHA pediatric cardiac arrest algorithm [23] and to standardize the scenario, defibrillation doses of 2 Joules per kg for the first attempt, and 4 Joules per kg for the subsequent second, third, and fourth attempts, were expected (see Figure 4).

Epinephrine and amiodarone drug doses had to be given just before or just after the second or third shock attempts, respectively (see Figure 5). The ROSC as demonstrated by a palpable pulse and signs of regaining consciousness corresponded to the end of the scenario.

Figure 4. American Heart Association (AHA) pediatric cardiac arrest algorithm: 2018 update (Duff et al, 2018). CPR: cardiopulmonary resuscitation; ET: endotracheal tube; IO: intraosseous; IV: intravenous; PEA: pulseless electrical activity; pVT: pulseless ventricular tachycardia; VF: ventricular fibrillation.

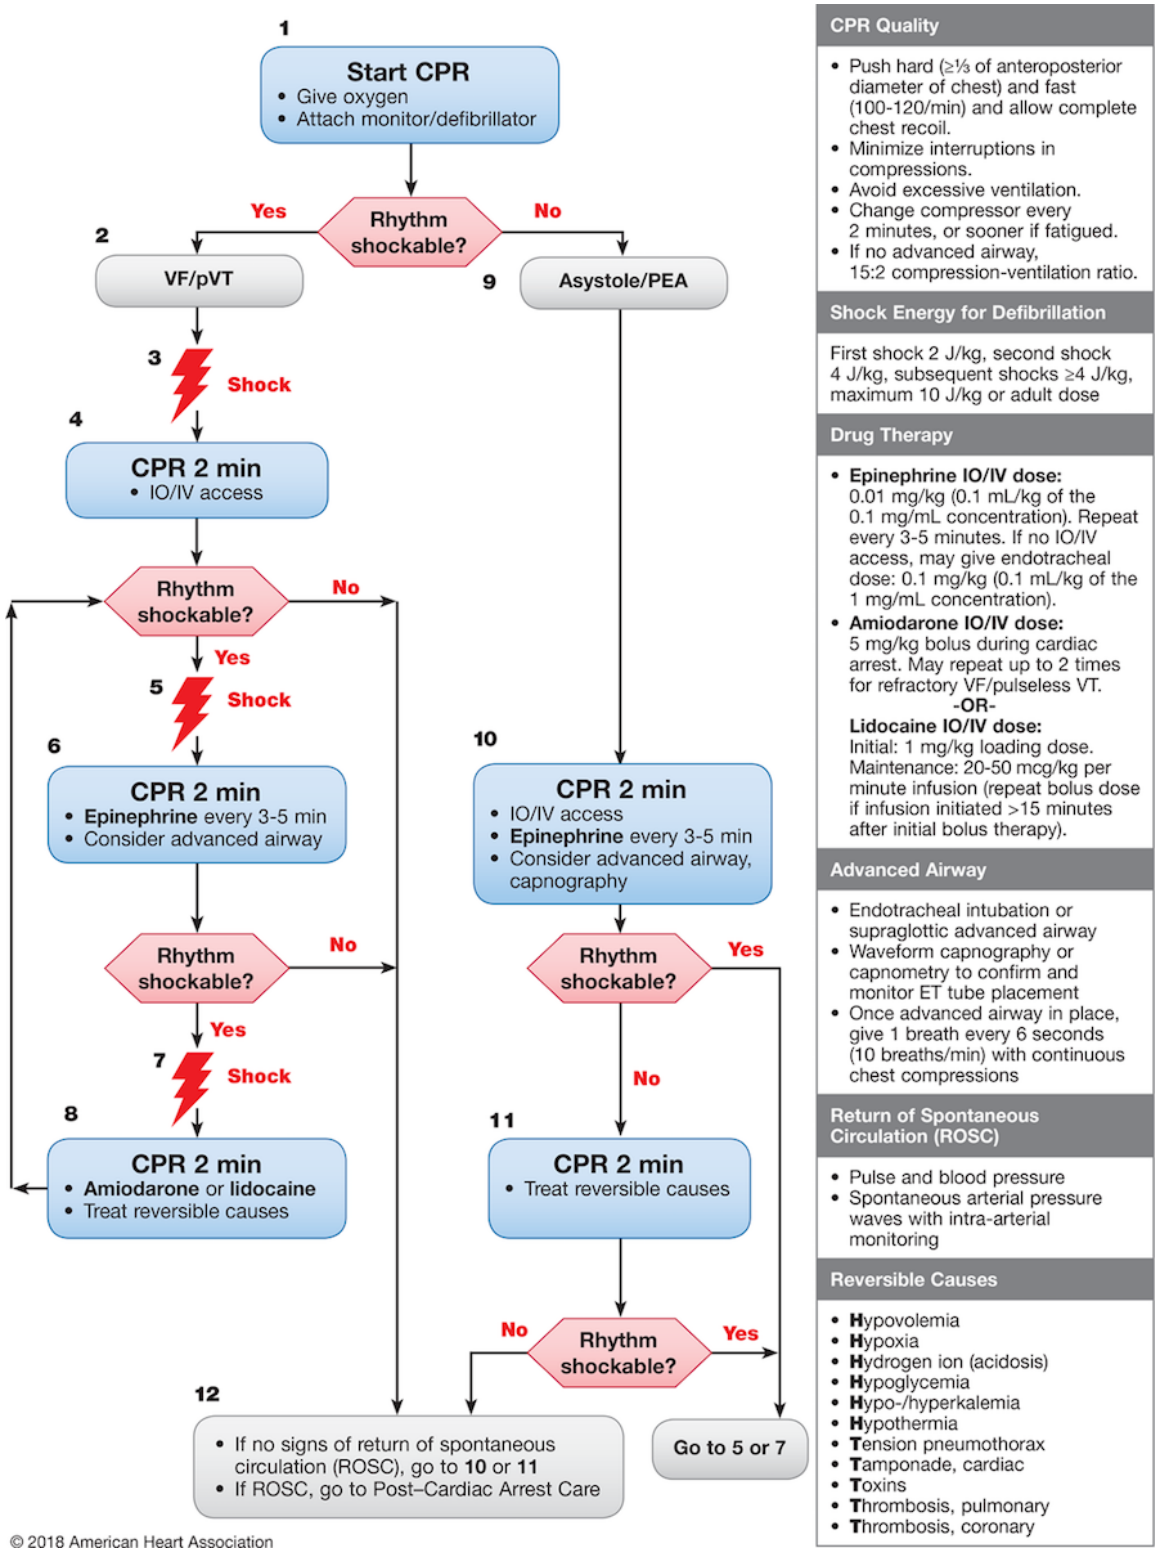

Figure 5. Summary of the ventricular fibrillation and pulseless ventricular tachycardia (pVT) cardiac arrest sequence. This original illustration is from the eBook edition of the Pediatric Advanced Life Support (PALS) Instructor Manual, published by the American Heart Association (AHA), 2015. CPR: cardiopulmonary resuscitation.

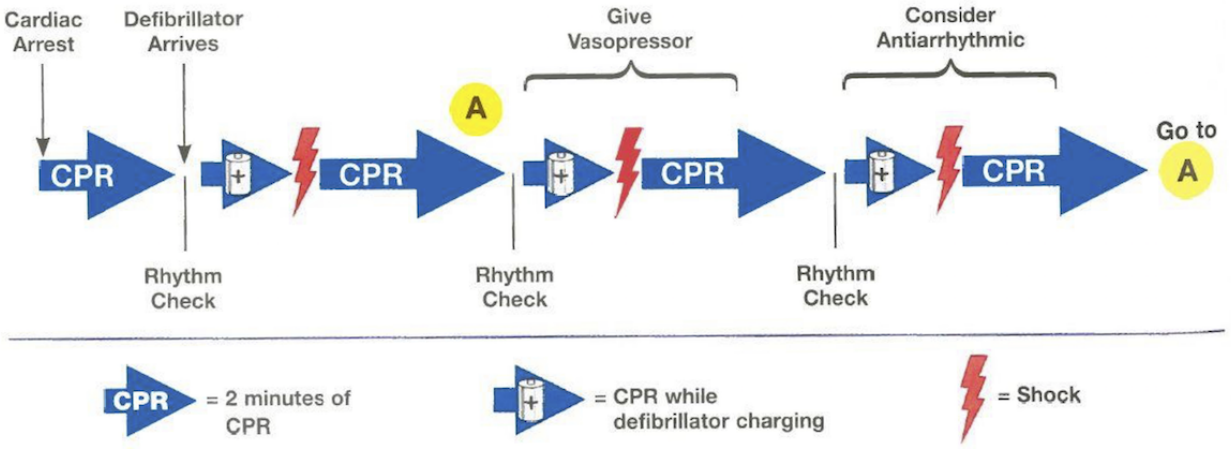

Outcomes

The primary outcome was the delay (in seconds) in each allocation group from the end of the clinical statement given by the study investigator to the first defibrillation attempt, as the expected survival advantage from early CPR can be significantly affected by a subsequent delay in defibrillation [24,25]. Secondary outcomes were the delay (in seconds) to initiation of chest compression; time to subsequent defibrillation attempts; time to administration of epinephrine and amiodarone; time interval (in seconds) between defibrillation attempts, drug doses, shock doses, and number of shocks; and perceived stress and satisfaction scores after completion of the scenario, as measured by a questionnaire using 10-point Likert scales (see Multimedia Appendix 3). The AHA recommends five cycles of chest compression (approximately 2 minutes) between each defibrillation attempt. The time spent by participants to perform chest compressions by compression cycles was defined as the hands-on time and was measured in seconds with a chronometer. All these outcomes were assessed for deviation from AHA guidelines.

Methods of Measurement and Data Collection

All actions (ie, primary and secondary outcomes) performed by the resident during the scenario were independently recorded by two trained investigators blinded to each other's records during the simulation, thus allowing an accurate assessment of timing and sequencing of actions and avoiding assessment bias. In the case of disagreement, a third independent evaluator helped reach a consensus. Data were manually retrieved and entered into a Microsoft Excel spreadsheet, version 16 (Microsoft Corporation). Unaccomplished actions were left blank and time was not assigned. Residents' privacy was preserved. Only the study investigators had access to the data.

Statistical Analysis

Power calculations were based on the detection of a 30-second decrease in time to the first defibrillation attempt between the two independent groups. A previous study has shown a mean time to first defibrillation of 92 seconds with an SD of 23 seconds [26]. Assuming a similar SD in each group of our study, 10 participants per group had to be recruited to provide the trial with 80% power at a two-sided alpha level of .05. To prevent a potential loss of power due to misspecification of assumptions, 13 participants were recruited per group, giving a total sample size of 26 participants.

For the primary analysis, we first evaluated the time elapsed between the onset of pVT and first defibrillation attempt. The Shapiro-Wilks test was used for normality analysis of the parameters. As most of the continuous variables were normally distributed, means and SDs with their 95% CIs were reported. Nonnormally distributed variables were analyzed using a Mann-Whitney test. Frequencies were reported as percentages. We used *t* tests to compare independent groups. No paired data were compared. Kaplan-Meier curves for time elapsed between the onset of pVT and first defibrillation attempt were estimated and compared using the log-rank (Mantel-Cox) test for bivariate survival analysis.

For the secondary analysis, we evaluated the time elapsed between the onset of pVT to subsequent defibrillation attempts and the delivery of both drugs. For normally distributed variables, means and SDs with 95% CI were reported. Nonnormally distributed variables were analyzed using a Mann-Whitney test. Frequencies were reported as percentages. We used *t* tests to compare independent groups. No paired data were compared. Kaplan-Meier curves for time elapsed between the onset of pVT and subsequent defibrillation attempts and delivery of both drugs were also estimated and compared using the log-rank (Mantel-Cox) test for bivariate survival analysis. Errors in cycles of chest compression-ventilation were measured as the deviation in percent from the experimental time spent in seconds compared to the 2-minute duration recommended by the AHA. Incorrect defibrillation or drug doses were measured as a deviation from the amount of energy delivered in Joules or drug doses in milliliters compared to AHA recommendations. A chi-square test was used to assess the relationship between absolute errors in defibrillation and drug doses expressed as categorical variables. Incorrect defibrillation mode was also measured. Absolute deviations were also analyzed. The mean

(SD) difference in deviation obtained with each method was reported with a 95% CI. A *t* test for unpaired data was used to compare interventions. Mean differences were reported by randomized group. Univariate linear regression analyses with 95% CI were performed to assess whether time to initiation of chest compression, defibrillation attempts, and drug delivery were associated with the number of postgraduate years or prior resuscitation experience as a provider in real-life and simulated environments. Means and SDs were determined for the perceived stress and satisfaction scores of individuals derived from the Likert-scale questionnaire and reported with descriptive statistics. A *P* value less than .05 was considered significant.

Interrater reliability was assessed by two observers who independently evaluated each resident's performance. Interrater reliability scores were calculated using the Cohen kappa coefficient for the shock and drug-dose errors. As the remaining outcomes were continuous variables, the Bland-Altman method was used to plot the difference of values reported by both observers against the mean value for each outcome. The limits of agreement were assessed by the interval of SD 1.96 of the measurement differences on either side of the mean difference. The null hypothesis that there was no difference, on average, between both reviewers was tested using a *t* test. The mean difference was reported with its 95% CI. Additionally, the intraclass correlation coefficients for times to each critical endpoint were assessed, assuming that raters were comprised of a sample from a larger population of possible raters. GraphPad Prism, version 8 (GraphPad Software), and SPSS, version 15.0 (SPSS Inc), were used for graph figures and to perform descriptive and statistical analyses.

Results

Study Participants

From August 30 to October 17, 2019, 26 pediatric residents were assessed for eligibility and randomly assigned to either the Guiding Pad app group (group A) (n=13) or the PALS pocket card group (group B) (n=13), without any dropouts or missing data (see Figure 6). Baseline characteristics were balanced in the two groups (see Table 1). In particular, we observed no statistically significant difference between the ages of both randomization arms (ie, no bias in randomization). We observed perfect interrater agreement for the scoring of the pVT scenario (see Table S1 in Multimedia Appendix 4, Table S2 in Multimedia Appendix 5, and Figure S1 in Multimedia Appendix 6).

Figure 6. Trial flowchart. PALS: pediatric advanced life support.

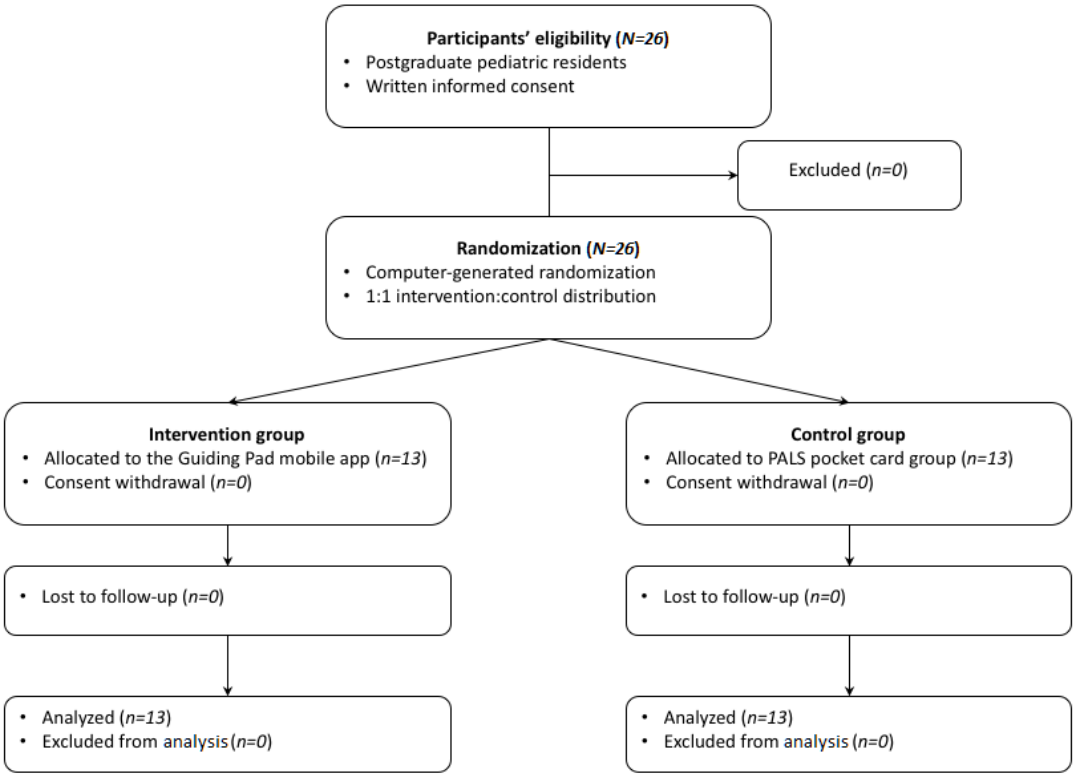

Table 1. Participants' demographics and clinical characteristics.

Demographics and clinical characteristics	Randomization arm	
	Guiding Pad (n=13)	PALS[a] pocket cards (n=13)
Age in years[b], mean (SD)	31.2 (5.5)	29.0 (2.2)
Sex (female), n (%)	9 (69)	10 (77)
Years of residency, mean (SD)	3.7 (2.3)	3.5 (0.9)
Number of basic life support providers among residents, n (%)	13 (100)	13 (100)
Number of PALS providers among residents, n (%)	9 (69)	11 (85)
Level of self-confidence[c] in following American Heart Association guidelines, mean (SD)	2.9 (1.1)	3.5 (0.7)
Number of residents having been enrolled in more than five resuscitations in the past, n (%)	4 (31)	7 (54)
Prior simulation-based resuscitations, mean (SD); total	6.5 (6.2); 84	4.8 (3.5); 62
Prior real-world cardiopulmonary resuscitations, mean (SD); total	9.2 (21.4); 120	7.8 (7.3); 102
Prior use of a manual defibrillator in either real-world or simulated environments, n (%)	10 (77)	9 (69)
Months since last manual-mode defibrillator use in either real-world or simulated environments, mean (SD)	9.5 (10.2)	13.9 (17.8)

[a]PALS: pediatric advanced life support.

[b]The age difference between the randomization arms was not statistically significant.

[c]Self-confidence was measured on a scale of 1 (not confident) to 5 (very confident).

Time to Critical Resuscitation Endpoint

Using the Guiding Pad app, 11 residents out of 13 (85%) initiated chest compressions within 60 seconds of the onset of pVT (9/13, 69%, within 30 sec), and 12 out of 13 (92%) successfully defibrillated within 180 seconds (see Figure 7). Mean time elapsed between the onset of pVT and first defibrillation attempt was 121.4 seconds (SD 26.7).

With PALS pocket cards, out of 13 residents, 10 (77%) started compressions within 60 seconds, 1 (8%) started compressions 277 seconds after onset of pVT, and 6 (46%) failed to discharge the defibrillator within 180 seconds. Mean time from initiation of chest compression to the first shock was significantly reduced for residents using the app (89.3 sec) than for those using the PALS pocket cards (163 sec; *P*=.002). Mean times to other critical resuscitation endpoints are summarized in Table 2. All defibrillation attempts, as well as amiodarone administration, were delivered significantly earlier in group A than in group B. However, the app was unable to speed up the delay before intraosseous access and epinephrine delivery (see Table 2 and Figure 8). We sought to analyze, in both groups, the difference in mean time to first defibrillation attempts between residents with or without previous defibrillation experience in either real-world or simulated environments, but with our small sample size we did not find any difference (with the app: 124.1 vs 112.3 sec, *P*=.53; without the app: 268.8 vs 186.1 sec, *P*=.09).

At the time of the study, 24 participants out of 26 (92%) were residents with more than one year of pediatric training (ie, postgraduate years). In a simple linear regression model, using the app was associated with a significant or borderline significant reduction in time to defibrillation attempts, regardless of the postgraduate years, and less scattered delays around the mean defibrillation time than when using the pocket cards (see Figure 9).

In group B, time to defibrillation attempts was inversely associated with the number of postgraduate years. In both groups, we observed no correlation between the time to initiation of chest compression or time to drug delivery and postgraduate years (see Figure 10). Moreover, we observed no relationship between previous CPR experience expressed as the number of prior CPR attempts on either a patient or a manikin and times to initiation of CPR, defibrillation attempts, or drug delivery (see Figure S2 in Multimedia Appendix 7 and Figure S3 in Multimedia Appendix 8).

Figure 7. Time to cardiopulmonary resuscitation (CPR) and defibrillation attempts. Kaplan-Meier curves of time elapsed between the onset of simulated pulseless ventricular tachycardia (pVT) and initiation of chest compression (ie, CPR) for the first, second, third, and fourth defibrillation attempts for residents using the Guiding Pad (GP) app vs conventional pediatric advanced life support (PALS) pocket cards (PCs). Log-rank (Mantel-Cox) test comparing curves: χ^2=0.0 and *P*=.97 for CPR; χ^2=13.9 and *P*<.001 for the first defibrillation attempt; χ^2=8.9 and *P*=.003 for the second defibrillation attempt; χ^2=13.3 and *P*<.001 for the third defibrillation attempt; and χ^2=9.5 and *P*=.002 for the fourth defibrillation attempt. ns: not significant.

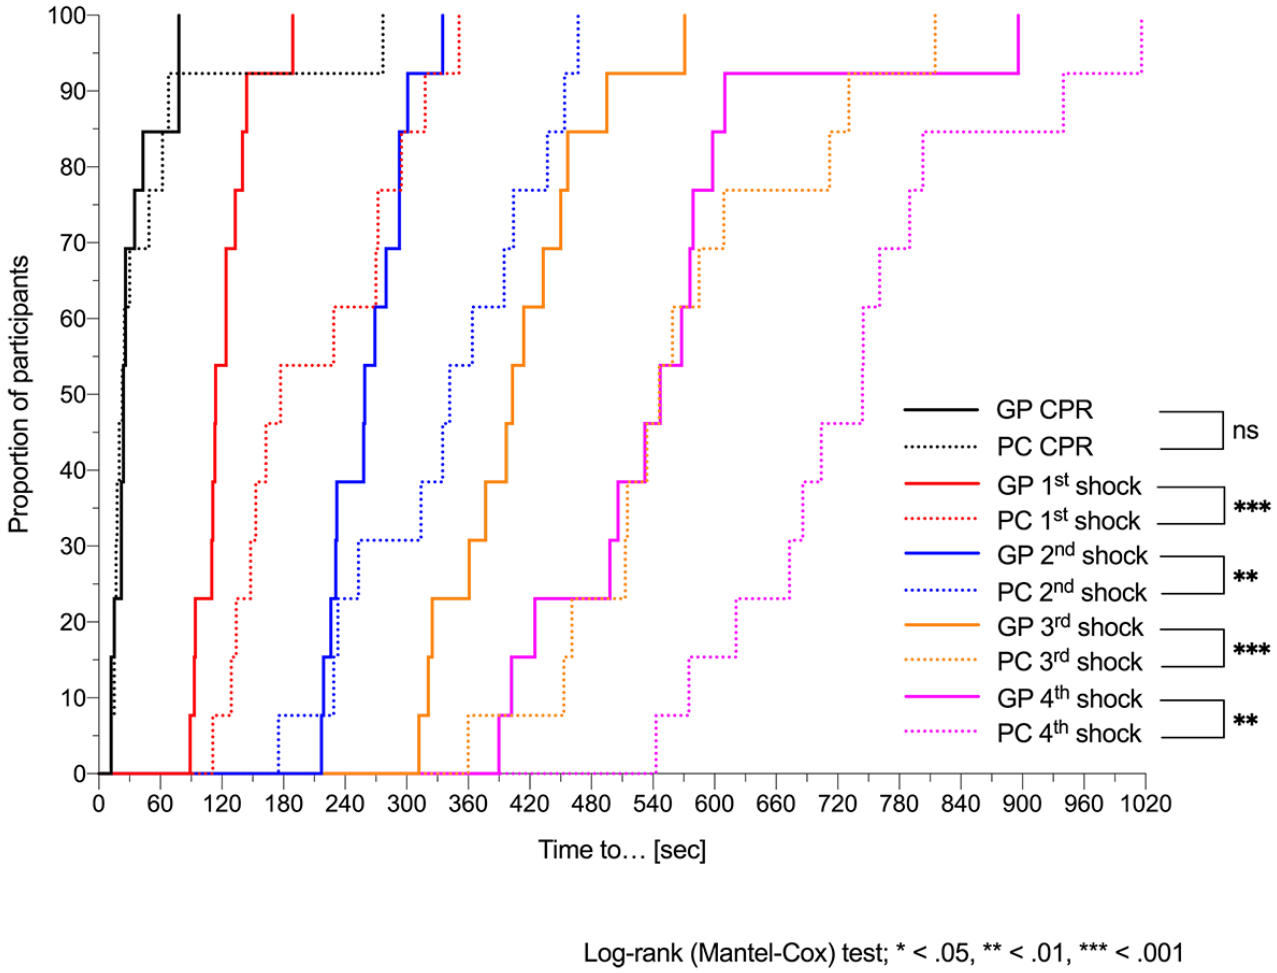

Table 2. Mean time to critical resuscitation endpoints.

Outcome	Mean time[a] for Guiding Pad app group (n=13), seconds		Mean time[a] for PALS[b] pocket cards group (n=13), seconds		Time difference[c], seconds	*P* value
	Mean (SD)	95% CI	Mean (SD)	95% CI		
Start chest compression	32.1 (22.1)	18.7-45.4	48.5 (71.1)	5.6-91.5	16.5	.91[d]
First defibrillation attempt	121.4 (26.7)	105.3-137.5	211.5 (81.2)	162.5-260.6	90.1	<.001
Intraosseous route	187.2 (45.4)	159.7-214.6	183.0 (71.3)	139.9-226.1	4.2	.86
Second defibrillation attempt	262.5 (36.7)	240.3-284.7	338.6 (93.8)	282.0-395.3	76.1	.01
Epinephrine	269.1 (74.8)	223.8-314.3	287.2 (82.9)	237.1-337.2	18.1	.56
Third defibrillation attempt	408.9 (74.1)	364.1-453.7	568.7 (124.4)	493.5-643.9	159.8	<.001
Amiodarone	455.5 (106.9)	391.0-520.1	598.2 (154.7)	504.7-691.7	142.7	.01
Fourth defibrillation attempt	548.2 (127.6)	471.1-625.4	738.5 (132.9)	658.2-818.9	190.3	<.001[d]

[a]The mean time in each allocation group refers to the delay in seconds from the end of the clinical statement given by the study investigator to each critical resuscitation endpoint.

[b]PALS: pediatric advanced life support.

[c]Time difference represents the absolute time difference between mean PALS pocket cards group and Guiding Pad app group outcomes.

[d]Mann-Whitney test.

Figure 8. Time to intraosseous (IO) route and drug delivery. Kaplan-Meier curves of time elapsed between the onset of simulated pulseless ventricular tachycardia (pVT) and the IO insertion, epinephrine, and amiodarone delivery for residents using the Guiding Pad (GP) app vs conventional pediatric advanced life support (PALS) pocket cards (PCs). Log-rank (Mantel-Cox) test comparing curves: χ^2=0.4 and *P*=.55 for the IO route; χ^2=0.6 and *P*=.44 for epinephrine; and χ^2=7.5 and *P*=.006 for amiodarone. ns: not significant.

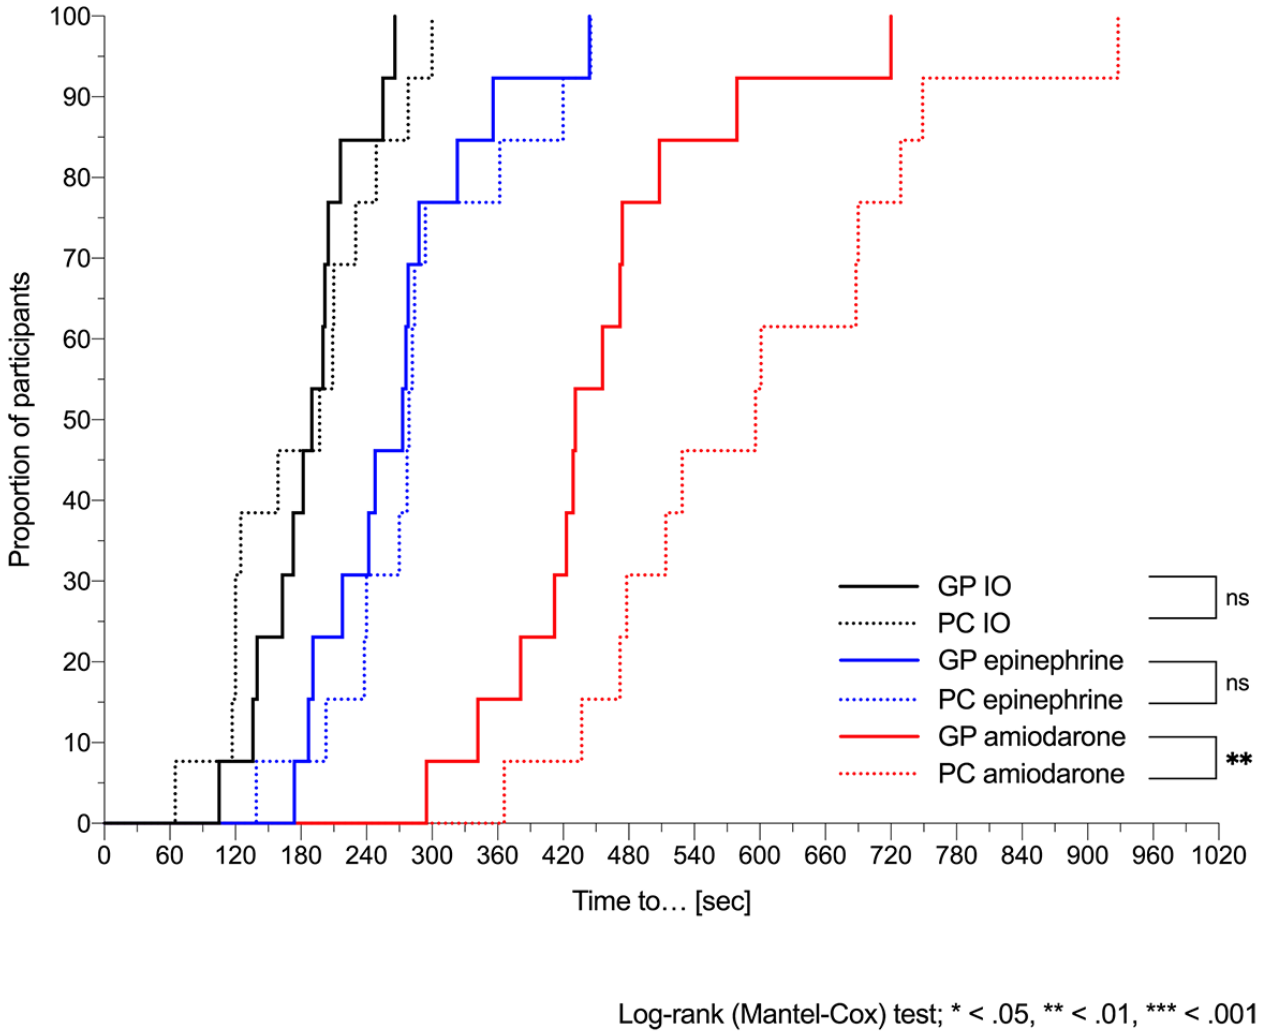

Figure 9. Association between time to defibrillation attempts and years of residency. Data are shown as a regression line (solid) with 95% CI (dashed lines). *P* values and r^2 values are based on simple linear regression analysis. White (Guiding Pad app) and grey (pediatric advanced life support [PALS] pocket cards) open circles denote each individual value.

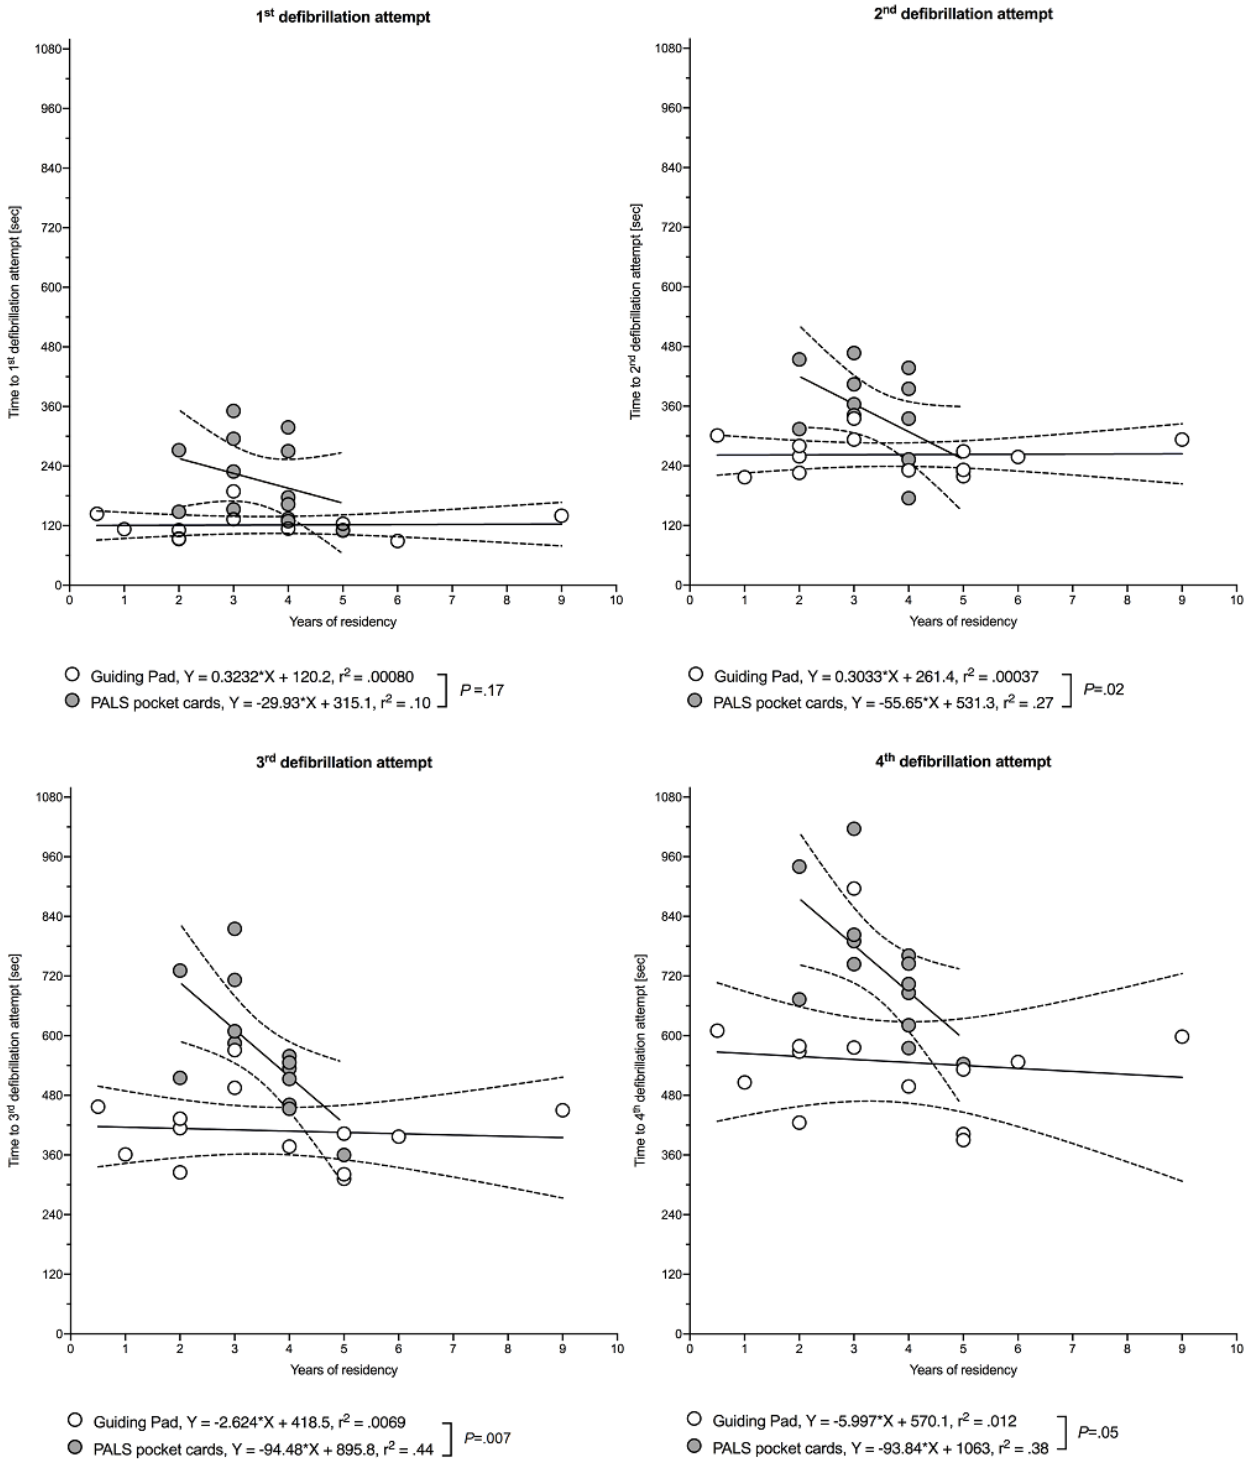

Figure 10. Association between time to chest compression or drug delivery and years of residency. White (Guiding Pad app) and grey (pediatric advanced life support [PALS] pocket cards) open circles denote each individual value. CPR: cardiopulmonary resuscitation.

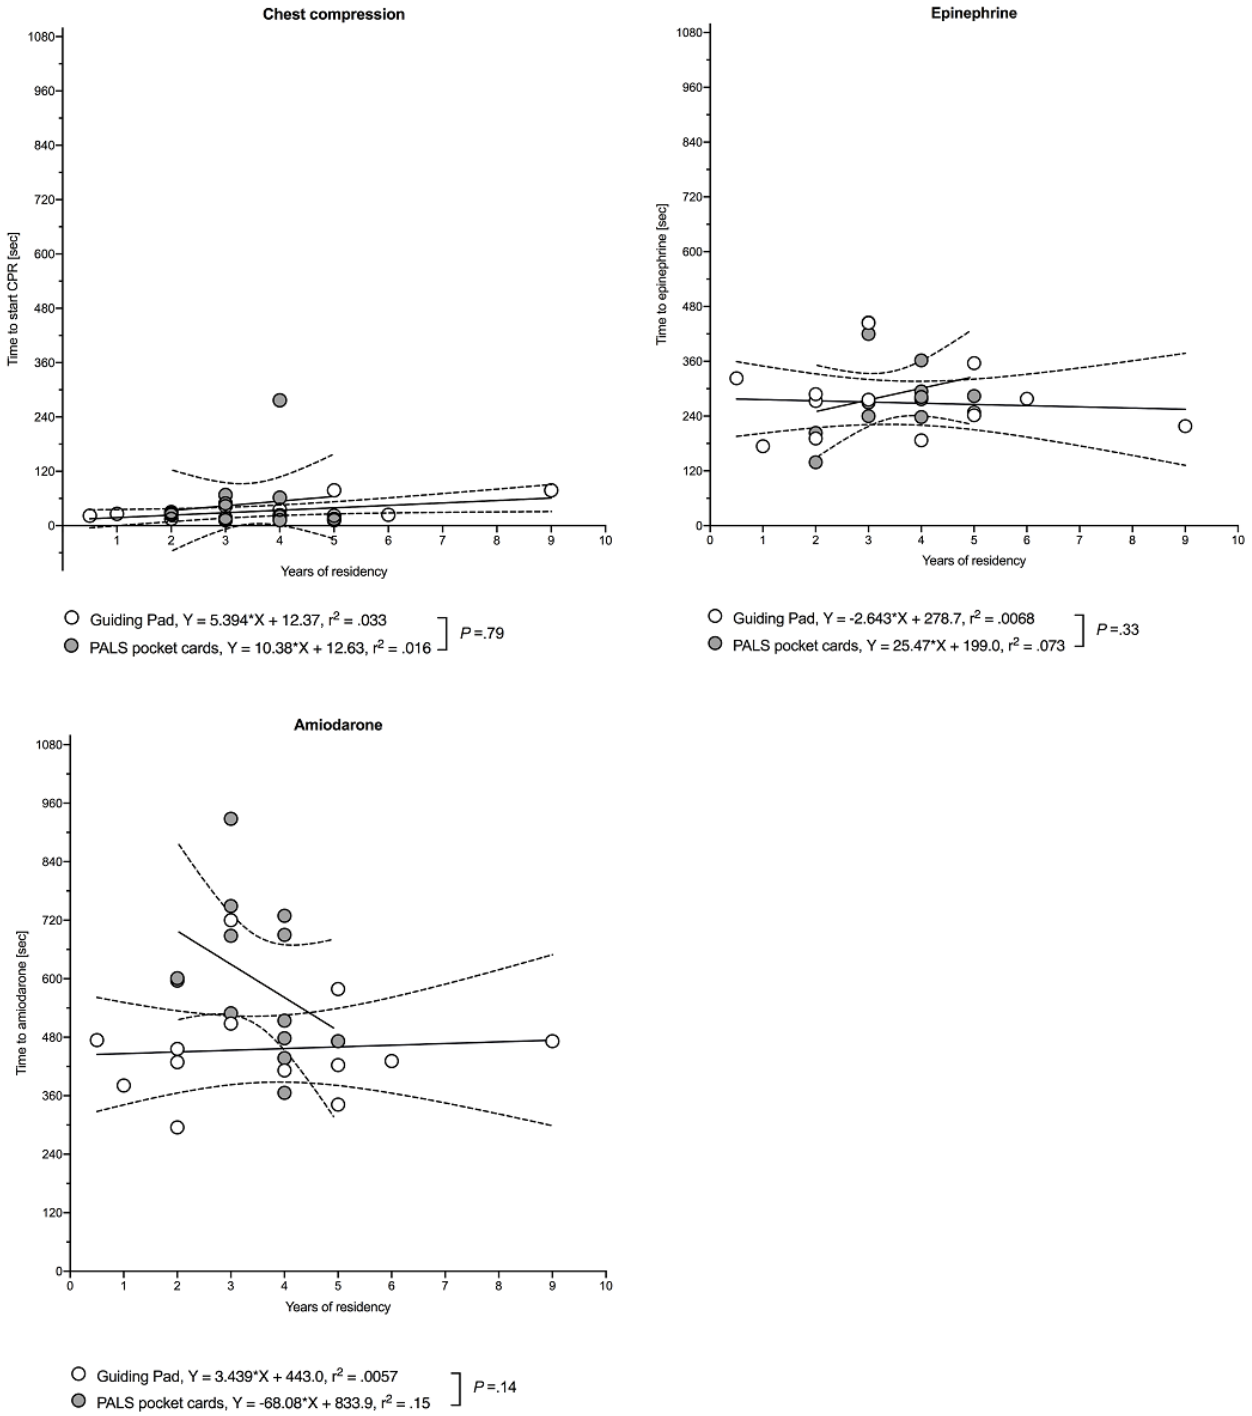


Errors and Deviations From the AHA pVT Algorithm

Errors and deviations from the AHA pVT algorithm are summarized in Table 3 and in Table S1 in Multimedia Appendix 4. The entire pVT algorithm was followed correctly in a stepwise fashion until ROSC by 12 out of 13 (92%) residents in group A and only 3 out of 13 (23%) residents in group B (*P*=.001) (see Table 4). Importantly, the pVT rhythm was recognized correctly in 51 out of 52 opportunities (98%) by residents using the app, but in only 19 out of 52 opportunities (37%) of those using the pocket cards (*P*<.001).

Table 3. Errors and deviations from the American Heart Association (AHA) pulseless ventricular tachycardia (pVT) algorithm with respect to critical resuscitation endpoints.

Critical resuscitation endpoint	AHA recommended dose	Guiding Pad app (n=13)			PALS[a] pocket cards (n=13)		
		Dose, mean (SD)	95% CI	Dose range	Dose, mean (SD)	95% CI	Dose range
First defibrillation attempt (J/kg)	2.00	2.00 (0)	2.00-2.00	2.00-2.00	1.97 (0.76)	1.51-2.43	0.60-4.00
Second defibrillation attempt (J/kg)	4.00	3.85 (0.55)	3.51-4.18	2.00-4.00	3.62 (0.96)	3.04-4.20	1.00-4.00
Epinephrine 0.1 mg/mL (mL/kg)	0.10	0.10 (0)	0.10-0.10	0.10-0.10	0.09 (0.03)	0.08-0.11	0.001-0.10
Third defibrillation attempt (J/kg)	4.00	4.15 (0.55)	3.82-4.49	4.00-6.00	3.87 (1.57)	2.92-4.82	0.52-6.00
Amiodarone (mL/kg)	0.10	0.10 (0)	0.10-0.10	0.10-0.10	0.10 (0.01)	0.10-0.10	0.10-0.14
Fourth defibrillation attempt (J/kg)	4.00	4.31 (1.11)	3.64-4.98	4.00-8.00	5.45 (1.67)	4.44-6.46	4.00-8.00

[a]PALS: pediatric advanced life support.

Table 4. Errors and deviations from the American Heart Association (AHA) pulseless ventricular tachycardia (pVT) algorithm with respect to defibrillation and drug factors.

Defibrillation and drug factors	Guiding Pad app (n=13), n (%)	PALS[a] pocket cards (n=13), n (%)
Correct number of shocks (N=52)	51 (98)	51 (98)
Error in shock or drug doses (N=78)	1 (1)	11 (14)[b]
pVT rhythm recognition (N=52)	51 (98)	19 (37)[c]
Correct AHA sequence (n=13)	12 (92)	3 (23)[d]

[a]PALS: pediatric advanced life support.

[b]Difference between Guiding Pad app and PALS pocket cards groups: *P*=.005 (Fisher exact test).

[c]Difference between Guiding Pad app and PALS pocket cards groups: *P*<.001 (Fisher exact test).

[d]Difference between Guiding Pad app and PALS pocket cards groups: *P*=.001 (Fisher exact test).

Out of 52 opportunities, 1 error in the defibrillation dose (2%) was committed during the whole scenario in group A. This resident delivered a second asynchronous shock at half the recommended energy dose (2 J/kg instead of 4 J/kg). Owing to a discontinuous adherence to the app by switching alternatively with his own CPR experience, he also failed to comply with the algorithm and gave a mistimed 5 mg/kg dose of amiodarone 3 minutes after an unnecessary additional (2 J/kg) second defibrillation attempt. This compares to 8 out of 52 (15%) errors in defibrillation doses during the whole scenario in group B (*P*<.03): 3 at the first defibrillation attempt (doses ranged from 0.6 to 4 J/kg instead of 2 J/kg); 2 at the second attempt (1.0 to 2 J/kg instead of 4 J/kg); and 3 at the third attempt (0.52 to 2 J/kg instead of 4 to 10 J/kg) (see Table 3). Out of 13 residents, 2 in group B (15%) wrongly used synchronized shocks, either at the first, second, or third attempts. In group A, the mean energy dose of the first defibrillation attempt was strictly in accordance with the recommendations, whereas the second, third, and fourth defibrillation attempts deviated from the AHA recommendations by 0.15 J/kg (95% CI of discrepancy: –0.49 to 0.18, *P*=.34), 0.15 J/kg (95% CI of discrepancy: –0.18 to 0.49, *P*=.34), and 0.31 J/kg (95% CI of discrepancy: –0.36 to 0.98, *P*=.34), respectively. In group B, all four mean defibrillation attempts deviated from the AHA recommendations by 0.03 J/kg (95% CI of discrepancy: –0.49 to 0.43; *P*=.89), 0.38 J/kg (95% CI of discrepancy: –0.97 to 0.20; *P*=.17), 0.13 J/kg (95% CI of discrepancy: –1.08 to 0.82; *P*=.77), and 1.45 J/kg (95% CI of discrepancy: 0.44-2.46; *P*=.009), respectively.

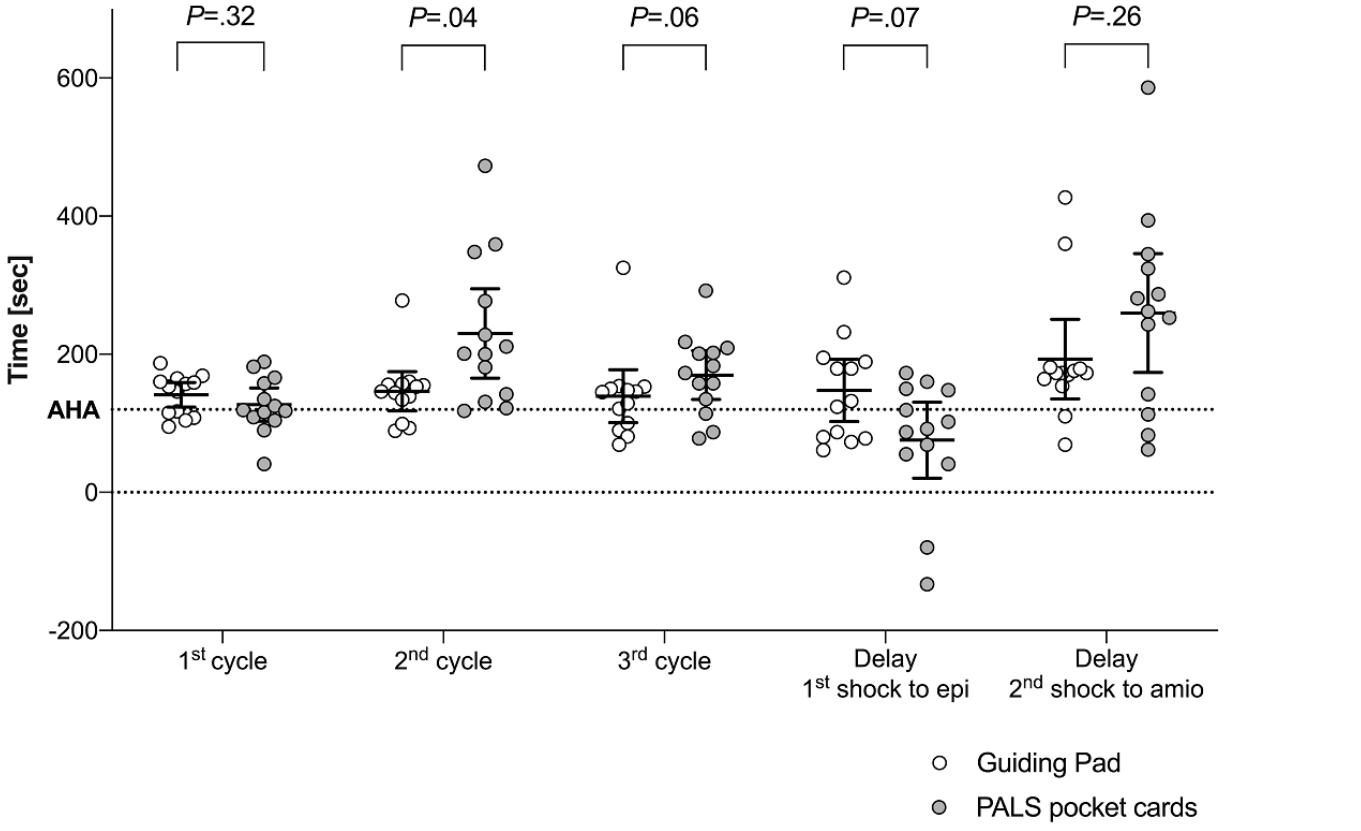
In group A, epinephrine drug doses were given according to AHA recommendations. However, in group B, epinephrine was delivered more than 2 minutes, on four occasions, either before the first (three times) or second (one time) shocks, and was once underdosed by 10 times the recommended dose. Regarding amiodarone, among card users, one resident wrongly ordered the drug before the first shock, another after the fourth shock, a third one at 1.4 times the recommended dose, and a resident even ordered a double dose before the fourth shock.

The hands-on time spent by cycles of chest compression between both groups is summarized in Figure 11. Using the Guiding Pad app, the mean time for the first, second, and third cycles of chest compression between each defibrillation attempt deviated from the AHA recommendations by 21.15 seconds (95% CI of discrepancy: 3.35-38.95; *P*=.02), 26.38 seconds (95% CI of discrepancy: –1.98 to 54.75; *P*=.07), and 19.30 seconds (95% CI of discrepancy: –18.88 to 57.49; *P*=.29), respectively. In group B, the mean time for the first, second, and third cycles of chest compression deviated from the AHA recommendations by 7.08 seconds (95% CI of discrepancy: –17.16 to 31.31; *P*=.54), 110.10 seconds (95% CI of discrepancy: 45.25-174.9; *P*=.003), and 49.85 seconds (95% CI of discrepancy: 14.58-85.11; *P*=.01), respectively. Mean delays between the first shock and epinephrine for the app and pocket card users

were 147.7 seconds (95% CI 102.6-192.7) and 75.6 seconds (95% CI 20.5-130.7), respectively (see Figure 11). Mean delays between the second shock and amiodarone for the app and pocket card users were 193.0 seconds (95% CI 135.2-250.8) and 259.6 seconds (95% CI 173.6-345.6), respectively (see Figure 11).

The questionnaire evaluating perceived stress and satisfaction scores was completed and returned by 100% of participants. Participants in groups A and B rated the overall perceived stress before the scenario with mean scores of 5.3 (95% CI 4.0-6.6) and 5.1 (95% CI 3.9-6.3), respectively (*P*=.78). During the scenario, the stress remained contained by the app users (mean score 4.8, 95% CI 3.4-6.2, *P*=.55), whereas it increased significantly for residents relying on the PALS pocket cards (mean score 6.8, 95% CI 5.9-7.8, *P*=.01) compared to app users (*P*=.01). Satisfaction tended to be greater for residents using the app (mean score 7.5, 95% CI 6.5-8.5) compared to those using pocket cards (mean score 5.9, 95% CI 4.4-7.4) (*P*=.07).

Figure 11. Time spent in seconds by cycles of chest compression and between defibrillation attempts and drug delivery during simulated pulseless ventricular tachycardia (pVT) scenarios. Solid horizontal lines denote mean and 95% CI. White (Guiding Pad app) and grey (pediatric advanced life support [PALS] pocket cards) open circles denote each individual value. The horizontal dashed line denotes the 120-sec American Heart Association (AHA) recommendation for a complete cycle. Delays between the first shock and epinephrine (epi) delivery, and between the second shock and amiodarone (amio) delivery, are expressed as the time to drug delivery minus the time to defibrillation attempt, by resident and by allocation group. A negative time point denotes a drug given before the expected defibrillation attempt.



Discussion

Principal Findings

In this randomized controlled trial, we report a reduced time to all defibrillation attempts and an improved adherence of approximately 70% to all CPR sequences of action outlined by the 2018 AHA pVT guidelines with the mobile app Guiding Pad compared with the PALS pocket reference cards among pediatric residents leading simulated CPR. Of note, this result was observed irrespective of residents' previous years of experience or prior CPR knowledge. Interindividual variance was also reduced with the app, suggesting a worthwhile benefit of its use by residents with various experience levels. To our knowledge, this is the first study to investigate the benefit of a mobile device app to improve the performance and adherence of pediatric residents to AHA resuscitation guidelines.

Standards of care acknowledge that a prompt defibrillation attempt is an important determinant of survival after cardiac arrest [27]. As outlined by Topijan et al, shorter duration of CPR is associated with higher rates of survival to discharge, supporting the concept of rapid recognition, prompt chest compression, and defibrillation as soon as possible [25]. During the first 15 minutes of CPR, survival and a favorable neurological outcome decrease linearly by 2.1% and 1.2% per minute, respectively [28]. Delays in initiating CPR have a detrimental effect on patient outcome, regardless of the quality of resuscitation [29]. Therefore, the AHA recommends that pulseless patients of any age should receive immediate CPR without delay starting with chest compressions followed by a defibrillation within 180 seconds of a shockable rhythm. In our study, approximately 80% of residents in both allocation groups started compressions within 60 seconds from the onset of pVT.

Importantly, mean time from initiation of chest compression to first shock was almost halved when using the app when compared to PALS pocket cards. Among residents using the app, 92% (12/13) defibrillated successfully in 180 seconds or less of pVT onset, whereas 46% (6/13) of PALS pocket card users failed to discharge the defibrillator within 180 seconds. This correlates well with the results of Hunt et al, who observed that despite the availability of AHA recommendations, 66% of pediatric residents failed to start compressions within 60 seconds from the onset of a simulated pVT, 33% never started compressions, only 54% successfully defibrillated within 180 seconds, and 7% never discharged the defibrillator [30]. A more recent study among first-year pediatric residents showed a median time of 50 seconds for the initiation of CPR and 282 seconds to first defibrillation [31]. Most alarmingly, the pVT rhythm in our trial was misidentified by almost 70% of residents holding the PALS reference cards in their hands. This could potentially negatively affect patient outcome as choosing the wrong electrical therapy, drugs, or algorithm in real life might impede the correct management of critically ill children and jeopardize their chance of survival.

Current AHA resuscitation guidelines emphasize 2 minutes of chest compressions between defibrillation attempts as optimal care for persistent pVT or ventricular fibrillation in children [32,33]. In this study, app users deviated less from the AHA, which reached statistical significance for the second and third cycles of chest compression. Moreover, following the first and second shocks and a 2-minute period of five cycles of CPR after each shock, antiarrhythmic drugs should be administered if the patient remains in cardiac arrest, with the aim of increasing defibrillation success with subsequent defibrillation attempts [32]. In this trial, both groups accurately administered epinephrine and amiodarone drug doses, with the exception of a 100-times underdosed epinephrine and a 1.4-times overdosed amiodarone dose in group B. On average, app users correctly respected a complete 2-minute cycle of chest compression-ventilation before administering epinephrine after the first shock. Conversely, and contrary to current AHA guidelines, pocket card users administered the drug too close to the first shock, possibly explaining the absence of a significant time difference to epinephrine administration between both groups, despite a significantly longer delay to deliver the first shock in group B. Due to further delays, amiodarone was delivered significantly later by more than 2 minutes among residents not using the app.

Prompt defibrillation is crucial for the termination of ventricular fibrillation or pVT in order to achieve ROSC [33]. The AHA 2018 guidelines recommend treating pVT or ventricular fibrillation in children with an initial dose of 2 J/kg [23]. For subsequent shocks, a dose of 4 J/kg is recommended, although higher energy levels may be considered up to an adult dose, if not exceeding 10 J/kg. In this trial, residents using the PALS pocket cards were more prone to deviate from defibrillation doses than those using the app. In a total of 52 defibrillation attempts, they deviated in 36% of cases. These deviations were reduced to 6% when using the app. It would be interesting in further studies to determine whether this would translate into fewer deviations in shock doses in real life.

While the app in this study offered better adherence to AHA resuscitation recommendations than conventional PALS pocket cards, we also found that it provided a relative advantage when compared to the Google Glass-based app dedicated to the same purpose [17]. The in-built small size of the screen was indeed a limiting factor reported by residents wearing the glasses, by hindering full display of algorithms. Usability issues were also observed with inopportune and time-consuming back-and-forth navigations throughout the algorithms. In this study, displaying the entire algorithm on the larger screen size of a tablet and paralleling stepwise patient-centered care guidance appeared to improve adherence to AHA guidelines and speed up skills, thus allowing residents to better manage simulated CPR. It would be interesting in further studies to assess this assumption with certified emergency physicians or paramedics in simulated and real-life in- or out-of-hospital environments. Given the evidence regarding the observed deviation from recommended resuscitation procedures, it might be also advisable to assess the educational impact of this app for the upstream training of rescuers' p-IHCA technical skills in further studies.

Limitations

Our study has some limitations. First, it was conducted during a resuscitation simulation–based scenario rather than tested in real-life situations. However, high-fidelity simulation is an essential method to teach resuscitation skills and technologies that cannot be practiced during real CPR, as the diversity among patients and their diseases makes such studies difficult to standardize in critical situations. The low occurrence of p-IHCA also limits the implementation of randomized trials in real life [34]. Moreover, standardizing the scenario and the environment helped to avoid effect modifiers by limiting the influence of undesired variables on the outcomes. Realism was achieved as reflected by the stress level experienced by participants, who considered the simulation to be as stressful as real CPR situations. Second, the 5-minute app training was dispensed just before the scenario. In real life, the interval between training and actual use would probably be months. However, training with the app months before the study would have unblinded participants to its purpose and could have created a preparation bias. Third, the sample size limited stratified analyses to estimate the impact of PALS certification on the outcomes, but a recent study observed that improved adherence to AHA recommendations was not directly associated with PALS-trained providers [7]. Finally, we acknowledge that our findings might not be generalizable to providers with extensive CPR experience, such as pediatric emergency physicians. As only residents were assessed in this trial, further studies would be valuable to assess this assumption.

Conclusions

A PALS-based mobile app designed for tablets to interactively support residents during pediatric CPR contributed to a shorter time to first and subsequent defibrillation attempts, fewer medication and defibrillation dose errors, as well as a better adherence to AHA recommendations, compared with the conventional PALS pocket reference cards. Taken together, our results suggest that residents are not accurately following AHA recommendations during pediatric CPR when only supported

by PALS pocket cards. A next step would be to determine, in real-life studies, whether this mobile app might benefit patients by improving the adherence and performance of residents to meet AHA resuscitation requirements in clinical practice.

Acknowledgments

We thank the residents for their contributions to the trial and Rosemary Sudan for providing editorial assistance. Geneva University Hospitals is the owner of the Guiding Pad app, which was not available at the time of submission on Google Play or the Apple App Store. This trial had financial support from the private foundation of Geneva University Hospitals (fund No. QS2-25). The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report.

Authors' Contributions

JNS was responsible for the literature search and reading of articles, writing of the manuscript, preparation of figures and tables, and statistical analysis. JNS, LL, SM, and AC were responsible for data collection. FE was responsible for the development of the project software. JNS, LL, SM, AC, and FE were responsible for the concept and design of the study and critical review of manuscript content. All authors have contributed to, seen, and approved the final submitted version of the manuscript; had full access to all the data, including statistical reports and tables, in the study; and can take responsibility for the integrity of the data and the accuracy of the data analysis. The corresponding author (JNS) confirms that he had full access to the participants' data and endorsed the final responsibility for the submission. He further affirms that the manuscript is an honest, accurate, and transparent account of the study being reported, that no important aspects of the study have been omitted, and that any deviations from the study plan have been explained.

Conflicts of Interest

None declared.

This randomized study was not registered. The editor granted an exception as ICMJE does not require a registration if the purpose of the study is to examine the effect only on health care providers rather than patients. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as retrospective registration does not prevent authors from changing their outcome measures retrospectively.

Abstract

Background: Diabetic retinopathy (DR), a common complication of diabetes mellitus, is the leading cause of impaired vision in adults worldwide. Smartphone ophthalmoscopy involves using a smartphone camera for digital retinal imaging. Utilizing smartphones to detect DR is potentially more affordable, accessible, and easier to use than conventional methods.

Objective: This study aimed to determine the diagnostic accuracy of various smartphone ophthalmoscopy approaches for detecting DR in diabetic patients.

Methods: We performed an electronic search on the Medical Literature Analysis and Retrieval System Online (MEDLINE), EMBASE, and Cochrane Library for literature published from January 2000 to November 2018. We included studies involving diabetic patients, which compared the diagnostic accuracy of smartphone ophthalmoscopy for detecting DR to an accurate or commonly employed reference standard, such as indirect ophthalmoscopy, slit-lamp biomicroscopy, and tabletop fundus photography. Two reviewers independently screened studies against the inclusion criteria, extracted data, and assessed the quality of included studies using the Quality Assessment of Diagnostic Accuracy Studies–2 tool, with disagreements resolved via consensus. Sensitivity and specificity were pooled using the random effects model. A summary receiver operating characteristic (SROC) curve was constructed. This review is reported in line with the Preferred Reporting Items for a Systematic Review and Meta-analysis of Diagnostic Test Accuracy Studies guidelines.

Results: In all, nine studies involving 1430 participants were included. Most studies were of high quality, except one study with limited applicability because of its reference standard. The pooled sensitivity and specificity for detecting any DR was 87% (95% CI 74%-94%) and 94% (95% CI 81%-98%); mild nonproliferative DR (NPDR) was 39% (95% CI 10%-79%) and 95% (95% CI 91%-98%); moderate NPDR was 71% (95% CI 57%-81%) and 95% (95% CI 88%-98%); severe NPDR was 80% (95% CI 49%-94%) and 97% (95% CI 88%-99%); proliferative DR (PDR) was 92% (95% CI 79%-97%) and 99% (95% CI 96%-99%); diabetic macular edema was 79% (95% CI 63%-89%) and 93% (95% CI 82%-97%); and referral-warranted DR was 91% (95% CI 86%-94%) and 89% (95% CI 56%-98%). The area under SROC curve ranged from 0.879 to 0.979. The diagnostic odds ratio ranged from 11.3 to 1225.

Conclusions: We found heterogeneous evidence showing that smartphone ophthalmoscopy performs well in detecting DR. The diagnostic accuracy for PDR was highest. Future studies should standardize reference criteria and classification criteria and evaluate other available forms of smartphone ophthalmoscopy in primary care settings.

KEYWORDS

diabetic retinopathy; smartphone; mobile phone; ophthalmoscopy; artificial intelligence; telemedicine

Introduction

Diabetic retinopathy (DR) is the leading cause of impaired vision worldwide [1]. One in three patients with diabetes mellitus (DM) have DR [2]. DR includes proliferative DR (PDR) and various levels of nonproliferative DR (NPDR). PDR, characterized by retinal neovascularization at the disc and elsewhere, displays signs of angiogenesis in response to retinal tissue hypoxia. Neovascularization potentially leads to preretinal and vitreous hemorrhage, resulting in visual loss and, eventually, tractional retinal detachment. It may also cause iris neovascularization with resultant increase in intraocular pressure, eventually leading to neovascular glaucoma [3]. Typical clinical features of NPDR include the following: (1) microaneurysms and intraretinal hemorrhages from weak capillary walls; (2) hard exudates from vascular protein leakage; and (3) cotton wool spots, caused by ischemic infarcts leading to fluid accumulation. Diabetic macular edema (DME), caused by the thickening of and fluid accumulation in the retina, can occur at any stage of DR [4].

Diabetic eye disease is treatable. Treatments include vascular endothelial growth factor inhibitors, panretinal or focal photocoagulation, and vitrectomy [5]. Strict glycemic and blood pressure control can also delay the development of DR or reduce DR severity [6]. Treatments available are more effective at halting or slowing visual loss than reversing visual impairment. Yet, most patients remain asymptomatic until the advanced stages of DR. Therefore, early detection of DR before irreversible loss of visual acuity is crucial to ensure better patient outcomes [7].

The gold standard diagnostic test for DR is the Early Treatment Diabetic Retinopathy Study (ETDRS) 7-field stereoscopic color fundus photography or fluorescein angiography [8]. However, fundus cameras are nonportable, expensive, and operator dependent, often requiring patients to sit upright [9,10]. Moreover, fluorescein angiography is invasive, costly, and associated with prominent side effects [11]. Thus, they are impractical for screening in primary care or mobile settings. Other accurate [12] and frequently employed DR identification approaches include the following: (1) ophthalmoscopy; (2) slit-lamp biomicroscopy; and (3) other forms of fundus photography [13]. Optical coherence tomography is an emerging technology that reliably identifies DME by quantifying retinal thickness [14], but it is expensive and bulky and it cannot accurately grade DR severity.

Smartphone ophthalmoscopy, the use of a smartphone's in-built camera for retinal imaging, could be a valuable method for detecting DR because of its affordability, portability, and ease of use compared with traditional approaches [15]. Various health care workers could potentially operate a smartphone-based retinal imaging device, without limiting this procedure to highly specialized staff. Images acquired by smartphones can be easily shared with and graded remotely by ophthalmologists or other trained graders via telemedicine. These benefits are particularly important in resource-constrained health care settings, such as rural areas in developing countries lacking medical equipment and trained health care professionals [16]. Several literature reviews [17-19] have discussed smartphone retinal imaging technology and underscored the huge potential of smartphone ophthalmoscopy for detecting DR. Given the potential of this novel approach, we performed a scoping review to systematically collate and assess evidence regarding the accuracy of smartphone ophthalmoscopy for DR identification.

Methods

Reporting Guidelines

This scoping review was reported in line with the Preferred Reporting Items for a Systematic Review and Meta-analysis of Diagnostic Test Accuracy Studies (PRISMA-DTA) guidelines [20] and conducted according to the Cochrane Handbook for Systematic Reviews of Diagnostic Test Accuracy [21]. We adopted a scoping review approach [22,23] because of a broad set of inclusion criteria. The protocol for this review was published in *BMJ Open* [24]. We were unable to register this protocol with PROSPERO as it does not include scoping reviews.

Search Strategy

We performed a librarian-assisted search on the Medical Literature Analysis and Retrieval System Online (MEDLINE) (Ovid), EMBASE (Ovid), and the Cochrane Library for papers published from January 2000 to November 2018. Articles published before 2000 were excluded because before that smartphone technology was limited. We used both medical subject headings (MeSH) and keywords relating to DR (eg, "diabetic retinopathy," "macular edema," and "diabetic maculopathy") and to smartphones (eg, "mobile health," "mobile phones," and "applications") or AI (eg, "artificial intelligence" and "machine learning"; Multimedia Appendix 1). We also explored the bibliography of both primary articles and reviews to identify potentially eligible studies missed by the electronic search.

Study Selection

The inclusion criteria were as follows: (1) studies evaluating the diagnostic test accuracy of smartphone ophthalmoscopy for detecting DR in patients with type 1 or 2 DM; (2) studies utilizing a smartphone's in-built camera for retinal imaging, including the use of any attachments externally fitted to the smartphone; (3) studies comparing smartphone ophthalmoscopy with any acceptable and commonly employed reference standard, such as fundus photography, indirect ophthalmoscopy, slit-lamp biomicroscopy, or fluorescein angiography; (4) studies employing any kind of health care professional to acquire the smartphone images. Language was not an exclusion criterion.

Examples of eligible smartphone ophthalmoscopy techniques include the following:

- Direct ophthalmoscopy: An adaptor is externally attached to a smartphone's camera. These adaptors usually contain polarizers that reduce artifacts from corneal reflections. The arrangement of polarizers, beam-splitters, and lenses produces an annular illumination pattern.
- Indirect ophthalmoscopy: This simpler, monocular design involves a single lens (eg, 20 D condenser) placed between the smartphone camera and eye. It can be mounted on the phone via hardware or manually held in position.

Covidence software (Veritas Health Innovation, Melbourne, Australia) was used to remove duplicated studies [25]. After a pilot screening of 20 citations to calibrate the judging criteria, two reviewers independently screened all articles retrieved from the search strategy by title and abstract, using Covidence. Subsequently, we screened the full text of the remaining articles and performed data extraction using a prepiloted form. Any disagreements were resolved through consensus.

Data Collection

A data extraction form (Multimedia Appendix 2) was created and piloted to record the following data from each study: (1) study author and date published; (2) sample size; (3) participant characteristics (eg, age, duration and type of DM); (4) information regarding imaging techniques (eg, details about smartphones and adaptors used, image resolution); (5) health care professional performing smartphone ophthalmoscopy; (6) reference standard used; and (7) test results (eg, true positives [TP], false positives [FP], true negatives [TN], and false negatives [FN]). Corresponding authors were contacted for additional details or missing data required to construct a 2×2 table. Two reviewers independently extracted study data using a data extraction template created in Microsoft Excel, with disagreements resolved via consensus.

Quality Assessment

The Quality Assessment of Diagnostic Accuracy Studies tool, QUADAS-2, consisting of descriptions and signaling questions, was used to assess the risk of bias and applicability of all included studies in four domains pertaining to (1) patient selection, (2) index test, (3) reference standard, and (4) flow of participants through the study and timing between the index test and reference standard [26]. Two reviewers independently assessed study quality, and disagreements were resolved via discussion until a consensus was reached.

Statistical Analysis

We constructed 2×2 tables based on data from each study. The sensitivity, specificity, positive likelihood ratio (LR+), negative likelihood ratio (LR−), diagnostic odds ratio (DOR), and area under summary receiver operating characteristic (SROC) curve were calculated using a random effects model because of the high expected heterogeneity [27]. We constructed SROC using the bivariate model where possible. Being both a hierarchical and random effects model, the bivariate model is preferred to the Moses-Littenberg SROC curve—the former method accounts for between-study heterogeneity. For SROC curves employing the bivariate model, elliptical 95% confidence regions were obtained by joining the individual confidence regions for logit sensitivity and logit specificity via parametric representations [28,29].

Heterogeneity was evaluated using chi-square (χ^2) and I^2 values of likelihood ratio tests (LRT) or DOR, with I^2<25%, 25–75%, and >75% representing low, moderate, and high degree of inconsistency, respectively. Threshold effect was measured using the Spearman correlation coefficient ρ between logits of sensitivity and specificity, with ρ closer to −1 indicating higher threshold effect and better fit of the SROC curve. If information regarding a condition's prevalence was available from the literature, we calculated the posttest probability using the Fagan nomogram. A P<.05 was considered statistically significant. All analyses were performed using Review Manager version 5.3 from the Cochrane Collaboration [30], METANDI and MIDAS commands in Stata 15.1 (StataCorp, College Station, Texas), Meta-Disc version 1.4 (Ramón y Cajal Hospital, Madrid, Spain) [31], and *mada* package in R.

Results

Study Selection and Study Characteristics

Our search strategy yielded 1571 unique records. Of those records, the full text for 41 articles was assessed, and nine studies [32-40] met the inclusion criteria (Figure 1). Two [32,33] of the included studies were conference abstracts. A total of 1430 diabetic patients (at least 2743 eyes) were recruited among these studies.

All studies reported smartphone fundoscopy techniques involving mydriatic, color, and nonstereoscopic imaging (Tables 1 and 2, Multimedia Appendix 3). A total of four studies originated from India, three studies from the United States, and one from Italy. All studies which reported data on gender recruited both males and females. These fundus photographs were graded by ophthalmologists, retinal specialists, or artificial intelligence (AI). In all, seven studies utilized direct ophthalmoscopy to acquire smartphone fundus images, while two studies [38,40] used indirect ophthalmoscopy.

A total of five studies [32,33,37,39,40] employed slit-lamp biomicroscopy as the reference standard, of which two studies complemented the examination with dilated indirect ophthalmoscopy [39,40]. In all, two studies [35,38] utilized 7-field mydriatic fundus photography using a tabletop fundus camera; one study [34] used *traditional in-clinic diagnosis* including a dilated eye examination; and one study [36] utilized ophthalmologists' grading of the same smartphone-acquired images as the reference standard. Overall, four studies [32,36,37,40] utilized the International Clinical DR Disease Severity Scale to grade DR; three studies [34,35,38] employed the Airlie House or modified ETDRS criteria; and one study [39] used the United Kingdom's National Health Service (NHS) guidelines. Referral-warranted DR (RWDR) was defined as moderate NPDR or worse or DME; vision-threatening DR (VTDR) as severe NPDR, PDR, or DME; and sight-threatening DR (STDR) as PDR or DME. Health professionals performing smartphone ophthalmoscopy included medical students, interns or assistants, retinal specialists, ophthalmologists, and ophthalmic photographers. Most studies reported no funding

sources or conflicting interests, while such information was unavailable for two studies [32,33]. In all, two studies [34,40] received funding, one of which disclosed multiple authors holding positions in DigiSight Technologies, Inc.

Figure 1. Flowchart depicting the identification of relevant studies.

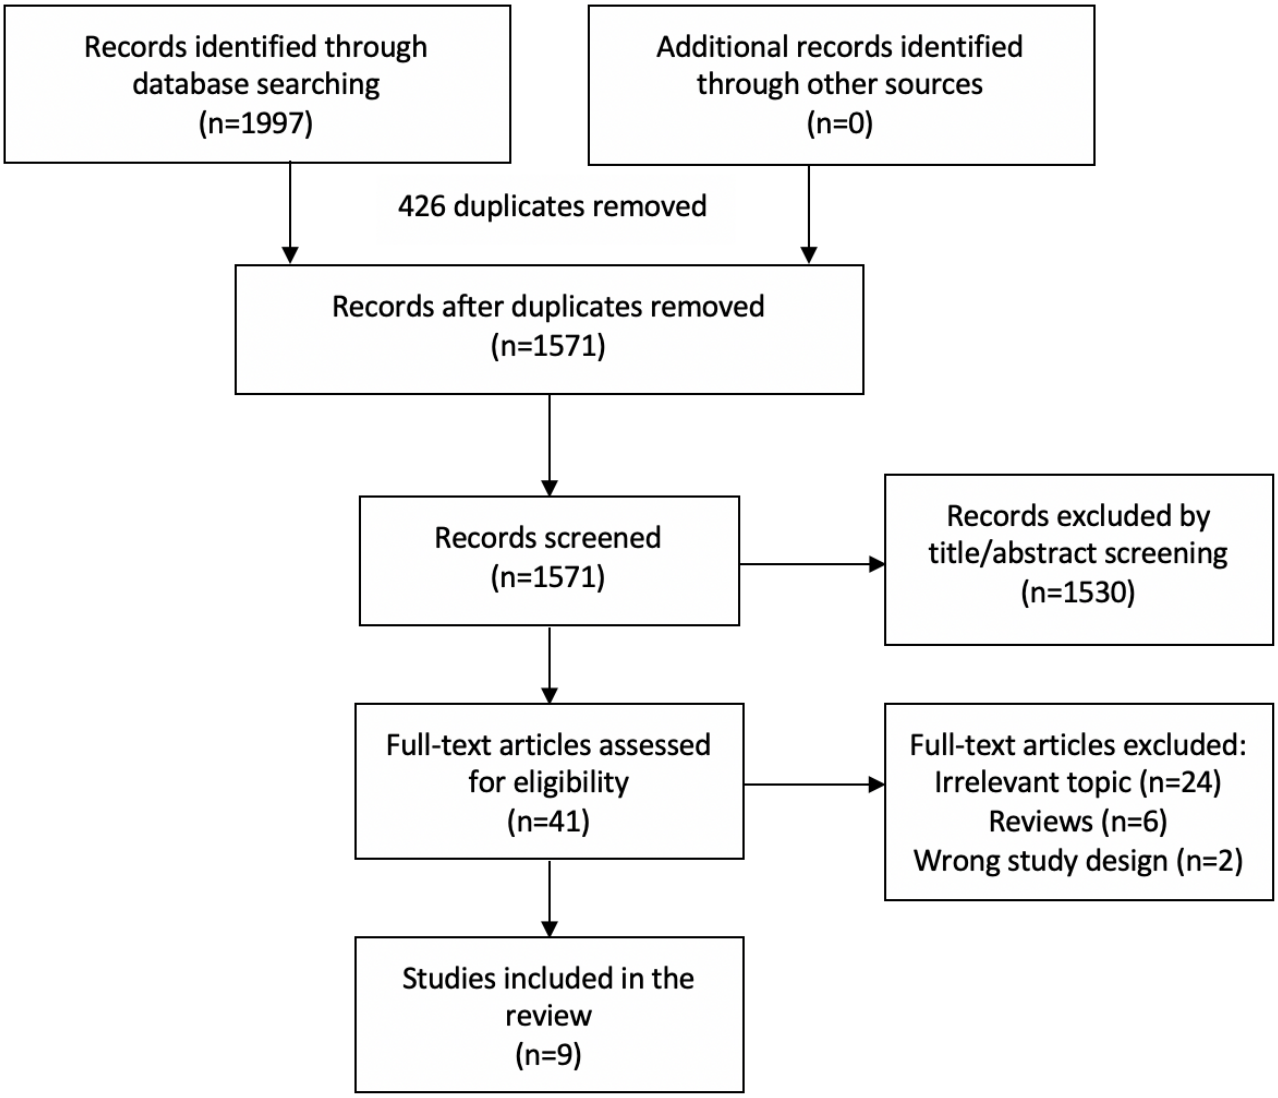

Table 1. Characteristics of included studies.

Study author, year	Country, setting	Sample size (patients/eyes)	Age (years), mean (SD)	Diabetes duration (years)		Diabetic retinopathy severity scale	Reference standard
				Mean (SD)	Range		
Bhat, 2016 [32]	N/A[a]	80/N/A	N/A	N/A	N/A	ICDR[b] severity scale; no referral defined as no or mild signs of DR[c].	Slit-lamp exam
Kim, 2017 [33]	United States, Retina Clinic	72/144	N/A	N/A	N/A	Referable DR defined as moderate NPDR[d] or worse, or DME[e].	Slit-lamp biomicroscopy
Kim, 2018 [34]	United States, Retina Clinic	71/142	56.7 (16.9)	N/A	N/A	Airlie House ETDRS[f] criteria; RWDR[g] defined as moderate NPDR or worse, or DME.	Gold standard dilated eye examination, with optical coherence tomography for DME
Rajalakshmi, 2015 [35]	India, Tertiary care diabetes hospital	301/602	53.5 (9.6)	12.5 (7.3)	N/A	Modified ETDRS criteria; STDR[h] defined as PDR[i] or DME	Mydriatic 7-standard field digital retinal photography
Rajalakshmi, 2018 [36]	India, Tertiary care diabetes hospital	301/602	N/A	N/A	N/A	ICDR severity scale; STDR defined as severe NPDR, PDR, or DME; RDR[j] defined as moderate NPDR or worse, or DME.	Remidio Fundus On Phone images graded by ophthalmologists
Russo, 2015 [37]	Italy, Diabetic center	120/240	58.8 (16.4)	11.6 (9.7)	N/A	ICDR severity scale; ETDRS criteria for DME; RWDR defined as moderate NPDR or worse, regardless of DME status.	Dilated slit-lamp biomicroscopy by a retinal specialist
Ryan, 2015 [38]	India, Ophthalmology clinic of a tertiary diabetes care center	300/600	48.0 (11.0)	N/A	0.1-37.2 years	Modified ETDRS criteria; VTDR[k] defined as severe NPDR or worse, or DME.	Mydriatic 7-field fundus photography by trained optometrists
Sengupta, 2018 [39]	India, Aravind Eye Hospital	135/233	54.1 (8.3)	10.7 (5.1)	N/A	National Health Service guidelines; VTDR defined as R2-level or worse (severe NPDR, PDR), or DME.	Dilated slit-lamp biomicroscopy (+90 D lens) and indirect ophthalmoscopy by retinal specialists
Toy, 2016 [40]	United States, Health care safety-net ophthalmology clinic	50/100	60.5 (10.6)	11.9 (8.4)	N/A	ICDR severity scale; RWDR defined as moderate NPDR or worse, or ungradable images.	Slit-lamp exam + dilated ophthalmoscopy by technicians

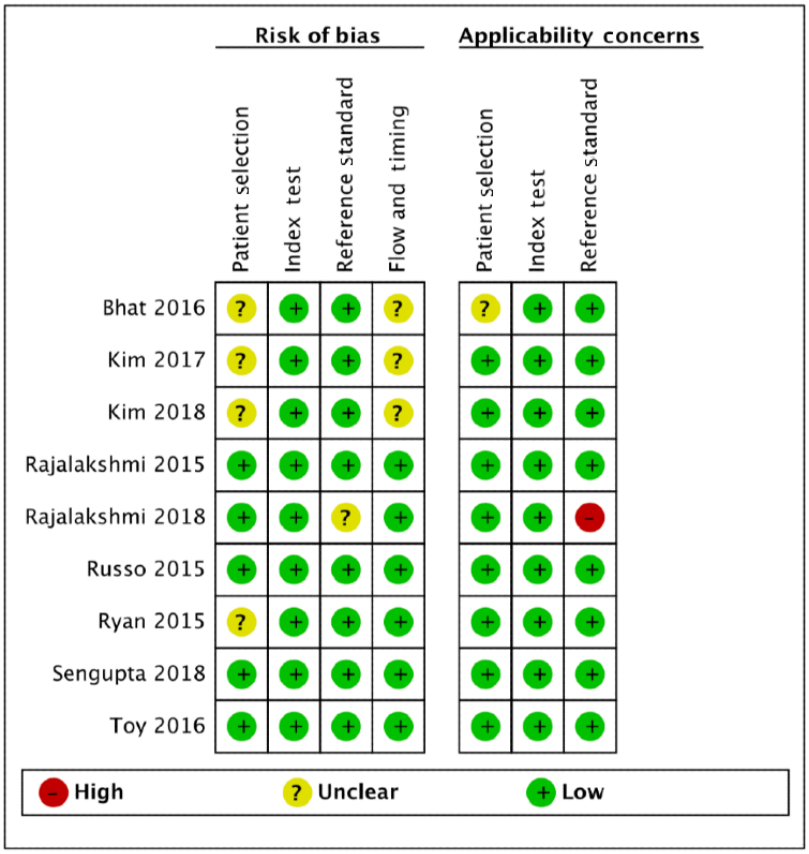
Quality Assessment

We carried out the quality assessment of the included studies using the QUADAS-2 criteria (Figure 2, Multimedia Appendix 4). Most studies were of high quality with low risk of bias and applicability concerns. A total of four studies had an unclear risk of bias for patient selection because of the lack of information regarding patient sampling or inappropriate exclusions. The two abstracts were of lower quality than the other studies because of the limited amount of information available. One study contained applicability concerns because it employed ophthalmologists' grading of smartphone fundoscopy images as the reference standard; it was excluded from the meta-analysis.

Figure 2. Quality of included studies assessed via Quality Assessment of Diagnostic Accuracy Studies–2 tool.



Meta-Analysis

Any Diabetic Retinopathy

In all, six studies (977 participants; Figures 3 and 4; Table 3) presented data on detecting any DR [34,35,37-40]. I^2_{LRT} was 96.8% (95% CI 94.6%-99.1%), χ^2_5=63.3, and ρ=−0.332. DOR was 100 (95% CI 27.4-368). Sensitivity and specificity ranged from 50% to 94% and 40% to 99%, respectively. The pooled sensitivity was 87.1% (95% CI 73.9%-94.2%); pooled specificity was 93.7% (95% CI 80.9%-98.1%). LR+ was 13.8 (95% CI 4.37-43.6); LR− was 0.138 (95% CI 0.066-0.287). The area under curve (AUC) was 0.957 (95% CI 0.936-0.972). Considering a pretest probability of 35.4% in diabetic patients [2], using the Fagan nomogram, the posttest probability for a positive and negative result was 88% and 7%, respectively.

We performed subgroup analysis by removing studies individually and investigating the effect on both I^2 and ρ. When one study [38] was removed, I^2 decreased to 93.0% (95% CI 86.8%-99.3%) and ρ decreased to −1.00, implying this study contributed to the heterogeneity. However, both the type of ophthalmoscopy (direct vs indirect) and reference standard used did not account for the heterogeneity.

Figure 3. Forest plot of the sensitivity and specificity of smartphone ophthalmoscopy in detecting different grades of diabetic retinopathy. AI: artificial intelligence; FN: false negatives; FP: false positives; NPDR: nonproliferative diabetic retinopathy; PDR: proliferative diabetic retinopathy; RWDR: referral-warranted diabetic retinopathy; STDR: sight-threatening diabetic retinopathy; TN: true negatives; TP: true positives; VTDR: vision-threatening diabetic retinopathy.

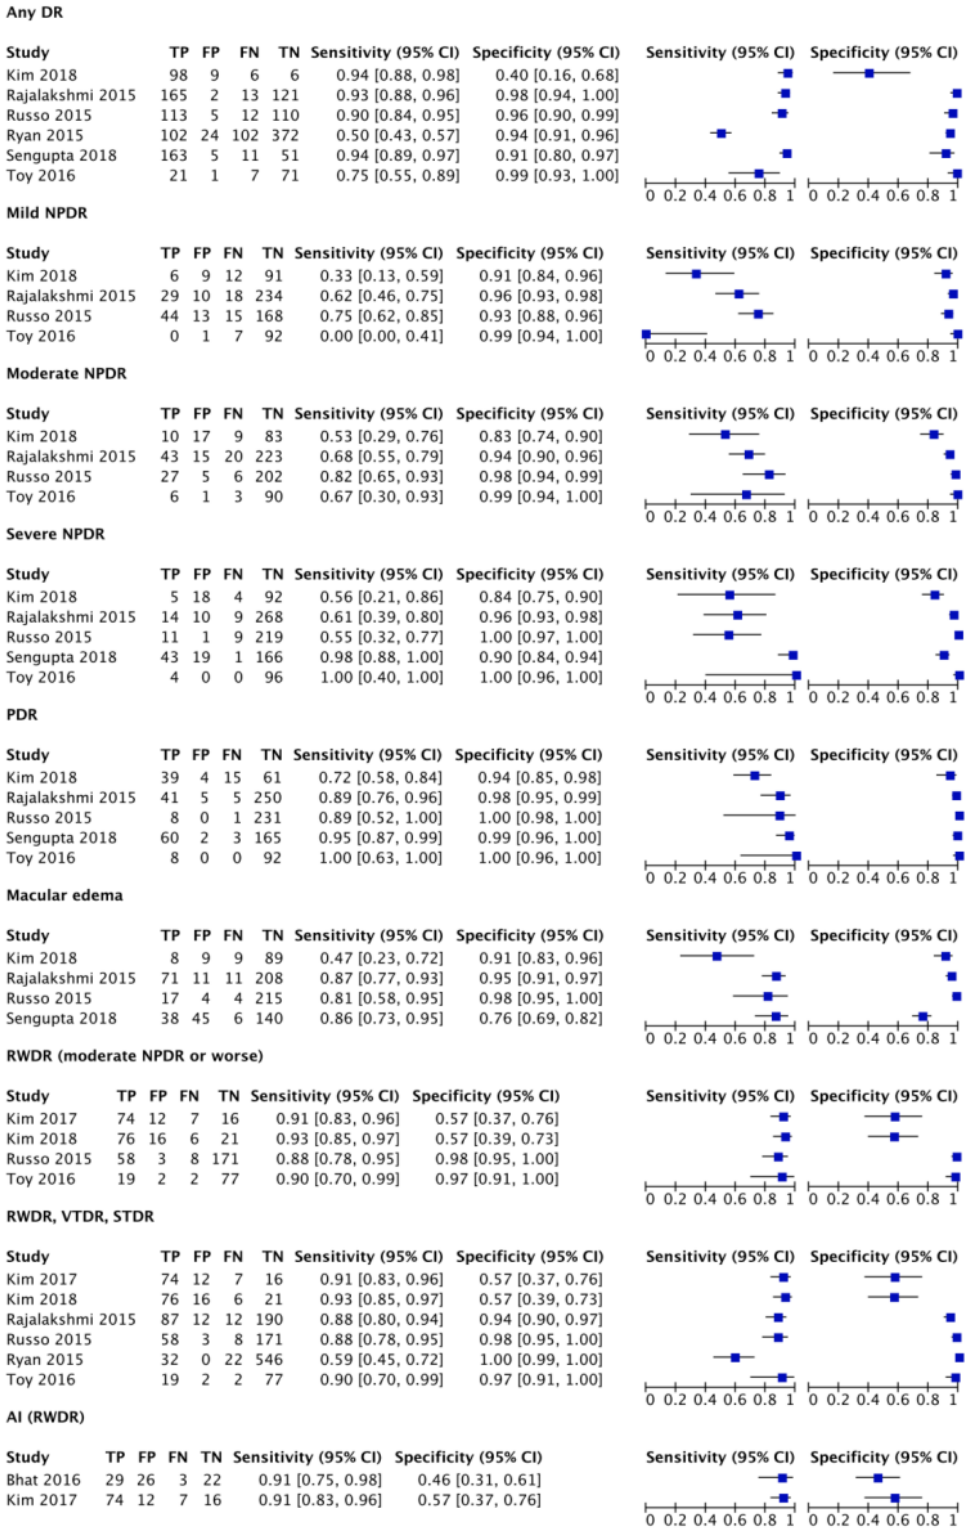


Figure 4. Summary receiver operating characteristic curves of smartphone ophthalmoscopy in detecting (A) any diabetic retinopathy; (B) mild nonproliferative diabetic retinopathy; (C) moderate nonproliferative diabetic retinopathy; (D) severe nonproliferative diabetic retinopathy; (E) proliferative diabetic retinopathy; (F) diabetic macular edema; (G) referral-warranted diabetic retinopathy, vision-threatening diabetic retinopathy, or sight-threatening diabetic retinopathy; (H) artificial intelligence to detect referral-warranted diabetic retinopathy. HSROC: hierarchical summary receiver operating characteristic.

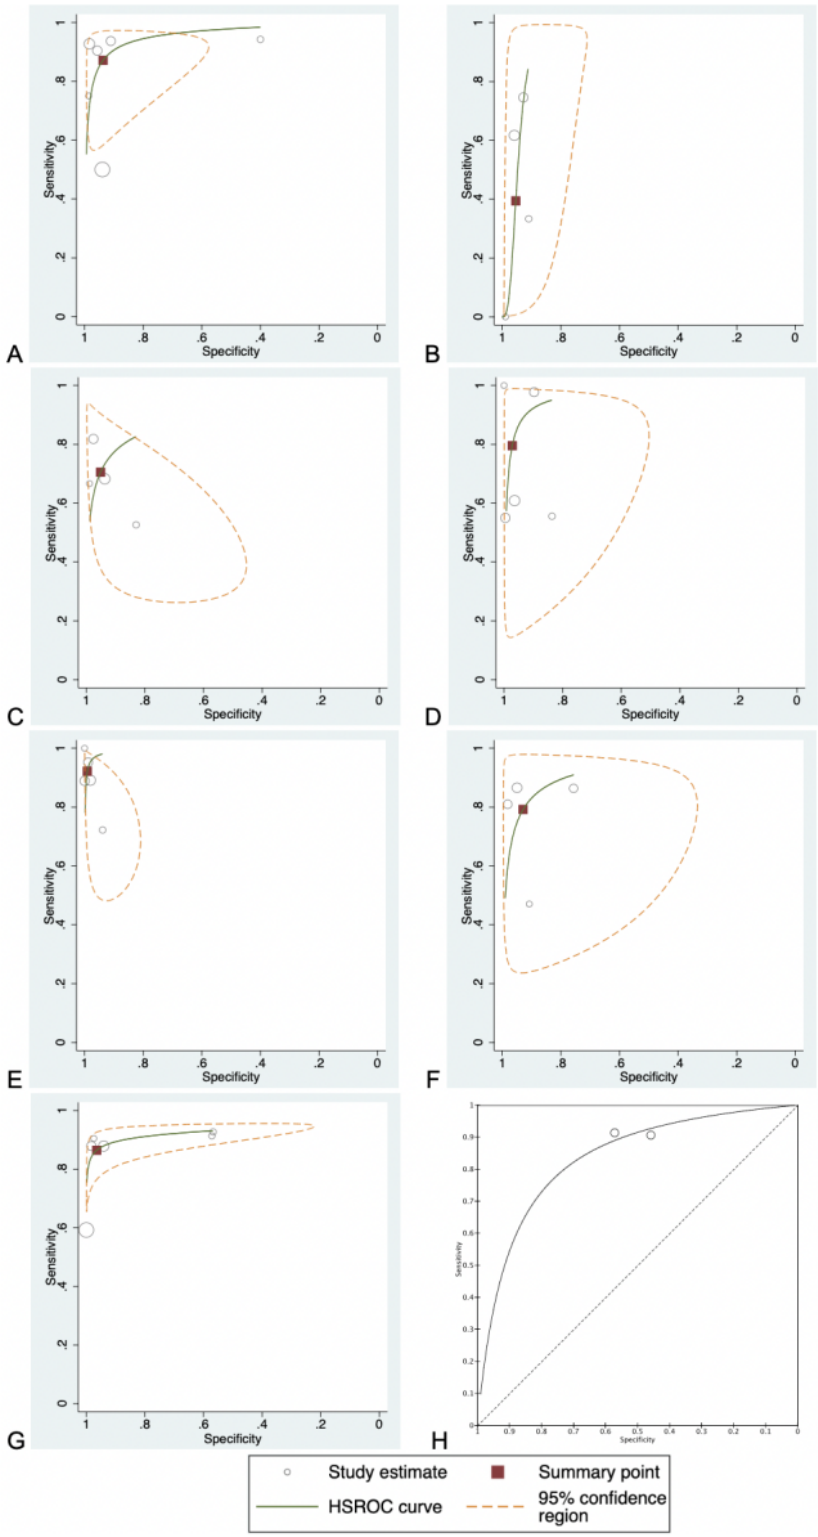

Table 3. Summary of smartphone ophthalmoscopy's test accuracy in detecting different grades of diabetic retinopathy.

DR[a] staging	Studies, n	Overall pooled sensitivity, % (95% CI)	Overall pooled specificity, % (95% CI)	Positive likelihood ratio (95% CI)	Negative likelihood ratio (95% CI)	Diagnostic odds ratio (95% CI)	Area under summary receiver operating characteristic curve (95% CI)
Any DR	6	87 (74-94)	94 (81-98)	14 (4.4–44)	0.14 (0.06-0.29)	100 (27.4-368)	0.957 (0.936-0.972)
Mild NPDR[b]	4	39 (10-79)	95 (91-98)	8.6 (3.6-20)	0.64 (0.32-1.3)	13.6 (3.14-58.5)	0.939 (0.915-0.957)
Moderate NPDR	4	71 (57-81)	95 (88-98)	15 (4.9-43)	0.31 (0.20-0.49)	46.9 (10.6-208)	0.879 (N/A)

[h]AI: artificial intelligence.

[i]N/A: not available.

Mild Nonproliferative Diabetic Retinopathy

In all, four studies (542 participants) presented data on detecting mild NPDR [34,35,37,40]. I^2_{LRT} was 81.5% (95% CI 60.6%-100%), χ^2_3=10.8, and ρ=−0.862. DOR was 13.6 (95% CI 3.14-58.5). Sensitivity and specificity ranged from 0% to 75% and 91% to 99%, respectively. The pooled sensitivity was 39.4% (95% CI 10.1%-79.0%); pooled specificity was 95.4% (95% CI 91.3%-97.6%). LR+ was 8.60 (95% CI 3.64-20.3); LR− was 0.635 (95% CI 0.323-1.25). One study [40] using a lens mounted on Paxos scope yielded a sensitivity of 0%. The AUC was 0.939 (95% CI 0.915-0.957).

Moderate Nonproliferative Diabetic Retinopathy

A total of four studies (542 participants) presented data on detecting moderate NPDR [34,35,37,40]. DOR was 46.9 (95% CI 10.6-208; I^2_{DOR}=85.4%; χ^2_3=20.6). Sensitivity and specificity ranged from 53% to 82% and 83% to 99%, respectively. The pooled sensitivity was 70.5% (95% CI 56.6%-81.4%); pooled specificity was 95.1% (95% CI 87.8%-98.2%). LR+ was 14.5 (95% CI 4.89-43.2); LR− was 0.310 (95% CI 0.195-0.492). The AUC was approximately 0.879.

One study [39] assessed the sensitivity and specificity of smartphone ophthalmology in detecting R1 disease (ie, mild and moderate NPDR) to be 88.2% (95% CI 85.7%-91.6%) and 83.4% (95% CI 78%-87%), respectively.

Severe Nonproliferative Diabetic Retinopathy

Overall, five studies (677 participants) presented data on detecting severe NPDR [34,35,37,39,40]. I^2_{LRT} was 94.0% (95% CI 88.9%-99.1%), χ^2_4=33.4, and ρ=−0.111. DOR was 134 (95% CI 17.5-1039). Sensitivity and specificity ranged from 55% to 100% and 84% to 100%, respectively. The pooled sensitivity was 79.5% (95% CI 48.6%-94.1%); pooled specificity was 97.1% (95% CI 87.7%-99.4%). LR+ was 28.4 (95% CI 6.06-133); LR− was 0.211 (95% CI 0.0688-0.645). The AUC was 0.965 (95% CI 0.945-0.978).

Removing one study [34] employing medical students and interns for smartphone ophthalmoscopy led to the greatest decrease in ρ to −0.639, indicating that the remaining studies fitted well within the SROC curve. However, removing the study utilizing indirect ophthalmoscopy [40] resulted in both a decrease in ρ and I^2 to −0.464 and 93.8% (95% CI 88.5%-99.2%), respectively. Thus, our subgroup analysis for *severe NPDR* was inconclusive.

Proliferative Diabetic Retinopathy

A total of five studies (677 participants) presented data on detecting PDR [34,35,37,39,40]. DOR was 1225 (95% CI 117-12,800; I^2_{DOR}=78.0%; χ^2_4=18.2). Sensitivity and specificity ranged from 72% to 100% and 94% to 100%. The pooled sensitivity was 92.1% (95% CI 79.1%-97.4%); pooled specificity was 99.0% (95% CI 96.1%-99.8%). LR+ was 96.6 (95% CI 21.9-425); LR− was 0.0789 (95% CI 0.0273-0.228). The AUC was approximately 0.979.

Removing one study [34] decreased I^2_{DOR} to 0.0%. This study employed a medical student and an intern to acquire smartphone ophthalmoscopy images, potentially resulting in heterogeneity. Removing the only study [35] using 7-field ETDRS fundus photography as a reference standard, or another study [40] utilizing indirect ophthalmoscopy, did not reduce I^2_{DOR}.

Diabetic Macular Edema

Although the diagnosis of DME generally requires stereoscopic retinal imaging, these studies used substitute markers, such as the presence of hard exudates or laser photocoagulation scars.

In all, four studies (627 participants) presented data on detecting DME [34,35,37,39]. I^2_{LRT} was 87.9% (95% CI 75.5%-100%), χ^2_3=16.6, and ρ=−0.038. DOR was 49.8 (95% CI 13.7–180). Sensitivity and specificity ranged from 47% to 87% and 76% to 98%, respectively. The pooled sensitivity was 79.2% (95% CI 63.2%-89.4%); pooled specificity was 92.9% (95% CI 82.3%-97.4%). LR+ was 11.1 (95% CI 4.22-29.5); LR− was 0.224 (95% CI 0.119-0.422). The AUC was 0.925 (95% CI 0.898–0.945). Considering a pretest probability of 7.48% in diabetic patients [2], using the Fagan nomogram, the posttest probability for a positive and negative result was 47% and 2%, respectively.

Referral-Warranted Diabetic Retinopathy

In all, four studies (313 participants) presented data on detecting RWDR [33,34,37,40]. I^2_{LRT} was 94.3% (95% CI 89.6%-99.1%), χ^2_3=35.3, and ρ=−1.00. DOR was 75.8 (95% CI 13.9-414). Sensitivity and specificity ranged from 88% to 93% and 57% to 98%, respectively. The pooled sensitivity was 90.5% (95% CI 85.5%-93.8%); pooled specificity was 88.9% (95% CI 56.2%-98.0%). LR+ was 8.13 (95% CI 1.63-40.5); LR− was 0.107 (95% CI 0.0721-0.159). The AUC was 0.921 (95% CI 0.894-0.941).

Referral-Warranted Diabetic Retinopathy, Vision-Threatening Diabetic Retinopathy, and Sight-Threatening Diabetic Retinopathy

Overall, six studies (914 participants) presented data on detecting RWDR, VTDR, and STDR [33-35,37,38,40]. I^2_{LRT} was 98.6% (95% CI 97.8%-99.4%), χ^2_5=139, and ρ=−1.00. DOR was 171 (95% CI 25.9-1142). Sensitivity and specificity ranged from 59% to 93% and 57% to 100%, respectively. The pooled sensitivity was 86.5% (95% CI 77.1%-92.4%); pooled specificity was 96.4% (95% CI 71.1%-99.7%). LR+ was 24.1 (95% CI 2.58-226); LR− was 0.140 (95% CI 0.0865-0.228). The AUC was 0.929 (95% CI 0.903-0.949). Owing to a good fit of the SROC curve, subgroup analysis was not performed.

One study excluded from the analysis found the agreement for detecting VTDR to be high, κ=0.76 (95% CI 0.68-0.85) [39].

Artificial Intelligence in Smartphone Ophthalmoscopy

In all, two studies (152 participants) presented data on detecting RWDR using AI to grade retinal images acquired via smartphone ophthalmoscopy compared with conventional slit-lamp biomicroscopy [32,33]. I^2_{LRT} was 0.0%. DOR was 11.3 (95% CI 4.92-26.1). Specificity ranged from 46% to 57%. The pooled sensitivity was 91.2% (95% CI 84.3%-95.7%); pooled specificity was 50.0% (95% CI 38.3%-61.7%). LR+ was 1.80 (95% CI 1.42-2.28); LR− was 0.167 (95% CI 0.088-0.316). Owing to the limited number of included studies, the fixed effects model Moses-Littenberg SROC curve was employed for this analysis, and a 95% confidence region was not available.

Another study (301 participants) compared an AI's grading of smartphone ophthalmoscopy images with the reference standard ophthalmologists' grading of the same images [36]. It reported a high sensitivity of 95.8% (95% CI 92.9%-98.7%), 99.1% (95% CI 95.1%-99.9%), and 99.3% (95% CI 96.1%-99.9%), and a specificity of 80.2% (95% CI 72.6%-87.8%), 80.4% (95% CI 73.9%-85.9%), and 68.8% (95% CI 61.5%-76.2%) for any DR, STDR, and RWDR, respectively.

Discussion

Summary of Results

Overall, smartphone ophthalmoscopy performed well in detecting DR. Depending on the severity of DR, smartphone ophthalmoscopy had different accuracy. Progressing from mild NPDR to PDR, we observed an increasing trend in smartphone ophthalmoscopy's sensitivity, specificity, and DOR. In addition, smartphone ophthalmoscopy had the best performance in detecting PDR, RWDR, VTDR, and STDR; these are important categories to detect as they can significantly affect vision. The lowest sensitivity was observed for detecting mild NPDR, mainly caused by one study enrolling only 7 participants with RWDR. The DOR was lowest for AI's detection of RWDR. There was also a low percentage of ungradable images across most studies, implying that smartphone ophthalmoscopy is relatively reliable. Common causes of ungradable images included cataracts, poor pupil dilation, vitreous hemorrhages, or poor image focus.

Most studies performed smartphone direct ophthalmoscopy utilizing one of four different attachments. The included studies also assessed two methods of indirect ophthalmoscopy. Smartphone ophthalmoscopy in the included studies surpasses the UK NHS targets requiring DR retinal imaging equipment to have a minimum resolution of 6 megapixels or 30 pixels per retinal degree [34,37]. Two studies [35,36] assigned DR grades at a patient level instead of assessing each eye individually. In some cases, smartphone apps were used to digitally stitch the multiple images obtained per eye or enhance the image acquisition process by facilitating ergonomic focusing and capturing of images. Videography was used in two studies

[37,38]. Different grading criteria and reference standards were applied across the included studies. High heterogeneity among studies was observed for most types of DR—especially for *moderate NPDR* and *PDR*—except for studies employing AI to detect RWDR. In other studies reporting on the use of non-AI smartphone ophthalmoscopy in *mild NPDR, RWDR only,* and *RWDR, VTDR, and STDR*, a significant proportion of heterogeneity can be attributed to the threshold effect.

The diagnostic accuracy of AI in grading smartphone ophthalmoscopy images was unexpectedly low. In two studies, the specificity and DOR of AI in detecting RWDR was lower than that of human graders (retinal specialists and ophthalmologists). Nevertheless, one of those studies employed both human and AI to grade identical smartphone-acquired images; the specificity of AI was higher than that of humans. In contrast, a 2015 study demonstrated that AI detects RWDR in smartphone ophthalmoscopy images with 100% sensitivity and 80% specificity (AUC 0.94) [41]. In addition, a recent review revealed that AI software achieved high sensitivity and specificity for detecting DR in datasets of fundus images acquired from other imaging modalities [42]. Finally, IDx-DR was the first commercially approved AI-based autonomous diagnostic system for DR detection. In a prospective study of 900 participants, this system attained high sensitivity and specificity of 87.2% (95% CI 81.8%-91.2%) and 90.7% (95% CI 88.3%-92.7%), respectively, in detecting more than mild DR [43].

Smartphone ophthalmoscopy is a safe means of acquiring retinal images [44]. One study [34] surveyed patients on their comfort levels while undergoing retinal imaging and revealed that all participants felt more comfortable with the light from Cellscope Retina than the light from slit lamps. Other studies [38,39] employing either an intrinsic smartphone light source or external light sources reported lower luminance than conventional fundus cameras.

Comparison to Existing Studies

To our knowledge, this is the first meta-analysis evaluating the diagnostic accuracy of smartphone ophthalmoscopy for detecting DR in diabetic patients. A meta-analysis [45] evaluated the agreement between smartphone retinal imaging and retinal cameras encompassing multiple eye pathologies such as DR, glaucoma, and ocular hypertension. It reported excellent image quality in 84.7% of smartphone images, with good diagnostic accuracy; combined κ agreement was 77.8% (95% CI 70.34%-83.70%), AUC=0.86. However, the patient selection was not limited to diabetic individuals. A large study [46] involving 1460 participants (2920 eyes) had previously evaluated the diagnostic accuracy of smartphone ophthalmoscopy for optic disc imaging. Videography was performed with Peek Retina adaptor attached to an 8.0-megapixel Samsung SIII smartphone. This technique demonstrated excellent agreement (weighted κ=0.69) with a reference standard tabletop fundus camera in measuring vertical cup-disc ratio. Using smartphone ophthalmoscopy, 79.5% of eyes were gradable, compared with 86.4% for tabletop retinal imaging. Furthermore, there was no significant difference between image quality acquired by professional and inexperienced photographers. This study reported a lower percentage of gradable eyes compared with most studies included in our scoping review. This could be attributed to inherent differences in the process of DR grading (which requires examination of the retina in general) compared with measuring cup-disc ratio (which specifically examines the optic disc). Regardless of sample size, the agreement of smartphone ophthalmoscopy with a well-established reference standard remains high.

Strengths

This scoping review aimed to provide a comprehensive analysis of the available literature in this field. Correspondingly, we had broad inclusion criteria encompassing different smartphone ophthalmoscopy techniques, reference standards, DR severity scales, and health care professionals. Smartphone retinal imaging is an emerging technology, and we wanted to capture as much of the available evidence as possible (Multimedia Appendix 5). The included studies were published relatively recently, from 2015 to 2018, heralding future breakthroughs in the diagnostic accuracy of smartphone retinal imaging as affordable and accessible means of DR detection.

Our study employed a comprehensive search strategy and examined studies from different countries involving different types of diabetic patients. At least two reviewers performed quality assessment and data extraction independently following Cochrane methodology. Based on the QUADAS-2 tool, most studies possessed minimal risk of bias and little applicability concerns. In particular, all included studies blinded or masked the graders.

Limitations

Although the protocol for this scoping review was published in *BMJ Open*, this protocol was not registered. Three studies [33,34,39] utilized two graders, thereby creating two separate 2×2 tables; to avoid double-counting, we averaged the TP, FP, TN, and FN values, and rounded those average values to the nearest whole number for analysis. For one study [39], we assumed none of the four excluded eyes had DME. Owing to the small number of studies and limited information available, we were not able to conduct a meta-regression analysis or assess for publication bias.

The large 95% CIs for most SROC curves indicate imprecision. Although only studies involving diabetic patients were included, most studies were conducted in tertiary health care settings: eye or diabetes clinics. These settings can afford tabletop or portable fundus cameras. Instead, smartphone ophthalmoscopy is more relevant for screening in primary settings or resource-constrained countries. All studies required mydriasis, despite the availability of nonmydriatic smartphone ophthalmoscopy attachments [17].

Implications for Future Research

Future studies on smartphone ophthalmoscopy could utilize more consistent reference standards, such as the gold standard 7-field ETDRS stereoscopic color photographs, and standardize the DR classification criteria. Such standardization minimizes bias and heterogeneity between studies. In addition, ultrawide-field retinal imaging may detect DR features outside

the 7-field ETDRS field of view, which may be of clinical significance [47]. More studies could focus on (1) indirect ophthalmoscopy or ultrawide-field retinal imaging; (2) nonmydriatic techniques; (3) AI; and (4) primary health care settings where the comorbidities and prevalence of DR in this demographic differs.

Conclusions

Smartphone ophthalmoscopy may have an important role in identifying DR in areas with limited access to expensive retinal imaging equipment and trained staff. Our findings show that smartphone ophthalmoscopy performs well in detecting DR. However, the included studies were scarce and heterogeneous and provided imprecise findings. Future studies should use more consistent reference standards and DR classification criteria, evaluate other available forms of smartphone ophthalmoscopy, and recruit participants from primary care settings.

Acknowledgments

The authors thank Ms Soong Ai Jia for her contribution to the data extraction stage of this review. The authors gratefully acknowledge funding support from Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore.

Authors' Contributions

LTC conceived the idea for this study. CHT and BK screened the articles, extracted the data, and performed the analysis. CHT and LTC wrote the manuscript. BK, HS, CT, and LTC revised the manuscript critically.

Conflicts of Interest

None declared.

Abstract

Background: Past mobile health (mHealth) efforts to empower type 2 diabetes (T2D) self-management include portals, text messaging, collection of biometric data, electronic coaching, email, and collection of lifestyle information.

Objective: The primary objective was to enhance patient activation and self-management of T2D using the US Department of Defense's Mobile Health Care Environment (MHCE) in a patient-centered medical home setting.

Methods: A multisite study, including a user-centered design and a controlled trial, was conducted within the US Military Health System. Phase I assessed preferences regarding the enhancement of the enabling technology. Phase II was a single-blinded 12-month feasibility study that randomly assigned 240 patients to either the intervention (n=123, received mHealth technology and behavioral messages tailored to Patient Activation Measure [PAM] level at baseline) or the control group (n=117, received equipment but not messaging. The primary outcome measure was PAM scores. Secondary outcome measures included Summary of Diabetes Self-Care Activities (SDSCA) scores and cardiometabolic outcomes. We used generalized estimating equations to estimate changes in outcomes.

Results: The final sample consisted of 229 patients. Participants were 61.6% (141/229) male, had a mean age of 62.9 years, mean glycated hemoglobin (HbA_{1c}) of 7.5%, mean BMI of 32.7, and a mean duration of T2D diagnosis of 9.8 years. At month 12, the control group showed significantly greater improvements compared with the intervention group in PAM scores (control mean 7.49, intervention mean 1.77; *P*=.007), HbA_{1c} (control mean −0.53, intervention mean −0.11; *P*=.006), and low-density lipoprotein cholesterol (control mean −7.14, intervention mean 4.38; *P*=.01). Both groups showed significant improvement in SDSCA, BMI, waist size, and diastolic blood pressure; between-group differences were not statistically significant. Except for patients with the highest level of activation (PAM level 4), intervention group patients exhibited significant improvements in PAM scores. For patients with the lowest level of activation (PAM level 1), the intervention group showed significantly greater

improvement compared with the control group in HbA_{1c} (control mean −0.09, intervention mean −0.52; *P*=.04), BMI (control mean 0.58, intervention mean −1.22; *P*=.01), and high-density lipoprotein cholesterol levels (control mean −4.86, intervention mean 3.56; *P*<.001). Significant improvements were seen in AM scores, SDSCA, and waist size for both groups and in diastolic and systolic blood pressure for the control group; the between-group differences were not statistically significant. The percentage of participants who were engaged with MHCE for ≥50% of days period was 60.7% (68/112; months 0-3), 57.4% (62/108; months 3-6), 49.5% (51/103; months 6-9), and 43% (42/98; months 9-12).

Conclusions: Our study produced mixed results with improvement in PAM scores and outcomes in both the intervention and control groups. Structural design issues may have hampered the influence of tailored behavioral messaging within the intervention group.

Introduction

Background

Type 2 diabetes (T2D) is a chronic disease with high rates of disability, impaired quality of life, and premature death [1-6]. The prevalence of T2D is increasing at an alarming rate in the United States; in 2017, the estimated number of patients was 30.3 million or about 9.4% of the adult population [2,3,7]. T2D is the leading cause of blindness, nontraumatic amputations, and adult renal failure [8], and it reduces life expectancy by 5 to 10 years [2]. On average, the medical expenditure of patients with T2D is about 2.3 times greater than that of a T2D-free individual [9]. The potential for mobile health (mHealth) technologies in the care of patients with T2D and other chronic conditions to date have assessed a variety of tools and techniques. Some of the most promising tools and techniques include regular collection of biometric devices (eg, glucometers, activity monitors [10,11], SMS messaging [10,12-16], secure email communication with clinical teams, and regular reporting of quality-of-life variables [17-20]). Each of these tools, used alone or in combination, has demonstrated varying degrees of effectiveness. In this study, we sought to incorporate several of the most promising mHealth capabilities in a patient-centered medical home (PCMH) workflow.

The concept of patient activation, detailed in our protocol [21], has been demonstrated to correlate with improved clinical outcomes, increased preventative care, and overall lower health care–related cost [22-25]. Research on increased activation and improved clinical outcomes using patient portal and personal health record (PHR)-based interventions have provided mixed results [16,26-33]. It is noteworthy that early manuscripts did not provide substantial detail related to the design and navigation of portal or PHRs or whether the embedded intervention included behavioral reinforcement. Several studies have demonstrated a relationship between increased patient activation and improved clinical outcomes (eg, hypertension, smoking, BMI, and glycated hemoglobin [HbA_{1c}]) [5,16,25,34-38], whereas other studies did not achieve significant improvement in clinical outcomes [5,37,39]. There is evidence to suggest that activated patients are more likely to practice healthy behaviors related to their diet [37,40] and physical activity [37,41], better manage their T2D [37], and obtain preventive screenings [42].

Objective

The primary goal of this research was to enhance patient activation and improve self-management of T2D using the US Department of Defense's (DoD) Mobile Health Care Environment (MHCE) in a PCMH setting. We hypothesized that the MHCE intervention will lead to improvement in patient activation, increase in T2D self-care, and improvement in clinical outcomes.

Methods

Trial Design

The trial design and methods are described in detail elsewhere [21]. This was a feasibility study within the DoD's Military Health System, which included a user-centered design phase and a feasibility trial conducted at two sites. In phase I, we assessed both patient and clinician preferences regarding MHCE technology capabilities and enhancements for T2D care. The phase II research was a single-blinded (patients only) 12-month feasibility study that incorporated randomization principles. We employed a 1:1 allocation ratio between the intervention and control groups.

The study was approved by the Institutional Review Boards (IRB) of Clemson University (#IRB2015-234) and the Madigan Army Medical Center (IRB #216073). The study was registered with ClinicalTrials.gov (NCT02949037) on October 31, 2016.

Participant Enrollment

Patients were recruited from the PCMH clinic schedule, provider referrals, distributed posters and fliers, and population health databases. Potential participants were scheduled for a screening visit with a study staff member to establish eligibility, discuss and execute an informed consent document, and were administered the Patient Activation Measure (PAM) instrument. Patients' PAM levels placed them in a stratified group, where patients were randomly allocated to intervention or control groups.

Clinicians practicing in the respective PCMH sites were invited to participate by the site's principal investigator; this was a convenience sample. The clinician participants met with their senior research associate to review the IRB-approved minimal-risk information sheet. For phase II, clinicians signed an informed consent document. The clinician participants were not blinded to the study.

Inclusion and Exclusion Criteria

Inclusion criteria for patient participation in phase I or II research included men and women (1) aged 18 years or older, (2) with the ability to understand and read English, (3) enrolled for primary care at one of the target PCMH sites, and (4) with a diagnosis of T2D. In addition, in phase II, we sought to recruit a maximum of 120 participants (per PCMH), with a proportional distribution of patients with PAM levels 1 through 4; a primer on PAM levels is included elsewhere [21,43]. As this is a feasibility study, we did not derive the 120 per site recruitment numbers from power calculations.

Inclusion criteria for clinician participation in phase I or II research included (1) physicians, physician assistants, nurse practitioners, or nurses at the target PCMHs and (2) providing care for patients with T2D.

Exclusion criteria for patient participation in phase I or II research included the following: (1) pregnant women; (2) non-English-speaking patients; (3) patients receiving hospice care; (4) patients having active cancer and receiving treatment with chemotherapy or radiation therapy; (5) patients taking warfarin; (6) patients that have been a recipient of gastric bypass or a similar procedure; (7) patients having a diagnosis of uncontrolled hypothyroidism; (8) patients having known Cushing syndrome; (9) patients being treated with oral steroids; (10) patients with known liver disease; (11) patients with a current diagnosis of cognitive impairments that would interfere with the use of technology; (12) patients having congestive heart failure, in New York Heart Association functional classification III or IV; and (13) patients unable to use a mobile device due to cognitive or physical impairments during initial screening.

Exclusion criteria for clinician participation in phase I or II research included the following: (1) not affiliated with the target site and (2) not providing care for patients with T2D.

Setting and Site Selection

We sought to purposefully assess MHCE use in T2D care in two distinctly different PCMH environments and locations. The patient base included those on active duty, retirees, and dependents who have typically spent years in the military.

The Madigan Army Medical Center was the US Army's second largest military treatment facility located in Tacoma, Washington, and was a tertiary facility with a level II trauma center and robust graduate medical education programs. They served a patient base of approximately 118,000 patients; about 7500 (or >6%) were living with T2D. Of the T2D population, about 15.00% (1125/7500) were active duty members or their dependents, and about 85.00% (6375/7500) were retirees and their dependents. Over half of the patients with T2D were aged 57-76 years. The study location within the medical center was an Internal Medicine PCMH with approximately 14,300 enrolled patients supported by a staff of 77 including 12 staff physicians and 8 residents.

The Mike O'Callaghan Federal Medical Center was a federal facility in the greater Las Vegas, Nevada area, which served approximately 47,000 patients; about 4500 (>9%) were living with T2D. Of the T2D population, about 4.00% (180/4500) were active duty members or their dependents, and about 96.00% (4320/4500) were retirees and their dependents. Over 72.00% (3240/4500) of the patients with T2D were aged ≥60 years. The study location within the medical center was a Family Medicine PCMH with approximately 7500 enrolled patients supported by a staff of 62 including 9 staff physicians and 26 residents.

Description of the Mobile Health Care Environment

The DoD's MHCE system is a secure health information system designed to support health services delivery and mHealth. The MHCE meets all physical and information security mandates, as prescribed by federal law and DoD regulation, for the protection of personal health information and personally identifiable information.

Intervention Overview

The intervention has been described elsewhere [21]. This intervention enhanced MHCE in several ways. First, the intervention enhanced the capacity to include collection and visualization of data from Bluetooth-enabled medical devices. This included mapping data from device output into the MHCE, developing data visualization appropriate for mHealth and clinical care (eg, graphing outcomes and temporal trend patterns), migrating data to an analysis cell, and developing decision-support algorithms that drive safety alerts and behavioral message reinforcement. The devices used in this study included a Bluetooth-enabled scale, glucometer, blood pressure reader, and activity monitor. Second, the intervention expanded the capacity of the MHCE analysis cell to manage large amounts of data and to conduct both routine reports and research applications. Third, the intervention added patient activation and associated measurement instruments to capture baseline and ongoing changes to patient activation. Fourth, the intervention expanded the MHCE messaging platform that research associates used to send tailored behavioral messaging to patients in an effort to influence greater activation and reinforce positive behavior. An annotated visual presentation of patient screenshots and workflow is included in Multimedia Appendix 1.

The MHCE was accessed by mobile phones and tablets that used either an IOS or Android platform. The MHCE requires internet access for patients to sync data from devices to the MHCE backend portal, to receive tailored behavioral messages, or to support other functions accessible by clinicians (Multimedia Appendix 2). During the study, patients received SMS messages with hyperlinks to a separate secure information system platform used for the administration and analysis of PAM and Summary of Diabetes Self-Care Activities (SDSCA) instruments.

Tailored Behavioral Messaging

A primary component of the MHCE system was tailored behavioral messaging. In this study, the research team developed behavioral messages tailored for each of the four PAM score levels; in total, we developed over 360 messages. The messages fell within 9 functional areas common to T2D care and the SDSCA survey: nutrition, home monitoring, physical activity, blood pressure, foot care, medications, smoking, glucose control, and general behavioral reinforcement. The message development process is outlined below (Textbox 1).

Textbox 1. Tailored behavioral messaging development process.

A multistage message development process was guided by patient activation levels and theoretical constructs relevant to those levels. Specifically:

- Step 1: Health behavior researchers developed messages tailored for each of the four Patient Activation Measure (PAM) score levels and five type 2 diabetes self-care behaviors measured by the Summary of Diabetes Self-Care Activities.
- Step 2: Messages were assessed by two-person teams for content accuracy, reading level, and message appropriateness for the PAM level. Messages were then revised based on this review process. A clinical advisory team consisting of clinicians and researchers reviewed and approved the messages for clinical relevance and content.
- Step 3: A pretest (n=21) of the messages with a population similar to those targeted for the larger study was administered. Each person was provided with a random sample of five messages based on their PAM level. They were then asked four close-ended questions and one open-ended question about the messages.
- Step 4: Researchers reviewed PAM level–specific messages and rated them as acceptable, questionable, or unacceptable based on appropriateness for PAM level, behavioral theory construct, reading level, and content accuracy. Messages were then revised based on this review process.

This process supported triangulation review of findings that yielded a set of 360 PAM-level appropriate messages. At each step in the process, messages were reviewed and revised based on research team member feedback (stages 2 and 4) or by potential study participant feedback (stage 3). Overall, the first two steps in the process produced messages with a high degree of acceptability by people very similar to the study population. Pretest participants found the messages to be encouraging, useful, applicable, and impactful. This indicates a high level of credibility with regard to the application of the theoretical constructs within the messages.

For patients with baseline PAM level 1, we used messages addressing the emotional state of feeling overwhelmed and passive with an emphasis on the importance of taking action. PAM level 2 messages were designed to build knowledge and self-efficacy and focus on taking small steps that can be accomplished without much in-depth knowledge. PAM level 3 messages focused on building self-management skills, such as goal setting and self-monitoring. PAM level 4 messages focused on avoiding relapse when stressed.

In phase II of our study, tailored behavioral messages were delivered to each intervention group participant, via the MHCE accessed through their mobile device, based on both senior research associate–initiated and algorithm-automated schedules and thresholds developed according to PAM level, SDSCA responses, and agreed-upon general rotation. Senior research associates used the MHCE backend portal control panel for manual rotational scheduling of messages delivered 3 days per week. Participant responses to the SDSCA and data from synced devices triggered additional messaging if their clinical readings from biomedical devices exceeded the established thresholds. If a patient's PAM level changed within the course of the study, the tailored behavioral messaging to that patient changed to align with the new PAM level.

Phase I User-Centered Design

In phase I, we captured feedback from patients on MHCE navigation, use of external devices, ease of use, and satisfaction. We collected baseline research participant data following informed consent. One researcher led individual participants through usability testing, and an additional researcher-observer recorded observations using an observation guide for recording time on task, number of attempts by task, task sequences, and participant questions/comments. Following a researcher-provided demonstration of the MHCE, each participant was requested to concurrently navigate each component of the MHCE system via a mini tablet device under their control. For each task, each participant was asked three open-ended questions to evaluate task-specific user satisfaction. The researcher delivered a brief demonstration of the external devices used in the study. Participants were requested to (1) manually upload data, (2) sync each device with the app, and (3) interpret graphs. The data collection instrument used in phase I is shown in Multimedia Appendix 3.

Researchers have evaluated usability by applying definitions and evaluation metrics guided by the International Organization for Standardization's 9241-11 usability framework and mHealth usability research [44]. Specific metrics to evaluate usability are effectiveness, efficiency, and satisfaction. Researchers used the Single Ease Question to evaluate informant satisfaction immediately after performing each task [45]. The system usability scale (SUS) was measured for overall informant satisfaction with the MHCE [46].

We assessed clinician preferences in phase I using focus groups at each study site. Two trained researchers facilitated focus groups using a semistructured interview guide to elicit feedback about the MHCE (Multimedia Appendix 4). A four-member team completed a thematically organized data analysis of the clinician and nurse feedback using an inductive narrative approach [47-49].

Phase II Controlled Study: Patient Enrollment and Study Flow

In phase II, we aimed to recruit 240 patients (120 per site), with one half assigned to a control group. Eligible patients were assigned to four strata according to their PAM levels. After all

patients were assigned, simple randomization was performed within each stratum to assign patients to either the MHCE (intervention) or control groups. Phase II research was conducted between July 2017 and November 2018.

Mobile Health Care Environment Intervention Versus Intervention-Lite (Control)

Patients in both the intervention and intervention-lite (control) groups received the device package mentioned above. These devices collected and recorded biometric data; participants were trained on the biomedical device and peripheral equipment use.

For the intervention group, the devices were mapped to the MHCE system accessible from the patients' mobile phone or an iPad mini tablet device. Data from their biomedical devices were visually presented in the MHCE with trend and scalable options. Safety algorithms were mapped to these clinical data to alert the participant and, depending on the measure, the clinical team when readings exceeded the established thresholds. The devices for the control group participants were not connected to the MHCE system.

Initial Outcome Measures for Patient Component

Primary outcome measures included the PAM scores. Secondary outcome measures in the study were (1) SDSCA responses, (2) clinical measures (Textbox 1), (3) comorbid conditions, and (4) SUS survey scores.

Patient Activation Measure Instrument

The self-reported PAM survey is associated with self-management behaviors, medication adherence, patient satisfaction, and quality of life [50,51]. Within a T2D-specific population, PAM is not related to knowledge regarding HbA_{1c} (the standard measure of average blood glucose level [52]), but it is associated with better glycemic control [53]. The PAM is a valid, reliable, unidimensional, and probabilistic Guttman-like scale instrument [43], and it is a standard tool to measure patient activation. We administered the PAM at screening visits in phases I and II and electronically every 3 months during phase II for both the intervention and control groups. In computing PAM in the analysis, we leveraged the 0-100 scoring mechanism based on licensing guidance from *Insignia Health*. PAM levels 1-4 are determined by the continuous PAM score.

Summary of the Diabetes Self-Care Activities Instrument

The SDSCA instrument is a brief self-report instrument for measuring levels of self-management across different components of the T2D regimen [54]. The SDSCA includes 11 core items associated with T2D self-care. The SDSCA has been successfully used in numerous T2D studies both within and outside the United States [54-58]. The SDSCA has been validated and is considered a standard instrument in T2D care for measuring self-care activities [54]. We administered the SDSCA at the intake visit for phase II and electronically every 2 weeks during phase II for both the intervention and control groups.

Clinical Measures

We collected clinical measures (Textbox 2) from patients at intake during phase I research. We collected and compared changes in clinical measures for both groups in phase II at 3 points: intake, midpoint (month six), and conclusion (month 12). Data were manually abstracted by senior research associates from the PHR. For patients assigned to the MHCE intervention group, the MHCE system recorded weight, systolic blood pressure, diastolic blood pressure, and blood glucose values to the MHCE module on a regular basis via Wi-Fi or Bluetooth-enabled peripheral equipment.

Textbox 2. Clinical measures in phase II.

- Glycated hemoglobin
- Low-density lipoprotein
- High-density lipoprotein
- BMI
- Abdominal circumference
- Systolic blood pressure
- Diastolic blood pressure

System Usability Scale Survey

The SUS survey is a 10-item Likert-like scaled survey used to convey a subjective assessment of system usability. The instrument was developed over 15 years ago and is used to measure the usability of websites [59]. In this study, we substituted the term "MHCE system" for the term "website" in the instrument. Phase I participants completed the SUS survey at the conclusion of the encounter. Phase II intervention group participants completed the SUS survey at the midpoint and study conclusion.

Comorbid Conditions

We assessed and documented comorbid conditions among both the control and intervention groups during the prescreening of eligibility, at intake, at study midpoint, and at study conclusion. Although not primary outcome measures, any change in comorbid conditions was assessed.

Data Analysis Strategy

We conducted the primary analyses for phase II using an intent-to-treat approach. Achievement of randomization was evaluated by comparing the baseline key variables between the MHCE intervention group and the control group. These baseline

characteristics were compared using Kruskal-Wallis tests for continuous variables, Cochran-Armitage trend tests for ordinal variables, and chi-squared tests for binary variables and multinomial variables. Exact tests were performed to account for categorical variables with small cell counts.

Generalized estimating equations (GEE) with an autoregressive correlation structure were used to test the hypotheses that patients who participated in MHCE had higher PAM, SDSCA, and improved selected clinical outcomes and comorbid conditions than their control counterparts. The predictors in the model included a binary variable for a group, a three- or five-level categorical variable for time (depending on the number of repeated measurements for the outcome), and their interaction. All models included covariate adjustment for site, age, sex, race, duration of disease, work status, and baseline physical activity level. As the intervention group messages were tailored to each subject based on their baseline PAM level, we examined the effect of intervention within each baseline PAM level by including a three-way interaction between intervention, time, and baseline PAM level in the GEE models. CIs are reported to assess changes within groups. Within-group changes (from baseline) in outcomes are deemed significant at the alpha=.05 level if the estimated CIs exclude 0. Between-group comparisons of change (from baseline) in outcomes are deemed significant for two-sided *P* values< 0.5.

GEE were also used to test the hypothesis that patients who engaged at a higher rate with the interactive and tailored mobile technology in MHCE realized greater improvement in PAM level, SDSCA, and clinical measures. We defined the main independent variable for MHCE usage by an indicator variable set to 1 if the percentage of days engaged with MHCE in a 3-month period exceeded 80% (strong adherence). As adherence varies with time, the GEE model assumed working independence for the correlation structure [60]. All GEE analyses were conducted using the Generalized Linear Model procedure in the Statistical Analysis System.

Results

Phase I—User-Centered Design Research Participants

The research team recruited 10 research participants per site, with 20 participants for phase I. The study sample was 70% (14/20) male, 65% (13/20) white, middle-aged (average 62.8, range 40-82 years), obese (median BMI 33.7, range 24.3-43.5), with elevated blood sugar levels (median HbA_{1c} 7.2, range 5.8-12.2), and increased patient activation, 75% (15/20) with PAM level 3 scores at intake. Phase I research was conducted between November and December 2016.

Phase I—Participant (Patients) Effectiveness With Mobile Health Care Environment Technology

Overall, participants performed better with goal-setting tasks (almost all completed these tasks without assistance), showed some difficulty with tasks that required manual entry (the majority could do so with little to no assistance), and had the most difficulty with Bluetooth syncing of devices (approximately half needed assistance or could not complete; Table 1).

Table 1. Phase I participant effectiveness with the technology. Here, n denotes the number of responses in each category.

Site and effectiveness	Blood pressure goal setting	Glucose goal setting	Weight goal setting	Steps goal setting	BP manual entry	BP sync with device	Glucose manual entry	Weight manual entry	Weight sync with device
Madigan, n									
Completed without help	9	9	9	5	7	1	7	5	4
Needed hints	1	0	1	4	3	7	3	5	3
Failed to complete	0	1	0	1	0	2	0	0	3
Nellis, n									
Completed without help	8	9	8	9	8	4	9	7	6
Needed hint(s)	2	1	2	1	2	6	1	3	4
Failed to complete	0	0	0	0	0	0	0	0	0
Combined, n									
Completed without help	17	18	17	14	15	5	16	12	10
Needed hint(s)	3	1	3	5	5	13	4	8	7
Failed to complete	0	1	0	1	0	2	0	0	3

Phase I—Participant (Patient) Efficiency With Mobile Health Care Environment Technology

Overall, goal setting and manual entry tasks took the least amount of time to complete, and Bluetooth syncing tasks took the most time (Table 2).

Phase I—Participants and System Usability Survey Results

All phase I participants were administered a SUS related to MHCE use. The survey results were very favorable and related to the usability of MHCE. Specifically:

- SUS overall, Mean (SD): 83.8 (SD 14.9)=A+

- Usability sub factor, mean (SD): 86 (SD 13.4)=A+
- Learnability subfactor, mean (SD): 75 (SD 27.5)=A−

Phase I—Results of the Qualitative Research Component (Patient Participants)

All participating participants indicated that the MHCE would "help them manage their diabetes" and give their health care provider a "better report of their health." As expected, patients rated navigation tasks as "less difficult" and peripheral device tasks, for example, syncing, as "more difficult." An overview of usability testing and patient feedback is included in Multimedia Appendix 5. Participants committed fewer errors with basic navigation tasks and more with peripheral devices. Patient participants suggested minor changes regarding the look and function of the app (Textbox 3).

Phase I—Results of the Qualitative Research Component (Clinicians)

Overall, clinicians voiced a sense of optimism for the MHCE system, tempered with recommendations aimed at improving the patient experience, clinician adoption, and use of the data it generated. Clinician participants also suggested changes related to quality and safety (Textbox 4).

Technology Adaptation Following Phase I Research and Before the Launch of Phase II

Patient and clinician suggestions were reviewed and incorporated as adaptations by our technology team within system constraints. A total of 29 specific recommendations were made to the technology team; 86% (25/29) of the recommendations were positively acted on and modifications occurred. Only 4 recommendations could not be supported (Textbox 5).

Table 2. Participant efficiency with technology.

Task	BP[a] goal setting	Glucose goal setting	Weight goal setting	Steps goal setting	BP manual entry	BP sync with device	Glucose manual entry	Weight manual entry	Weight sync with device
Madigan, mean[b] (SD)	55.02 (37.08)	19.83 (7.80)	40.18 (45.57)	61.31 (54.80)	48.00 (31.01)	121.74 (28.09)	32.09 (15.96)	54.09 (38.54)	65.08 (27.18)
Nellis, mean (SD)	51.53 (53.12)	30.29 (18.77)	19.02 (12.67)	19.91 (11.75)	46.44 (32.56)	103.04 (47.05)	30.10 (20.95)	35.37 (23.98)	68.09 (37.23)
Combined sites, mean (SD)	53.18 (45.00)	25.64 (15.50)	29.60 (34.31)	40.61 (44.04)	47.22 (30.97)	111.90 (39.37)	31.09 (18.15)	44.73 (32.69)	66.75 (32.25)

[a]BP: blood pressure.

[b]Mean denotes mean time in seconds.

Textbox 3. Participants' suggestions for Mobile Health Care Environment improvement.

- Suggestion #1: To increase the size of icons as they were difficult to see.
- Suggestion #2: To improve glucose graph responsiveness.
- Suggestion #3: To increase the font size for the Mobile Health Care Environment (MHCE) interface.
- Suggestion #4: To allow past dates for manual entry into the MHCE.

Textbox 4. Clinicians' suggestions related to app safety alert functions.

- Change default blood glucose entry to "Unclassified," forcing patient entry of "after meal," "bedtime," or "fasting."
- Define "after meal" glucose as >120 min post meal.
- Simplify safety alerts on the backend clinician portal.
- Add icons besides safety alerts.
- Add patient target ranges on graphs.

Textbox 5. Recommendations that could not be adopted.

1. Desire for additional colors (limited colors were available).
2. Remove signal and refresh buttons (component of the base system).
3. Add alert icons (limited icon choices available).
4. Automatic syncing of devices (system could not support).

Safety Algorithms Developed and Deployed in Phase II

The research team developed and implemented a series of safety alerts into the MHCE technology. These include thresholds and alerts for high/low blood glucose, high/low blood pressure, and weight loss/gain. Details on safety alerts are identified in a report attached as Multimedia Appendix 6.

Phase II—Participant Randomization, Retention, and Comorbidities

A total of 240 participants met the study eligibility criteria and were randomized (117 to control group and 123 to intervention group). Of the 117 participants randomized to the control group, 5 withdrew before intake, 3 declined participation, and 2 did not meet the inclusion/exclusion criteria. Of the 123 participants randomized to the intervention group, 6 withdrew before intake, 3 declined participation, 1 did not meet the inclusion/exclusion criteria, and 2 did not provide reason. Thus, the final sample size consisted of 229 participants, with 112 randomized to the control group and 117 randomized to the intervention group.

Study retention and participation was high; 93.0% (213/229) of participants remained in the study through 12 months: 99.1% (111/112) in the control group and 86.3% (101/117) in the intervention group. One participant who withdrew from the control group cited a lack of ability to use the physical activity monitor as their primary reason for discontinuation. Of the 16 participants who did not complete the 12-month intervention, 8 cited technical issues with MHCE as their primary reason, 6 listed either a time constraint or relocation as their primary reason, and 2 were lost to follow-up. The specific technical issues cited by the 8 participants withdrawing from the study were not fully known. Anecdotal evidence received by the senior research associates suggested that a few patients were frustrated with system upgrades and challenges with occasional manual synching of devices.

Throughout the 12-month study, 20.6% (21/102) presented new comorbidities in the control group, and 11% (11/96) of subjects presented new comorbidities in the intervention group (χ^2_1=3.2; *P*=.07). On the basis of the covariate-adjusted GEE model, the estimated odds of a new comorbidity throughout the study was 2.27 times higher for the control group than for the intervention group (χ^2_1=3.9; *P*=.047).

Phase II—Baseline Characteristics

Table 3 provides the study baseline demographics and outcomes at baseline. Participants had a mean age of 62.9 (SD 10.3) years, a mean BMI of 32.7 (SD 6.2), and were 61.6% (141/229) male. Mean HbA_{1c} was in the high range (mean 7.5%, SD 1.4%). The mean duration of T2D was 9.8 (SD 7.5) years. The study cohort was well educated; 87.8% (201/229) attended some college and 55.5% (127/229) had a college degree or higher. In this sample, 10% (23/229) of patients had a baseline PAM level of 1 (14/112, 12.5% in control group, 9/117, 7.7% in intervention group), 14.8% (34/229) had a baseline PAM level of 2 (19/112, 17.0% in control group, 15/117, 12.8% in intervention group), 51.5% (118/229) had a baseline PAM level of 3 (55/112, 49.1% in the control group, 63/117, 53.8% in the intervention group), and 23.6% (54/229) had a baseline PAM level of 4 (24/112, 21.4% in control group, 30/117, 25.6% in intervention group). Between group differences were not statistically significant (*P*=.13). The control and intervention groups were well balanced on most baseline characteristics, with the exception of work status (unemployment: 77/112, 68.8% in the control group, 59/117, 50.4% in the intervention group; full-time employment: 27/112, 24.1% in control group, 42/117, 35.9% in intervention group; *P*=.02), baseline low-density lipoprotein (LDL) cholesterol (control group: mean 97.1, SD 39.1; intervention group: mean 80.9 (SD 36.5); *P*=.001). Due to this imbalance, we adjust for these variables in all models.

Table 3. Characteristics of phase II participant demographics and outcomes at baseline.

Variable	Total	Group		*P* value
		Control	Intervention	
Demographics				
Age (years), mean (SD)[a]	62.9 (10.3)	63.2 (9.8)	62.5 (10.8)	.49

Phase II—Primary Outcomes

Within- and between-group comparisons based on GEE are displayed in Table 4. For each intervention group, we assessed changes in the outcome between baseline and month 6 and baseline and month 12. For each group, CIs that exclude 0 indicate a significant change in the outcome between baseline and a given month. *P* values <.05 indicate that this change in the outcome was significantly different between the intervention and control groups. At months 6 and 12, statistically significant improvements were seen in the control group for PAM (month 6: control group improvement=4.81, 95% CI 2.21 to 7.42; month 12: control group improvement=7.49, 95% CI 4.44 to 10.55). That is, improvement in PAM for the control group was 4.81 between baseline and month 6 and 7.49 between baseline and month 12. Although the intervention group showed slight improvement in PAM, these improvements were not statistically significant (month 6: intervention group improvement=1.57, 95% CI −1.34 to 4.48; month 12: intervention group improvement=1.77, 95% CI −1.02 to 4.57). The improvement in the control group was significantly greater than the improvement in the intervention group at month 12 only (month 6: between-group difference=3.24; *P*=.10 and month 12: between-group difference=5.72; *P*=.007).

For each group, estimates (and the corresponding CIs) are given for the *change* in outcome between month 6 and baseline and month 12 and baseline. CIs that exclude 0 indicate statistically significant within-group change between a given month (ie, month 6 or 12) and baseline. The first *P* value column corresponds to testing whether the change in outcomes between month 6 and baseline is different between the 2 groups. The second *P* value column corresponds to testing whether the change in outcomes between month 12 and baseline is different between the 2 groups.

Table 4. Analysis of change from baseline at midpoint and study end.

Outcome	Month 6			Month 12		
	Control, OR[a] (95% CI)	Intervention, OR (95% CI)	*P* value	Control, OR (95% CI)	Intervention, OR (95% CI)	*P* value
Patient Activation Measure score	4.81 (2.21 to 7.42)	1.57 (−1.34 to 4.48)	.10	7.49 (4.44 to 10.55)	1.77 (−1.02 to 4.57)	.007
Summary of Diabetes Self-Care Activities score	7.52 (5.43 to 9.61)	7.52 (5.30 to 9.73)	>.99	6.97 (4.40 to 9.55)	7.52 (5.06 to 9.97)	.77
Glycated hemoglobin	−0.36 (−0.57 to −0.14)	−0.18 (−0.36 to 0.01)	.21	−0.53 (−0.78 to −0.29)	−0.11 (−0.28 to 0.07)	.006
BMI (kg/m^2)	−0.31 (−0.62 to 0.00)	−0.28 (−0.53 to −0.02)	.86	−0.45 (−0.82 to −0.07)	−0.36 (−0.62 to −0.10)	.72
Waist (inches)	−0.57 (−0.96 to −0.19)	−0.76 (−1.09 to −0.44)	.46	−1.46 (−1.95 to −0.98)	−1.49 (−1.90 to −1.07)	.95
Diastolic blood pressure (mm Hg)	−1.83 (−3.81 to 0.15)	−0.58 (−2.30 to 1.14)	.35	−2.18 (−3.98 to −0.38)	−1.72 (−3.22 to −0.22)	.70

[a]OR: odds ratio.

Phase II—Secondary Outcomes

At month 6, the control group exhibited statistically significant improvements in HbA_{1c} and LDL cholesterol (as indicated by the CIs in the first column of Table 4). Both intervention and control groups exhibited statistically significant improvements in SDSCA, BMI, and waist size. However, the differences between the intervention and control groups on improvements in these outcomes were not significantly different at month 6 (as indicated by *P* values >.05 in the third column of Table 4). At month 12, statistically significant improvements occurred in SDSCA, BMI, waist size, and diastolic blood pressure in both the intervention and control groups. The control group also exhibited significant improvements in HbA_{1c} and LDL cholesterol at month 12, and these improvements were significantly greater compared with those of the intervention group (HbA_{1c}: between-group difference=−0.42; *P*=.006 and LDL cholesterol: between-group difference=−11.52; *P*=.01).

Phase II—Stratified Analyses by Baseline Patient Activation Measure Level

The intervention is tailored according to baseline PAM level, and therefore, we expect the effect of intervention over time to differ by subjects' baseline PAM level. To test this, a three-way interaction term for the intervention group, time, and baseline PAM level was incorporated into the above GEE models. The results for the change between baseline and end of study (month 12) for each group, stratified by baseline PAM level, are presented in Tables 5 and 6.

Within each baseline PAM level, estimates (and corresponding CIs) are given for the *change* in outcome between month 12 and baseline for both the intervention and control groups. CIs that exclude 0 indicate statistically significant within-group change between month 12 and baseline for subjects in a given PAM level. The *P* value column corresponds to testing whether the change in outcomes is different between the intervention and control groups within a given PAM level.

Among subjects with baseline PAM level 1, both intervention and control groups exhibited significant improvements in PAM score at month 12 (control group improvement=20.38, 95% CI 13.05 to 27.71; intervention group improvement=15.93, 95% CI 8.99 to 22.87); however, between-group differences did not reach statistical significance (*P*=.39). On secondary outcomes, the control group exhibited significant improvements in waist size, diastolic, and systolic blood pressure. The intervention group exhibited significant improvements in SDSCA, HbA_{1c}, BMI, waist size, and HDL cholesterol. Statistically significant between-group differences occurred only in HbA_{1c}, BMI, and HDL cholesterol, indicating that the intervention group exhibited greater improvement in these outcomes compared with the control group (HbA_{1c}: between-group difference=−0.43, *P*=.04; BMI: between-group difference=−1.80, *P*=.01; HDL cholesterol: between-group difference=8.42, *P*<.001).

Table 5. Analysis of change from baseline to study end by baseline Patient Activation Measure level.

Outcome	Baseline PAM[a] level 1			Baseline PAM level 2

[a]PAM: Patient Activation Measure.

[b]OR: odds ratio.

Among subjects with baseline PAM levels 2 and 3, both the intervention and control groups exhibited significant improvements in PAM, SDSCA, and waist size. However, between-group differences were not statistically significant. The control group also exhibited significant improvements in HbA_{1c}; between-group differences were significant among those with baseline PAM level 3 only (between-group difference=−0.45; *P*=.02). The intervention group also exhibited significant improvement in BMI among subjects with PAM level 3, but the between-group differences did not reach statistical significance.

Among subjects with baseline PAM level 4, the intervention group exhibited a significant decrease in PAM (intervention group change=−10.49; 95% CI −16.54 to −4.44), whereas control subjects exhibited no significant change (control group change=−1.44; 95% CI −7.39 to 4.50). This difference in change

was statistically significant (between-group difference=−9.05; *P*=.04). The control group exhibited significant improvements in SDSCA, HbA_{1c}, and BMI. Both groups exhibited significant improvements in waist size. However, between-group differences did not reach statistical significance in these outcomes.

Phase II—Participant Engagement and Usability

The percentage of subjects who engaged with MHCE at least 50% of the days in each time period was 60.7% (68/112) for months 0-3, 57.4% (62/108) for months 3-6, 49.5% (51/103) for months 6-9, and 43% (42/98) for months 9-12. The percentage of subjects who engaged with MHCE at least 80% of the days in each time period was 41.1% (46/112) for months 0-3, 41.7% (45/108) for months 3-6, 14.6% (15/103) for months 6-9, and 26% (25/98) for months 9-12. Strong adherence, defined engagement with MHCE on at least 80% of days in each time period, was associated with improvement in all outcomes. However, only the association with HbA_{1c} reached statistical significance (mean improvement=0.35; *P*=.049).

The mean SUS score for the MHCE group was 75.6 (SD 17.3) at month 6 and 76.8 (SD 14.8) at month 12. Strong adherence was associated with a higher SUS score (average increase=5.01; *P*=.04). As SUS was not recorded for the control group, group differences could not be compared.

Discussion

Principal Findings

The primary goal of this large feasibility study was to enhance the PAM level and improve self-management of T2D care using the DoD's interactive and tailored MHCE system for T2D in a PCMH setting. To this end, we hypothesized that a user-centered design process would successfully shape the development of the MHCE for use in the self-management of T2D care. The research team engaged both patients and clinicians, observing patient and clinician overall satisfaction with the MHCE, high SUS (A+ and A−) scores, and 29 offered recommendations for system improvement; 86% (25/29) of these recommendations resulted in intervention modifications before feasibility testing. The methods and findings from the study's phase I research align well with the aging barriers addressed by Wildenbos et al [61]. These include cognitive, physical ability, perception, and motivational barriers.

When comparing this study with comparable mHealth studies, there were differences in participant demographics. Specifically, our research participants tended to be older (age: mean 62.9 years, SD 10.3) than participants in other studies [36,38,62-69] and had a larger BMI (32.7 kg/m^2, SD 6.2 kg/m^2) at baseline [62,64-66,68]. This study engaged a substantial percentage, 59.4% (136/229), of unemployed participants; most of them were military retirees. Finally, our research participants were members of a PCMH site within one of two military treatment facilities (ie, military run hospitals) and as such typically received health care services with no (or minimal) out-of-pocket costs. A descriptive primer on this federal health system has been published [70].

Overall retention was high in this study, 93.0% (213/229) for the 12-month study, which is consistent with other mHealth projects [66] and demonstrates the feasibility of conducting a PCMH intervention among T2D patients. The 12-month duration of this study was longer than loosely comparable studies, which generally targeted a 9-month [36,63], 6-month [64,65], or 3-month duration [38,62].

The team hypothesized that the use of the MHCE would increase the PAM and self-care activities of patients with T2D and that patients who engage at a higher rate with the MHCE would realize improvement in clinical measures. In our study, both intervention and intervention-lite (control) groups showed significant improvement from baseline to 12 months in SDSCA (measuring self-care activities) as well as in BMI, waist size, and diastolic blood pressure control. A somewhat surprising finding in the study is that only the control group exhibited significant improvement in the PAM score. Furthermore, improvements in the control group exceeded improvements in the intervention group for most clinical outcomes.

However, a closer analysis of the data reveals a complex yet intriguing pattern of how mHealth intervention effectiveness can vary by the baseline level of patient activation. With the exception of patients with the highest level of activation (PAM level 4), all intervention group patients exhibited significant improvements in the PAM score. Furthermore, the intervention appears to be superior to control for patients with the lowest level of activation (PAM level 1). In this class of patients, the intervention group showed significantly greater improvements at the end of the study in HbA_{1c}, BMI, and HDL cholesterol levels compared with the control group (these were the only significant differences between the groups). This finding may suggest that in a resource-limited health system environment, a targeted investment in mHealth to support self-management of T2D for PAM level 1 patients may yield optimal results compared with patients who are more activated. With the more activated patient, demonstrating higher PAM scores, a less costly peripheral device (eg, glucometer, activity monitor, and scale) may by itself enhance self-care activities.

Our finding that the intervention group exhibited significant improvements over the control group in several cardiovascular outcomes in T2D patients with baseline PAM level 1 is consistent with previous findings that text messaging is effective in helping patients with T2D achieve better glycemic control [16,36,71]. Although tailored messaging did not generate superior results compared with the control group for patients with higher PAM levels, it does not suggest that the PAM-aligned tailored behavioral messaging was faulty or should be discarded. In our study, the DoD technology partners secured the tailored behavioral messaging embedded within the MHCE under an indicator labeled as "health tips." However, because of privacy concerns, patients could only see the message after logging into the MHCE mobile app through its security layers to view the message. The multistep process of accessing the messages was indirect and could have been overlooked on the patients' personal cell phone. Future efforts should consider redesigning the MHCE (or mHealth platforms) to accommodate nonpersonal health information (PHI) and tailored health

message delivery to the patient in his/her preferred communication process. Most of this will likely be via mobile app push notifications and/or text messaging. Several published studies have successfully leveraged tailored health messaging (without PHI), delivered in a direct delivery process via text messaging to participants [16,36,69]; one study was very short term in nature [69].

Although SUSs remained constant throughout the study and were associated with increased patient engagement, overall patient engagement with the MHCE system decreased throughout the study period. Decreased engagement may be partly explained by frustration with system upgrades and synching of devices expressed by some patients, along with the multistep process of MHCE discussed above. However, high levels of initial patient engagement in other mHealth projects that drop off after 6 to 12 months have been observed [16,63,72]. This might suggest that systems such as the MHCE may be optimally deployed in self-care of T2D for periods up to about 6 months; lengthy engagement (>6 months) may not generate the desired results.

Limitations

Our study design is not immune from potential threats to validity. Both the intervention and control groups were issued the same clinical outcome measuring devices and completed the biweekly SDSCA survey. However, we do not have information on whether patients in the control group did the synchronization of their measuring devices to their mobile phones, tablet computers, or desktop/laptop computers for viewing and tracking purposes. Therefore, we cannot rule out the possibility that a substantial proportion of the control group had access to visualized tracking information similar to the intervention group. For these patients, improvement in these outcomes may be explained by the same mechanisms whereby self-weighing is linked with weight loss [73]. Another limitation of the study is that food intake and daily activities outside the research sites are uncontrolled due to the nature of this type of field experiment.

Finally, although our study included user-center design testing (including solicitation of user design preferences) and ultimately generated a high retention rate for the 12-month study, patient engagement with MHCE decreased throughout the course of the phase II study. This trend was also seen in previous mHealth projects, and future studies should therefore consider incorporating follow-up participant assessments of continued engagement. If implemented following phase I, this may help the understanding of discontinued engagement and provide opportunities for improvement.

Acknowledgments

Research was extramurally funded by the US Army Medical Research Acquisition Activity contract #W81XWH-15-C-0070. The funder did not influence the design of the study or strategies related to its collection, analysis, or interpretation. The views expressed are those of the authors and do not reflect the official policy of the US Department of the Army, the Department of the Air Force, the Department of Defense, or the US Federal Government.

Authors' Contributions

RG initially conceptualized the study, and both RG and LR wrote the initial draft of the manuscript. PC, RG, KE, MH, KC, and JM assisted in the setting of the narrative, enrollment strategies, and institutional review board–related issues. The technical aspects of the intervention and MHCE description were authored by JL and RG. The biostatistics and data analysis strategies were developed by LC, LS, and LR. The patient activation activities in the study were coordinated by MH, KC, JM, AS, KP, and KE. The user-centered design and qualitative component were researched and authored by JW, SG, and KE. The outcome measures component was conceptualized and authored by PC, KT, LS, LZ, JW, LC, MH, and KE. The clinical components, including the inclusion and exclusion criteria, were developed by PC, JM, MH, KE, and RG. The Military Health System review and components were authored by JM, MH, KE, and RG. Active site Principal Investigators in the study were PC and RM. Acquisition and formatting of data for analysis were conducted by KT, LC, MA, and EH. Statistical analyses were conducted by LR, KT, BL, and LS. Interpretation of the data was performed by LR, RG, LS, and KT. All authors read, contributed to, critically reviewed, and approved the final manuscript.

Conflicts of Interest

JL and AS are federal employees charged with oversight of the DoD’s MHCE mHealth system used in the study. None of the other authors report any conflicts of interest.

Abstract

Background: Social anxiety disorder is a highly prevalent and burdensome condition. Persons with social anxiety frequently avoid seeking physician support and rarely receive treatment. Social anxiety symptoms are frequently underreported and underrecognized, creating a barrier to the accurate assessment of these symptoms. Consequently, more research is needed to identify passive biomarkers of social anxiety symptom severity. Digital phenotyping, the use of passive sensor data to inform health care decisions, offers a possible method of addressing this assessment barrier.

Objective: This study aims to determine whether passive sensor data acquired from smartphone data can accurately predict social anxiety symptom severity using a publicly available dataset.

Methods: In this study, participants (n=59) completed self-report assessments of their social anxiety symptom severity, depressive symptom severity, positive affect, and negative affect. Next, participants installed an app, which passively collected data about their movement (accelerometers) and social contact (incoming and outgoing calls and texts) over 2 weeks. Afterward, these passive sensor data were used to form digital biomarkers, which were paired with machine learning models to predict participants' social anxiety symptom severity.

Results: The results suggested that these passive sensor data could be utilized to accurately predict participants' social anxiety symptom severity (r=0.702 between predicted and observed symptom severity) and demonstrated discriminant validity between depression, negative affect, and positive affect.

Conclusions: These results suggest that smartphone sensor data may be utilized to accurately detect social anxiety symptom severity and discriminate social anxiety symptom severity from depressive symptoms, negative affect, and positive affect.

Introduction

Background

Social anxiety disorder (SAD) affects approximately 13% of Americans [1]. It is characterized by an intense, persistent, and exaggerated fear of evaluation or scrutiny in social situations and associated with behavioral avoidance [2]. SAD has a high socioeconomic cost, as it is associated with increased risk of school dropout, reduced productivity in the workplace, and lower quality of life [3]. Individuals with SAD symptoms are also at increased risk for developing depressive disorders [4], with comorbidity rates estimated between 30% and 70% in clinical and community samples [5-7].

Broadly speaking, anxiety around social situations (eg, fear of rejection or embarrassment) is relatively commonplace and can negatively impact individuals even outside the confines of this diagnostic category [8]. Furthermore, given the social inhibition and private anguish inherent to this pathology, SAD symptoms are often mistaken for shyness by others or perceived as a character flaw by the individual. As a result of these misconceptions, the nuanced effects of the condition are frequently underreported and underrecognized. Indeed, individuals with SAD often avoid consulting physicians about their psychological problems [9], and studies estimate that only 35% of individuals who meet clinical criteria receive treatment [3]. Thus, a sizable proportion of individuals who are struggling with SAD symptoms and could benefit from intervention go unaided. Moreover, there is a large time gap between disorder onset and the individual receiving treatment, with 36% experiencing SAD for more than 10 years before seeking help [10]. Currently, much of our understanding of the occurrence and presentation of SAD symptomatology is based on dispositional measures that have limited ecological validity. There is a great need for novel methodologies to improve our understanding and ability to identify individuals who may be vulnerable to developing this debilitating condition.

Smartphones have shown promise in recent years as ecologically valid tools for monitoring and predicting one's behavior and psychological state [11-14]. Specifically, passive usage and sensor data streams (eg, accelerometers, microphones, and GPS) offer insight into momentary behaviors that can serve as proxies for important mental health variables. The overarching goal of harnessing such data is to better understand, predict, and ultimately intervene when subtle behaviors are suggestive of problematic pathology. These data can be used to evaluate indicators of pathology over time with minimal burden or cost to the individual, researchers, or the broader health care system. Previous research examining patterns of smartphone use by socially anxious individuals have investigated a number of constructs including level of smartphone *addiction* [15,16], communication preferences (eg, preference for texting over voice calls) [17], behavioral markers before outgoing phone calls [18], location data (ie, using GPS) [19], and use of camera and health-related apps [20].

Previous Findings

Despite the promise of offering a better understanding of the contextual factors related to SAD symptom severity, most of the current research to date has not examined whether symptom severity can be accurately predicted utilizing only sensor data (ie, without additional severity indicators). This investigation is necessary to assess the utility of smartphone sensor data as a stand-alone predictive tool. Particularly, research is needed to determine whether passive sensor data could present a viable alternative to traditional assessments. Some research has examined the within-sample correlations of specific sensor metrics related to SAD symptom severity with significant correlations between some passive sensor data, including location, movement, calls, and texts [19,21]. However, correlations presented in previous publications have been based on general linear models utilizing the entire dataset and, consequently, may overfit the sample and overestimate how well these models would generalize to new independent samples [22]. In addition, the correlations used in these methods were not based on machine learning models, which can combine features to better predict SAD symptom severity (consequently, the absolute correlations between these features and social anxiety were only 0.01-0.36). The study by Boukhechba et al [21] was the only previous study that used the same publicly available data contained within this study.

To date, few researchers have investigated the out-of-sample accuracy of predicting social anxiety from these passive sensors [17,20]. Rather than examining SAD symptom severity continuously, one such study created three categories of SAD symptom severity (low, mid, and high) [18], which artificially and arbitrarily changes the scale and reduces the variance of the outcome [23]. Although previous researchers were successful in predicting social anxiety severity from phone calls, the out-of-sample prediction only explained 15.38% of the total variation in symptoms based on the statistics reported [19], indicating that the majority of the variance is explained by other variables not captured in the model. Consequently, although passive sensor data hold promise in assessing constructs related to SAD symptom severity, more research is needed to determine whether passive data can accurately predict symptoms to the degree that they represent a potential alternative to traditional assessments.

Study Aims

This study sought to test the utility of passive smartphone sensor data (ie, incoming and outgoing calls, text messages, and accelerometer data), gathered over 2 weeks via the Sensus mobile app as predictors of SAD symptoms in an unselected sample of undergraduates. Studies show that anxiety symptoms are common in undergraduate populations [24], and analog samples are useful for examining this pathology on a continuum [25]. Moreover, the study also utilized this sample to limit the influence of heterogeneity, given that undergraduates often experience similar environmental stressors and life phases. We hypothesized that we would be able to accurately predict SAD symptom severity with at least moderate accuracy (correlations greater or equal to 0.5 between out-of-sample predicted and observed social anxiety symptom severity) [26]. We also hypothesized that the predicted SAD symptom severity would show discriminant validity, evidenced by significantly higher correlations between the observed and predicted SAD symptom severity, compared with correlations with measures of affect (ie, depression symptoms, negative affect, and positive affect). Furthermore, given the novel nature of these data, we had some exploratory aims namely, we were interested in whether the data indicated any nuanced biomarkers that may be worth examining in future iterations of this work.

Methods

Participants

The current sample comes from a public use dataset [21]. A total of 72 undergraduate students within the United States consented to participate in the study (37/72, 51% female, mean age 19.8 years, SD 2.4; age range 18-23 years; 30/72, 41% white, 27/72, 37% Asian, 3/72, 4% black, 3/72, 4%

Latinx/Hispanic, and 9/72, 12% multiracial or unspecified). Participants were recruited through email advertisements sent to university email listserv for undergraduate students and the psychology department study participant pool. Participants were required to own their own Android devices (with an operating system 4.3 or higher). Although 72 participants were enrolled, only 59 with any phone calls, text data, and accelerometer data across the study period were a part of this study (all three channels were required to be included in the current analysis).

Measures

Social Interaction Anxiety Scale

The Social Interaction Anxiety Scale (SIAS) represented the primary outcome for this study [27]. The SIAS assesses the level of anxiety experienced in social situations using 20 self-report statements. Participants rate each of these items on a 0 (*not at all characteristic of me*) to 4 (*extremely characteristic of me*) Likert scale. In comparing patient populations with nonpatient populations, the SIAS demonstrated superior ability in differentiating SAD from nonanxious controls, with 82% to 86% sensitivity and 82% to 90% specificity using a cutoff point of 34 [28,29]. The SIAS also demonstrated high convergent validity (r=0.72) with the social phobia scale [28]. Previous research suggests that the optimal cutoff score for differentiating clinically significant SAD for the SIAS is 36 and that this cutoff point results in 93% sensitivity and 60% specificity in differentiating SAD from other clinically anxious groups, including panic disorder and agoraphobia [30]. Thus, the SIAS has strong convergent and discriminant validity in assessing a range of social anxiety symptoms. Moreover, the internal consistency of the SIAS in the current sample was good (alpha=.83) [11].

Depression, Anxiety, and Stress Scale—Depression Scale

The Depression, Anxiety, and Stress Scale (DASS-21) was used to assess depressive symptoms as a measure of discriminant validity for the study. The depression scale has excellent convergent validity (r=0.78 with the personal disturbance depression scale, r=0.66 with the Hamilton depression scale) [31] and adequate discriminant validity (r=0.62 for personal disturbance anxiety scale, r=0.59 for the Hamilton anxiety scale) [31]. The depression scale also has excellent internal consistency in the current sample (alpha=.91) [11].

Positive Affect Negative Affect Schedule

The positive affect negative affect schedule (PANAS) is a commonly utilized measure of positive and negative affect and was used in this study as a means of assessing discriminant validity [32]. The PANAS is a 20-item instrument that asks participants to rate the degree to which they experience positive (eg, *alert*, *inspired*, *enthusiastic*) and negative (eg, *distressed*, *upset*, *guilty*) affect *in general* on a 1 (*very slightly or not at all*) to 5 (*extremely*) Likert scale. The negative affect subscale of the PANAS has demonstrated convergent validity with the Beck Depression Inventory (r=0.58), the Hopkins Symptom Checklist (r=0.74), and the State Trait Anxiety Inventory state anxiety scale (A-State; r=0.51); while the positive affect subscale is negatively correlated with these measures (rs=−.35, −.19, and −.35, respectively [32]). Both subscales exhibit good internal consistency (alpha negative affect=.87, alpha positive affect=.88 [32]; note that the raw items were not reported for this sample, so the internal consistency of these scales is unknown for the current sample).

Passive Sensor Data

Accelerometer data were collected once per second (1/Hz) for the duration of the study. Notably, accelerometers sampled at this frequency have been used to detect related psychopathology (eg, major depression and bipolar disorders; pain and worry severity) [33-35]. Likewise, incoming and outgoing calls and text timestamps were recorded during the study period (note that the text message content was not included). Passive sensor data were collected for approximately 2 weeks (mean 16.41 days, SD 2.69).

Procedure

The study was approved by the institutional review board at the University of Virginia. Participants received partial course credit or payment for their participation, and they were told that the study examined how their thoughts and feelings interacted with their daily environment. They were also instructed on the type of data that would be collected from their mobile phones. Individuals provided informed consent and attended two laboratory visits. During the first laboratory visit, they completed the SIAS and other measures (not relevant to this study). After this, participants installed the Sensus mobile app onto their own Android phones. They returned approximately 2 weeks later, where they completed additional measures and were debriefed (although the authors may have collected these same measures during the follow-up assessment, only the baseline assessments were released).

Planned Analyses

Overview of Analyses

Before any analyses, a set of biomarkers was created for each person's data. Note that passive sensor data are based on within-person variation (ie, changes over time), and yet the primary hypothesis is based on a between-person question (ie, stable individual differences across people, which matches previous research conceptualizing anxiety disorders as dynamical systems) [36]. Consequently, the same set of biomarkers was extracted separately for each person from the time series of their passive sensor data, and, then, these biomarkers were used for interindividual analyses.

Accelerometer Biomarkers

The accelerometer data were processed consistently with a previously published procedure [33]. The first feature creation was used to describe the overall distribution of the outcome scores; this included the following raw data metrics: (1) the mean, (2) median, (3) mode, (4) minimum, (5) maximum, (6) skewness, (7) kurtosis, and (8) SD. Furthermore, we included (9) the root mean square of successive difference from 1 and 2 lags difference, and (10) the first through 99th quantiles in increments of 1 percentile. Thus, these features were predominantly created to extract relevant signals related to the functional form of the raw data.

The second set of features was created to represent the autoregressive dynamic nature of the raw data, which can measure complex relationships of temporal stability and oscillatory patterns while imposing a constraint for smoothness. This was constructed using the differential time-varying effect model, which is based on a generalized additive modeling framework utilizing the following formula for each person. In particular, the mean of $y_{i,l'}$, $\mu_i \equiv E(y_{i,l'})$ is linked to a semiparametric predictor, η_i, expressed as:

$$\eta_i = f_1(TD_{i,l})y_{i,l}$$

Here, y represents the raw data for each measurement i, at lag l. Note that l' represents a stacked vector of the outcome such that the same time series is stacked repeatedly to account for each potential lagged relationship l. The term f_1 represents a smooth based on a thin-plate regression spline. Note that the term f_1 is a nonparametric component wherein the effects of a series of covariates on the mean of the transformed dependent response variable are of unknown functional forms. TD reflects the time difference between the measurement occasion i and lag l. The primary term interest is thus: $f_1(TD_{i,l})y_{i,l}$, which is a varying-coefficient model representing the linear relationship between the lagged outcome of y on itself at later time points as a function of nonlinear time differences [37]. Features were created separately for each person's raw data (ie, one model per person). The extracted feature was the predicted varying-coefficients across the entire time series from all possible lags.

The third set of features was based on the spectral analysis, wherein each of the estimated power spectral densities was recovered for the raw data [38]. This represents the decomposed cyclical patterns that are common throughout the time series within the data. The power density describes the degree of strength of the variation in the raw data as a function of frequency. There was no missing accelerometer biomarker data.

Text Message Biomarkers

Notably, the text message data were much sparser than the accelerometer data, and consequently, fewer biomarkers could be derived. The distributional outcomes described within the accelerometer biomarkers above (eg, mean, median, mode, etc) were applied to the vector of the time difference between the text messages with the goal of processing the distribution of the time difference between adjacent text messages (attempting to capture whether the participant engaged in text messages with long delays or shorter-time periods). This was first applied for all text messages, then all incoming text messages, and, finally, all outgoing text messages. The typical distribution variance between persons was also captured by taking the same distributional features of the time differences for each person that the person contacted, and then calculating the SD of the distribution of time differences (note that this was to account for the potential that a socially anxious person may vary in the speed with which they text back persons with whom they are close as opposed to persons with whom they enjoy a more distant relationship). This resulted in a measure of how much variation there was in the length of time between contacts. Finally, the last feature that was extracted was the number of total texts. There was no missing text message biomarker data.

Call Biomarkers

The following features were created to process the call data: (1) the total number of calls, (2) the percentage of calls that were missed, (3) the percentage of calls that came during times the phone was idle (ie, to capture a time in which they might have been interrupted from their current tasks, which could facilitate avoidance among those with high social anxiety), (4) the number of total persons that the participants contacted, and (5) the distribution features extracted from the time differences between calls (ie., similar to the text messages, this approach was to account for how long it would take a person to call someone back, which we suspected could be higher in persons with high social anxiety). There was no missing call biomarker data.

Machine Learning

After each of the features were created, an ensemble of extreme gradient boosting machines (*XGboost*) was utilized. Extreme gradient boosting machines are learning algorithms composed of several weak tree-based learners. They have shown to be more robust at predicting outcomes compared with many traditional algorithms and are often the algorithm that consequently wins machine learning competitions for this reason. The lower level extreme gradient boosting learners were blocked in the following way: (1) predicting social anxiety from the accelerometer distribution features (which constituted one model), (2) predicting social anxiety from the accelerometer autoregressive dynamics (which comprised a second model), (3) predicting social anxiety from the accelerometer spectral densities (trained based on spectral densities in blocks of 1000 features each), (4) predicting social anxiety from the text message biomarkers, and (5) predicting social anxiety from the call biomarkers. Note that each of the extreme gradient–boosting models utilized leave-one-out cross-validation, such that the features that were extracted were the predictions from the model without including that participant in the model (ie, all features were out-of-sample predictions). Finally, the final ensemble model was trained based on the model predictions of the lower order models, with the higher-order model also being based on an extreme gradient boosting model. The final ensemble model also utilized leave-one-out cross-validation, such that the final model was based on an out-of-sample prediction.

Outcome Metrics

The primary outcome of interest was the correlation between the predicted and observed SAD symptom severity scores. In addition, the discriminant validity of the predicted SAD symptom scores was also compared by comparing the correlation between the SAD symptom scores based on the smartphone biomarkers and depression, negative affect, and positive affect. As there was missing data in the depression (5% missing), negative affect (14% missing), and positive affect (14% missing), multiple imputation was utilized to estimate the correlations for the discriminant validity. Similar to Ortiz et al [39], discriminant validity was compared by comparing the correlations between predicted SAD symptom severity based on the smartphone biomarkers and the observed SAD symptom

severity strength, compared with the correlation between the smartphone biomarkers and depression, negative affect, and positive affect, respectively [40].

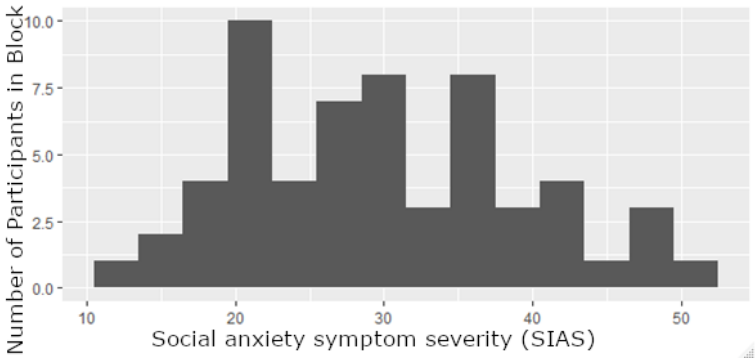
The variable importance from the model ensemble was identified, such that the most important feature will be extracted and plotted to determine the most important contribution to the model predictions. In addition, the t-distributed stochastic neighbor embedding (t-SNE) plot was examined from the lower order ensemble models and the final predictions to visualize the degree of separation between the predictors and social anxiety symptoms. The t-SNE plot is a visual depiction of how well the machine learning models naturally separate different degrees of SAD symptom severity. The variable importance of the primary feature was also extracted from the higher-order ensemble, as well as from the lower order model to determine the single most influential digital biomarker of the predictions of SAD symptom severity.

Results

Percentage of the Sample With Clinical Anxiety

The distribution of the SAD symptom severity is depicted in Figure 1. The mean of the SIAS was 29.125, with an SD of 9.407, and a range from 11 to 52. On the basis of previous validated cutoffs (score of 34 on the SIAS), 36% (21/59) of the sample was above the primary cutoff, suggesting they were at clinical levels of SAD. In applying the more conservative cutoff of 36 used in clinical outpatient samples to differentiate anxiety from other anxiety disorders, a total of 34% (21/59) of the sample was very likely to have clinically significant social anxiety (and not merely other anxiety disorders, based on the results of a previous study suggesting that this clinical cutoff discriminated SAD from other anxiety disorders [30]).

Figure 1. Social anxiety symptom severity based on the social interaction anxiety scale.



Primary Results

Convergent Validity

The results suggested that there was a strong correlation between predicted and observed social anxiety symptom severity r=0.702, 95% CI 0.543-0.812; P<.001 (see Figure 2 for a plot of the individual level predictions). Supporting our hypothesis, the bounds of the 95% CI suggested that the strength of the correlation was above 0.5. See Figure 3 for a visual depiction of the degree of separation of the lower order ensemble model features and SAD symptom severity.

Figure 2. Z-scores of the predicted social anxiety disorder (SAD) severity and the observed SAD symptom severity for each participant. Note that the patient index represents each of the 59 participants and not a continuous metric. SAD: social anxiety disorder; SIAS: social interaction anxiety scale.

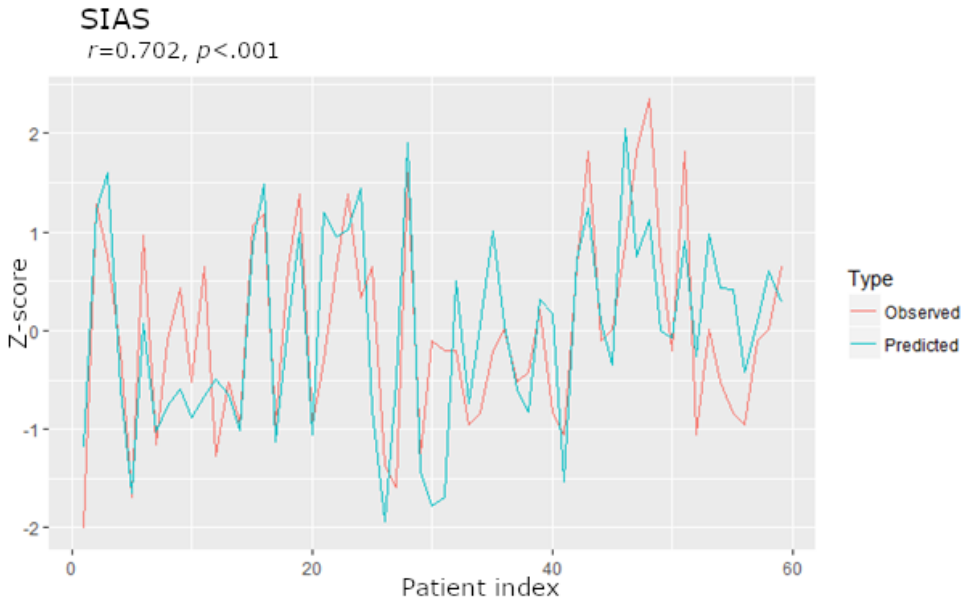


Figure 3. t-distributed stochastic neighbor embedding (t-SNE) plot depicting the ensembled model features (ie, the predictions extracted from the lower order ensembles) and the observed social anxiety symptoms. Note that closer points in the t-SNE are shown to be similar to one another, and dissimilar objects are shown to be farther away from one another. Note that the axes themselves are used to reduce the dimensionality of the machine learning features, so the Dimension 1, Dimension 2, and Dimension 3 labels are not of interest. This plot shows the ability to differentiate the level of social anxiety symptom severity based on the ensembled model features. As can be seen, the combination of the lower order ensembles was able to well differentiate SAD symptom severity. SAD: social anxiety disorder; SIAS: social interaction anxiety scale; t-SNE: t-distributed stochastic neighbor embedding.

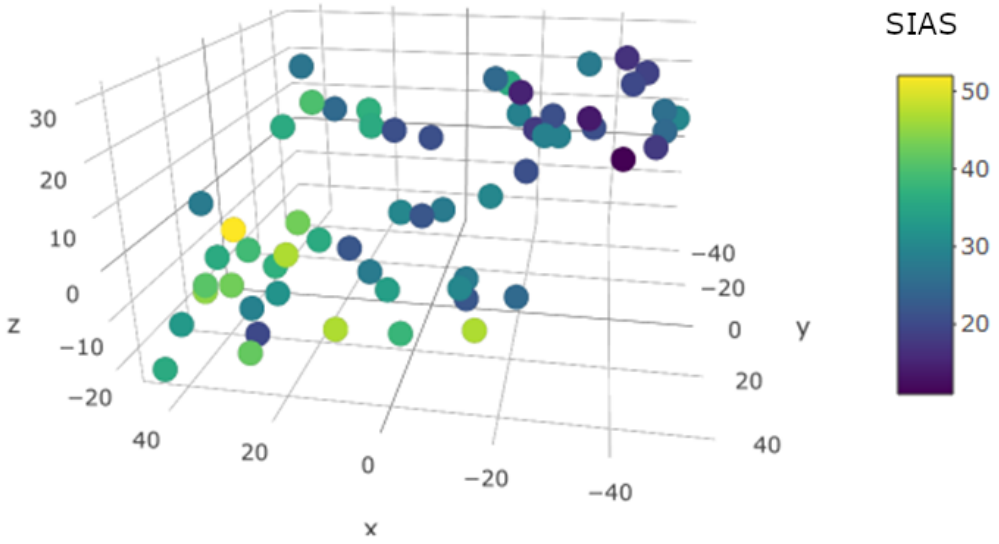


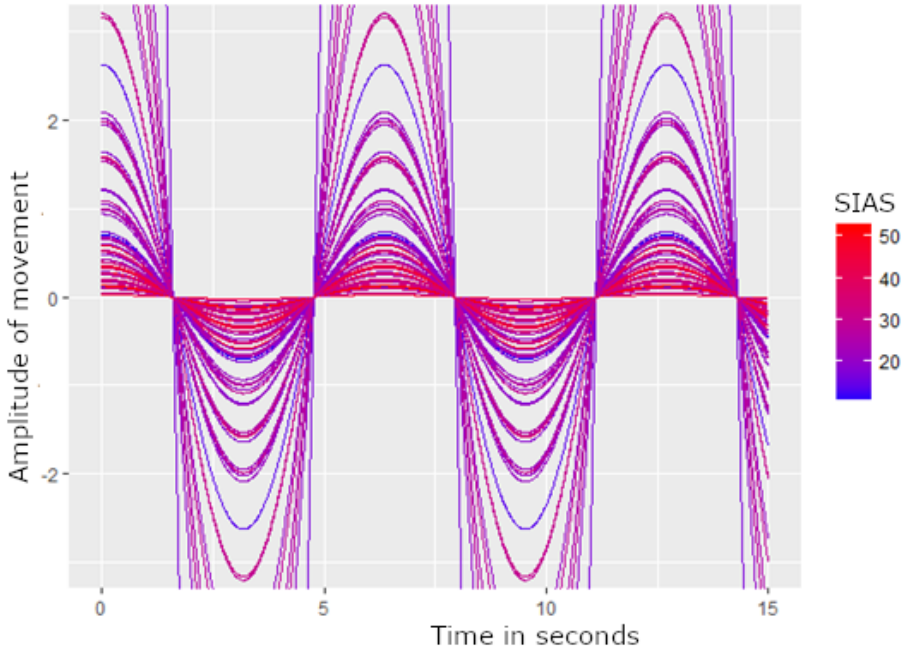
Discriminant Validity

Regarding the discriminant validity of the measure, the results suggested that there was a weaker but positive relationship between the predicted SAD symptom severity from smartphone biomarkers and depression severity (r=0.357, 95% CI 0.112-0.562; P=.005), and this correlation is significantly lower than that between the predicted SAD symptom severity from the smartphone biomarkers and the observed SAD symptom severity (Z=3.441; P<.001). Likewise, the predicted SAD symptom severity from smartphone biomarkers had a positive correlation with negative affect (r=0.384, 95% CI 0.143-0.583; P=.003), and the correlation is significantly lower than that between the predicted and observed SAD symptom severity (Z=3.484; P<.001). The predicted SAD symptoms had a nonsignificant negative correlation with positive affect (r=−0.138, 95% CI −0.380 to 0.122; P=.32), which was significantly lower than the correlation between predicted and observed SAD symptom severity (Z=5.980; P<.001). The magnitude of the variance explained was also more than three times greater between the predicted and observed SAD severity, compared with the variance explained by the predicted SAD severity and each of the discriminant constructs. This suggests that smartphone biomarkers demonstrate discriminant validity between depression, negative affect, and positive affect. Note that the partial correlation between the predicted SAD severity and the observed SAD severity was also still strong and significant when controlling for depression, positive affect, and negative affect (r=0.502, 95% CI 0.283 to 0.671; P<.001).

Exploratory Aims

Note that based on the variable importance metrics, the oscillations occurring every 6.35 seconds appeared to be the most influential contributor to the final ensemble model (see Figure 4). Graphical depictions of the results showed clear differences in amplitude between those with higher social anxiety symptoms and those with lower social anxiety symptom severity, such that those with low social anxiety tended to have greater oscillatory frequency patterns during this 6-second timespan.

Figure 4. Oscillations of movement at approximately every 6 seconds and the relationship to social anxiety symptom severity. Note that each line represents a separate person. The lines are shaded from blue (low social anxiety symptoms) to red (high social anxiety symptoms). This graph clearly depicts that those with high social anxiety symptoms tended to have lower amplitudes of these 6-second oscillations than those with higher social anxiety symptoms. SIAS: social interaction anxiety scale.



Discussion

Principal Findings

Our data indicated that calls, texts, and movement patterns captured by individuals' smartphones over 2 weeks provided sufficient information to predict severity of SAD symptoms with moderately strong accuracy (r=0.702), and that these patterns can also accurately discriminate social anxiety from depression (r=0.357), negative affect (r=0.384), or positive affect (r=−0.138). Although preliminary, these data are promising, as they suggest that simple behavioral information that is already passively collected for most individuals in the United States may represent a highly feasible, low-cost, low-burden, and specific mechanism for identifying people who are vulnerable to experiencing problematic levels of social anxiety.

Note that the present findings provide unique and incremental contributions of the previous public use dataset [21]. In particular, the previous research trained models based on the entire dataset and did not use a holdout sample, which may result in overfitting the sample and overestimate how well these models would generalize to new independent samples [22]. In addition, the correlations used via these methods were not based on machine learning models, which may combine features to better predict SAD symptom severity (consequently, the absolute correlations between these features and social anxiety were only 0.01-0.36) [21]. By utilizing a combination of features, rather than single features, the correlations were substantially better within the current sample despite being based on out-of-sample predictions.

The current findings are particularly notable when one considers the concurrent validity of SAD symptom measures. In particular, the convergent validity of these predictions is approximately equivalent to the convergent validity between established social anxiety symptom scales (eg, r=0.730 between the SIAS and the Liebowitz Social Anxiety Scale) [41]. This suggests that the accuracy of these behavioral phenotypes is approximately equivalent to the validity of symptom measures, which is particularly noteworthy given that self-report scales are known to tend to overly correlate with one another more strongly than other methods due to the artifact of shared method variance alone [42]. This has important implications for the field of psychology, as behavioral profiles are not based on subjective feelings, but rather replicable observable phenomena. Although this work is preliminary and more work is needed to develop a broader constellation of digital biomarkers, these behavioral profiles may be interesting outcomes to help organize and conceptualize psychiatric disorders themselves.

This study has many notable strengths. In particular, the smartphone app collected passive data from participants over 2 weeks continuously (once per second), allowing for rich behavioral signals that are well beyond the temporal precision available in existing social anxiety measures. Likewise, this study also applied some cutting-edge machine learning techniques in analyzing these digital biomarkers. This study also utilized leave-one-out cross-validation to examine the overall performance, which directly examines the degree to which the trained model generalizes to unseen data, and these models continued to suggest that they had high predictive accuracy. Finally, this study included a large percentage of those at clinical levels of SAD.

Limitations

This study has some limitations that provide direction for future research. First, our sample size was modest, and participants were all undergraduate students, which may limit the

generalizability of findings as SAD affects individuals of all ages and educational backgrounds. Furthermore, although 36% (20/59) of the sample reported symptom severity above the suggested clinical cutoff on the SIAS, we did not use a clinical sample in this study. Thus, it will be important that future replications of this work be conducted in larger, more representative samples. Larger samples would also allow for more power to test possible moderating variables (eg, gender). Second, passive data collection does not allow us to quantify the type of social contact that someone may be experiencing (ie, it may be difficult to infer whether someone is contacting a relative or a distant acquaintance). Third, the current models were trained to predict between-person differences, and, consequently, it is unknown whether the results would generalize to predicting within-person variability.

Our data also revealed that the most influential contributor to the predictive model was oscillatory frequency patterns during a 6.35-second timespan, such that less socially anxious individuals evidenced greater oscillatory frequency than high-social anxiety counterparts. Given the nature of the speed, we suspect that this reflects the length of several sequential strides during walking (ie, where this pace would reflect a slightly below average stride of six consecutive strides based on persons average walking pace) [43]. We suspect that this oscillatory pattern occurred as it best reflected continued walking frequency (ie, between 1 and 2 strides in a local environment likely has very high instability as persons only navigate very little distance). Nevertheless, given the novel nature of this metric, the true implications of this finding are unclear. It is possible that this pattern reflects persons with low social anxiety walking at a consistent confident and steady pace, whereas persons with high social anxiety walking might walk more quickly and less confidently or at an irregular pace. Continued research is needed to clarify the degree to which this finding is specific to this population, and the relevance of this metric for our understanding of symptom presentation.

Conclusions

Taken together, our study extends recent efforts to utilize passive smartphone sensor data to improve the field's ability to detect nuanced behavioral indicators of problematic pathology [44,45]. This is especially important for individuals with social anxiety, given that the occurrence of these symptoms is more frequent than is typically reported. However, this method of harnessing naturally occurring behavioral data is certainly relevant for identifying and better understanding a range of maladaptive thoughts and behaviors that underlie psychiatric conditions more broadly.

Conflicts of Interest

NJ is the owner of a free app entitled Mood Triggers. He does not receive any direct or indirect revenue from his ownership of the app (ie, the appl is free; there are no advertisements, and the data are only being used for research purposes). SW has received salary support from Telefonica Alpha, Inc. She is a presenter for the Massachusetts General Hospital Psychiatry Academy in educational programs supported through independent medical education grants from pharmaceutical companies. Abstract

Background: As breast cancer survival rates improve and structural health resources are increasingly being stretched, health providers require people living with and beyond breast cancer (LwBBC) to self-manage aspects of their care.

Objective: This study aimed to explore how women use and experience social media to self-manage their psychosocial needs and support self-management across the breast cancer continuum.

Methods: The experiences of 21 women (age range 27-64 years) were explored using an in-depth qualitative approach. The women varied in the duration of their experiences of LwBBC, which facilitated insights into how they evolve and change their self-management strategies over time. Semistructured interviews were analyzed inductively using a thematic analysis, a polytextual analysis, and voice-centered relational methods.

Results: The use of multiple social media platforms, such as YouTube, Facebook, WhatsApp, and Twitter, enabled women to self-manage aspects of their care by satisfying needs for timely, relevant, and appropriate support, by navigating identities disrupted by diagnosis and treatment and by allowing them to (re)gain a sense of control. Women described extending their everyday use of multiple platforms to self-manage their care. However, women experienced social media as both empowering and dislocating, as their engagement was impacted by their everyday experiences of LwBBC.

Conclusions: Health care professionals (HCPs) need to be more aware, and open to the possibilities, of women using multiple social media resources as self-management tools. It is important for HCPs to initiate value-free discussions and create the space necessary for women to share how social media resources support a tailored and timely self-managed approach to their unique psychosocial needs.

KEYWORDS

breast cancer; social media; internet; self-management; psychosocial health; survivorship

Introduction

Background

Breast cancer remains the most common type of cancer in women [1]. Owing to the improvements in early diagnosis, treatment, and an aging population [2,3], survivorship rates and life expectancy for women living with and beyond breast cancer (LwBBC) are increasing. However, as health care systems are increasingly stretched, with significant gaps developing in health care resource provision, increasing patients' abilities to engage

in positive self-management behaviors when living with long-term conditions [4,5] has become a global issue [6].

Self-management—defined as "awareness and active participation by the person in their recovery, recuperation, and rehabilitation, to minimize the consequences of treatment, promote survival, health and well-being" [7]—is reported to support patient empowerment, increase self-efficacy, and lead to behavioral changes, while reducing demands on health care resources [4,5,7-9]. However, Rogers et al [9] suggest that more attention needs to be placed on the "contexts, resources, practices, priorities, and networks of patients living with a chronic condition to identify the nuanced ways in which self-care support and long-term condition management can be integrated into the open systems of people's everyday lives."

Women LwBBC report many ongoing and unmet psychosocial needs [10,11], including pain, fatigue, fear of recurrence, lymphedema, and hair loss [12-19]. As these complex issues require ongoing support, attending to the everyday resources, practices, priorities, and patient networks that women engage in for their own self-care, could offer health care professionals (HCPs) insights for better health care outcomes.

Social media have the potential to support women LwBBC to manage aspects of their own self-care, including managing unmet psychosocial needs. Social media are defined as a group of Web-based apps that enable the creation and sharing of user-generated content [20]. They offer patients instant access to information and new connections through easy access to other users [21]. Social media have become taken for granted health information resources [22,23] and include, for instance, a cancer tag ontology of hashtags on Twitter that links patients, doctors, caregivers, and advocates. This includes a weekly tweet chat in relation to breast cancer—#bcsm (breast cancer social media) [24,25]. However, research on social media use by women LwBBC is limited to a small number of studies [24,26-39]. These studies have focused either on discrete platform use (eg, Facebook, Twitter) or have adopted methods such as secondary data analysis [26-38], which do not acknowledge the complex ways in which social media are used and experienced by women LwBBC. Furthermore, research on social media as a component of electronic health interventions [6] ignores the experiences of women using commercial social media platforms to create, use, maintain, and generate grassroots informational and storytelling spaces, such as blogs, and community spaces, such as Facebook groups, to support their own self-management. Facebook groups can be *open*, *closed*, or *secret*. *Open* means anyone can see the group, who is in it, and can join it. *Closed* groups can also be seen by anyone. The group's name, description, and member list are publicly visible; however, only those who have been invited to a closed group can see its posts. A *secret* group is not publicly visible. Women must ask to join secret breast cancer groups and are added by a moderator, and only group members can see group posts. As women are generating digitally mediated support together in Web spaces, understanding how women LwBBC use social media to support self-management and self-care practices can help target informational and psychosocial support more appropriately and provide useful information to HCPs about women's self-management practices.

Objective

This study aimed to explore how women use and experience social media to self-manage their psychosocial needs and support self-management across the breast cancer continuum.

Methods

Design

A qualitative study was used to explore women's use of social media to support self-management when LwBBC as we were unable to find previous studies that explored use of multiple social media for this purpose. Semistructured interviews, including visual methods were developed to gain rich, detailed data [40]. Photographs were introduced into the interview setting through photo elicitation (social support images provided by the research team, eg, friends being together, families, HCPs, and mobile technologies, eg, women using mobile phones or laptops) or photo production (photographs taken by women to communicate their experiences of LwBBC) to elicit or trigger conversation [41]. An interview guide was developed by the research team.

Sample and Sample Size

Women had to be 18 years or older, with a previous diagnosis of breast cancer. It was not a requirement that women had to use social media at the present time. We were interested in women's experiences of social media use at any time since diagnosis. We were mindful that some women may have used social media at some point but had not found it helpful. It was as important to capture these experiences. We were interested in how women's experiences of social media use varied in relation to time since diagnosis. We purposefully recruited women who had been LwBBC for less than twelve months, between 1 and 5 years, and 5 years or more, with equal numbers (n=7) recruited for each temporal period postdiagnosis. Participants emailed the lead researcher (CU) to register interest in participating after seeing study details online (in breast cancer Facebook groups [n=12], Twitter [n=2], charity websites [n=1]) or offline via cancer support centers (n=2), posters (n=1) or through word of mouth (n=3). In total, 44 women were interested in the study. Of the 44 women, 21 consented to participate, with 1 known to CU. Women decided which type of interview—photo elicitation or photo production—they wished to participate in.

Data Collection

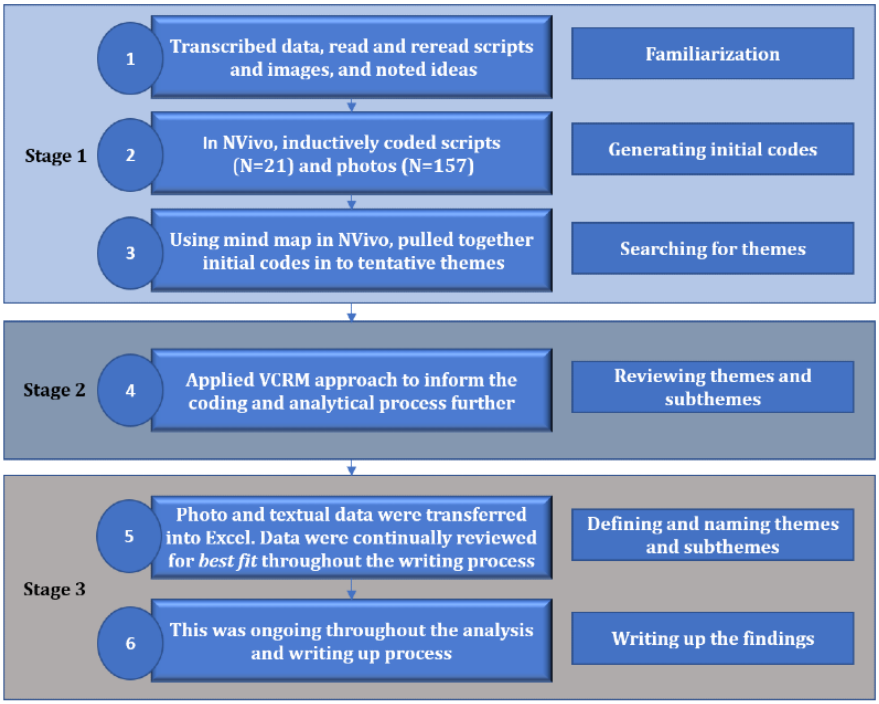
Face-to-face interviews carried out by CU were audio recorded and video recorded. The question structure was kept deliberately broad to enable women to have as much space as possible to explore their experiences of social media use. The first half of all interviews followed the same structure using the interview guide to ask broad questions related to personal experiences of breast cancer—women's overall social media use and use in relation to LwBBC. In the interviews using photo-production techniques, women then shared the photographs they had taken to discuss how they communicated their experiences of LwBBC with others. In the interviews, using photo elicitation techniques, Wortman's [42] study on social support was used to support probing questions. Photographs provided by the research team

were used to prompt responses related to possible providers of social support, including HCPs, work colleagues, friends and neighbors, family including children and parents, partners, peers, and service providers, for example, charities. Interviews took place in university or community settings. Field notes were written after each interview. Considerations about data saturation were guided by the concept of information power [43], that is, the more relevant information a sample holds, relevant to the study, the fewer participants are needed—researcher subjectivity [44] and taking a pragmatic approach to sample size [45], given the resources available. On the consent form, women were asked how they wanted quotes to be credited, that is, with their own name or a pseudonym. Most participants (16/21, 76%) waived their rights to anonymity. Pseudonyms are used for those who retained anonymity. Ethical approval was granted by the University of Salford (approval number: HSCR 15-71).

Data Analysis

Data were analyzed using thematic analysis [46], polytextual thematic analysis [47], and the voice-centered relational method [48] approaches. Figure 1 shows a review of the steps taken. Transcripts (including photographs) were inductively coded in NVivo (QSR International, version 11) by CU. Monthly review meetings were held with AMCR, AG, and JC to reflect on coding, to review field notes, and for thematic development.

Figure 1. Data analysis process flowchart. (VCRM: voice-centered relational method).



Participants' Review

Participants were invited to review the findings via email. Of 21 participants, 18 (86%) responded to the invitation and were forwarded the findings. Three photo-elicitation participants did not respond to the emailed invitations. The summary of the findings invited participants' responses by phone or email. Nine participants (9/18, 50%) responded. All (9) accepted the findings. Some offered comments about aspects of the findings that resonated with them. Others offered thanks for the opportunity to be involved.

Results

Characteristics of the Study Sample

A total of 21 women (age range: 27-64 years at the time of diagnosis) participated. Interviews lasted between 55 and 168 min (mean 99 min). The number of photographs (n=157) taken ranged from 3 to 47 (mean 17). Participants' characteristics are provided in Table 1.

Table 1. Participants' characteristics (N=21).

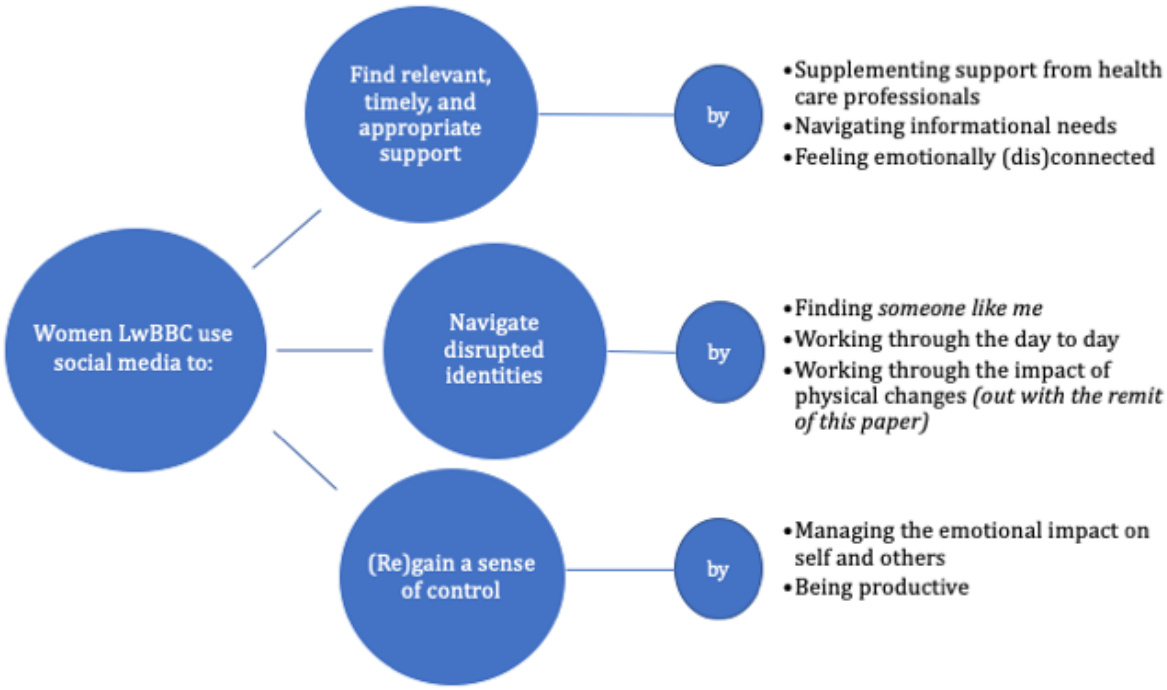
[a]DCIS: ductal carcinoma in situ.

Themes

A total of 3 main themes with 8 subthemes were identified in relation to why women use social media to support their experiences of LwBBC (Figure 2). For the purposes of this paper, the most relevant themes and subthemes that inform HCPs about women's use related to self-care and self-management were discussed. Working through the impact of physical changes, a subtheme identified as part of the wider PhD study, was, therefore, not discussed here.

Figure 2. Thematic map: women's use of social media to support self-management when living with and beyond breast cancer.



Theme 1: Finding Relevant, Timely, and Appropriate Support

Most women were active social media users at the time of their diagnosis. Extending their day-to-day use to find support was a logical extension of existing social media practices. Women described gaining support on social media through 3 subthemes: supplementing support from HCPs, navigating informational needs, and feeling emotionally (dis)connected.

Supplementing Support From Health Care Professionals

Women highly valued the clinical expertise provided by HCPs; however, collectively, they described themselves as cautious users of secondary health care provision. They avoided *mithering* or *bothering* breast care nurses, as *they never have enough time*. Phoning the breast care nurse was viewed as intrusive:

> *I don't want to be bothering them with phone calls when they are in clinic.* [Sarah, time since diagnosis <12 months]

Therefore, women who described using social media to gain support felt unwilling or unable to access their HCPs. Indeed, all women using social media described how easy access to experiential support from other women LwBBC reduced their sense of needing to access HCPs. Furthermore, sometimes women decided that they no longer needed to seek reassurance from their general practitioner:

> *I mean I tried to make appointments with my GP, but you know the way things are going with the NHS [National Health Service] and all that. It is like three weeks until my next appointment. I don't need to now. I just go on the group [Facebook group] and think' oh, OK, alright yeah.* [Jojo, time since diagnosis 1-5 years]

Instead, women can experience closed and secret groups on Facebook, as providing immediate, relevant responses that reassure and inform:

> *There would be people to talk to rather than having to ring up the nurse, leave a message on the breast cancer nurse line, feeling really bad because they are really busy, and they are running around doing other things and then waiting for them to ring me back perhaps that same day perhaps not that same day erm, to this was...this immediacy that, you know, we get used to with technology erm...* [Jayne, time since diagnosis 1-5 years]

Women at all stages of the breast cancer continuum described their social media use as supplementing professional support and as a way to gain agency by removing their reliance on HCPs as the source of all breast cancer knowledge. By using social media to address questions and concerns quickly, women voiced notions of feeling empowered.

Navigating Own Informational Needs

Initially, women used information searching as a coping strategy. For some, information searching began after diagnostic testing and before formal diagnosis. Women reported experiencing information overload in the clinical setting and used social media to fill knowledge gaps at key points in their *patient journey*, outside of the formal clinical encounter:

> *Because there's that much information, you can't possibly take it all in at the appointment. And when they tell you, you are almost kind of shocked anyway. So, you don't digest any of it. Nothing is retained. Absolutely nothing is retained.* [Nicola, time since diagnosis 1-5 years]

Women described *Googling* and seeking information from other women LwBBC on social media as common practice. Cancer charity websites, such as Cancer Research UK and Breast Cancer Care, were considered *legitimate*, *trustworthy*, and *up to date*. They were often women's first port of call. However, when women wanted further information relating to their own specific experiences, they described these sites as providing insufficient breadth or depth to satisfy their needs. In addition, some women experienced informational support from breast cancer charities as leaflet driven, which was misaligned with their everyday information-seeking practices. Women supplemented static Web- and leaflet-based information with active (eg, liking, commenting, sending messages) and passive consumption (eg, lurking) [49,50] of other women's experiences of LwBBC. Women described lurking in closed Facebook breast cancer groups immediately after diagnosis, which provided a *depth* of knowledge and built women's confidence to advocate for themselves:

> *You kind of come across a post and there'll be like 47 comments, by the time you've read all of that you've had quite an in-depth insight into that particular issue, so I just read a lot.* [Kirsty, time since diagnosis <12 months]

Using Twitter to follow and learn from other women, LwBBC was described as supporting joint decision making with HCPs:

> *I found Twitter really useful in that because then I started following lots of people, so by the time I spoke to people I was already pretty well informed, or I felt like I was anyway, um, obviously it gave me the opportunity to ask some questions then.* [Sheena, time since diagnosis <12 months]

In addition, women used YouTube to gain visual information relating to practical aspects of treatment and managing the effects of treatment, including lumpectomy, radiotherapy, and mastectomy procedures. Some women used YouTube to watch mastectomies *to see what they did* for greater knowledge and understanding.

Women supplemented Web-based information through active and passive consumption of experiential knowledge principally using Facebook, YouTube, and Twitter. By moving in and out of platforms and different groups on platforms, women gathered information at the appropriate time for them, determined by them. This supported women's ability to cope with the amount of information they encountered when newly diagnosed and supported adjustment and informed anticipation of what the next stage in their breast cancer experience entailed at different stages of the breast cancer continuum. By engaging in seeking, sifting, evaluating, and sharing information, women validated their experiences and were better equipped to advocate for themselves across a range of everyday settings.

Feeling Emotionally (Dis)connected

Some women used different social media platforms to navigate feelings of disconnection from other people to mediate relationships that provided emotional support and to connect with other women who shared similar experiences. Many described family and friends as *uncomfortable* because *they don't know what to say.* Some women talked about *my breast cancer* in everyday WhatsApp conversations. In this space, conversations about cancer were normalized, as women voiced their experiences while also providing family and friends with space and time to craft effective supportive responses. By publicly posting photographs as status updates on Facebook, women reported a sense that their story was being seen and heard. However, social media use was entangled in specific experiences. For instance, women showed highly tailored approaches to accessing emotional support at times, which were particularly challenging, such as the week of receiving chemotherapy. Women described these as important connections that reduced the sense of isolation and feelings of loneliness, which they felt unable to share with their family. Social media enabled connection with those who *understand* at a time when women felt disconnected from their normal support structures:

> *And those times when you are sat home for a week, bored out of your brains, feeling like death, it's quite*

> *nice to connect with somebody that's going through the same thing, yet you've not got the energy to talk so, you know what I mean, so it's been really good for that because I think I would have felt quite lonely…yeah.* [Sarah, time since diagnosis <12 months]

This emotional connectedness was described by 2 women as *a lifesaver*:

> *I cannot think of a single source that would provide even close to the amount of...even close to the amount of support the YBCN [Younger Breast Cancer Network] has provided for me. I never looked elsewhere.* [Delphi, time since diagnosis 1-5 years]

Many women preferred gaining emotional support through closed or secret Facebook groups or other platforms such as WhatsApp, Skype, and FaceTime, as these digital spaces supported intimate conversations, feelings of proximity, and "the reality of it [breast cancer] sometimes." Women described using different platforms simultaneously to scale how private or public they were about different aspects of their experiences. After finding social media groups or digital spaces that satisfied individual needs, some women developed personal relationships with other women LwBBC, which remained significant and important to them many years after their original diagnosis.

Theme 2: Navigating Disrupted Identities

Women described how breast cancer presented challenges to their sense of identity, which they navigated in numerous ways. The following 2 subthemes are relevant to HCPs: *finding someone like me* and *working through the day to day*.

Finding Someone Like Me

Postdiagnosis, many women used social media to find *someone like me*. Connecting with women in the *same boat*, who looked similar and were experiencing similar treatments helped reduce feelings of uncertainty. Women used different approaches to find women on social media, including looking for women of a similar age, with the same breast cancer type, and at the same stage *of the cancer journey.* Similarly, women targeted groups related to their experiences following particular treatments, including being *flat* postmastectomy, or having lymphedema. Most of the Facebook groups that women joined were grassroots, closed, and moderated:

> *A lot of us didn't want reconstruction and some were thinking about going flat completely and one of them mentioned the Flat Friends group cos I, I wear a (pause) prosthesis; I didn't have reconstruction I decided to join that group cos at one stage I thought erm do I go flat completely?* [Millie, time since diagnosis >5 years]

The need to find *similar others* on social media continued for some women along the breast cancer continuum. When women felt a difference between themselves and others, they sought out women in other groups they more closely identified with.

Some women identified difficulties with the notion of *someone like me* when they described experiencing the *hierarchy of suffering* [51], "whereby some kinds of suffering, pain, and misfortune are perceived as more difficult or signify a somewhat unique, superior source of suffering" (p.953). The *hierarchy of suffering* was described as invalidating personal experiences, and some women moved away from breast cancer discussions on Twitter and Facebook to actively manage their self-care. They described using social media to support their psychosocial health by extending friendships and interests with *similar others* with similar other interests, outside of breast cancer.

Working Through the Day to Day

Women at all stages of LwBBC described having to work through aspects of their breast cancer experience daily. For those with secondary breast cancer or further along the breast cancer continuum, many women detailed the impact and side effects of treatment as *constant reminders* and reported physical, emotional, psychological, and social challenges. Some women proactively used Twitter and Facebook to support themselves in the hospital setting while receiving treatment. This relieved pressure on the family to attend appointments, particularly for those living with secondary breast cancer:

> *I can't have somebody coming every three weeks with me, it's...who's got time? Who's got the energy? Who's got the effort? I don't mean that in a bad way, I know that it's a drag.* [Jo, time since diagnosis <5 years]

For Jo, working through the day to day involved using social media to extend the clinical encounter to her social networks. She used her iPad to connect with her Twitter followers during treatment, drawing on support in real time as and when she needed it.

For some women, *work* was experienced by managing side effects daily as a result of their treatment. Social media, including YouTube, were used to find solutions to alleviate the discomfort experienced, including managing lymphedema. However, regular emotional labor was also required to cope with anxiety created by social media posts when women discussed nonadherence to clinical guidelines. A total of 11 women, all at different stages of the breast cancer continuum, discussed issues with tamoxifen adherence. Women shared how nonadherence and being challenged about their own adherence created dissonance and anxiety for others:

> *And then I look on the [...] network and quite a few people say, "why are you having Tamoxifen? I'd put up a fight against that. I'm not on Tamoxifen I don't think it's a good idea. I'm having this drug instead and erm" so again that [….] is, now I am having a bit of a worry and a bit of a wobble about being on this Tamoxifen.* [Michelle, time since diagnosis <12 months]

Although some women felt conflicted when other women LwBBC challenged clinical guidelines, many women used social media as a tool to gain a sense of control.

Theme 3: (Re)gaining a Sense of Control

Women described (re)gaining a sense of control through 2 subthemes: managing the emotional impact on self and others and being productive**.**

Managing the Emotional Impact on Oneself and Others

Women described seeking to control the emotional impact of LwBBC on others by shielding them from aspects of LwBBC. Often, women made use of messaging services when initially diagnosed to inform others to (re)gain some control over disseminating their *news*. In the closed Facebook groups, women at all stages of LwBBC were able to have conversations, which they felt they could not have, or did not want to have, with close family and friends. They described how conversations with other women LwBBC enabled them to be *more honest*, able to process concerns without putting additional *burden* on loved ones, and which they had control over in terms of timing:

> *through social media I think you can be a little bit more honest because (pause) you've not got as much invested in their feelings. If you know, what I mean and they're going through it so you can't shock or scare them or make them feel (pause). There's no guilt in telling somebody on social media that yeah you do feel like shit, do you know what I mean, cos they're not going to come rushing round to your house, so there's that distance so I think you can definitely feel you can be more honest* [Sarah, time since diagnosis <12 months]

Women were purposeful in determining which platforms best supported their preferred communicative approaches and controlled when to publish personal information. WhatsApp provided women with a sense of intimacy, privacy, and connectedness, both with women LwBBC and their family/friends. Where women did not use WhatsApp and were not members of closed Facebook groups but were Facebook users, they posted to achieve responses that were (emotionally) manageable by controlling how they conveyed their experiences:

> *I would post "first out of six chemos. Last chemo – nailed it." That kind of thing. Erm, I do put it as very matter of fact. I did not say anything like "chemo is crap. I feel awful." And I would never post anything like erm, "I'm really down today" or anything like that. It was always very upbeat. I didn't want anyone to pity me.* [Wendy, time since diagnosis 1-5 years]

Women also reported having to learn to protect themselves emotionally when using social media, as sometimes content was experienced as threatening. Women reported anxiety—"you don't know what you're going to find"—when searching for content or reading about others' experiences. Women described strategies to control exposure to content so that it did not impinge negatively on their psychological health. This included prompt closing of content identified as having the *wrong atmosphere* and turning off push notifications from Facebook groups. Women described adopting flexible strategies of joining and leaving groups and conversations to reduce the negative impact on their sense of well-being across the breast cancer continuum. Any sense of information threat was met with a change in strategy, including avoidance and adaptation. Therefore, although women described social media as enabling them to compartmentalize and control aspects of their experiences, women also articulated the challenges of access to 24-hour information about breast cancer brings. Women emphasized the need to find ways to control access to other women's experiences, continual contact with *support* groups, and different types of content.

Being Productive

Women LwBBC reported using their experiences productively through their social media use. In one way some women (re)gained a sense of control by creating contemporary social media–based health resources. These resources were often borne out of the lack of service provision and included the development of new Web-based spaces including Twitter chats (#bbcww) and Facebook groups: for younger women with breast cancer, to support children of parents affected by cancer, and for women who wish to remain *flat.*

Some women over 12 months postdiagnosis felt *productive* by *giving back* through sharing personal experiences with women more recently diagnosed. However, many acknowledged this support as draining and adapted their level of involvement and exposure to content to meet their own self-care needs at any given point in time.

Similarly, engaging with oncologists on social media was seen to support women in making decisions about their own health care. Examples of successful advocacy were acknowledged by others LwBBC as something to *learn from:*

> *I've been able to then go to my Oncologist and say, "Look at this, this is what they're doing over in America, when are we getting it here?" Or "this is the treatment now available, when can I have it?"* [Jo, time since diagnosis >5 years]

For Jo, trying to influence other women LwBBC to develop positive attitudes toward improving their physical health provided purpose. By sharing updates on her own exercise goals, she sought to engage women in positive self-management behaviors. Jo used social media to inform, educate, and encourage others to be physically active to increase women's chances of accessing future treatments or surgical procedures through a focused approach to healthy, active living.

Women's photographs also demonstrated social media being used to actively challenge debilitating cancer narratives, which circulate in the mainstream press and on the Web. Countering problematic cancer narratives and having the right to reply was described as providing emotional release. Some women LwBBC, therefore, use social media as an opportunity for voice and reframing cancer conversations, which reduced their sense of disempowerment. Women can, therefore, develop complex social media identities that enable them to regain a sense of control through immersion in, shaping of, and sharing of expertise with others in ways that reciprocally supports their own individual needs.

Discussion

Principal Findings

This research identified 3 themes relating to women's use of social media to support self-management: *finding timely, relevant, and appropriate support* (support); *navigating*

disrupted identities (identity); and *(Re)gaining a sense of control* (control).

Women negotiate their entitlement to care [52] and use social media to supplement information provided by HCPs [53-55]. Significantly, women LwBBC at all stages of the breast cancer continuum are concerned about limiting demands on HCPs, for fear of *mithering* or *bothering*. This is supported by studies that show patients with cancer as reluctant to discuss psychosocial concerns with their clinicians [56] and users of online health communities (n=89) describing HCPs as *too busy for detailed discussions* [54]. To supplement the available support, some women are actively involved in digital labor in relation to meeting some of their psychosocial needs. Digital labor in a social media context relates to the unpaid creation of Web-based content and information [57]. In so doing, women articulate the perspective that they are reducing the potential demand for health resources. Rather than moving into new support environments postdiagnosis, such as using Web-based breast cancer charity forums, women's digital labor includes adapting and changing the *social* spaces they already use or occupy on social media, as demonstrated with the collaborative establishment of #bcsm [24,25] on Twitter. Evidence suggests that those who have diverse networks—characterized by numerous and varied network members (family, friends, acquaintances, and groups) who are in frequent contact with the individual—have better self-management capabilities among those with long-term conditions [58]. Furthermore, those with diverse networks use formal health care services less often than those in restricted, minimal family, family, or weak tie networks, presumably because of the increased number of connections [58]. Most often, the social spaces used are a logical extension of everyday use with women moving across platforms to suit their unique needs [59], in line with the trend for users to have accounts or profiles on multiple platforms [60-62]. Facebook, YouTube, WhatsApp, and Twitter were the most frequently used platforms in this study. Women adopt complex Web-based searching strategies to satisfy multiple needs, including timeliness (immediacy), relatability (women like me), and authenticity (experiential experts).

The first theme reports how women, by moving in and out of different groups and social media platforms, gain a sense of self-efficacy by gaining information at the appropriate time for them, determined by them. This supports women's ability to cope with the amount of information they encounter at challenging times along the breast cancer continuum and supports adjustment and informed anticipation of what the next stages in their cancer experiences entail. Using different social media platforms at different times demonstrates active and conscious decision making in tailoring connection and information seeking according to specific needs at any point in time.

Feeling an emotional connection to other women LwBBC was a significant factor in using social media, particularly when women felt disconnected from their usual support structures. Some women found that WhatsApp provided *mediated intimacy* [63] and supported the continuation of relationships postdiagnosis that felt disconnected or strained when face to face. By introducing everyday experiences of LwBBC into WhatsApp group conversations, women normalized conversations about cancer and succeeded in attending to their need to talk about their experiences. Women experienced WhatsApp as enabling message recipients to craft effective supportive responses.

The second theme captures the challenges for women in navigating disrupted identities and coping with *biographical disruption* [64-66]. Social media afford opportunities to link with and learn from *similar others*. When women experience a gap in service provision, they create or join niche groups [67] to find *likeminded* women. However, sometimes women find that participating in Facebook groups or on Twitter disrupts the validity of their experiences. They withdraw to better support their self-care. Women's experiences encapsulate the ongoing debate about the *internet's potential to create and diminish community* [68] with women experiencing participation as both positive and negative, sometimes simultaneously. More research is required to understand whether participation in social media conversations impacts adherence to clinical guidelines, including tamoxifen adherence and engagement in physical activities.

In the third theme—*(Re)gaining a sense of control*—women work to limit the *burden* of LwBBC on their families by self-managing aspects of emotional work through other women on social media. WhatsApp and Facebook Messenger were sometimes used following initial diagnosis to inform others. This was protective of psychosocial health by removing uncertainty around sharing the *diagnostic narrative* and afforded a sense of control through framing experience to influence the type of response required. On Twitter and in closed and secret groups, managing exposure to other women's experiences is challenging. Strategies employed to limit exposure to potentially threatening content support previous research [69] and align with women's approaches to information searching in relation to breast screening [70]. Similarly, push notifications on smartphones controlling the flow of information [71] from breast cancer groups acted as negative *constant reminders* of breast cancer. Being able to control information flow by changing notifications enabled a sense of control. The ability to use social media to compartmentalize the experiences of LwBBC was seen as a benefit of social media use.

Clinical Implications

Although evidence suggests that social media are shifting aspects of the patient-provider relationship [72], the original research aims of this study did not include generating outcomes for HCPs as a specific objective. However, the findings indicate that there are opportunities for HCPs and patients to work closer together to understand the benefits of social media use to support self-management. To encourage open conversations with patients, it may be useful for HCPs to encourage women LwBBC to share if and how they are addressing their self-management needs through their interactions with other women on social media. Given that many breast cancer groups on Facebook are closed or secret and WhatsApp groups are encrypted, there are challenges for researchers and HCPs alike in gaining awareness of what is shared in these spaces without dialog. Understanding which platforms or specific groups women find useful as self-management tools could enable

practitioners to signpost other women to social media resources that women find beneficial. Discussing the knowledge gained by women through platforms and social media groups provides opportunities for HCPs to support women's appraisal of information and could encourage open discussion about different approaches to self-management. Furthermore, there are opportunities for breast care nurses and oncologists to guest-moderate *chats* in grassroots social media spaces to support women's decision making and strategies for self-management.

Limitations

This was a qualitative study to understand the complexity of women's social media use when LwBBC. However, it did not provide insight into the relative extent of different aspects of social media use across a broad and representative population and did not provide insights into men's experiences of social media use when LwBBC. Further research should attempt to capture quantitative data to identify how social media use develops self-efficacy when LwBBC, supports self-management behaviors and impacts the overall sense of health and well-being across the cancer continuum.

Implications for Future Research

The ability to determine how, when, and where to access 24-hour support using social media provides opportunities for women globally to proactively engage in self-management practices unavailable a decade ago. Although women use social media in part to reduce demand on health care services, it is unknown whether use supports decision making or exacerbates issues within the clinical setting, for example, through poor decision making, which later increases demand for clinical services. Understanding HCPs' perceptions of the use of social media to support 24-hour self-managed care is an area for further research inquiry.

Acknowledgments

This study was funded as a doctoral study by the University of Salford. The authors would like to acknowledge Breast Cancer Care, Macmillan Cancer Support, and the grassroots Facebook groups—YBCN, Flat Friends, UK breast cancer group for survivors and sufferers, and the Word of Mouth Mammography e-Network for sharing details of this study to support recruitment and thank all the women who generously participated in this research.

Abstract

Background: Instagram is a social media platform that enables users to share images and videos worldwide. Some nurses have used Instagram to document their experiences as a nurse and have subsequently gained microcelebrity status—that is, a user who purposefully seeks to amass a substantive Web-based following and has become recognized as a niche area of interest.

Objective: This study aimed to identify the characteristics and behaviors of microcelebrity nurses who act as influencers on Instagram and use their nursing profile to gain attention and presence on the Web.

Methods: A qualitative, exploratory, nonparticipatory content analysis of media and text generated by a purposeful sample of 10 registered nurses who use Instagram and sustain a definable microcelebrity status was conducted. In this study, manifest and latent data were examined to gain an understanding of the characteristics and behaviors of nurses who have attained microcelebrity status on Instagram.

Results: Data analysis revealed 5 themes of Instagram posts: (1) engaging Instagram users, (2) educational opportunities and insights, (3) nursing-related humor, (4) emotions experienced by nurses, and (5) media and narratives including patient details or work context. Messages were primarily positive in nature; however, multiple potential privacy, ethical, and professional issues were noted throughout the posted content.

Conclusions: The findings of this study help to expand the current knowledge related to the use of social media platforms such as Instagram, especially in regard to the emergence of nurses who use this form of technology to achieve or maintain a microcelebrity status. This study calls for additional research on nurses' attainment of microcelebrity status on social media as well as further policy development to adequately prepare nurses to navigate social media.

Introduction

Significance

Every month, more than one billion people use the photo- and video-sharing social media platform, Instagram [1]. As a mobile photo-sharing platform, Instagram users can post photos and videos that are shared with other Instagram users, customized through the use of image processes (ie, filters), textual captioning up to 2200 characters in length, and hashtags [2]. Instagram users interact with others through a dynamic process of *liking* and *commenting* on the posted media as well as *following* fellow users. The number of followers an Instagram user has is publicly displayed on a user' s account page, regardless of the user's privacy settings [3].

Owing to the interactive nature of Instagram and the ability to identify the number of followers a specific user possesses, a behavior demonstrated by some Instagram users of purposefully cultivating and amassing a substantial Web-based following has become a recognized phenomenon, that is, if a social media user gains both substantial attention and a distinct following

within their group of followers, they are said to have attained *influencer* or *microcelebrity* status on social media [4-8]. Many individuals, including some nurses, have begun to purposefully leverage the connective powers of Instagram to generate microcelebrity persona through their Web-based presence.

At present, there are numerous Instagram accounts that exclusively feature content related to the nursing profession that has amassed sizable followings of more than 10,000 users, arguably pushing them toward microcelebrity status on Instagram [5,6,8]. However, given the potentially sensitive nature of the nursing role and related patient care, the use of Instagram by some users to post content related to the nursing profession is an area in need of deeper exploration. For instance, sharing of elements related to client care details and personal health information with the public raises potential concerns about the professional, ethical, and legal ramifications of such accounts and their related users.

Previous research examining the motivations of Instagram users and their use of social media platforms has found aspects related to (1) attention seeking; (2) social support; (3) belonging; (4) social interaction; (5) documentation; (6) learning about other users' lives; and (7) self-expression, as being important to users [9-13]. Within the nursing literature, several reasons have been explored regarding why nurses use social media platforms such as Instagram. The use of social media by nurses may assist in providing benefits for both nurses and patients, in part because of the ability to rapidly share information, assist users who are geographically isolated, and engage in health care planning [14-24].

Although social media have several potential benefits for nurses, challenges have also been identified with social media use in the profession. Social media posts can be disseminated to vast audiences immediately, which can have unintended results, especially if posts lack sensitivity or breach personal health information [16,17,20,22,23,25-27]. Given the subtle and encompassing nature of social media platforms to provide users with a false sense of security and privacy, the risk for health care providers to unintentionally cross professional boundaries on the Web is a contemporary reality for all nurses [17,18,23,25,28,29].

The consequences for nurses who breach patient privacy or confidentiality on social media are significant, including possible job termination, investigation and reprimand from nursing board(s), monetary fines, and loss of licensure. Furthermore, nurses may face civil or criminal charges, resulting in a potential jail time [17-20,28]. In recent years, there have been several instances of nurses violating the Health Insurance Portability and Accountability Act (HIPAA) policies on social media and being disciplined for their actions [20,26,27]. In Texas, a pediatric nurse posted comments on Facebook about a patient with measles who she cared for. No advertent personal information was disclosed; however, the nurse was terminated for HIPAA violation [26].

As a result of ongoing concerns related to unprofessional social media use, nurses are advised to use social media with caution and awareness regarding what they are posting [17,19,20,28]. Nurses are prohibited from posting any images or videos depicting patients or any content that would enable a patient to be recognized. In addition, nurses are warned that it is possible to violate privacy policies without explicitly disclosing patient information [17,19,20,28]. In fact, most instances of nurses violating patient privacy and confidentiality on social media are accidental in nature [17,28]. Finally, nurses are advised to refrain from interaction with patients over social media or use substantial caution in doing so [17,18,28,30-32].

Although the current body of literature examining social media usage by nurses contains insights into both positives and negatives of social media usage, there is an absence of research exploring the growing presence of microcelebrities in the profession who use platforms such as Instagram to showcase their interpretation of the profession. To proactively ensure the safety and privacy of patients and health care professionals in the coming years, it is necessary to examine the current characteristics and behaviors of nurse influencers who use Instagram to expose various elements of the nursing profession, especially those with significant Web-based followings.

Purpose of the Study

The purpose of this study was to identify the characteristics and behaviors of nurses who have attained microcelebrity status on Instagram and use their nursing profile to gain attention and presence on the Web.

Methods

Overview

This study was an exploratory, nonparticipatory content analysis of publicly available data found on Instagram, guided by Graneheim and Lundman's qualitative content analysis framework [33]. The framework developed by Graneheim and Lundman was selected for the study to enable researchers to gain a rich understanding of information by analyzing both manifest and latent data [33]. In this study, data were examined to identify the characteristics and behaviors of *microcelebrity Instagram users* [33]. The underlying meaning of posts was examined to gain an understanding of the types of messages being projected by microcelebrity Instagram users.

An initial step in Graneheim and Lundman's content analysis framework is the identification of the unit of analysis [33]. In this study, the unit of analysis was a textual description of the microcelebrity Instagram users' Instagram posts, including the direct caption and the researcher's description of each post. Once created, the unit of analysis was divided to form meaning units. The meaning units for this study were written descriptions of each individual Instagram post and the exact accompanying caption. The meaning units were condensed to summarize the manifest content of each Instagram post. After the manifest content emerged, abstraction took place, in which the summarized meaning units were further analyzed for their latent content and labeled with a code. Codes were grouped into subcategories and categories [33]. The categories were reviewed and revised, as emergent themes were identified [33].

Ethics Approval

The Western University Health Sciences Research Ethics Board deemed this study did not require ethical clearance for completion.

Sample

Purposive sampling was used to enable variation in identifying the characteristics and behaviors of nurses with active microcelebrity status on Instagram. To be included in the study, the following needed to be met: (1) the user's Instagram account had to be publicly available, possessing a minimum of 10,000 followers; (2) the 10 most recent posts from the user must have been created between 2017 and 2018; (3) all content should be written in English; (4) the majority of the user's content had to be focused on the nursing profession; and (5) the user must have self-identified as a registered nurse in their Instagram account description. Owing to the exploratory nature of this study, the sample was limited to registered nurses. A small sample enabled researchers to gain a rich understanding of the phenomenon within this group.

A priori, it was estimated that analysis of 10 to 15 microcelebrity Instagram accounts would result in data saturation. The amount of data to be collected from 10 to 15 microcelebrities (with 10 posts per individual) was deemed to be sufficient and comparable with other studies that used purposeful samples of social media data [34-36].

To obtain the sample, hashtag and keyword searches were performed on Instagram using the following search terms: *#nurse(s)*, *#registerednurse*, *#rn* as well as *nurse(s)*, *registerednurse*, and *rn*. These terms were selected to aid the identification of relevant Instagram accounts. When a hashtag is searched on Instagram, results consist of publicly available Instagram posts that have been tagged with the hashtag. Posts are displayed as *top posts* and *most recent* posts. *Top posts* populate hashtags that are trending, displaying 9 of the most liked posts containing that hashtag [3]. For each search, the 9 *top posts* for every hashtag were selected, and the Instagram user who created the post was identified and examined for study eligibility. Sampling was limited to the *top posts* search results, as the study aimed to identify Instagram users with active microcelebrity status.

Following the hashtag search process, an Instagram keyword search was conducted to identify additional eligible Instagram users. When an Instagram keyword search is conducted, the results populate, as a list of Instagram accounts that are relevant to the keyword searched. The first 10 results of each keyword search were assessed for study eligibility. Through the sampling process, 10 Instagram accounts were selected for the study. To protect the privacy of Instagram users, each account was randomly assigned a participant code number between 01 and 10.

Data Collection

The data collection and analysis framework for the study was developed from Graneheim and Lundman's [33] framework for qualitative content analysis. The data for this study consisted of each of the 10 microcelebrity Instagram user's 10 most recent posts (images, videos, and captions). To collect data, the researcher examined each Instagram user's posts individually. All study data were collected between September 2017 and August 2018. Each microcelebrity Instagram user was identified, and their 10 most recent posts were labeled in reverse chronological order. For each Instagram post, the researcher copied and pasted the entire caption to a secured word document. Then, the researcher described the manifest content of the post's photo or video in the written text. For example, the manifest content of microcelebrity Instagram user 10's, post 7 was captured as follows:

> *A collage of three images of the microcelebrity Instagram user. Image one: Microcelebrity Instagram user walking towards a retail store with a shopping cart. Image two: Microcelebrity Instagram user sleeping in a bed. Image three: Microcelebrity Instagram user sitting on a couch holding a glass of wine, an ice cream carton, and a pizza box. The heading of the collage states, "What nurses do on their days off..." The caption states, "This is my life! ... Please tell me I'm not alone."* [Microcelebrity Instagram user 10, Post 7]

The data collection process was completed for the 10 most recent posts of each of the 10 Instagram users, totaling 100 Instagram posts for analysis.

Data Analysis

From the unit of analysis, meaning units were created by dividing the text into each microcelebrity Instagram user's content and further subdividing them into individual Instagram posts. Thus, the meaning units for this study comprised a written description of each Instagram post. The meaning units were then condensed to summarize the manifest content of each Instagram post [33]. Through this process, the researcher abridged the direct meaning of both the photo or video and caption into a shortened textual description.

Following summarization, meaning units were exported to NVivo 12 (QSR International) for further analysis. Then, the process of abstraction took place, in which the summarized meaning units were analyzed for their latent meaning and labeled with a code. Once each post was coded, the codes were analyzed for similarities and differences and grouped into subcategories and then into categories. The categories were then reviewed, discussed, and revised. Once the revision process was complete, emergent themes were identified [33].

Results

Overview

Through data analysis, 5 themes emerged: (1) *engaging Instagram users*, (2) *educational opportunities and insights*, (3) *nursing-related humor*, (4) *emotions experienced by nurses*, and (5) *media and narratives including patient details or work context*. Seven of the microcelebrity Instagram users appeared to be female, and 3 microcelebrity Instagram users appeared to be male. Three of the microcelebrity Instagram users stated that they live in the United States of America, whereas the

geographic locations of the remaining microcelebrity Instagram users were unknown.

Engaging Instagram Users

Commonly, microcelebrity Instagram users interacted with followers by generating discussion within their posts. Multiple microcelebrity Instagram users posted questions related to the nursing profession or clinical knowledge and encouraged responses in the post's comment field. For example, microcelebrity Instagram users encouraged discussion related to dealing with a negative workplace culture and strategies to find a new nursing job. In addition, microcelebrity Instagram user 05 created multiple problem-solving posts that encouraged users to test nursing-related knowledge (Microcelebrity Instagram user 05, posts 2 and 10).

Along with a generic discussion of the profession or clinical knowledge, most microcelebrity Instagram users also created personalized brands based on some elements of their unique physical, cultural, or personality characteristics (eg, gender, ethnicity, and religion) and reinforced elements of this personalized brand within their Instagram posts. For example, microcelebrity Instagram user 04 repeatedly engaged in self-branding by highlighting the personal characteristics that made him unique. Microcelebrity Instagram user04 stated:

> *When people say, "What's a nurse?" They think of Florence Nightingale, a female wearing a little hat, white dress with a stethoscope. They don't automatically think of someone who's a Bilingual/Hispanic Male or a different culture ethnicity all Tatted covered with Ink...thats a MAN of GOD.* [Post 7]

Multiple microcelebrity Instagram users engaged in other branding activities by encouraging users to purchase individualized products that they developed or endorsed. Furthermore, promoting external merchandise and products was common, as 8 of the microcelebrity Instagram users promoted at least one merchandise or product that was not their own creation. For instance, microcelebrity Instagram users promoted businesses selling nursing-related uniforms, equipment, or services as well as non-nursing-related companies (eg, Cherokee Uniforms, Peloton, and Johnson & Johnson). In all these examples, it was unclear if the microcelebrity Instagram users were compensated for creating posts.

Educational Opportunities and Insights

Nursing-related educational opportunities and insights were a prominent theme of Instagram posts. Microcelebrity Instagram users encouraged followers to attend nursing-related educational events and posted photos of themselves at nursing conferences. In addition to promoting formal educational opportunities, multiple microcelebrity Instagram users shared their insights related to clinical nursing skills. For example, microcelebrity Instagram user 05 posted medication dosage questions, along with information about the medication, and encouraged users to complete the problem and comment on the solution. In addition, microcelebrity Instagram users provided their opinions on the various roles that nurses undertake. For example, microcelebrity Instagram user 04 posted 3 video clips in which operating room nurses discuss their responsibilities. In the videos, operating rooms were shown to appear to be in use, including patients on operating tables. It is unclear if the videos are real or performed; however, the videos appear realistic. Finally, only 2 posts related to obtaining formal nursing education at an undergraduate or master's level, both of which shared a general motivational message about persevering through the challenges associated with nursing school.

Nursing-Related Humor

In this study, the use of humor was evident in several Instagram posts. Frequently, humor was used in a manner that may only be understood by those with the contextual knowledge that comes with working as a health care professional, such as:

> *Remember don't over resuscitate your self with turkey and beer or you might end up with Abdominal Compartment Syndrome!* [Microcelebrity Instagram user 03, Post 3]

Another example was related to the experiences that nurses may encounter at the workplace. Microcelebrity Instagram user 01 posted an image of a white background with overlaying text:

> *"What were his respirations?" First of all, I haven't counted respirations since nursing school.* [Post 8]

The caption reads:

> *Too slow, too fast, normal, prepare to intubate. Those are the rates.* [Microcelebrity Instagram user 01, Post 8]

To fully understand these forms of humor, readers must possess the requisite knowledge of medical terminology as well as the contextual knowledge associated with working as a health care provider.

Humor was observed in multiple Instagram posts, as microcelebrity Instagram users described potentially stressful situations. Microcelebrity Instagram user 08 posted a series of memes, depicting a professional basketball player holding his arms out, mouth open, appearing shocked, and disgruntled during a game. The headings were as follows:

> *When ICU refuses to take report because the patient is "too unstable."* [Microcelebrity Instagram user 08, Post 5]
>
> *When your A&Ox4 patient decides they're too tired so they just pee in the stretcher.* [Microcelebrity Instagram user 08, Post 5]

The caption further read:

> *I wish I could say all of the above scenarios are made up-but no no, they're all real life.* [Microcelebrity Instagram user 08, Post 5]

Similar to the previous examples, users require contextual and clinically based knowledge to interpret the meaning of this post.

Emotions Experienced by Nurses

Inspiration, motivation, and encouragement were the most prominent emotions displayed by Instagram users, as every microcelebrity Instagram user shared at least one post demonstrating these emotions. Several posts were positive in

nature, as microcelebrity Instagram users presented optimistic captions or portrayed nurses as heroic figures. For example, microcelebrity Instagram user 02 expressed gratitude by stating:

> *There are many forms of family...For me, my work family is as much a part of my life as my real one...There's something about the few quiet moments on a morning like this before the chaos starts when you're reminded to give thanks for countless reasons.* [Post 9]

In addition to the positive emotions associated with the nursing profession, microcelebrity Instagram users described the challenges they experienced while nursing. The challenges described by microcelebrity Instagram users included mental and physical exhaustion, learning how to prioritize tasks, manage time, deal with workplace bullying, and shiftwork. Although many challenges associated with nursing were identified, every Instagram post that discussed a challenge concluded with a positive message. For example, microcelebrity Instagram user 02 stated:

> *Today was, legitimately, a "Top 3 Worst Shifts I've Ever Had as an ICU Nurse" kind of day. Nothing went right...& things just got worse by the hour...I'm exhausted...But no matter how bad the day gets—& trust me, in our world, it can get ugly—only your work family knows how to make you crack a smile...I genuinely believe that the long, ugly days & crazy hours impact how you see the world. Smile because you have love. Smile because you have life. Smile because life is precious, & every moment with loved ones matters...Give thanks, even after a long & torrid day.* [Post 8]

In these posts, microcelebrity Instagram users consistently shared messages of encouragement, despite experiencing challenging situations associated with the nursing profession.

Media and Narratives Including Patient Details or Work Context

Multiple Instagram posts depicted scenarios in which the photo or video appeared to have taken place in a workplace setting or potentially include patient information. For instance, multiple Instagram posts appear to depict patients in the hospital, although the sources of the images are not cited. microcelebrity Instagram user 03 posted an image of a patient's abdomen undergoing a surgical procedure, providing education on abdominal compartment syndrome in the caption. It is unclear if the patient consented to have this photo taken or if consent was obtained to post the image on Instagram. In another post, microcelebrity Instagram user 03 posted an image of a patient sitting in a stretcher, covered in dried blood, smiling, and surrounded by hospital staff members. The caption was unrelated to the image, asking volunteers for a trauma course. In addition, microcelebrity Instagram user 04 posted a series of video clips showing what appeared to be multiple patients on operating tables while receiving preprocedure treatments. No qualification was made in the post as to whether the patients depicted in the image were actually real or standardized patient actors.

Furthermore, several of the microcelebrity Instagram users' Instagram posts consisted of images that appear to have been taken in workplaces, with no patients seen. Multiple posts depicted microcelebrity Instagram users dressed in work attire while in hospital settings; other posts showed patient care areas with no patients present.

Discussion

Principal Findings

The findings of this study have identified a gap between nursing research, policy, and practice. Previous research has recommended the integration of social media with the nursing profession; however, policies continue to advise nurses to keep their professional lives separate from any social media use [14,28,37-40]. Further inquiry should be conducted to determine why this gap exists and identify how elements of policy and practice can be integrated in a safe and efficient manner.

All 10 microcelebrity Instagram users attempted to engage with followers, which supports previous research suggesting that a primary motive for Instagram use is social interaction [9]. Eight microcelebrity Instagram users directly participated in self-branding or merchandise solicitation. In particular, microcelebrity Instagram user 04 consistently promoted their personal brand, attempting to generate a distinct persona through reinforcement of this brand to their followers. It appears that microcelebrity Instagram user 04 may have been attempting to use his charismatic nature to help foster a sizable Web-based following by capitalizing on their personal brand as a *unique selling point* [6,7,41]. Furthermore, microcelebrity Instagram users consistently engaged with followers by generating discussion, which may have been in an attempt to gain social support and encourage feelings of belonging, as this has been found to be a primary motivation for Instagram use [9-11].

An interesting finding of this study was that many microcelebrity Instagram users used Instagram to share learning opportunities and describe their understanding of nursing-related clinical information. For example, microcelebrity Instagram users challenged followers to answer questions about medication administration. In addition, microcelebrity Instagram users described their perspective on the roles and responsibilities that nurses have in specific work environments, including areas such as the operating room. Sharing insights about nursing-related learning has not previously been identified as a primary reason for Instagram use. The findings from this study suggest that microcelebrity Instagram users may also use Instagram to promote educational opportunities such as courses and conferences. The reasons why microcelebrity Instagram users promoted these learning opportunities are unknown.

Humor was frequently demonstrated by microcelebrity Instagram users, often used in a manner that required the reader to have contextual knowledge to understand clinical abbreviations and terms used in the caption, in conjunction with the corresponding image. In addition, self-enhancing humor appeared to be used as a way to manage potentially stressful situations [42]. For example, microcelebrity Instagram user 08 posted a series of memes that described situations that could be

experienced in nursing. However, depending on the reader's contextual understanding, the post may be interpreted as a form of mockery for not following the directions or advice given by the health care provider.

It was also common for microcelebrity Instagram users to express their emotions through Instagram posts, which has been previously identified as a motive for Instagram use [9,11]. However, previous literature suggests that self-expression on Instagram is achieved primarily through the process of creating, editing, and posting images [9,11]. In this study, self-expression was often conveyed through heartfelt captions rather than the images themselves. Images included in the posts with meaningful captions frequently appeared to be unrelated to the caption. Most often, the unrelated images were of the microcelebrity Instagram user standing alone and smiling. In these posts, it appears as though microcelebrity Instagram users were primarily using the captions to express themselves, as opposed to creating unique images as a form of self-expression.

Five posts generated by microcelebrity Instagram users appeared to potentially depict patients, although the sources of the images and videos are unknown. As such, it is unclear if the images and videos contained patients or actors. The overwhelming consensus from nursing practice regulators is that nurses should refrain from posting any content on social media that contains patients or patient information [28,37-40]. Similarly, previous research advises nurses to refrain from posting patient information on social media [14,16-18,20,28,37-40]. However, an image posted by microcelebrity Instagram user 03 showed an open abdomen during a surgical procedure. Similarly, microcelebrity Instagram user 04 posted a series of videos showcasing an operating room environment, with what appeared to be patients awaiting surgical procedures. The uncertainty as to whether these posts show real patients or standardized patient actors demonstrates the need for further research to guide education and policy development. If the posts are depicting actual patients, there needs to be further research regarding the response of other clinicians witnessing this behavior as well as regarding how infection control practices may be compromised by staff taking pictures amid surgical procedures.

Finally, several posts showed the microcelebrity Instagram user posing in a workplace setting, dressed in work attire, with no overt patient health information displayed. At present, professional nursing guidelines do not specify whether or not it is appropriate to post an image of oneself in a workplace [37-40]. However, the Registered Nurses Association of Ontario (a professional association for Ontario nurses, who often publish clinical practice guidelines) [40] suggests that if there is uncertainty if a post is appropriate, the user should refrain from posting. Given that multiple microcelebrity Instagram users post workplace-based images, further work should be completed to determine how health care organizations interpret the depiction of their facilities via social media channels, especially when these images are instantaneously amplified by the significant following possessed by microcelebrity Instagram users.

Nurses' Social Media Use

Over the last decade, practical recommendations and policies developed by both researchers and regulatory bodies have begun to emerge in an effort to help mitigate social media–related risks by expressing the expectations of nurses and reinforcing best practice guidelines [14,17,19,28,37-40]. Much of the available advice regarding nurses' social media use portrays social media use in a negative manner, focusing on what not to do [21]. However, some literature does exist on how nurses can use social media in a positive manner. For example, nurses are encouraged to build a personal brand and express their opinions in health-related conversations on social media platforms, provided they are aware of and comply with privacy as well as relevant workplace policies [19,43]. In this study, multiple microcelebrity Instagram users developed personal brands and voiced their opinions on various nursing-related topics via Instagram. The findings of this study also demonstrate that nurses may be violating regulatory policies, as evidenced by images and videos of what appear to be patients. The findings of this study demonstrate a need for further guideline development that focuses on what nurses should be doing on social media to maintain professionalism and protect patients' rights.

Implications for Nursing Education and Practice Policies

The findings of this study highlight the need for further education and practice policy development with regard to nurses' Instagram use. Incongruencies currently exist between (1) how recommendations for integrating social media into nursing practice are enacted by some nurses; (2) the current guidelines for social media use by nurses; and (3) the ways in which nurses use social media, especially those possessing Web-based microcelebrity status. Although previous research has recommended that social media be integrated with nursing practice, current policies strongly urge nurses to avoid any and all contact with patients over social media [37-40]. In contrast, the findings of this study demonstrated that nurse microcelebrities actively engage and interact with thousands of Instagram users and generate personalized interpretations of the nursing profession via social media. In addition, in this study, multiple microcelebrity Instagram users posted images or videos that appeared to have depicted patients receiving care. Although the sources of the posts are not specified, the content of these posts directly contrasts existing guidelines for nurses' social media use. For the nursing profession, it is imperative for nursing education, professional regulatory bodies, and employers to develop more robust and dynamic policies and guidelines related to the appropriate use of social media within the profession [16,21], especially with the growing presence of Web-based nurse microcelebrities.

At present, a gap exists in the policy regarding Instagram and other social media use by nurses who have attained a microcelebrity status. The findings of this study suggest that nurses who have achieved microcelebrity status may use Instagram for a variety of purposes, and there needs to be clarity in what is considered appropriate professional behavior. Given the rapid evolution of social media, it is imperative that both

education and policy initiatives make efforts to maintain relevancy as related to new usages of these kinds of technology, including nurses who actively use these platforms to seek Web-based microcelebrity status.

Limitations

A limitation of the study was the noninteractive nature of the research, whereby only secondary analysis of preexisting Instagram photos and textual content were analyzed. Owing to the methodology and ethical requirements of the study, no participants examined in this study were contacted to comment on the findings emerging from the data analysis. Thus, ensuring appropriate representation of data, as opposed to the researcher's interpretation of data, was a challenge of this qualitative content analysis [33].

Finally, this study focused exclusively on registered nurses who had achieved a level of microcelebrity status only on Instagram. Although Instagram is one of the most popular social media platforms in 2019, different or more nuanced findings may have emerged if nursing microcelebrities who used other social media platforms (ie, YouTube and Twitter) were included in the study [1].

Future Directions

The findings of this study support the need for further research in several domains related to nurses who have attained microcelebrity status on Instagram. Further research should be completed in both the qualitative and quantitative paradigms to develop a well-rounded understanding of the concept of nurses seeking microcelebrity status on social media. Future explorations should also be conducted to determine who are following nurse microcelebrity Instagram user accounts and their reasons for doing so. The examination of merchandise endorsement as well as the reactions of microcelebrity Instagram users' followers to Instagram advertisements is also a worthwhile area for subsequent exploration. Similar research may be conducted on alternate groups of health care professionals, such as physicians, to identify if similar behaviors occur outside of the nursing profession. Finally, there is an urgent need for further research on the risks associated with nurses posting images and videos depicting patient care on Instagram.

Conclusions

The findings of this study suggest that posting characteristics and behaviors of registered nurses who have attained microcelebrity status on Instagram include (1) *engaging Instagram users*, (2) *educational opportunities and insights*, (3) *nursing-related humor*, (4) *emotions experienced by nurses*, and (5) *media and narratives including patient details or work context.*

Implications exist for nursing professionals in terms of potential privacy, professionalism, and ethical challenges associated with social media use. As social media platforms continue to thrive and evolve, nurses must be able to effectively use social media while maintaining professionalism. Nursing practice policies and guidelines must be updated to include recommendations pertinent to nurses with microcelebrity status, to maintain nurses' professionalism and to protect patients' safety.

Acknowledgments

HK's graduate studies were supported by the Ontario Graduate Scholarship (2017-2018). The authors would also like to thank the reviewers for their thoughtful and constructive feedback.

Authors' Contributions

HK and RB contributed to the design of the study. HK implemented the study design, data collection, and data analysis under the advice and supervision of RB. KJ contributed to the finalization of the analysis and generation of the manuscript.

Abstract

Background: Work-life balance is associated with health behaviors. In the face of digitalization, understanding this link requires a theory-based investigation of problematic internet use and perceived stress, which are so far unknown.

Objective: On the basis of the compensatory carry-over action model, this study aimed to determine whether problematic internet use and perceived stress mediate the relationship between health behaviors and work-life balance in two groups of internet users from different environments (residents in Germany and China). We also investigated whether the place of residence was a moderator.

Methods: An online questionnaire (N=877) was administered to residents from Germany (n=374) and China (n=503) in 3 languages (German, English, and Chinese). Moderated mediation analyses were run with health behaviors as the independent variable, work-life balance as the dependent variable, problematic internet use and perceived stress as the mediator variables, and place of residence as a potential moderator.

Results: On a mean level, individuals in Germany reported less problematic internet use and more health behaviors than individuals in China; however, they also had lower work-life balance and higher perceived stress. Results showed that health behaviors seem to be directly related to work-life balance in both groups. Among the residents of Germany, a partial mediation was revealed (β=.13; *P*=.01), whereas among the residents of China, a full mediation was found (β=.02; *P*=.61). The mediator role of perceived stress was compared with problematic internet use in all the serial models and the parallel model. Residence moderated the relationship between health behaviors and work-life balance: The interrelation between health behaviors and work-life balance was stronger in Germany (β=.19; *P*<.001) than in China (β=.11; *P*=.01) when controlling for other variables.

Conclusions: The findings of this study are in line with the compensatory carry-over action model. To promote work-life balance, individuals should perform health behaviors to help overcome problematic internet use and perceived stress. Both problematic internet use and perceived stress mediated health behaviors and work-life balance partially in German study participants and fully in Chinese study participants.

Introduction

Work-Life Balance

Increasingly, many people struggle with maintaining a work-life balance [1] and have to manage issues arising from a poor work-life balance, such as sickness, limitations in the ability to work, and absence of work [2]. There has been increasing attention on how best to achieve a work-life balance in the modern society, which has been investigated by researchers from different perspectives. Work time (eg, long work hours) has been found to have a negative association with work-life balance [3-5]. When exploring the ways to decrease this issue, it was found that the internet can help change the traditional work model to a more flexible model. The use of emails, smartphones, and home computers, for example, makes it possible to work without having a typical *nine-to-five* workday [6], which may help to maintain a work-life balance. However, it was also found that excessive internet use can decrease work-life balance [7-9]. Perceived stress was also found to be an important factor that affects work-life balance negatively [10], but which could be mitigated by health behaviors [9]. Previous evidence has indicated that health behaviors (eg, regular physical activity and healthy diet) help to prevent stress [11]. Moreover, health behaviors, such as regular physical activity and healthy nutrition of employees, have also been recommended to maintain a work-life balance [12-14].

Health Behaviors

Common important health behaviors include both health-promoting behaviors [15], for instance, physical activity [16,17] and a healthy diet (eg, sufficient water intake and fruit and vegetable intake) [18,19], and health-risk behaviors [16,17], such as smoking status [16,20,21] and alcohol consumption status [22,23]. Previous studies have found that different single health behaviors are interrelated [16], such as diet and exercise [24,25] and smoking and alcohol consumption [18]. There is increasing focus on how to help employees maintain their work-life balance. Besides efforts by employers, employees can also help themselves to improve their work-life balance by performing health behaviors after work. Employees' health behaviors are the focus of this study that sought to explore how people's health behaviors interrelate with work-life balance.

Perceived Stress and Problematic Internet Use as Mediators

As described earlier, not only health behaviors but also problematic internet use and perceived stress have been found to play a role in work-life balance [10,26]. The *compensatory carry-over action model* by Lippke [27] provides an approach to understanding the underlying psychological and behavioral mechanisms of multiple behaviors related to an outcome. However, the model has not yet been applied to the main focus of this paper, that is, work-life balance, internet use, and health behaviors. According to this model, different behaviors are not isolated; rather, they interact with each other in complex ways. Emotionally relevant higher-level goals (such as work-life balance) drive different health behaviors by initiating and strengthening behavior-specific intentions [27]. If individuals have set a higher-level goal and did not reach this goal (eg, because of situations such as work stress), their well-being is affected [28-30]. As previous studies have indicated, most people experience different stressors within their lives, which can interfere with adopting and maintaining behaviors [27]. In line with this model, perceived stress has been found to be a negative indicator of quality of life [31-33]. Moreover, it has been found that stress acts as a mediator between work-family conflict and psychological health [34]. Previous evidence has also indicated that health behaviors (eg, regular physical activity and healthy diet) help to prevent stress [11] and maintain a work-life balance [12-14]. Among a sample of working individuals, higher perceived stress was found to be associated with a higher fat diet and less physical activity [35,36]. Perceived stress may be one factor that undermines the positive relationship between health behaviors and work-life balance. However, the mediator role of perceived stress between health behaviors and work-life balance has received limited attention in previous research. This study is a novel effort to fill this gap, in particular, to help understand the interrelation of different health behaviors and internet use behavior on the basis of the *compensatory carry-over action model*.

Previous studies have also found that poor health behaviors, such as inadequate nutrition intake, were related to problematic internet use [7-9]. According to the *compensatory carry-over action model* [27], the outcome experience (eg, problematic internet use) from one behavior (eg, internet use behavior) may also affect a higher-level goal (eg, work-life balance) together with another behavior (eg, health behavior). Although the internet may help to arrange flexible work time and in turn maintain work-life balance [6], for some people, problematic internet use can also harbor hazards to their work-life balance [7-9]. Moreover, time is a finite resource, the use of which must be divided among individual needs, work, and family needs [37]. Problematic internet use may occupy the time one could spend on physical activity, family, and work and is thus negatively related to work-life balance. Excessive internet use has been found to be associated with behaviors that negatively affect people's health, mood, work, and occupation [38]. So far, little is known about the relationship between health behaviors and work-life balance, while also considering the risk brought by problematic internet use. Owing to the large number of people suffering from the consequences of problematic internet use [39], it is important to examine how health behaviors combined with problematic internet use interrelate with work-life balance.

Some studies have indicated that problematic internet use has a direct impact on perceived stress [40,41], for example, it was found that problematic internet use is related to perceived stress and negative feelings, such as depression and anxiety [42,43]. Other studies have shown that perceived stress plays an important role in problematic internet use [44,45]. According to the *compensatory carry-over action model* [27], both perceived stress and problematic internet use may mediate the relationship between health behaviors and a higher-level goal (ie, work-life balance).

In this study, this underlying mechanism of this relationship was explored by comparing two possible serial models, with perceived stress and problematic internet use as serial mediators.

If problematic internet use is assumed to influence perceived stress, then the chain is as follows: health behavior → problematic internet use → perceived stress → work-life balance. If one assumes that perceived stress influences problematic internet use, then the chain is as follows: health behavior → perceived stress → problematic internet use → work-life balance.

Place of Residence Differences Among Study Variables

Previous studies have shown large cultural differences between China and Germany [46,47]. For example, according to Hofstede's empirical framework, Germany is representative of a *Western* country and individualistic society, in which people consider their needs over the needs of the organization to which they belong. Conversely, China is representative of an *Eastern* country and collectivistic society, in which people put the needs of the organization before individual needs [48-52].

On the basis of these differences, previous studies comparing work-life balance between *Western* and *Eastern* companies revealed that work-life balance ranks higher in Western companies than in Eastern companies, as more attention is given to it [53]. The contexts of work-life conflict and solution in China are significantly different from those found in Western countries [54]. Some studies have found that in Eastern countries, family, including elderly parents, may provide advice and emotional support when people need help in maintaining a work-life balance [55,56]. Culture has been found to moderate the relationship between work resources and work-family conflict [57]. Although health behaviors as personal resources [58] were found to be associated with work-life balance [12-14], the moderator role of the place of residence between health behaviors and work-life balance still needs to be investigated.

The difference in health behaviors between Western countries, such as European countries and the United States, and Eastern countries, such as China, was investigated in previous studies [59,60]. Factors such as the geographic, historical, and economic development stage of a country and the coping mechanisms of its citizens may affect people's health behaviors, such as food preferences and physical activity [61,62]. For example, the number of facilities for physical activity provided by the government (eg, parks) may inhibit or facilitate participation in physical activity, depending on the socioeconomic status [62]. It has been found that fruit intake and physical activity have higher prevalence in Western countries [63], and the percentage of nonsmokers is higher in Eastern countries than that in Western counties [63]. Differences in perceived stress exist between Western and Eastern countries as well [64,65]. For problematic internet use, previous studies have shown that Eastern counties have a higher internet addiction score than Western countries [66,67].

Proposed Research Questions

On the basis of these previous research findings and the *compensatory carry-over action model*, this study sought to understand and explore the mechanisms underlying the relationship between health behaviors and work-life balance.

The following two major research questions were addressed:

1. Do problematic internet use and perceived stress mediate the relationship between health behaviors and work-life balance in both Germany and China?
2. Does the country of residence moderate the relationship between a healthy lifestyle and work-life balance?

Methods

Participants

The online survey included 877 participants (538/877, 61.3% women). German (98/877, 11.2%) and English (276/877, 31.5%) versions of the questionnaire were used to collect data in Germany (group 1: residents in Germany), and a Chinese (503/877, 57.4%) version of the questionnaire was used to collect data in China (group 2: residents in China). A minimum sample size of 233 was used in both groups. The participants' ages ranged from 17 to 65 years (mean 30.0, SD 10.8).

Procedure

Data were gathered from residents in middle-sized cities in Germany (Bremen) and China (Shijiazhuang). As Germany is the second most popular migration destination in the world [68] and English is widely spoken in Germany, both German and English versions of the questionnaire were provided for the participants to freely choose the language they prefer (no significant differences were found between the German and English versions of the questionnaire in the pilot analyses). Residents in China were provided with the Chinese version of the questionnaire.

The online questionnaires were used to collect data from October 2016 to August 2018 through email (in Germany and China), Facebook (in Germany), and link distribution face to face (with the help of the research assistants in Germany and with the help of primary school teachers who distributed the questionnaires among the pupils' parents at parent-teacher conferences in China). Participants answered multiple-choice questions by clicking the appropriate check box and open questions by inputting text content. On the first page of the survey, all participants were informed of the confidentiality, anonymity, and voluntary nature of their responses and given the opportunity to obtain the study results by providing contact information on the page. Those who clicked the box to provide their informed consent could continue to the questionnaire pages. The study received ethical approval by the Ethics Commission of the German Association of Psychology (Deutsche Gesellschaft für Psychologie, EK-A-SL022013). The link for the survey was sent to the staff and students in universities. Study participants were also asked to forward the invitation and the link to families and friends in Germany and China.

Measures

Health behavior was operationalized from the summation of 5 items: physical activity, sufficient water consumption, nutrition, smoking status, and alcohol consumption status. For the purposes of analysis, each behavior was coded into a binary variable, with 0 representing the unhealthy option. *Physical activity* was assessed with the short form of the International Physical Activity Questionnaire [69], which has been tested for use in adults and has shown cross-cultural validity and reliability

[70]. This questionnaire covers mild, moderate, and strenuous physical activities. Participants indicated the duration (in minutes) and frequency (in days) of each activity domain per week. Minutes per week were multiplied by days per week to obtain a sum score per activity domain and then added for total activity per week. Total physical activity was classified as 1 (those who fulfilled the World Health Organization's recommendation of ≥2.5 hours per week) and 0 (physical activity <2.5 hours per week).

S*ufficient water consumption* was assessed by the question, "Please think about your typical weeks, do you drink 1.5 L of non-alcoholic and non-caffeinated beverage (water, juice, fruit and herbal tea) during the day?" and it was possible to answer with yes (1) or no (0). This question has been shown to have acceptable reliability and validity [16]. *Nutrition* was measured by the question, "Please think about your typical weeks, do you eat five or more servings of fruit and vegetable per day?" and was to be answered with yes or no. This question has also been shown to have acceptable reliability and validity [71]. *Smoking status* was assessed by asking participants "Are you a smoker?" Answers were classified into 1 (nonsmoker or ex-smoker) and 0 (occasional smoker or regular smoker). The *alcohol consumption status* was assessed by asking participants "Do you drink alcohol on a regular basis?" and was classified as 1 (no) and 0 (yes). Both the smoking and alcohol questions have been shown to have acceptable reliability and validity [72]. All different health behaviors were summed, with 0 indicating the fewest health behaviors performed and 5 indicating the performance of all health behaviors on the recommended level.

Work-life balance was measured by using a 5-item scale [73] consisting of employees' satisfaction with their achieved balance between work and private life. Answers were on a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). Sample items were "I am satisfied with the balance between my work and private life."; "It is difficult for me to balance my work and private life"; and "I am meeting the requirements of both my work and my private life." The Cronbach alpha was .81 in this study.

Perceived stress was measured with 2 questions from the Perceived Stress Scale [74], as in previous studies [75]—"In the last month, how often have you felt nervous and stressed?" and "In the last month, how often have you felt difficulties were piling up so high that you could not overcome them?"—and it was rated on a 5-point Likert scale. The Cronbach alpha was .75 in this study.

Problematic internet use was assessed with the Internet Addiction Questionnaire (ISS-10r) [76]. The current version includes 10 items with answer scores on a scale of 1 to 4 ranging from completely disagree to agree completely (eg, "I often spend more time on the internet than I intended"). For the evaluation of problematic internet use, ISS-10r sum values of the 5 subscales (loss of control, withdrawal symptoms, development of tolerance, negative consequences on work and performance, and negative consequences on social relationships) were utilized. The total score can vary from 20 to 80 and distinguishes 3 types of internet use: no problematic internet use (20-49), problematic internet use tendency (50-59), problematic internet use (60-80). The ISS-10r is one of the validated tools to assess problematic internet use, and the Cronbach alpha was .81 in this study.

Participants also answered sociodemographic questions, including those on age, gender, height, weight, marital status, employment status, and education level.

Statistical Analysis

A correlation analysis was performed to investigate the relationships between health behaviors, perceived stress, problematic internet use, and work-life balance in both groups (group 1: residents in Germany and group 2: residents in China). Moderated mediation analyses were run with health behaviors as the independent variable, work-life balance as the dependent variable, problematic internet use and perceived stress as the mediator variables, and place of residence as a moderator in both groups. Moderated mediation analyses were performed using SPSS version 24 (IBM Corp) and PROCESS [77]. Significance was accepted at an alpha level of .05.

Results

Preliminary Analyses

In this survey, 42.6% (374/877) of participants completed the German or English version of the questionnaire (group 1: residents in Germany), and 57.4% (503/877) of participants completed the Chinese version of the questionnaire (group 2: residents in China). When comparing health behavior items between these 2 different places of residence groups, *Physical activity* participation was higher in group 1 than in group 2 (245/374, 65.5% vs 277/503, 55.1%; *P*=.002), more participants have S*ufficient water consumption* in group 1 than in group 2 (270/374, 72.2% vs 213/503, 42.3%; *P*<.001), more participants drink alcohol on a regular basis (*alcohol consumption status*) in group 1 than in group 2 (180/374, 48.1% vs 125/503, 24.9%; *P*<.001), and there were no significant differences in *Nutrition* (*P*=.35) and *Smoking status* (*P*=.85) between the 2 groups. When comparing other variables between these 2 different places of residence groups, problematic internet use and work-life balance scores of group 2 were significantly higher than those of group 1, whereas perceived stress and health behaviors were lower in group 2. Descriptive statistics are presented in Table 1.

Table 1. Descriptive statistics of main study variables in the 2 groups (N=877; group 1: residents in Germany and group 2: residents in China).

Variables	Group 1, mean (SD)	Group 2, mean (SD)	Total		*t* test (df)	*P* value
			Mean (SD)	Range		
Age (years)	26.7 (12.5)	32.5 (8.4)	30.0 (10.8)	17-65	−8.24 (875)	<.001
Problematic internet use	41.8 (11.6)	44.2 (11.9)	43.2 (11.8)	20-80	−2.96 (875)	.003
Perceived stress	5.3 (1.8)	4.6 (1.5)	4.9 (1.6)	2-10	6.32 (875)	<.001
Health behaviors	3.0 (1.1)	2.9 (1.2)	2.9 (1.2)	0-5	2.44 (875)	.02
Work-life balance	16.5 (4.5)	18.0 (4.1)	17.4 (4.3)	5-25	−5.36 (875)	<.001

Correlation Analyses in Different Groups

Table 2 displays the bivariate Pearson correlation between health behaviors, problematic internet use, perceived stress, and work-life balance. In both groups, health behaviors were positively correlated with work-life balance, whereas problematic internet use and perceived stress were negatively related to a healthy lifestyle and work-life balance.

Table 2. Pearson correlation of variables in 2 groups.

Group 1[a]	Group 2[b]					
	1	2	3	4	5	6
1. Gender[c]	N/A[c]	−0.07	−0.19	0.10	0.02	−0.04
2. Age	−0.11	N/A	−0.05	−0.36	−0.20	0.15
3. Health behaviors	−0.04	−0.06	N/A	−0.12	−0.27	0.11
4. Problematic internet use	0.15	−0.40	−0.16	N/A	0.32	−0.22

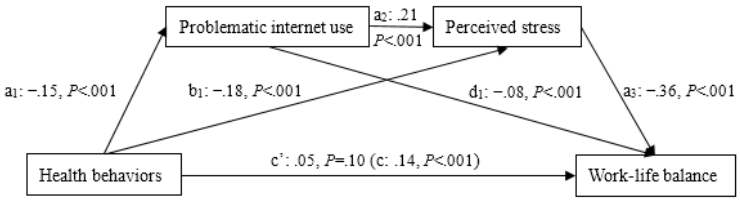
Testing for Mediation Effects

The first aim of the study was to examine whether problematic internet use and perceived stress mediate the relationship between a healthy lifestyle and work-life balance in general. Two possible serial mediation models and one parallel model were estimated and assessed to investigate the mediator roles of problematic internet use and perceived stress.

Serial Mediation

Serial mediation assumes "a causal chain linking the mediators, with a specified direction of causal flow" [78]. Model 6 of PROCESS was used to test 2 possible chains: (1) health behavior → problematic internet use → perceived stress → work-life balance and (2) health behavior → perceived stress → problematic internet use → work-life balance. The proposed research model for chain 1 and results after controlling for covariates (age and gender) are presented in Figure 1. The mediation effect accounted for 19% of the total effect: $F_{5,871}=39.78$; $P<.001$. The residual direct effect was not significant (c' in Figure 1). There were significant indirect paths from health behaviors to work-life balance through problematic internet use (a_1d_1, β=.01, 95% CI 0.002 to 0.03) and perceived stress (b_1a_3, β=.06, 95% CI 0.04 to 0.09). Furthermore, the indirect path from health behaviors to work-life balance through both problematic internet use and perceived stress was also significant ($a_1a_2a_3$, β=.01, 95% CI 0.01 to 0.02). When substituting the order of the mediators to test chain 2, the indirect path remained significant with $P<.001$, but the effect was weaker (β=.003, 95% CI 0.001 to 0.01).

Figure 1. Serial mediation model and path coefficients predicting work-life balance. Path $a_1 \rightarrow a_2 \rightarrow a_3$ is the full serial mediation path (1). Path a_1d_1 is the path from health behavior to work-life balance through problematic internet use. Path b_1a_3 is the path from health behavior to work-life balance through perceived stress.



Parallel Mediation

Parallel mediation assumes that problematic internet use and perceived stress do not influence each other when they mediate the relationship between health behaviors and work-life balance. Model 4 of PROCESS [77] was used to examine parallel mediation. The results of all participants are displayed in Table 3. After controlling for covariates (ie, age and gender), the results revealed that health behaviors were negatively associated with problematic internet use (model 2), which in turn was also interrelated with work-life balance (model 4). In addition, health behaviors were found to be negatively associated with perceived stress (model 3), which was also linked negatively to work-life balance (model 4).

The residual direct effect was not significant, with P=.10 (model 4). The indirect effect of problematic internet use was β=.01, 95% CI 0.002 to 0.03, and the indirect effect of perceived stress was β=.08, 95% CI 0.05 to 0.11. Most variance could be explained in model 4, predicting work-life balance with health behaviors, problematic internet use, and perceived stress.

Results exploring the mediation effects in group 1 and group 2 are shown in Figure 2. In group 1, the residual direct effect was still significant (β=.13; P=.01) after including the mediators indicating a partial mediation only. The indirect effect of problematic internet use was β=.02, 95% CI 0.003 to 0.05; the indirect effect of perceived stress was β=.07, 95% CI 0.03 to 0.11. The mediation effect accounted for 23% of the total effect ($F_{5,368}$=22.48; P<.001).

In group 2, the residual direct effect was not significant (β=.02; P=.61) when including the mediators, indicating a full mediation. The indirect effect of problematic internet use was β=.01, 95% CI 0.001 to 0.04; the indirect effect of perceived stress was β=.07, 95% CI 0.04 to 0.11. The mediation effect accounted for 12% of the total effect ($F_{5,497}$=14.06; P<.001).

Table 3. Mediation effects of health behaviors on work-life balance.

Predictors	Model 1[a] (work-life balance)		Model 2[b] (problematic internet use)		Model 3[c] (perceived stress)		Model 4[d] (work-life balance)	
	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value	β (95% CI)	*P* value
Gender[e]	.04 (−0.10 to 0.18)	.53	.14 (0.02 to 0.27)	.03	−0.10 (−0.23 to 0.03)	.14	.02 (−0.11 to 0.15)	.76
Age (years)	.02 (0.01 to 0.03)	<.001	−0.03 (−0.04 to −0.03)	<.001	−0.03 (−0.03 to −0.02)	<.001	.01 (0.001 to 0.01)	.02
Health behaviors	.14 (0.08 to 0.21)	<.001	−0.15 (−0.22 to −0.09)	<.001	−0.21 (−0.28 to −0.15)	<.001	.05 (−0.01 to 0.12)	.10
Problematic internet use	N/A[f]	N/A	N/A	N/A	N/A	N/A	−0.08 (−0.15 to −0.01)	.02
Perceived stress	N/A	N/A	N/A	N/A	N/A	N/A	−0.36 (−0.42 to −0.29)	<.001

[a]R^2=0.06, $F_{3,873}$=17.73, P<.001.

[b]R^2=0.14, $F_{3,873}$=47.55, P<.001.

[c]R^2=0.11, $F_{3,873}$=36.83, P<.001.

[d]R^2=0.19, $F_{5,871}$=39.78, P<.001.

[e]Gender was dummy coded with 1=female and 2=male.

[f]N/A: not applicable.

Testing for Mediated Moderation

The second aim of the study was to examine whether place of residence moderates the relationship between health behavior and work-life balance. This was tested with a mediated moderation analysis (model 8) of PROCESS [77], and the results are displayed in Table 4. In model 1, the total effect of the health behaviors on work-life balance was significant, and this association was not moderated by the place of residence. In model 2, the direct effect of health behaviors on problematic internet use was significant, and this association was also not moderated by the place of residence. In model 3, the direct effect of health behaviors on perceived stress was significant, and this association was also not moderated by the place of residence. In model 4, the direct effect of health behaviors on work-life balance was significant, and there was a significant moderation effect of the place of residence.

To further demonstrate the pattern of this moderation effect, the interaction effect by simple slopes between health behaviors and place of residence on work-life balance is plotted in Figure 3. The simple slope test revealed that in group 1, the interrelation between health behaviors and work-life balance was significant (β=.19; *P*<.001), whereas this relation was weaker in group 2 (β=.11; *P*=.01). All predictors accounted for 20% of the variance in work-life balance in this model.

Table 4. Mediated moderation effects of health behaviors on work-life balance.

Predictors	Model 1[a] (work-life balance)		Model 2[b] (problematic internet use)		Model 3[c] (perceived stress)		Model 4[d] (work-life balance)

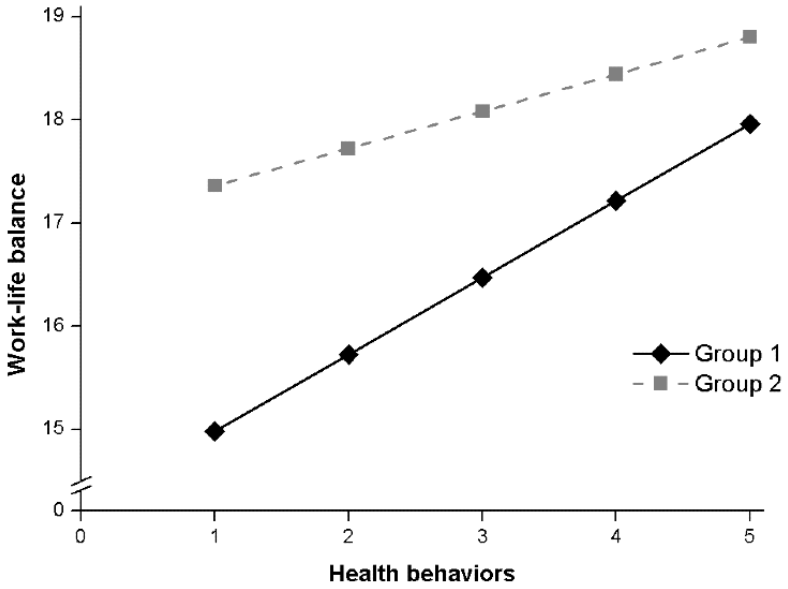
Figure 3. Interaction of health behaviors and residence on work-life balance (Group 1: residents in Germany; Group 2: residents in China).



Discussion

Principal Findings

An online questionnaire assessed residents from Germany (n=374) and China (n=503) in 3 languages (German, English, and Chinese). On a mean level, individuals in Germany reported less problematic internet use and more health behaviors than individuals in China; however, they also had lower work-life balance and higher perceived stress. This study is one of the first studies to explore the potential mechanisms through which health behaviors impact work-life balance [10,26,79]. Results revealed that health behaviors were indirectly related to work-life balance through perceived stress and problematic internet use, and the mediator role of problematic internet use was not prominent in either of the serial models or the parallel model. There was a partial mediation in Germany (group 1) and a full mediation in China (group 2). The relation between health behaviors and work-life balance was significant in group 1, whereas it was weaker in group 2. This study utilized the *compensatory carry-over action model* as the underlying understanding in investigating how health behaviors interrelate with employees' work-life balance.

Mediator Roles of Stress and Problematic Internet Use

When testing the mediator roles of stress and problematic internet use, in both serial and parallel mediation models, the residual direct effect was not significant, which indicated that problematic internet use and perceived stress fully mediated the indirect association between health behaviors and work-life balance. In the serial mediation models, the chain health behavior → problematic internet use → perceived stress → work-life balance was superior to the chain health behavior → perceived stress → problematic internet use → work-life balance. However, the effect size was small. Neither of the proposed serial models revealed a large mediating effect. In the parallel model, results exploring the mediation effects in the Germany group and the China group revealed that in the Germany group, the residual direct effect was significant. This may indicate that problematic internet use and perceived stress partially mediated the indirect association between health behaviors and work-life balance. In the China group, the residual direct effect was not significant, which is because problematic internet use and perceived stress fully mediated the indirect association between health behaviors and work-life balance.

Although health behaviors in general were better in Germany than in China, the work-life balance score was lower. According to the model, this was because of the significant difference in the mediator-perceived stress, which was much higher in Germany than in China. This is in line with previous studies [79].

The mediator role of perceived stress in this study is consistent with previous studies, which found that perceived stress could be mitigated by health behaviors [9] and affected work-life balance negatively [10]. Thus, perceived stress management is of high importance. This result also supports the *compensatory carry-over action model*, as work-life balance is not only associated with predictor variables related to health behaviors but also with mediator variables, such as perceived stress. To the best of our knowledge, this is the first study that clarifies the mediator roles of perceived stress and problematic internet use in a healthy lifestyle consisting of different single health behaviors and work-life balance in different countries of residence.

Although previous studies have found health behaviors to be negatively associated with problematic internet use [7-9], which in turn affects work-life balance [80-82], in this study, the meditation role of problematic internet use was not prominent compared with the perceived stress mediator. This may be because of the interaction between perceived stress and problematic internet use. This study revealed that there was a significant relationship between problematic internet use and perceived stress. Previous studies have indicated that problematic internet use has a direct impact on perceived stress [40,41]; however, perceived stress may also come from other aspects, such as occupational, interpersonal, or financial stresses

[83]. Moreover, previous research has demonstrated that perceived stress plays an important role in problematic internet use [44,45]. It is difficult to judge which factor affects the other, as it depends on circumstances, and this study was only cross-sectional.

Apart from perceived stress and problematic internet use, the path between health behaviors and work-life balance may also be explained by other variables, such as gender. Gender differences have been found in relation to health behaviors in previous studies [84], and they have also been highlighted in work-life balance studies [5]. Some studies have found that women often have more difficulty maintaining a balance because of pressures at work and social role demands at home [85,86]. However, other studies have indicated that men and women report similar levels of work-life balance [87]. Other studies have shown that women tend to present a more positive work-life balance attitude compared with men [88]. Further studies that focus on the organization of work taking the employee's gender difference into account are recommended.

Moderation Role of Place of Residence

This study found that problematic internet use score in China was higher than that in Germany. This is in line with the previous studies, which found that people of an Asian background, such as Chinese, have higher problematic internet use scores than people from Europe or the United States [66,89].

Countries of residence rather than countries of birth were compared in this study, as it has been found that the effects on people's individual life from the place of residence appear to be higher than those from the place of birth [90]. From a closer look at country differences in health behaviors, it seems that the country where one lives provides the context within which a certain kind of behavior is shaped. In the case of Germany, it would be of interest to study the role of the country as a context variable in the health life and behavior of its residents, regardless of their cultural origin. Not only health behaviors but also work-life balance was different because of the country of residence, which involves influences of the natural environment, language, religion, custom, and particular ways of life [91,92]. This study found that the indirect association between health behaviors and work-life balance was moderated by the place of residence. The relation between health behaviors and work-life balance was significant in residents living in Germany, whereas it was weaker in residents in China.

This finding is in line with and further supports previous studies that explored health behaviors related to work-life balance [12,14,17,26,93]. This study also replicates studies that examined work-life balance across different societies [53]. The result showing that the relation between health behaviors and work-life balance was significant in Germany, whereas it was weaker in China, supports the *compensatory carry-over action model*. The model permits different applicability in 2 distinct countries of residence, from which, besides health behaviors, work-life balance could be affected by different factors. Previous studies have found that in Eastern countries, gender socialization plays an important role in one's perception toward work-life balance [53]. Moreover, although age was controlled in this study, other variables such as family responsibility status may be associated with work-life balance as well. Previous studies have indicated that older and married individuals felt less stressed than younger and unmarried people [75]. The possibility of married status in many Chinese participants might modulate the effect of health behaviors on work-life balance as well. This argument should be further explored in future research.

In this study, compared with residents in China, more people in Germany engaged in physical activity for at least 2.5 hours per week and drank enough water, whereas more people in Germany drank alcohol than people in China. These findings are in line with previous studies that have investigated health behaviors in Western countries and Eastern countries [63]. The moderation of the place of residence provides a broad perspective toward the promotion of work-life balance among 2 very diverse groups of countries of residence. By contrasting residents from China and Germany as representatives of prevailing Eastern and Western lifestyles, respectively, we may be able to gain a more global perspective in this issue. Professionals in the medical field should advise their patients in China to engage in more health behaviors and patients in Germany to find ways of lowering perceived stress to balance their lifestyle more adequately.

Limitations

Some limitations of this study should be addressed. First, this was a cross-sectional survey, which limits causal inferences. Moreover, there was a significant age difference between participants in the 2 groups. Although age and gender were included as control variables in this study, other variables such as family responsibility status may be associated with different ages and may impact the results as well. Second, health behaviors only included physical activity, nutrition and water intake, and smoking and alcohol status. However, other behaviors, such as dental hygiene adherence and sexual behaviors, are also related to health and may have an influence. Third, perceived stress was measured with only two items by using the shortened version of the measurement scale, and the Cronbach alpha was not high. The accuracy may not be as good as a full version. Finally, the data were mainly collected within Germany and China. Although participants with a migrant background were able to complete the English version of the questionnaire, the sample range was still limited. Moreover, the years of residence were not controlled, but it may also impact individuals' behaviors. Further studies should overcome these limitations by using longitudinal and experimental designs and considering more aspects and potential factors. It would also be valuable to include more people with different backgrounds regarding their country of residence while controlling other influences.

Conclusions

In summary, this study sheds light on how people's health behaviors interrelate with work-life balance, perceived stress, and problematic internet use. It provides evidence that health behaviors are indirectly related to work-life balance through perceived stress and problematic internet use. This study revealed a partial mediation among residents in Germany and a full mediation among residents in China. The relation between health behaviors and work-life balance was stronger in Germany,

whereas it was weaker in China. Besides performing health behaviors, helping people to relieve their perceived stress and spend only healthy amounts of time with the internet seems essential to maintain a better work-life balance. Future research should be performed in different countries and in different languages, and should be well grounded on a culture theory, such as Hofstede's cultural dimensions theory [48,49].

Abstract

Background: Approximately 42.5 million adults have been affected by mental illness in the United States in 2013, and 173 million people have been affected by a diagnosable psychiatric disorder in China. An increasing number of people tend to seek health information on the Web, and it is important to understand the factors associated with individuals' mental health information seeking. Identifying factors associated with mental health information seeking may influence the disease progression of potential patients. The planned risk information seeking model (PRISM) was developed in 2010 by integrating multiple information seeking models including the theory of planned behavior. Few studies have replicated PRISM outside the United States and no previous study has examined mental health as a personal risk in different cultures.

Objective: This study aimed to test the planned risk information seeking model (PRISM) in China and the United States with a chronic disease, mental illness, and two additional factors, ie, media use and cultural identity, among college students.

Methods: Data were collected in both countries using the same online survey through a survey management program (Qualtrics). In China, college instructors distributed the survey link among university students, and it was also posted on a leading social media site called Sina Weibo. In the United States, the data were collected in a college-wide survey pool in a large Northwestern university.

Results: The final sample size was 235 for the Chinese sample and 241 for the US sample. Media use was significantly associated with mental health information–seeking intentions in the Chinese sample (P<.001), and cultural identity was significantly associated with intentions in both samples (China: P=.02; United States: P<.001). The extended PRISM had a better model fit than the original PRISM.

Conclusions: Cultural identity and media use should be considered when evaluating the process of mental health information seeking or when designing interventions to address mental health information seeking.

KEYWORDS

information seeking behavior; mental health; cross-cultural comparison

Introduction

Background

In the United States, about 42.5 million adults have been affected by various kinds of mental illness in 2013, which means that 1 in 5 Americans have had a diagnosable mental disorder [1]. In China, approximately 173 million people experience a diagnosable psychiatric disorder [2]. People in the United States who are not mental health professionals tend to recognize serious mental issues, such as schizophrenia, as mental illness. Mental disorders, such as depression and paranoia, which also require proper treatment, are often not perceived as mental disorders [3,4]. The situation is worse in China; the majority of people have a negative attitude toward mental health counseling services [5]. Some Asians see admitting to having a mental illness as bringing disgrace to the family and believe that willpower could maintain mental health to some extent [6,7]. Traditional Chinese culture and the history of medicine do not define mental illness separately from neurological disorders [8], whereas in the United Sates, psychiatrists are trying to incorporate medical treatment with counseling services that can help analyze the social and environmental factors of patients.

Moreover, Chinese culture has been known as a collectivistic culture, where group members traditionally put group interests and community values ahead of individual interests [9]. Therefore, people who suffer from mental illness may refuse to seek counseling services because of the concern that they may bring shame to the family or community. In the United States as well, there is stigma around mental health. Even among professional health care workers, negative attitudes toward mental illness are pervasive [10]. Therefore, individuals may avoid interpersonal communication and turn to the internet for information related to mental health.

With the ubiquitous use of the internet (eg, used by more than 3 billion people throughout the world) [11], people now have unparalleled access to information. In the United States, 72.00% of internet users have sought health information online in 2013[12]. In China, research has found that more than 80% of individuals experiencing a specific health condition (ie, people with epilepsy) have sought information related to their illness [13]. One study found that 18% of adult internet users in the United States had searched for mental health information online [14]. Using the internet for mental health information has been found to be prevalent among young adults. Horgan and Sweeney [15] found that 30.8% of their participants, who were college students, had used the internet for information related to mental health, conducting searches mainly on depression. This may be tied to the age of onset for mental illness; three-quarters of all chronic mental illnesses begins by the age of 24 years [16]. College may also be a risky time for students' mental health, and college students tend to feel depressed and anxious during their college life [17]. Previous studies have found that more than 20% of college students reported mental health problems in both China [18] and the United State [19], and they are also heavy media users [20]. Thus, mental health information seeking is of importance among a college population. Therefore, a college student sample was used for this study. As the United States and China are two typical but distinct cultures that can represent different populations in mental health information seeking, a cross-cultural study was conducted in these 2 countries among college students.

The Planned Risk Information Seeking Model

There has been a fair amount of studies about health-related information seeking since the 1990s [21]. In 2010, Kahlor [22] developed the planned risk information seeking model (PRISM) by integrating multiple information seeking models including the theory of planned behavior [23], the risk information seeking and processing (RISP) model [24], and the augmented RISP model [25]. PRISM [22] proposes that subjective norms, attitude toward seeking, and perceived seeking control will be positively associated with seeking intent; affective response to risk and perceived knowledge insufficiency will be positively related with seeking intent; perceived knowledge partially mediates the effects of attitude, seeking-related subjective norms, and perceived control on perceived knowledge insufficiency; and risk perception will be positively related to affective risk response.

When proposing PRISM, Kahlor [22] assessed the topic of general health risk information seeking, finding the model a good fit for the data, although the predicted path of knowledge insufficiency to seeking intent was not supported. Additional research has found support for PRISM to be an acceptable model for predicting information seeking intentions [26-28]. Hovick et al [29] found that original variables in PRISM better fit their data than an expanded model with past seeking behavior, source beliefs, and outcome expectancies regarding the context of cancer risk. However, Ho et al [27] extended PRISM in Singapore by adding media use and found the extended PRISM had a better fit than the PRISM. Few studies have replicated PRISM outside the United States and/or compared the relationships within PRISM under different cultural contexts. Furthermore, Willoughby and Myrick [28] found, in an examination of PRISM in two health contexts, that although some of the paths were not supported in the model, PRISM was a good fit for two health contexts: sexual health and cancer. No previous study has examined mental health as a personal risk in different cultures. This study aimed to examine whether PRISM is a good fit for the data in both China and the United States regarding mental health.

Media Use

Although PRISM incorporates a number of constructs from various theories, it does not include the construct of media use. Media use can serve as a source of knowledge and provide important information; it can also be affected by knowledge needs and remind information seekers to stay alert. Previous research found media use to be a mediator in PRISM for predicting impersonal risk information seeking, specifically examining climate change [27]. Media use has not been assessed as a predictor in PRISM when examining personal risks. Personal risks may be more emotional than impersonal risks [30]. This study used a personal risk, mental health, as a context to replicate and extend the current model.

Demographics, ideology, personality traits, and social persuasive effects influence media use [31]. According to the reinforcing spirals framework [31], media can influence attitudes and behaviors; furthermore, media use can also influence future media use or avoidance. In information seeking, media are often seen as information sources. Media use has been found to be associated with health information seeking for impersonal risk [27,32]. In addition, people who engage with one media channel for health information are more likely to engage with other media channels in their search for health information [33].

The reinforcing spirals framework highlights the potential timeline and mechanisms for how media use might work. For example, a person who has had a family member experience depression might be primed to have certain attitudes and opinions. After seeing a commercial for a medication for depression, the person might be more likely to seek out additional information on signs and symptoms because of their own personal past experiences and also the information they were exposed to through the media.

A number of studies have shown that media use could influence perceived knowledge and intentions within the context of health [34-36]. Little research has examined the relationship between media use and variables within PRISM under the context of mental health.

Cultural Identity

Another factor not included in PRISM is cultural identity, which is identification with a particular cultural group [37]. Even with the same cultural background, people can have different levels of cultural identity. Few studies about information seeking have examined the role of cultural values and how different levels of cultural identity affect the process of information seeking. One cross-cultural study discovered that people from different cultures, such as a communitarian culture (eg, Chinese culture) and an individualistic culture (eg, US culture), tend to perceive variables differently in risk information seeking [38]. Although this research assessed risk information seeking across cultures, it did not include cultural identify as a predictor. Our study assesses the potential role of cultural identity as a predictor of mental health information seeking.

Hofstede [39] defines culture as "the collective programming of the mind, which distinguishes one group or category of people from another." Even under the same cultural context, individuals can experience different levels of cultural identity. Cultural identity was defined as an individual's identification with a particular cultural group [37]. A strong cultural identity is accompanied with a deep understanding of group values, social norms, and certain behaviors endorsed by the community members [37]. For example, Chinese culture values tend to stigmatize mental health and not talk about it. If someone instead believed it was normal to have mental issues and believed it was healthy to talk with a therapist, this person's cultural identity of Chinese culture regarding mental health would be low.

Chinese culture, as a typical Asian culture, is known as highly collectivistic with value placed on group members' opinions and a focus on cooperation in group settings [39,40]. There is evidence that Chinese value social norms more and are more likely to maintain the existing social structure than people from individualistic cultures [41,42]. Therefore, we believe that the seeking intent of mental health information will be weaker among a Chinese sample not only because of the previous treatment of mental health in China but also because many individuals from a collectivistic culture see having mental health issues as losing face or bringing damage to the family's reputation [6]. Moreover, the cultural value of the United States is recognized as individualistic [39], and people from individualistic cultures are more likely to accept mental health counseling [6].

Research Questions and Hypotheses

On the basis of the previously discussed literature, we proposed the following research questions and hypotheses to help assess how the additional variables may impact behavioral intentions and the utility of the PRISM model at predicting behavioral intentions in different samples:

- Research question (RQ) 1: Is PRISM a good fit for both the Chinese sample and the US sample of young adults on the topic of mental health information seeking?
- Hypothesis 1: Media use will be positively related to seeking intention in the Chinese (H1a) and US (H1b) samples.
- Hypothesis 2: Cultural identity will be negatively associated with mental health information seeking intentions among participants in the Chinese sample.
- Hypothesis 3: Cultural identity will be positively associated with mental health information seeking intentions among participants in the US sample.
- RQ2: What are the relationships between media use and perceived knowledge, perceived knowledge insufficiency, affective response, risk perception, attitude, and subjective norms in the PRISM in the mental health information seeking process in both samples?
- RQ3: What are the relationships between cultural identity and variables of PRISM in the mental health information seeking process in both samples?
- RQ4: Does the extended PRISM account for more variance in seeking intentions than the PRISM in both the Chinese (RQ4a) and US (RQ4b) samples?

Methods

Sample and Procedure

Data were collected in both countries using the same online survey through a survey management program (Qualtrics). The studies were similar in all aspects, except during the recruitment phase. Participants in the United States were recruited from a college participation system called Sona, a cloud-based subject pool. Participants in China were recruited from 2 universities in China and a social media site. Although the methods differ, both provided a sample of college students that was obtained as a convenience sample. These differences in recruitment were due, in part, to logistical issues. The researchers did not have access to a participant pool in China but wanted a comparable population of college students in the same age range. The University Institutional Review Board reviewed the study

proposal, and the project was determined to be exempt for both samples.

In China, 2 college instructors in 2 different universities distributed the anonymous survey link to their students using online class announcements and the survey link was also posted on a leading social media site called Sina Weibo to ensure an equivalent sample size. Sina Weibo is often seen as the "Chinese Twitter" and is a microblogging website in China. The questionnaire was translated into Chinese and was cross-examined by an English instructor of a university in China to verify whether the 2 survey versions were consistent. Two students volunteered to pretest the survey, and the completion time was around 15 min. Respondents needed to be 18 years or older to participate. One researcher posted the study description including study information, target population, survey link, and incentive information on Sina Weibo, and snowball sampling was used to distribute the survey link. At the beginning of the online survey, students needed to give their consent to participate in the study by selecting "I am 18 or older and agree to participate." An incentive of CNY ¥260 (US $37.02) or an equivalent prize was provided in the form of a random drawing. At the end of the survey, participants were provided with another link to enter their email address for a chance to win the incentive. The email addresses were only used for the draw, and participants could not be identified by either the researchers or the instructors. The data collection lasted for about a month, and the completion rate was 77.6%. Incomplete questionnaires and surveys that took less than 2 min to complete were not included in the final analysis.

In the United States, the data were collected in a college-wide subject pool (Sona) in a large Northwestern university. Respondents were recruited among undergraduate students from different majors, and participants were offered extra credit for participating in the study. Participants signed up in Sona and then were directed to the survey in Qualtrics. Participants needed to give consent before they could proceed to the main questionnaire. The data collection process lasted less than 2 months. The completion rate was 96.78%. Students had options for alternate assignments to receive similar credit for their courses. Questionnaires that were incomplete and took less than 2 min to finish were not included in the final analysis.

Measurement

We used the existing measures of attitude toward seeking, subjective norms, perceived seeking control, perceived current knowledge, risk perception, affective response, perceived knowledge insufficiency, and seeking intent from Kahlor [22].

Attitude Toward Seeking

Seven 7-point scale statements were used to measure respondents' attitude toward seeking mental health information. Questions asked whether seeking mental health–related information was "bad" or "good," "unhelpful" or "helpful," "worthless" or "valuable," "unproductive" or "productive," "harmful" or "beneficial," "foolish" or "wise," and "not useful" or "useful." Items were averaged to create a scale (United States: alpha=.95, mean 5.91, SD 1.11; China: alpha=.90, mean 5.56, SD 0.97).

Seeking-Related Subjective Norms

Five 5-point Likert-type items measured the degree of agreement with statements regarding subjective norms (eg, "Most people who are important to me think that I should seek information about risks to my mental health.") Items were averaged to create a scale (United States: alpha=.92, mean 2.81, SD 1.13; China: alpha=.91, mean 2.62, SD 1.03).

Perceived Seeking Control

Four 5-point Likert-type items measured the degree of agreement with statements regarding perceived seeking control (eg, "I can readily access all the information about risks to my mental health that I need"). Items were averaged to create a scale (United States: alpha=.90, mean 3.47, SD 0.91; China: alpha=.91, mean 3.23, SD 0.98).

Risk Perception

Three 11-point items measured risk perception related to mental health (0=not at all and 10=extremely) with the following statements: "How serious are the current threats to your mental health?" "How likely are you to have some mental health issues in the next year?" and "If you were to have some mental health issues in the next year, how serious do you think it would be?" Items were averaged to create a scale (United States: alpha=.88, mean 3.86, SD 2.31; China: alpha=.88, mean 5.32, SD 2.30).

Affective Response

Two 5-point Likert-type items asked respondents to indicate their degree of worry and fear. The statements were "Current risks to my mental health are scary" and "Current risks to my mental health are worrisome." The items were averaged to create a scale (United States: alpha=.94, mean 2.39, SD 1.26; China: alpha=.89, mean 2.76, SD 1.14).

Perceived Current Knowledge

A statement measured perceived current knowledge by asking respondents the following: "Rate your mental health risk knowledge on a scale of 0 to 100, where zero means knowing nothing about risks to your mental health and 100 means knowing everything you could possibly know about risks to your mental health" (United States: mean 57.48, SD 24.30; China: mean 64.09, SD 18.06).

Perceived Knowledge Insufficiency

The measurement of sufficiency threshold asked the following: "Think of that same 0 to 100 scale again. This time, estimate how much knowledge you need to deal adequately with risks to your mental health. You might feel you need the same, more, or possibly even less information about this topic. Using a scale of zero to 100, how much information would be sufficient for you" (United States: mean 66.14, SD 23.45; China: mean 74.92, SD 17.34).

Seeking Intentions

Five 5-point Likert-type items measured seeking intent (eg, "I plan to seek more information about risks to my mental health in the near future"). Items were averaged to create a scale (United States: alpha=.97, mean 2.90, SD 1.07; China: alpha=.94, mean 2.98, SD 1.01).

Media Use

We adapted Brossard and Nisbet's [43] scale. Eight 7-point items measured participants' attention paid to mental health information in health magazines, newspapers, TV news reports, entertainment TV programs, online forums, social media, news reports on the internet, and medical applications (eg, "How much attention have you paid to mental health information on social media?"). Items were averaged to create a scale (United States: alpha=.82, mean 3.34, SD 1.17; China: alpha=.84, mean 3.47, SD 1.22).

Cultural Identity

We measured cultural identity with Usborne and Taylor's [37] Cultural Identity Clarity Scale. Eight 11-point items measured respondents' agreement or disagreement with statements such as "My beliefs about my cultural group often conflict with one another" and "My beliefs about my cultural group seem to change very frequently." Some items were reverse coded, and all items were averaged to create a scale (United States: alpha=.87, mean 5.68, SD 1.89; China: alpha=.76, mean 5.33, SD 1.67).

Data Analysis

As we wanted to examine a college student sample across both countries, we only used those who were college students in the both samples. As the measurements were used in former studies and have high reliability (high Cronbach alpha), we computed the items to create one variable for each construct and then conducted path analyses in Mplus version 7.11 to evaluate the paths and model fit. The models included gender as a control variable.

Results

Sample Statistics

After data cleaning, each sample had more than 200 participants complete the survey (United States: N=241; China: N=235). In the US sample, more than one-third of the sample reported being male (n=83) and less than three-quarters, female (n=158). Participants' ages ranged from 18 to 32 years (mean 20 years, SD 1.97). Almost two-thirds of the respondents (n=160) reported being white and >10.0% (n=27) as Asian. In the Chinese sample, almost 90.0% (n=209) were female. Respondents ranged from 18 to 27 years (mean 21 years, SD 7.98). Basic descriptive results of the variables are shown in Table 1.

Table 1. Basic descriptive results.

Variable	United States, mean (SD)	China, mean (SD)	Range
Attitude toward seeking	5.91 (1.11)	5.56 (0.97)	1-7
Seeking-related subjective norms	2.81 (1.13)	2.62 (1.03)	1-5
Perceived seeking control	3.47 (0.91)	3.23 (0.98)	1-5
Risk perception	3.86 (2.31)	5.32 (2.30)	0-10
Affective response	2.39 (1.26)	2.76 (1.14)	1-5
Perceived current knowledge	57.48 (24.30)	64.09 (18.06)	0-100
Perceived knowledge insufficiency	66.14 (23.45)	74.92 (17.34)	0-100
Seeking intentions	2.90 (1.07)	2.98 (1.01)	1-5
Media use	3.34 (1.17)	3.47 (1.22)	1-7
Cultural identity	5.68 (1.89)	5.33 (1.67)	0-10

Model Fit

For the Chinese sample, the replicated PRISM did not have a good fit, whereas the extended model with 2 additional variables, attention to media and cultural identity, had a good model fit. The replicated PRISM of the US participants did not have a good model fit, whereas the extended PRISM of the US sample had an acceptable model fit (see Table 2 for all model fit information). According to Browne and Cudeck [44], root mean squared error of approximation values less than 0.08 can be considered as the reasonable error of approximation. A comparative fit index and Tucker-Lewis index close to or greater than 0.95 represent a good fit. A normed chi-square value less than 5 indicates a good fit [45]. Thus, RQ1 was answered.

Table 2. Summary of model fit.

Model	Chi-square (*df*)	Root mean squared error of approximation	Comparative Fit Index	Tucker-Lewis Index
China PRISM[a]	55.4 (2.41)	0.078	0.91	0.89
China Extended PRISM	57.1 (1.59)	0.050	0.96	0.93
US PRISM	90.1 (3.91)	0.110	0.77	0.70
US Extended PRISM	75.4 (2.09)	0.067	0.92	0.86

[a]PRISM: Planned Risk Information Seeking Model.

The Planned Risk Information Seeking Model of the Chinese Sample

Some significant paths of Kahlor's [22] PRISM were not significant in the Chinese sample (Figure 1) Perceived seeking control was not significantly related to seeking intention, seeking-related subjective norms were not significantly related to perceived information insufficiency, and seeking-related subjective norms were not significantly related to perceived current knowledge.

The Planned Risk Information Seeking Model of the US Sample

The paths and standardized coefficients of the replicated PRISM of the US sample are presented in Figure 2.

Figure 1. The planned risk information seeking model of the Chinese sample. Dashed lines denote hypothesized nonsignificant paths. The model includes effects of control variables, which are not displayed. (.000) represents significant path coefficients at the .001 level and (.01), at the .05 level.

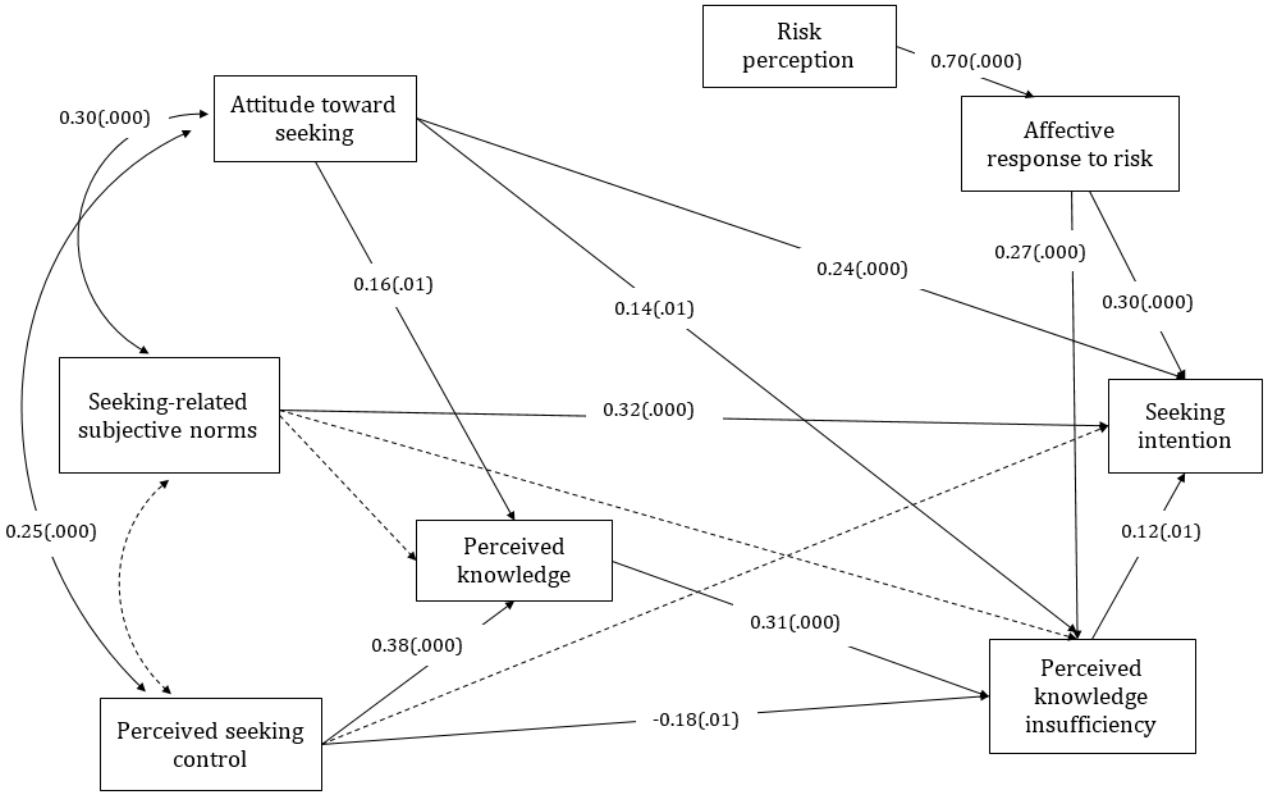

Figure 2. The planned risk information seeking model of the US sample. Dashed lines denote hypothesized nonsignificant paths. The model includes effects of control variables, which are not displayed. (.000) represents significant path coefficients at the .001 level and (.01), at the .05 level.

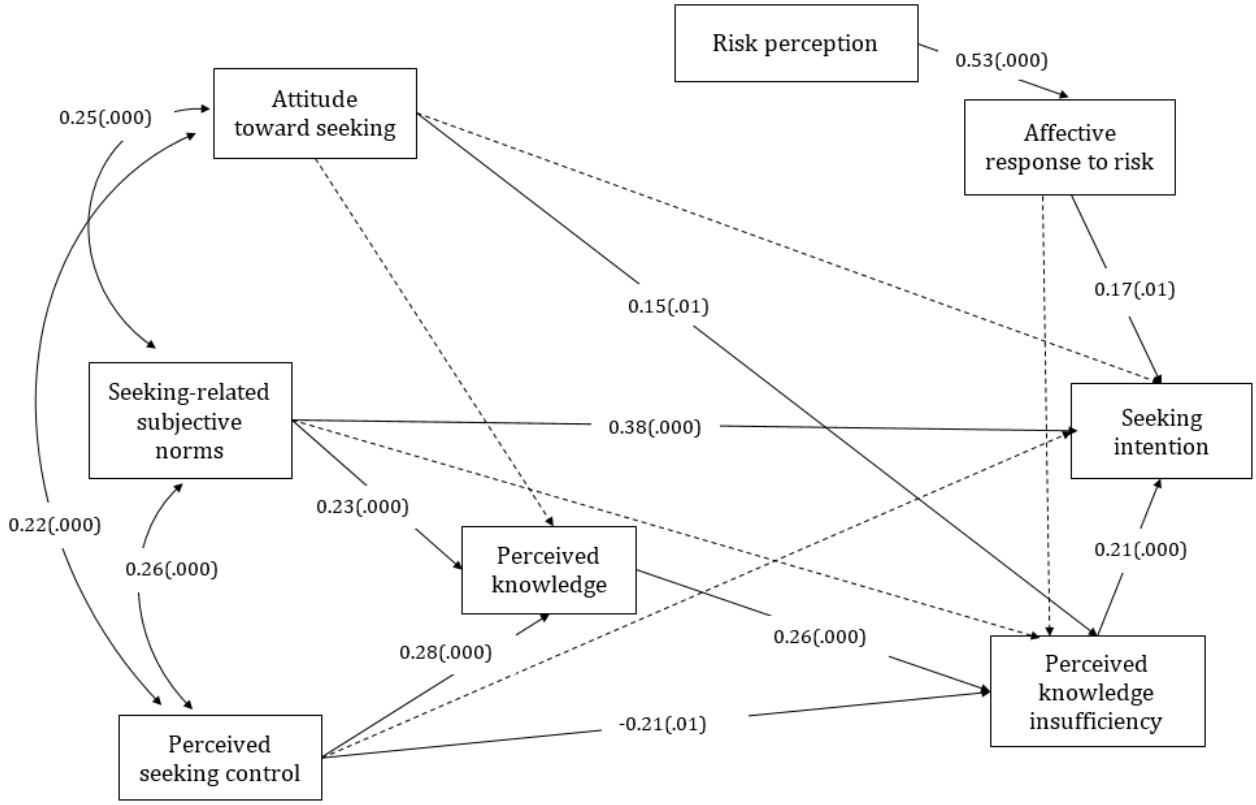


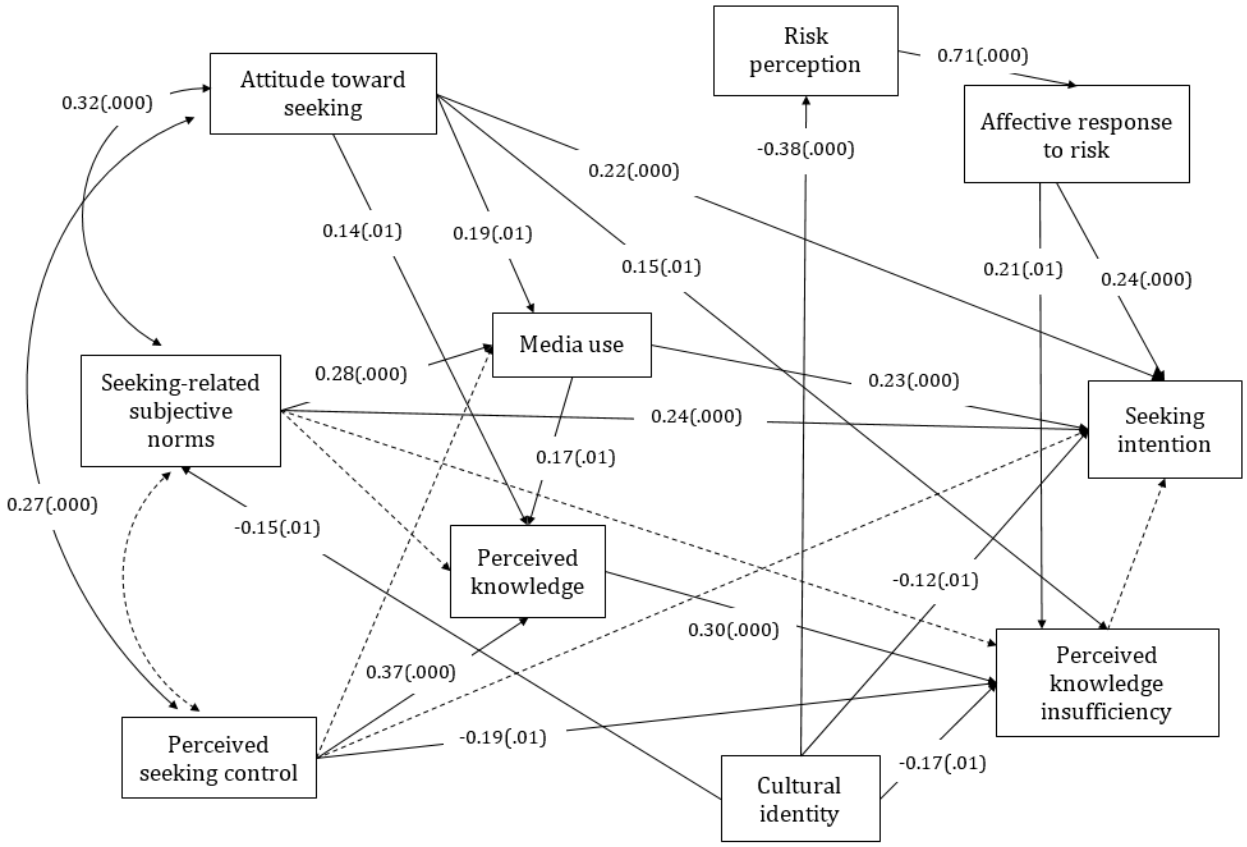
The Extended Planned Risk Information Seeking Model of the Chinese Sample

The Chinese extended model with media use and cultural identity are shown in Figure 3. Attitude toward seeking (β=.22; *P*<.001), seeking-related subjective norms (β=.24; *P*<.001), affective response to risk (β=.24; *P*<.001), media use (β=.23; *P*<.001), and cultural identity (β=−.12; *P*=.02) were significantly associated with information seeking intention. Therefore, H1a and H2 were supported.

In addition, attitude toward seeking (β=.15; *P*=.02) and seeking-related subjective norms (β=.28; *P*<.001) and perceived knowledge (β=.17; *P*=.002) were significantly associated with media use. Cultural identity was significantly associated with perceived knowledge insufficiency (β=−.17; *P*=.003), risk perception (β=−.38; *P*<.001), and seeking-related subjective norms (β=−.15; *P*=.02). These answered RQ2 (What are the relationships between media use and the variables of the PRISM?) and RQ3 (What are the relationships between cultural identity and variables of the PRISM?) in the Chinese sample.

The replicated Chinese PRISM accounted for 35.9% of the variance in information seeking intention, whereas the extended model in the Chinese sample accounted for 41.4% of the variance in information seeking intention, answering RQ4a.

Figure 3. The extended planned risk information seeking model of the Chinese sample. Dashed lines denote hypothesized nonsignificant paths. The model includes effects of control variables, which are not displayed. (.000) represents significant path coefficients at the .001 level and (.01), at the .05 level.



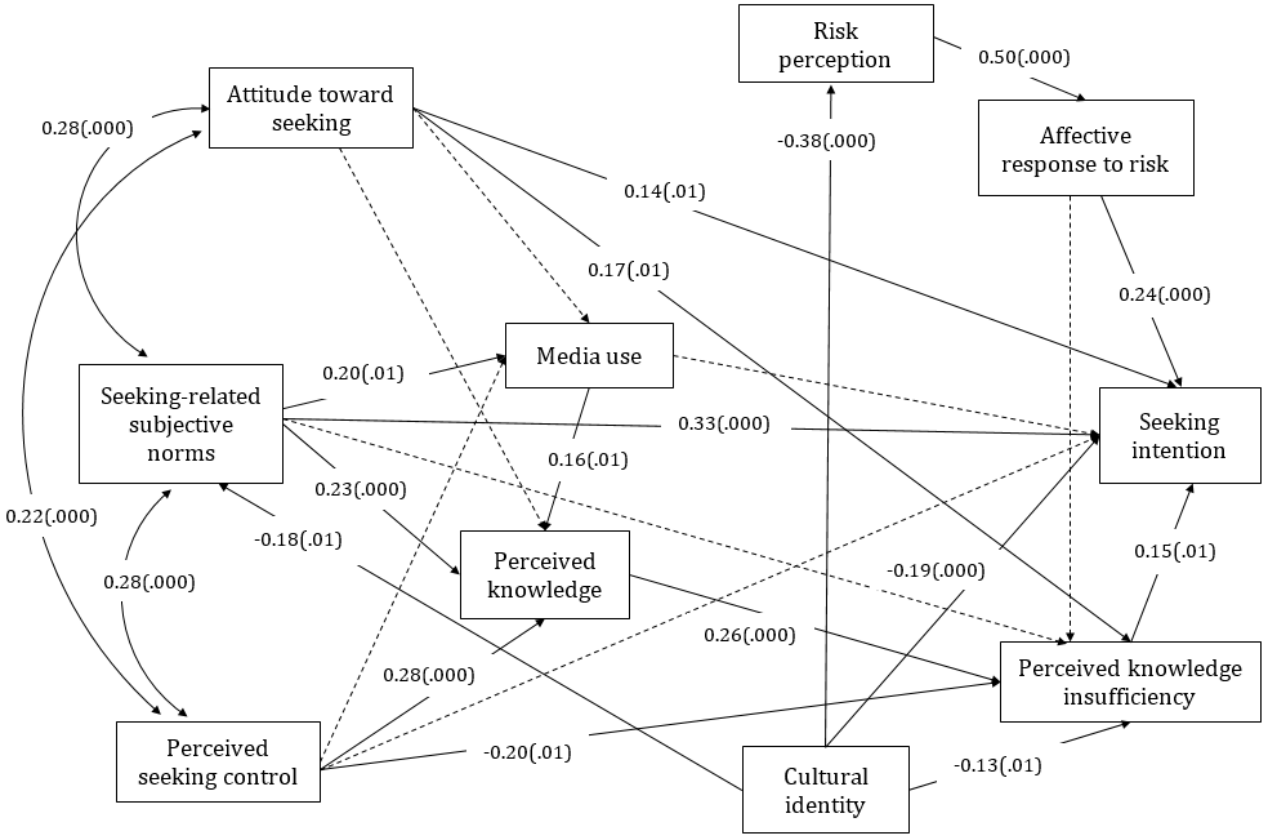
The Extended Planned Risk Information Seeking Model of the US Sample

In the US extended PRISM (see Figure 4), attitude toward seeking (β=.14; *P*=.005), seeking-related subjective norms (β=.35; *P*<.001), perceived knowledge insufficiency (β=.14; *P*=.005), affective response to risk (β=.24; *P*<.001), and cultural identity (β=−.19; *P*<.001) were significantly associated with information-seeking intentions. Thus, H1b and H3 were not supported.

In addition, media use was significantly associated with subjective norms (β=.20; *P*=.001) and perceived knowledge (β=.16; *P*=.004). Perceived knowledge insufficiency (β=−.13; *P*=.02), risk perception (β=−.38; *P*<.001), and seeking-related subjective norms (β=−.18; *P*=.002) were significantly associated with cultural identity. These answered RQ2 (What are the relationships between media use and the variables of the PRISM?) and RQ3 (What are the relationships between cultural identity and variables of the PRISM?) in the US sample.

In the US sample, the PRISM accounted for 30.6% of the variance in information seeking intention, whereas the extended model accounted for 40.3% of the variance in information seeking intention. So RQ4b, which asked whether the extended PRISM accounted for more variance in seeking intention than the PRISM in the US sample, was answered.

Figure 4. The extended planned risk information seeking model of the US sample. Dashed lines denote hypothesized nonsignificant paths. The model includes effects of control variables, which are not displayed. (.000) represents significant path coefficients at the .001 level and (.01), at the .05 level.



Discussion

Principal Findings

In this study, we tested the PRISM model in a sample of US and Chinese college students in the context of mental health. We then added additional variables to the model and compared results across cultures. In terms of the model, the original PRISM model was not a great fit with our data in either samples. Consistent with the results of Kahlor [22], we found that attitude toward seeking and seeking-related subjective norms significantly predicted intention to seek mental health information in both samples. In addition, attitude toward seeking and perceived seeking control significantly predicted perceived knowledge insufficiency. Perceived seeking control influenced seeking intention indirectly by its effects on perceived knowledge and perceived knowledge insufficiency in both samples. Some studies have found a significant role of perceived control in predicting intent to seek help regarding mental health in China [46]. However, perceived control of searching for mental health information does not require professional evaluations, accessibility, cost, and time, which indicates that for personal risks, such as mental health, perceived seeking control may not directly be related to information seeking intention. Risk perception was found to have a direct effect on affective response to risk in all of our models, consistent with the path in the PRISM [22]. Affective response to risk significantly predicted seeking intention and perceived knowledge insufficiency in both samples.

The extended PRISM that we tested included 2 additional variables, ie, media use and cultural identity, and had a better model fit than the PRISM in both the US and Chinese samples. An important finding in this study is the role of media use in PRISM. Our finding is inconsistent with Ho et al's [27] study. Their study demonstrated that media use impacted risk perception and impacted affective response directly and seeking intention indirectly regarding climate change among a Singapore population; however, among our Chinese sample, we found that media use was directly associated with intention to seek mental health information. Mental health as a personal threat could produce a stronger emotional response than impersonal risks, such as climate change [27]. People in China who pay more attention to this issue may have a greater intention to explore more about this personal risk, as they have limited knowledge of professional mental health services and counseling. Another explanation is that people who pay more attention to mental health information have the need for mental health information, so they intend to seek more information regarding mental health [47]. In the Chinese sample, media use was influenced by attitude toward seeking and subjective norms and impacted perceived knowledge, which is consistent with the findings of Ho et al [27]. In the US sample, media use was influenced by subjective norms and had influences on perceived knowledge. We did not find a direct effect of media use on seeking intention in the US sample, which is consistent with the study by Ho et al [27].

Another contribution of this study was that cultural identity significantly predicted seeking intention, perceived knowledge

insufficiency, risk perception, and subjective norms related to information seeking in both samples, which contributes to the extended PRISM in predicting personal risk. However, cultural identity negatively predicted seeking intention in both samples, which indicates that lower levels of identification of the cultural group is associated with higher levels of seeking intention toward mental health information seeking. We predicted that cultural identity would have opposite effects on the Chinese and US participants' information seeking intentions based on the assumption that mental health problems are stigmatized in China while less so in the United States. However, the results showed that people who are less identified with the cultural values regarding mental health issues in their cultures are more likely to seek mental health information, which suggests that mental health issues are stigmatized to some extent in both samples.

Cultural identity is positively related to self-esteem and well-being [48]. If the respondent scored lower on cultural identity, he or she is more likely to have an unclear group identity. This finding reveals that for an issue, which was perceived as stigmatized in both individualistic and collectivistic cultures [6,10], a lower level of cultural identity may act as an unclear group identity to reduce the constraints of a group culture, which could have a direct influence on mental health information seeking. Previous research has found that an unclear cultural identity could reflect a high level of normlessness, which means no clear norms guidance [37]. We found that lower levels of cultural identity were associated with high levels of subjective norms related to mental health information seeking, which means that perceptions of the people with a lower cultural identity about others' expectations on mental health information seeking are inconsistent with the majority of people in the society. Several studies have shown that culture has an impact on risk perceptions among different culture groups [38,49]. On the basis of our results, people with unclear or dissimilar group identities tend to have higher risk perception about mental health information seeking.

Overall, we found that media use and cultural identity can be two variables useful for predicting seeking intentions regarding personal risks such as mental health. With 2 additional variables added in the PRISM, variance accounted for in seeking intentions by the models increased in both samples. Owing to the specificity of the context, the 2 samples with different cultural backgrounds have distinguished results in some perspectives, which again emphasize the importance of culture. We believe that the traditional thought of mental health in China played an important role in explaining these findings as mental health is still a stigmatized issue in China. In addition, the mental health counseling system is not as thoroughly developed in China [50] as in the United States, making this topic less familiar among our Chinese sample. Such differences in perceptions of mental health may directly alter the disease progression. As a chronic disease, early interventional treatment of mental health and the access to additional information during long-term treatment can significantly affect the prognosis of patients, which illustrate the importance of correctly recognizing a mental health issue at an early stage.

These findings can be used in campaigns promoting the seeking of mental health information and can help researchers and practitioners understand the process of personal risk information seeking, especially when the topic has a strong cultural context. The findings also have theoretical implications. Some of the paths are inconsistent from past research regarding personal cancer risk using PRISM [29], and we found that additional variables may provide a better fit for the models based on our topic of mental health.

Limitations and Future Studies

This study is not without limitation. First, we used a convenience sample for both populations. The results of using the sample of college students may not generalize to other subgroups, although it does allow us to assess relationships between key constructs. Second, this study used cross-sectional data and only measured variables at a specific time point without the ability to decide causality. Third, due to a relatively small sample size, we chose to conduct a path analysis. Further studies could conduct a structural equation model. In addition, as our context is a personal risk and often a stigmatized issue, future studies could use a more general concept to examine the role of media use and cultural identity. Moreover, the spiral role of media use should be explored in the future as media use can also influence risk perception and other variables such as attitudes and subjective norms.

Conclusions

Overall, this study extended the PRISM to include important aspects that could vary based on culture, including cultural identity and media use. We found that both cultural identity and media use were associated with information-seeking intentions regarding mental health topics and including the variables in the PRISM allowed the model to account for additional variance in information-seeking intentions. These results can help researchers and health practitioners as they continue to grapple with sensitive health and risk issues, such as mental health. Potential patients may benefit from the findings, changing the progression of the disease and how it is treated, leading to more appropriate treatment solutions.

Abstract

Background: Among a variety of dynamics that may have effects on internet-related behaviors, cultural orientation is particularly important. Previous studies suggest that individualism is a strong determinant of certain behaviors. In addition, findings suggest that vertical individualism may lead to the development of more tolerance for addiction and aggression on the internet.

Objective: This study aimed to investigate whether vertical individualism has significant positive effects on cyberbullying and internet addiction and whether horizontal individualism has significant negative effects on cyberbullying and internet addiction. A theoretical model was specified to test the relationships among vertical versus horizontal individualism, cyberbullying, and internet addiction.

Methods: A total of 665 college students were selected using a convenience sampling method and willingly participated in the study. Participants' ages ranged from 17 to 19 years (mean 17.94 years, SD 1.12 years). Of the group, 462 were women (462/665, 69.5%), and 203 were men (203/665, 30.5%). Study majors represented were mathematics (113/665, 17%), sciences (102/665, 15.3%), instructional technology (99/665, 14.9%), psychology (98/665, 14.7%), and others (253/665, 38.1%). Self-report instruments were used to measure vertical/horizontal individualism, cyberbullying, and internet addiction.

Results: Results show a significant positive effect of vertical individualism (effect size 0.10) and significant negative effect of horizontal individualism (effect size –0.12) on cyberbullying. In addition, the direct effect of vertical individualism on internet addiction was significant (effect size 0.28), but the direct effect of horizontal individualism was not (effect size –0.05). Internet addiction had a significant direct effect on cyberbullying (effect size 0.39) as well as an intervening effect on the relationship between vertical individualism and cyberbullying. Results also indicate significant gender differences in cultural patterns and internet addiction.

Conclusions: The findings suggest that horizontal and vertical individualism have significant effects on internet addiction. The findings also suggest that vertical individualists are more vulnerable to internet addiction. Further, the findings indicate a significant relationship between internet addiction and cyberbullying.

KEYWORDS

vertical individualism; horizontal individualism; cyberbullying; internet addiction

Introduction

Background

Among a variety of dynamics that may have effects on internet-related behaviors, cultural orientation is particularly noteworthy [1-4]. Hofstede [5] identified four key cultural orientations of people, among which individualism versus collectivism is one of the rather more frequently investigated dimensions [5-8]. In his conceptualization, individualism is defined as the tendency to which "an individual is supposed to take care of himself/herself" [9], and collectivism is the tendency "to which an individual remains integrated into a group" [10]. Triandis [11] argued that individualism and collectivism emerge from status-equal (ie, horizontal) versus status-unequal (ie, vertical) relationships and therefore identified horizontal versus vertical individualism and horizontal versus vertical collectivism. Our study focused on the effects of horizontal versus vertical individualism.

Triandis [11] argued that individualists tend to emphasize an autonomous self-concept, whereas collectivists are inclined to consider themselves as a part of the group. Therefore, an independent versus interdependent self is one of the distinctive characteristics of the two [10]. Contrary to collectivists, individualists prioritize personal goals over the group goals. Internal processes such as attitudes predict social behaviors among individualists. However, among collectivists, social behaviors are predicted by subjective norms, obligations, and perceived duties [12]. Individualists tend to drop a relationship when the cost of the relationship exceeds their personal benefits; however, collectivists try maintaining the relationship even if the cost surpasses their personal benefits [13].

Triandis [11] also identified additional personality characteristics that differentiate between horizontal individualism and vertical individualism. He suggested that vertical individualism defines the self as autonomous, different, and unequal in status with others. Competition is one of the key aspects of vertical individualism. On the other hand, horizontal individualism defines the self as autonomous and independent but also equal to the self of others. Floros et al [14] found that internet addicts exhibit higher impulsivity and help-rejecting behaviors, suggesting that character and personality are significant factors in predicting internet addiction.

Brady [15] described cyberbullying as "the use of communication-based technologies including social networking sites to engage in deliberate harassment or intimidation of other individuals or groups of persons using online speech or expression." Contemporary research shows that cyberbullying is an increasingly epidemic problem among children [16] as well as adolescents [17]. Casas et al [18] found that bullying is strongly influenced by personal and contextual factors. For example, they argue that empathy was a significant predictor of cyberbullying. Similarly, Mishna et al [19] suggested two main risk factors for involvement in cyberbullying: the increasing use of technology [20] and the lack of face-to-face interactions associated with social cues [21,22]. In addition, Smith et al [23] found that being a cyber-victim is correlated with internet use. That is, the more intensive use of the internet, the higher the likelihood of cyberbullying. Therefore, we decided to investigate the effect of internet addiction on cyberbullying.

Based on the cognitive-behavioral model of Davis [24], internet addiction is conceptualized as "an impulse control disorder" [25] and found to be related to a wide range of psychosocial complications [26,27], including cyberbullying [28,29]. Internet addiction or problematic internet use [30] is one of the central research areas for college students. In addition, assessment instruments [31] and screening methods [32] have been developed in the area of problematic internet use or internet addiction. However, the potential association between internet addiction and individuals' cultural orientations (ie, individualism) has not been sufficiently investigated. In general, previous studies showed positive associations between individualism and addictive behavior [33,34] or aggressive behavior [35]. Accordingly, we focused on the effect of the relationship between vertical versus horizontal individualism and internet addiction on cyberbullying.

Cyberbullying and internet addiction have been relatively more frequent themes of recent research [36,37]. However, the lack of previous studies on the impact of cultural individualism on cyberbullying or internet addiction calls for an investigation [38]. Therefore, the purpose of this research was to fill the gap in prior studies by studying the role of internet addiction in the association between vertical versus horizontal individualism and cyberbullying. Such an investigation is warranted for the screening, identification, diagnosis, prevention, and treatment of cyberbullying and internet addiction.

Hypotheses

In general, individualists tend to behave autonomously and prioritize their personal preferences [39]. Hooker [40] argues that individualists have a stronger sense of private space and are more likely to prefer loose personal ties [41]. However, previous studies have reported significant individual differences between horizontal individualists and vertical individualists [42-44].

Horizontal individualism is described as "a model of independent self that fosters a propensity to value uniqueness and social equality," whereas vertical individualism describes "an autonomous self that garners gratification through competition and personal achievement" [8,11]. Vertical individualists are particularly concerned with comparing themselves with others and are likely to enjoy "competition, hedonism, and acquiring status through rivalry" [45]. Vertical individualists prefer to accept inequality and acknowledge the importance of status as well as social rank, whereas horizontal

individualists prefer to accept interdependence and equal status for all [11]. We deduced from previous studies that vertical individualists emphasize competition, prestige, hedonism, and status more than horizontal individualists [8].

Previous studies on substance dependence suggested a positive correlation between individualism and addictive behavior [33]. In addition, Bergmüller [35] found that individualism is a strong determinant of aggressive behavior. Ogihara and Uchida [46] found that individualism is negatively related to the number of intimate friends and subjective well-being. These findings suggest that vertical individualism may lead to the development of more tolerance for addiction and aggression. Thus, we theorized that people who score higher for vertical individualism would be more inclined to cyberbullying and internet addiction. We hypothesized that vertical individualism would have a significant positive effect on cyberbullying (H1a) and internet addiction (H1b), whereas horizontal individualism would have a significant negative effect on cyberbullying (H2a) and internet addiction (H2b).

Social repercussions are among the most negative consequences of internet addition [47]. Ko et al [48] suggested that individuals with internet addiction are more likely to have aggressive behaviors. Recent studies also showed significant relationships between internet addition and cyberbullying [28,29]. For example, Gámez-Guadix et al [49] found that cyberbullying was predicted by problematic internet use. You and Lim [29] and Chang et al [50] suggested that internet addiction is associated with cyberbullying. Therefore, we hypothesized that the degree of internet addiction would be positively related to cyberbullying [H3].

According to Hofstede [5], individuals may behave differently depending on their cultural orientations. Therefore, we used horizontal and vertical individualism as extraneous variables in the theoretical model shown in Figure 1. Further, we included internet addiction as an intervening variable between individualism and cyberbullying.

Methods

Participants

A total of 665 freshmen from two state universities in the central part of Turkey who were selected using a convenience sampling method willingly participated in the study. The participants completed an anonymous online survey and received extra course credit for participation. Participants' ages ranged from 17 to 19 years (mean 17.94 years, SD 1.12 years). Of the group, 462 were women (462/665, 69.5%), and 203 were men (203/665, 30.5%). Students from mathematics (113/665, 17%), science (102/665, 15.3%), instructional technology (99/665, 14.9%), psychology (98/665, 14.7%), and other departments (253/665, 38.1%) were represented in the study.

Measures

We used a total of 67 items: 18 items for individualism (10 items for horizontal individualism and 8 items for vertical individualism), 23 items for cyberbullying, and 26 items for internet addiction. All instruments asked participants to rate their level of agreement using a 5-point Likert scale ranging from "strongly disagree" to "strongly agree."

The Individualism-Collectivism Scale

Singelis et al [8] developed the Individualism-Collectivism scale to examine differences in vertical versus horizontal individualism and vertical versus horizontal collectivism. Evidence for the validity and reliability of the scale has been documented [8]. Of the 18 individualism items, 8 items measure vertical individualism, and 10 items measure horizontal individualism (for sample items, see Table 1). Wasti and Erdil [51] adapted the scale into Turkish and reported that the Cronbach α internal consistency coefficients were .67 for horizontal individualism and .73 for vertical individualism. However, in this study, we obtained Cronbach α values of .81 and .82 for horizontal and vertical individualism, respectively.
