Table 5. Evaluation measures derived from using the GRHANITE Linkage Tool on the pathology results gold-standard dataset.

Linkage approach	Gold standard (N=86,538)	HIV results			Hepatitis C results		
	Sensitivity, n (%)	N	Positive predictive value, n (%)	Estimated specificity, (%)	N	Positive predictive value, n (%)	Estimated specificity, (%)
Accept all	82,345 (95.15)	1427	1245 (87.25)	90.52	3908	3866 (98.93)	99.32
Year of birth match	82,212 (95.00)	1412	1234 (87.39)	90.71	3817	3777 (98.95)	99.34
Sex match	81,689 (94.40)	1257	1143 (90.93)	93.20	3810	3775 (99.08)	99.42
Year of birth and sex match	81,560 (94.25)	1263	1152 (91.21)	93.42	3775	3741 (99.10)	99.43
Two or more linkage keys	57,330 (66.25)	257	256 (99.6)	99.74	2809	2795 (99.50)	99.67
Linkage key type 3 plus sex match	76,928 (88.90)	1090	984 (90.28)	92.98	3626	3596 (99.17)	99.49

Estimating Specificity Using Discordant Test Results

In the derived HIV dataset, the number of linked EMRs containing an initial positive Western blot result ranged from 1090 to 1427 with all linkage approaches except when two or more linkage keys are needed. The linkage approach which requires two or more linkage keys to match resulted in 257 linked EMRs. The PPV was between 87% and 91% for the first 4 linkage approaches and estimated specificity ranged from 90% to 93%. When fewer EMRs were linked because of the different linkage approaches, both PPV and specificity improved (Table 5).

In the derived hepatitis C dataset, with the first 4 linkage approaches, in excess of 3700 linked EMRs contained an initial positive hepatitis C antibody result, with a drop to 2809 records when two or more linkage keys are needed. The PPV was greater than 98.9% and an estimated specificity was over 99% for all six linkage approaches (Table 5).

Discussion

Principal Findings

This paper describes a comprehensive evaluation of a system of probabilistic record linkage using a privacy-preserving software tool within a large-scale health surveillance system. The results showed that this software provides a highly reliable and accurate system for linking routinely collected EMRs through the generation of linkage keys reliant on available identifying information. Optimizing the record linkage involves an appropriate balance between the sensitivity (correctly identifying records belonging to the same person) and specificity (ensuring records that belong to different people are not linked) as well as what will best suit the study design objectives and populations under study without impeding the interpretation of study results.

The high performance of the linkage tool when applied to the relatively small PrEPX gold-standard dataset was related to the data completeness for EMRs in the PrEPX trial compared with the completeness of data in the pathology results gold-standard dataset (Tables 2 and 4). Participants in PrEPX were required to have a Medicare number to be enrolled and have three monthly follow-up visits, which allowed multiple opportunities for the staff at clinics to record any missing identifying information [13]. Where the underlying identifiers are robust and duplication is at a minimum, the probability of missed matches is negligible. In addition, with the PrEPX gold-standard dataset, there was 100% specificity for all linkage approaches, indicating that the linkage tool does not falsely link records in a small sample of EMRs where there was unlikely to be individuals with similar identifying details (name, date of birth, and Medicare number).

When the linkage tool was applied to the larger pathology results gold-standard dataset, sensitivity ranged between 89% and 95% where the linkage approach relied on a single linkage key matching. However, with the approach that requires records to link on two or more linkage key types, sensitivity was reduced to 66%. This is attributable to 22% of EMRs only having a single linkage key type available for linkage, which is mostly because of the Medicare number not being available. The inclusion of laboratory records in the pathology results gold-standard dataset may contribute to a lower sensitivity as a result of patient identifier errors such as mislabeling and recording of laboratory samples [14], compared with the completeness of personal identifiers within clinic EMRs. The final linkage approach where pairs of EMRs were only linked when matched on linkage key type 3 (which does not require the Medicare number) and sex, resulted in 89% sensitivity. This approach was included in the analysis to simulate the performance of the linkage tool when the Medicare number is not available. This is important to evaluate in Australia as a significant proportion of participating sites within ACCESS are funded through jurisdictional governments and do not record patient Medicare numbers [15].

Limitations

The main challenge in evaluating the GRHANITE Linkage Tool was the development of gold-standard datasets given the deidentified nature of EMRs in ACCESS. Researchers rarely have access to gold-standard datasets on which to perform linkage validation outside large administrative health data sources, and our gold-standard dataset of 86,538 records was comparable with other published studies [16]. The gold standards required records with enough supplementary information for deterministic matching where we could be certain that matches belonged to the same individual and nonmatches belonged to different individuals. Therefore, to generate the gold-standard datasets, there were a limited number of records we could use to accurately calculate sensitivity and specificity of the linkage tool. Although the pathology results gold-standard dataset contained over 80,000 records, one limitation of the evaluation was the inability to identify the correctly unmatched EMRs, which meant specificity could not be directly measured. However, given ACCESS is focused on the surveillance of BBV and STI, we were able to evaluate specificity within the pathology results dataset by examining the concordance of linked test results for HIV and hepatitis C. As expected, linkage specificity was inversely related to sensitivity. In addition, using discordant antibody results, we assumed that any discordant result was attributable to incorrect record linkage as opposed to an error in laboratory test results. However, given the very high sensitivity and specificity of the HIV western blot and antibody tests for HIV and hepatitis C, any testing errors would be minimal. The observed difference in PPV and estimated specificity between the HIV and hepatitis C datasets could be attributed to (1) differences in the sensitivity and specificity of the underlying laboratory tests for HIV and HCV and (2) potentially greater rates of anonymous HIV testing, whereby public laboratories do not require full names for HIV testing [15].

Beyond the false-positive record linkages identified by examining the concordance of linked test results for HIV and hepatitis C, there is potential for other false-positives to occur in cases where individuals share common patient identifiers, such as twins. Given the deidentified nature of ACCESS data, without the actual identifying demographic values, these niche cases cannot be identified. The small impact of these false-positives is not expected to impact the main purpose of public health surveillance using ACCESS. For other research projects that require a lower level of false-positive record linkage, particularly if it is known to contain a high proportion of individuals sharing common patient identifiers, then using a linkage approach that only accepts linkage based on a match of multiple linkage keys would minimize false-positives. In addition, ensuring concordance of other extracted data, such as sex, year of birth, HIV, and hepatitis C testing history, can reduce the level of false-positive record linkages to acceptable levels.

Conclusions

Evaluating record linkage is an important part of assessing the utility of surveillance and research systems for answering key population-level research questions or for accurately describing population-level trends using linked data. Our findings suggest that the GRHANITE Linkage Tool is appropriate for accurately linking individuals' episodes of care and underpins the ability for ACCESS to perform privacy-preserving linkage of patient medical records.

Abstract

Background: Maintenance of good health and a healthy lifestyle have significant impacts on the lives of university students. However, university students are prone to engage in risky health behaviors, resulting in impaired health status. Electronic health (eHealth) literacy is an important factor in maintaining a healthy lifestyle. However, no studies have assessed the eHealth literacy levels and the associated lifestyle behaviors among university students in Japan.

Objective: The purposes of this study were to clarify the eHealth literacy level, the participant characteristics associated with eHealth literacy, and the association of eHealth literacy with lifestyle behaviors of students in a Japanese university.

Methods: A questionnaire-based cross-sectional study of 3183 students at a national university in Japan was conducted. eHealth literacy was quantified using the Japanese version of the eHealth Literacy Scale (eHEALS). The association between participant characteristics (gender, school year, department of study, and living status) and eHEALS score was assessed using *t* tests. Additionally, the associations of eHealth literacy with lifestyle behaviors (exercise, smoking, alcohol consumption, etc.) were evaluated using logistic regression analyses.

Results: The mean eHEALS score was 23.6/40 points. The mean eHEALS score for students in medical departments was 27.0/40 points, which was 2.9 points higher than that of nonmedical students ($P<.001$). Similarly, the graduate school participants had higher scores than the undergraduate students. The proportion of participants who exercised regularly was higher in the high eHEALS score group than in the low score group, with an adjusted odds ratio of 1.39 ($P<.001$).

Conclusions: The eHealth literacy level of university students in Japan was comparable to that of the general Japanese population. Graduate students, as well as those in medical departments, had higher eHealth literacy. Furthermore, students with higher eHealth literacy had better exercise routines.

Introduction

Healthy lifestyle behaviors, such as exercising regularly, sleeping well, and eating breakfast, have a significant impact on university student life. For example, students with healthy lifestyles achieve higher academic degrees than those without [1,2]. Moreover, an unhealthy lifestyle during university life, including smoking and alcohol use, tends to persist after graduation and is highly likely to create risk of lifestyle-related diseases in later life [3,4]. However, university students are prone to engage in risky health behaviors [5]. The transition from high school to university involves a drastic change in lifestyle, as students often start living away from their parents, developing new social networks, and having more free time than before [5]. Accordingly, a decline in university students' health status is associated with these lifestyle changes [6-8]. Therefore, the maintenance of a healthy lifestyle is a challenge for university students.

Health literacy is defined as an individual's knowledge, motivation, and skills to access, understand, evaluate, and apply health information [9]. Studies have shown that people with high health literacy have healthy lifestyles [10]. Therefore, improving health literacy has been identified as a public health goal and a significant health care challenge globally [11]. Currently, health information is often obtained through the internet, especially by members of the younger generation, including university students [12,13]. Collecting data through the internet is different from collecting data through books and leaflets, and it requires specific skills; people must not only be health literate but must also be able to find, understand, and appraise information using digital services and technology [14]. Accordingly, electronic health (eHealth) literacy—the ability to search for, evaluate and use health information on the internet to solve health problems—is considered to be an essential factor for university students to maintain a healthy lifestyle and good health status [15]. According to the Lily model [16], eHealth literacy consists of six core skills (or literacies), which are classified into two types: analytic skills (traditional, media, and information) and context-specific skills (computer, scientific, and health). Therefore, health literacy is one of the literacies that comprise the concept of eHealth literacy [16]. The eHealth Literacy Scale (eHEALS) is an 8-item questionnaire that was developed based on the Lily model and measures a broad overview of self-perceived eHealth literacy skills [12]. The eHEALS has been translated globally and is widely used to assess eHealth literacy levels [14]. Studies have evaluated the eHealth literacy levels of university students in different countries [15]. However, the eHealth literacy level can vary among countries. Specifically, the eHealth literacy level of Japanese people may be lower than those of people in European countries [17]. The eHealth literacy level of students in Japanese universities has not been studied.

In the general population, many personal and social background characteristics, including age, gender, household income, educational level, and occupation, are associated with health literacy levels [17,18]. Among university students, male gender, higher school year, medical study department, higher academic achievement, and higher family income are associated with higher eHealth literacy levels [19-26]. However, these studies have limitations, such as relatively small numbers of participants [19,21,23,26] and recruitment of student participants from only medical and nursing departments [21,24,25]. Therefore, a study with a larger number of participants, including both nonmedical and medical students, is required to clarify the relationship between student characteristics and eHealth literacy.

Studies have shown that people with higher eHealth literacy have healthier lifestyles than those with lower eHealth literacy in the general population [18]. Regarding university students, only a few studies have reported on the association between eHealth literacy and lifestyle behaviors, such as regular exercise, healthy eating, and regular sleep, in Taiwan, Greece, and the United States [20,22,27]. However, the numbers of participants in these studies [20,22,27] were relatively small. Furthermore, the influence of eHealth literacy on lifestyle behavior may vary depending on the country, cultural background, and degree of internet use [17,19,21].

The purposes of this study were to clarify the eHealth literacy level, the participant characteristics associated with eHealth literacy, and the association of eHealth literacy with lifestyle behaviors of students in a Japanese university.

Methods

Recruitment

This study was a questionnaire-based cross-sectional study performed at Chiba University, Japan. Chiba University is a national university with 13,983 students at the time of the study. Of those, 5306/13,983 (37.9%) were female and 8677/13,983 (62.1%) were male. Furthermore, 10,547/13,983 (75.4%) were undergraduate students, and 2430/13,983 (17.4%) students were studying medical sciences, including medicine, nursing, and pharmacy. Inclusion criteria were students who underwent on-campus medical examinations from April to May 2019. Exclusion criteria were students who declined to participate and who did not understand the Japanese questionnaire. Furthermore, students with incomplete answers to the questionnaire were excluded. We recruited participants during 12/19 checkup days. Of 13,983 university students, 5310 (38.0%) underwent the checkup during the 12 days. Of those, 1918/5310 (36.1%) declined to participate, and the remaining 3392 students (63.9%) answered the questionnaire. No student was excluded because of inability to understand the Japanese questionnaire. After excluding 209 students with incomplete answers, the data from 3183 students were used for analysis. The Chiba University Ethics Committee approved this study (approval number 01-02). The data were collected anonymously. No gifts or payments were given to participants for participating in this study.

eHealth Literacy Level

The questionnaire consisted of questions on eHealth literacy, participant characteristics, and lifestyle behaviors.

The Japanese version of the eHealth Literacy Scale (eHEALS) was used to quantify eHealth literacy [12,28]. Both the original and Japanese versions of the scale have sufficient reliability and validity to evaluate the eHealth literacy of adults [12,28]. The eHEALS consisted of eight questions, including four items related to internet capability and four items related to the utilization of health information [12]. Answer options were provided with a 5-point scale from "I totally do not think so (1)" to "I think so quite (5)" for each item. The total score of eight items was calculated, with a higher score indicating a better eHealth literacy level. The participants were divided into two groups using the mean eHEALS score for statistical analysis: a high score group (≥24, n=1659) and a low score group (<23, n=1524) .

Participant Characteristics

The participant characteristics included gender, school year, department of study, and living status. Answers for school year (first to sixth year of undergraduate studies and first to fourth year of graduate school) were dichotomized into undergraduate and graduate [20]. Answers for department of study (undergraduate: education, engineering, science, horticulture, humanities, public affairs, law, politics and economics, liberal arts and sciences, literature, medicine, nursing, pharmacy; graduate: education, horticulture, medical and pharmaceutical sciences, nursing, science and engineering, and law school) were divided into medical (undergraduate: medicine, nursing, pharmacy; graduate: medical and pharmaceutical science and nursing) and nonmedical [19,21]. Answers for living status (living alone, living with parents or partner, living in a dormitory, and other) were classified into living alone and living with others.

Lifestyle

Lifestyle behaviors were assessed using the questions on exercise, breakfast, smoking, alcohol consumption, and hours of sleep. Answers for exercise frequency (≥3 days/week, 1-2 days/week, 1-2 days/month, none) were dichotomized into ≥1 day/week and <1 day/week for statistical analysis [18]. Answers for breakfast (every day, 5-6 days/week, 1-4 days/week, none) were divided into ≥5 days/week and <5 days/week [29]. For smoking, the answers for the three choices (yes, no, previously) were divided into nonsmoker (no, previously) and current smoker (yes) [30]. Answers concerning alcohol consumption (do not drink, 1-2 days/month, 1-2 days/week, ≥3 days/week) were categorized into <3 days/week and ≥3 days/week [31]. Answers for hours of sleep (≤6 hours, 7-8 hours, ≥9 hours) were dichotomized into sufficient (7-8 hours, ≥9 hours) and insufficient (<7 hours) [29]. Additionally, the participants' BMI (kilograms per square meter) was recorded as a proxy of lifestyle. The answers were provided with either underweight (<18.5), normal (≥18.5, <25), overweight (≥25, <30), or obese (≥30) [32]. Overweight and obese were combined into one "overweight" category [32]. Although the answer for BMI was self-reported, we assume it was accurate because the participants' BMIs were measured during the health examination immediately before they participated in the questionnaire survey.

Statistical Analysis

Demographic data on the participants' characteristics and lifestyle were expressed using descriptive statistics. Numbers and frequencies were used for categorical variables. Means and standard deviations were used for continuous variables because most of the data had a normal distribution. Participants were dichotomized into two groups depending on the characteristic (eg, undergraduate/graduate). The eHEALS scores were compared between groups using Student *t* tests. Furthermore, the associations of eHEALS scores with lifestyle behaviors were assessed using logistic regression analysis. The explanatory variable was the eHEALS score group (low/high), and the objective variables were lifestyle behaviors. The odds ratio (OR) was calculated for a healthy lifestyle in the high eHEALS group; the low score group served as the reference. Unadjusted ORs and ORs adjusted for participant characteristics (gender, school year, department of study, and living status) were expressed. Bonferroni corrections were conducted to adjust for multiplicity. Accordingly, statistical significance was set at *P*<.013 for the association between participant characteristics and eHEALS score and at *P*<.007 for the association between eHEALS score and lifestyle behavior.

Results

Participant Characteristics

Of the 3183 participants, 878 (27.6%) were female, and 2549 (80.1%) were undergraduate students (Table 1). Students in medical departments comprised 346/3183 (10.9%) of the survey participants.

For lifestyle behaviors, 1757/3183 (55.2%) participants exercised ≥1 day/week (Table 2). Only 140/3183 (4.3%) were current smokers, and 166 (5.2%) drank alcohol ≥ 3 days/week. Although 281/3183 (8.8%) participants were overweight, 480 (15.1%) were classified as underweight.

Table 1. Participant characteristics (N=3183).

Characteristic	Participants, n (%)

eHealth Literacy Level

The mean eHEALS score was 23.6/40 points (SD 6.8). The mean scores for each item ranged from 2.7 to 3.1. The lowest score for was obtained for Q6: “I have the skills I need to evaluate the health resources I found on the internet,” and the highest score was obtained for Q8: “I feel confident in using information from the Internet to make health decisions.”

Association Between Participant Characteristics and eHEALS Score

The mean eHEALS score for medical students was 2.9 points higher than that for nonmedical students (*P*<.001, Table 3). The eHEALS score was higher for graduate students than for undergraduate students (*P*=.003). However, the difference between the groups was 0.9 points. There was no difference between female and male gender (*P*=.18) or between students living alone and living with others (*P*=.02).

Table 3. Association between participant characteristics and eHEALS score (N=3183).

Characteristic (n)	eHEALS[a] score, mean (SD)	*P* value
Gender		
Male (2305)	23.6 (7.0)	.18
Female (878)	23.3 (6.3)	
School year		
Undergraduate (2549)	23.4 (6.8)	.003

[a] eHEALS: eHealth Literacy Scale.

Association of eHEALS Score With Lifestyle

Overall, participants in the high eHEALS score group had a healthier lifestyle than those in the low score group (Table 4). In the high score group, 984/1659 students (59.3%) exercised regularly (≥1 day/week), while in the low score group, 773/1524 (50.7%) exercised regularly. The adjusted OR for the high score group was 1.39 (*P*<.001, Table 4). Also, 1141/1659 (68.8%) and 991/1524 (65.0%) participants in the high and low score groups, respectively, had breakfast regularly (adjusted OR 1.24; *P*=.007). Interestingly, the risk of being overweight was higher in the high score group (adjusted OR 1.49; *P*<.001). However, the number of overweight students was low in both groups, namely 176/1659 (10.6%) in the high score group and 105/1524 (6.9%) in the low score group.

Table 4. Association of eHEALS score with lifestyle (N=3183). OR values are for the high eHEALS score group (n=1659) relative to the low score group (n=1524).

Lifestyle behavior	Unadjusted OR[a] (95% CI)	*P* value	Adjusted[b] OR (95% CI)	*P* value	Model *P* value
Regular exercise	1.42 (1.23-1.63)	<.001	1.39 (1.21-1.61)	<.001	<.001
Regular breakfast	1.18 (1.02-1.37)	.02	1.24 (1.06-1.45)	.007	<.001
No smoking	1.24 (0.88-1.74)	.22	1.18 (0.8-1.67)	.36	<.001
Alcohol <3 days/week	0.80 (0.59-1.10)	.17	0.82 (0.59-1.12)	.21	<.001
Sufficient sleep	1.10 (0.96-1.27)	.17	0.91 (0.79-1.06)	.22	<.001
Overweight (n=2703)[c]	1.58 (1.23-2.05)	<.001	1.49 (1.20-2.02)	<.001	<.001
Underweight (n=2902)[d]	0.93 (0.76-1.13)	.47	.94 (0.77-1.15)	.54	.14

[a] OR: odds ratio.

[b] Adjusted for gender, school year, department of study, and living status.

[c] n=1421 (52.6%) and n=1282 (47.4%) in the high and low eHEALS score groups, respectively.

[d] n=1476 (50.9%) and n=1426 (49.1%) in the high and low eHEALS score groups, respectively.

Discussion

Principal Findings

We showed that the average eHEALS score of students at a Japanese national university was approximately 24 points out of 40. Several personal background characteristics, including school year and department of study, were associated with a high eHEALS score. Additionally, students with higher eHEALS scores demonstrated better exercise behaviors. To the best of our knowledge, this is the first such study of Japanese students and one of the largest studies to clarify the eHealth literacy levels and related lifestyle behaviors of university students. Our results provide important information to help university students improve their eHealth literacy and achieve healthier lifestyles.

eHealth Literacy Level

In this study, the mean eHEALS score of the participants was 23.6/40 points. This value is comparable to that of general Japanese adults, whose mean score was 23.5 points [28,29]. However, studies from other countries have reported higher scores. For example, the mean eHEALS score of 192 students at an Iranian medical and health science university was 28.2 points [21]. In a study of 422 American college students, most of whom were undergraduate students, the mean score was 31.9 [27]. The eHEALS scores of the general population in several Asian, American, and European countries were also relatively high, ranging from 28.1-30.5 [33-36]. In addition to the lower eHealth literacy level of Japanese people, the general health literacy level, measured by using the European Health Literacy Survey Questionnaire (HLS-EU-Q47) [37], was lower in Japan than in European countries [17]. Therefore, the health literacy level in Japan appears to be low not only in university students but in Japanese people in general. There are some potential explanations for the lower health literacy of Japanese people. First, accessible and understandable public health information sites, such as the National Institutes of Health website in America [38] and the National Health Service website in Britain [39], are not available in Japan [17]. Therefore, Japanese people may have difficulty acquiring health literacy. Poor accessibility to health information can affect the eHealth literacy levels of college students in other countries as well [21]. Second, surveys by the Japanese Cabinet Office and the Ministry of Education, Culture, Sports, Science and Technology suggest that students and younger people have lower self-esteem in Japan than in other countries [40]. Because we assessed self-reported health literacy levels, the students who participated in this study may have rated their health information skills lower than the actual levels [41]. Further research is needed to clarify the cause of low health literacy in Japanese university students. Additionally, our results indicate that there is significant room for improvement in the eHealth literacy of Japanese university students [15].

Association Between Participant Characteristics and eHEALS Score

In this study, undergraduate and graduate students in the medical sciences (ie, medicine, nursing, and pharmacy) had higher eHEALS scores than those in nonmedical departments. This result was consistent with a study of 566 Taiwanese college students, in which medical students had higher eHealth literacy in all dimensions than nonmedical students [20]. A higher eHealth literacy level in medical students was also observed in a survey of 192 Iranian university students [21]. These results are understandable because medical students are more exposed to medical and health information in their curriculum.

The graduate student participants had higher eHEALS scores than undergraduate students, although the difference in the mean score was only 0.9 points. In studies of medical and nursing students, a higher school year was associated with higher eHealth literacy [19,21,24]. Additionally, a survey of 630 Danish university students showed higher health literacy among students in master's degree programs than among those in bachelor's degree programs [26]. Our study showed a similar association between school year and eHealth literacy in a broader range of student populations, including medical and nonmedical students. A possible explanation for our result is that eHealth literacy levels improve during university life. Another explanation is that students with higher eHealth literacy are selected for admission to graduate programs. Further longitudinal studies are necessary to clarify this issue. Combining the results of this study and those of previous studies, education programs to improve eHealth literacy should focus on early-degree and nonmedical students.

Association of eHEALS Score With Lifestyle

This study showed that participants in the high eHEALS score group exercised more frequently than those in the low score group. This association was significant after adjusting for participant characteristics. A relationship between higher eHealth literacy and better exercise behaviors is consistently found in Taiwanese, American, and Greek university students [20,22,27] as well as in adult internet users in Japan [29]. In this survey, 1426/3138 participants (44.8%) exercised <1 day/week. Promoting regular exercise to this population would be a fundamental part of healthy lifestyle promotion. The results of this study suggest that eHealth literacy education improves exercise behaviors.

In this study, a higher eHEALS score was associated with regularly eating breakfast. Our result was in line with previous studies, which showed that higher eHealth literacy was correlated with healthy diet behavior among American and Taiwanese college students [20,27]. People who did not eat breakfast reported suboptimal dietary behavior, such as unhealthy food choices and eating snacks [42]. Furthermore, skipping breakfast is associated with several lifestyle-related diseases [43,44] and lower academic achievement in college students [2]. Therefore, regularly eating breakfast serves as an indicator of an overall healthy lifestyle [42]. However, breakfast skipping is prevalent among young adults [45] and university students [46]. In this study, 1051/3183 (33.0%) of participants ate breakfast less than five times a week. Therefore, enhancing eHealth literacy could promote regular breakfast eating among university students.

Smoking and excessive alcohol were not associated with eHEALS score. Our results were consistent with general surveys of Japanese adults, in which the eHEALS score [29] and the general health literacy level [47,48] were not associated with smoking or alcohol consumption but were associated with exercise and balanced nutrition. Similarly, no association of eHealth literacy with smoking or alcohol was found in Greek university students [22]. This may be because the rates of habitual drinkers (166/3183, 5.2%) and current smokers (140/3183, 4.4%) were low in this study; thus, it is difficult to assess the association of eHealth literacy with alcohol and smoking [48]. Indeed, percentages of habitual drinkers and smokers have declined among young Japanese people in the past decade [49]. Another possible reason is that other environmental factors, such as friends, independent living, and family history, may affect the drinking and smoking behaviors of university students more than their eHealth literacy [50].

Limitations

This study has several limitations. First, this study was conducted at a single national university. Therefore, the results may not apply to university students from other backgrounds. For example, the type of university (ie, public or private) could affect the students' eHealth literacy levels [19]. Although approximately 3400 students from a wide range of school years and departments were enrolled in this study, further studies that include multiple universities are needed. Second, the participants of this study may not represent the general Chiba University student population. For example, only 878/3183 (27.6%) of participants were female, while 38% of Chiba University students are female. Third, we recruited participants who had undergone health checkups. People who undergo health checkups are more health-conscious and have healthier lifestyles than those who do not [51]; the eHealth literacy level may have been even lower if students who did not undergo health examinations had participated in the survey. Fourth, several participant characteristics that can be associated with eHealth literacy, such as academic achievement [22], family income [22], educational level of parents [26], student health history [26], and internet skills [19], were not surveyed because of the practicality limits of administering the questionnaire at the health examination. Fifth, because this study was designed as a cross-sectional study, the causal relationship of eHealth literacy with lifestyle was not clarified. Future studies that evaluate the effects of eHealth literacy education are needed to confirm the causality. Finally, we used eHEALS, which was developed in 2006, to quantify the eHealth literacy levels of the participants. However, the utilization of the internet has changed significantly since the scale was developed. Specifically, social media and mobile devices are among the most popular ways to use the internet among younger people [52]. Therefore, although this scale is a valid measurement and has been used widely, it may not fully represent the eHealth literacy levels of university students [53].

Conclusions

The eHealth literacy level of Chiba University students was comparable to that of the general Japanese population. Graduate students, as well as those in medical departments, had higher eHealth literacy levels. Furthermore, the students with higher eHealth literacy levels demonstrated better exercise behaviors. Interventions to address eHealth literacy could help improve students' lifestyles, although further research is warranted.

Abstract

Background: There is a documented need to build capacity for theory- and evidence-informed knowledge translation (KT) and patient engagement (PE) practice in health research. Dissemination of foundational content online coupled with social media promotion may build capacity by increasing awareness, knowledge, and positive attitudes.

Objective: This retrospective study sought to (1) describe exposure and engagement of the KnowledgeNudge KT and PE dissemination strategy (online blog and Twitter profile) over 2 years and (2) identify and compare characteristics of individual posts with the most and least exposure and reach.

Methods: Exposure was assessed by blog site views per month and Twitter profile impressions per month. Engagement was assessed by Twitter profile interactions per month. Descriptive statistics were calculated for 6-month blocks and compared using one-way analysis of variance or Student *t* test. Individual post exposure was assessed by average post views per week. Individual post reach was assessed by average post reads per week. High- and low-profile blog posts with the highest and lowest 10th percentile for exposure and reach were identified.

Results: A total of 99 posts and 755 tweets were published during the study period. There was a significant increase in exposure (P=.004) and reach (P<.001) during the final 6 months. Seven high-profile and 6 low-profile posts were identified. High-profile posts had a significantly greater average word count than low-profile posts (P=.003). There were no other significant differences between posts.

Conclusions: The increases in KnowledgeNudge exposure and engagement offer preliminary evidence in support of this dissemination strategy for the practice of KT and PE. Variation in individual post exposure and reach warrants further exploration to tailor content to user needs. Future work will include a prospective evaluation strategy to explore the effect of KnowledgeNudge on awareness, knowledge, attitudes, and behavior.

knowledge translation; dissemination; blog; Twitter

Introduction

Knowledge translation (KT) is an evolving discipline dedicated to advancing the synthesis, exchange, dissemination, and application of knowledge to optimize health, health care delivery, and the health care system [1]. It is a dynamic and iterative process that occurs throughout complex interactions between evidence producers and users [1], including but not limited to people with personal experience of a health issue (as a patient, family member, friend, or caregiver). The conceptual and evidence foundation for KT is growing rapidly, alongside growing recognition of the need for meaningful and active involvement of individuals with personal experience of a health issue in all stages of the research process (known in Canada as patient engagement [PE]) [2].

Accordingly, the need to build capacity to practice theory- and evidence-informed KT and PE has been identified in multiple studies [3-8]. For example, in a 2015 qualitative study of health researchers in Manitoba, Canada, KT education and training resources were identified as most needed to support practicing KT [7]. Similarly, in a 2017 survey of Manitoba health researchers, 81% of respondents indicated the need for training and educational resources to practice PE [9]. While the need for training has been consistently demonstrated, potential solutions need to consider known barriers to participation such as competing priorities and cost, which were identified in a 2014 Canadian study of knowledge translation training needs [10].

Dissemination of foundational resource material may help to build capacity for practicing theory- and evidence-informed KT and PE by facilitating distribution and awareness of seminal works, current best evidence and practices, and ongoing critical debates in the field [8]. In turn, dissemination may lead to increased knowledge and positive attitudes toward theory- and evidence-informed KT and PE, ultimately leading to improved skills and stimulation of behavior change [11]. Although effective dissemination strategies specific to KT and PE content have not been determined, online resources that use web-based technologies have emerged as a popular dissemination strategy due to their potential to reach large numbers of users [12] and have been shown to increase self-reported knowledge, skills, and information exchange in a time- and cost-efficient manner [13,14]. The impact of online dissemination resources may be enhanced when coupled with social media, which is rapidly growing in use in health research and care [15]. A 2015 study of 852 health researchers reported that 26.9% used social media for obtaining research evidence and almost all (95.9%) participants considered social media important for obtaining and disseminating research evidence [16]. Disseminating evidence through social media has also been shown to be effective in stimulating behavior change among health research users. For instance, a 2015 study of 317 clinicians found that 70% of participants reported changing or intending to change their practice after receiving evidence-based practice information through social media [17].

To address the established need to build capacity for practicing evidence-informed KT and PE, the KnowledgeNudge dissemination strategy was developed and launched in 2016. KnowledgeNudge consists of an online blog (a web-based collection of self-published content) [18] and accompanying Twitter profile [19]. The objective of KnowledgeNudge is to increase awareness, knowledge, and positive attitudes of KT and PE and related best practice concepts, considerations, and resources. The ultimate goal of KnowledgeNudge is to influence uptake of evidence-informed and/or best practice behaviors in KT and PE. Target audiences include health researchers, practitioners, and people with lived experience of a health issue. The editorial team comprises an academic KT scientist, KT and PE practice leads, and knowledge brokers with 4 to 10 years of experience. Contributors include a core group of KT scientists, academic trainees, research coordinators, KT and PE practice leads, and knowledge brokers (n=12), as well as guest posts from external health researchers and practitioners, patients/health consumers, and knowledge brokers with related expertise (n=9). Weekly blog posts summarize theoretical concepts, offer practice guidance, and provide opinions on issues of debate. Blog posts are intentionally short (less than 2000 words) and are written in a tone that is engaging, unique, and conversational and uses principles of plain language to appeal to a wide range of readers. Tweets are posted to promote each new blog post. Tweets direct readers to new content on the day of publication and through multiple follow-up posts in the first week. When new posts are not available, tweets promote existing posts.

There is consistent recognition of the need for outcome evaluation in established KT process models [20] and best practice recommendations for online KT tools and dissemination approaches [12]. As an important foundational step in evaluation of the KnowledgeNudge dissemination strategy, the overall goal of this study was to examine spread of KnowledgeNudge during its first 2 years. This concept was operationalized using recommended key performance indicators for social media use in health promotion: exposure, engagement, and reach [21]. Exposure reflects the number of times content has been viewed on a social media application. Engagement has been defined as an indicator of linking social medial to action, at its lowest level indicating some active interaction or participation, with individuals acknowledging agreement or preference for the content [21]. Reach indicates the number of individuals who have contact with the social media application and the related content [21].

The primary objective of this study was to describe and determine changes in exposure and engagement of the KnowledgeNudge blog and Twitter profile over a 2-year period (objective 1). The secondary objective was to identify and compare characteristics of individual posts with the most and least exposure and reach (objective 2). For the purpose of this study, exposure was measured through blog site views and Twitter profile impressions, and engagement was evaluated through Twitter profile interactions. Individual post exposure was evaluated through post views and reach through post reads.

Methods

Study Design

A retrospective descriptive quantitative study was conducted from August 1, 2016, through July 31, 2018. Given the nonidentifiable nature of the secondary data used for analysis, research ethics approval was not sought per Article 2.4 of the 2014 Government of Canada Tri-Council Policy Statement on Ethical Conduct for Research Involving Humans [22].

Data Collection

For objective 1 (describe and determine changes in exposure and engagement of the KnowledgeNudge blog and Twitter profile), study data were extracted from standard use metrics available for the KnowledgeNudge blog site account (hosted on WordPress from August 2016 to February 2017 and on Medium from March 2017 to July 2018) and KnowledgeNudge Twitter profile. For objective 2 (identify and compare characteristics of individual posts with the most and least exposure and reach), metrics for individual posts were collected on October 1, 2018, allowing the last post in the study period (published on July 25, 2018) to accumulate metrics for 68 days. Individual post data were not available for the period August 2016 to February 2017 due to the change in site host and the inability to retrospectively retrieve individual post data from WordPress once the account was closed.

Outcomes

The primary study outcomes were exposure and engagement of the blog site and Twitter profile (objective 1), as well as individual post exposure and reach (objective 2) [23,24]. Exposure was defined as the total number of KnowledgeNudge blog site page views per month and the total number of Twitter profile impressions per month. Engagement was defined as the total number of Twitter profile engagements per month. Individual post exposure was defined as the average number of views per week, calculated for each post by dividing the total number of post views over the study period by the number of weeks since the post was first published. Individual post reach was defined as the average number of reads per week, calculated for each post by dividing the total number of reads for the study period (a metric provided by Medium, in which a read is counted when someone remains on the post page for the estimated amount of time it takes to read the entire post) by the number of weeks since the post was first published. Secondary outcomes included individual post content characteristics of post topic (knowledge translation, patient engagement, both, or other); post type (conceptual, practice, or other); when each post was published (dividing the study period into 6-month bins); the number of tweets used to share each post during the study period; and the total number of words per post (excluding the title, subtitle, and author information).

Data Analysis

Descriptive summary statistics were calculated for all variables (values reported are mean and standard deviation). To determine characteristics of individual posts, a combination of deductive and inductive coding was used. First, the research team met and developed a coding framework that consisted of two broad coding categories by topic (KT and PE) and three subcategories by type (practical issues or practice, theoretical concepts or conceptual, opinions, or other). Practice posts were defined as those providing information on tools and resources for KT and PE; conceptual posts were defined as those providing evidence-based information on the science of KT and PE based on peer-reviewed literature; and opinion posts were defined as those providing expert opinion on KT and PE science and practice. Two team members independently coded individual posts. An additional category was included for posts that specifically identified as relevant to both KT and PE, and all other posts that did not fit in the developed categories were coded as other (for example, informative posts about staff members). Coding disagreements were resolved through discussion. Kappa scores were calculated to determine interrater reliability of individual post coding, which was found to be strong for post topic (=.85) and moderate for post type (=.66) [25].

To determine changes in exposure and engagement over time (objective 1), a 1-way analysis of variance was conducted to assess average blog site exposure over time and Twitter profile exposure and engagement for each 6-month block. Post hoc comparisons were completed using the Tukey honestly significant difference (HSD) test. Statistical significance was set at $P<.05$.

To identify and compare individual posts with the most and least exposure and reach (objective 2), posts were ranked separately by exposure and reach (average weekly views and reads, respectively). High-profile posts were identified as those in the 10th highest percentile for both exposure and reach, and low-profile posts were identified as those in the 10th lowest percentile for both exposure and reach. Posts with missing data (those originally posted on WordPress and imported to Medium) were included in identification of high-profile posts but not in identifying low-profile posts in order to avoid categorizing these posts as low profile when exposure and reach could not be accurately measured for the entire study period. Tweets per post, word count, and exposure and reach of high- and low-profile posts were compared with a Student t test [26]. A 2-sided Fisher exact test was used to compare time of publication (by 6-month block), topic, and type of post for high- and low-profile posts [27].

Results

KnowledgeNudge Production Summary

A total of 99 posts were published during the study period (average 4 posts per month). Average post length was 818 words (range 246 to 1908). Of the total posts, 59% (58/99) were characterized as KT, 29% (29/99) as PE, 5% (5/99) as both KT and PE, and 7% (7/99) as other topics such as providing information about the KnowledgeNudge team. Half of the posts (49/99) were coded as practice, 31% (32/99) as conceptual, 12% (12/99) as opinion pieces, and 6% (6/99) as other. A total of 755 tweets were produced during the study period. Most tweets directly promoted individual posts (599/755, 79.3%), while the remainder promoted related content via retweets.

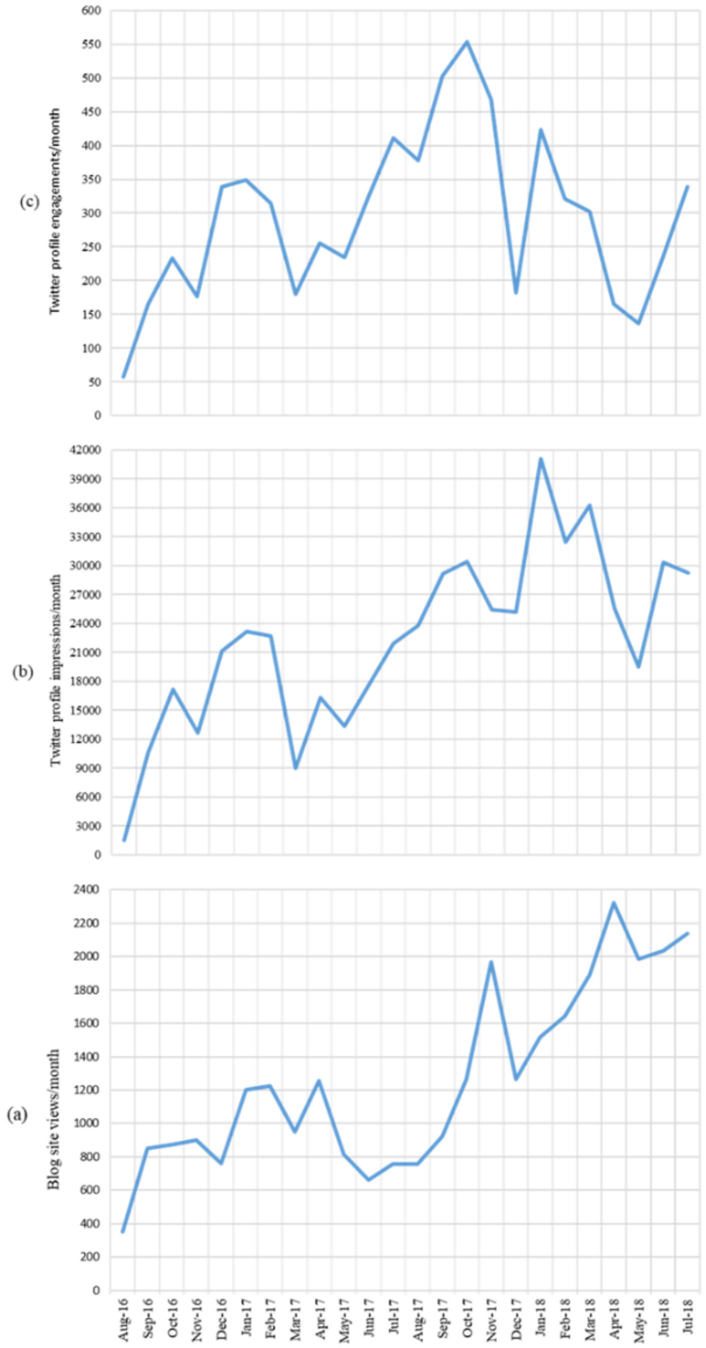
Objective 1. Exposure and Engagement of KnowledgeNudge

Monthly exposure and engagement are displayed in Figure 1. Average blog site exposure was 1263 (SD 549) site views per month during the study period (range 353 to 2322). There was a significant increase in blog site exposure over time ($F_{3,20}=17.9$, $P<.001$). Post hoc comparisons using the Tukey HSD test showed that average blog site exposure was significantly greater in the last 6-month block (2002 [SD 229] views per month) than the first (823 [SD 275] views per month) and second (944 [SD 248] views per month) 6-month blocks ($P=.001$) and the third (1283 [SD 432] views per month) 6-month block ($P=.003$). There was no significant difference in average blog site exposure between the first, second, and third 6-month blocks.

Average Twitter exposure was 22,320 (SD 9139) impressions per month (range 1522 to 41,112). A significant increase was seen in exposure over time ($F_{3,20}$=9.0, P<.001). Post hoc comparison using the Tukey HSD test showed that average Twitter exposure significantly increased from the first 6-month block (14,374 [SD 7903] impressions per month) to the third 6-month block (29,190 [SD 6371] impressions per month; P=.003) and to the last 6-month block (28,899 [SD 5780] impressions per month; P=.004). Post hoc comparison using the Tukey HSD test also revealed a significant increase in Twitter exposure between the second 6-month block (16,818 impressions per month), third 6-month block (P=.02), and last 6-month block (P=.02).

Average Twitter engagement was 294 (SD 124) engagements per month (range 57 to 554). There was a significant effect of time on average engagement ($F_{3,20}$=4.2, P=.02). Post hoc comparison using the Tukey HSD test showed a significant increase in average Twitter engagement between the first 6-month block (220 [SD 119] engagements per month) and the third 6-month block (418 [SD 131] engagements per month; P=.02). There were no other significant differences between the 6-month blocks.

Figure 1. KnowledgeNudge blog site exposure (a), Twitter exposure (b), and Twitter engagement (c) over 2-year period. There was a significant increase in blog site exposure (P<.001) and Twitter exposure (P=.004) between the first and last 6 months of the study period. No significant difference was seen in Twitter engagement between the first and last 6 months.



Objective 2: Individual KnowledgeNudge Post Characteristics

The average exposure of individual posts was 4.8 (SD 8.8) views per week (range 0.3 to 79). The average reach of individual posts was 1.7 (SD 1.7) reads per week (range 0.1 to 12). The average word count of individual posts was 988.3 (SD 429.3; range 434 to 1908). The average number of tweets per post was 7.1 (SD 2.3; range 3 to 11). Seven posts were identified as high profile, and 6 posts were identified as low profile. Comparison between high- and low-profile posts using a Student *t* test showed there was a significant difference between high- and low-profile posts for exposure (t_1=2.2, *P*=.02) and reach (t_1=4.9, *P*<.001). The word count of high-profile posts was significantly greater than that of low-profile posts (t_1=3.4, *P*=.003). There was no significant difference in the number of tweets per post between high- and low-profile posts (t_1=1.7, *P*=.06). There was no significant difference between high- and low-profile posts in terms of time of publication (*P*=.66), topic (*P*=.12), or type (*P*=.44). Characteristics of individual high- and low-profile posts are reported in Table 1.

Table 1. Characteristics of high- and low-profile KnowledgeNudge posts (those within the highest and lowest 10th percentile for both exposure and reach).

Discussion

Principal Findings

The goal of this study was to explore changes in exposure and engagement of the KnowledgeNudge KT and PE dissemination strategy during its initial 2-year period. By formally measuring and documenting changes in exposure and engagement of the KnowledgeNudge strategy, this study adds to the growing body of literature on the use of social media in dissemination science and demonstrates important contributions for building capacity in the practice of high-quality KT and PE practices. The findings establish a foundation for future studies to explore in-depth the impact of KnowledgeNudge content on KT and PE practice behaviors.

An important finding was the significant increase in blog site exposure between the first and last 6-month periods, providing evidence of increased spread of information on foundational issues of KT and PE. The significant increase in Twitter profile exposure during the study also provides evidence of growing network size. The absence of significant changes in Twitter profile engagement between the first and last 6-month periods is arguably less important, as the Twitter profile served to encourage users to visit the primary blog site and was not the primary source of KT and PE content. We also observed considerable variation in reach among the individual posts. Post topic and type coding did not suggest any trends influencing variation between posts with the highest and lowest reach.

The findings of this study are consistent with published evaluations of exposure and engagement in online dissemination blog strategies and Twitter activity in related domains of health [28-30]. The increase in exposure is a precursor to increase in awareness. The findings also support the goals of KnowledgeNudge by increasing the spread of information on foundational issues relating to the practice of KT and PE. A 2019 scoping review of core competencies for KT identified 19 individual competencies specific to addressing primarily knowledge, skills, or attitudes [31]. Although individual posts were not coded according to this framework, the KnowledgeNudge strategy as a whole seeks to address aspects of each of these competency domains. For example, the KnowledgeNudge dissemination strategy addresses many of these individual competencies related to the domain of knowledge including sharing of knowledge, increasing awareness of evidence resources, and promoting the understanding of research process, KT, and dissemination activities [31]. However, it has yet to be determined whether the KnowledgeNudge dissemination strategy addressed the domains of skills and attitudes. Moving forward, this core competency framework could be used to guide development of KnowledgeNudge content and evaluation approaches.

Although we did not directly assess factors that contributed to the increase in blog site exposure, using Twitter as a promotional strategy has been associated with increase in website traffic [29,32]. For example, a study of a website and Twitter profile aimed at disseminating resources related to child health found that an increase in Twitter exposure was associated with increased website reach [29]. Other factors that might have contributed to the increase in exposure of the blog site include posting content on a regular basis (on average one post per week) and publishing on subject matter identified as being of interest to readers through annual reader surveys. Similarly, having a team of authors with a wide of range of expertise also contributed to producing content covering a vast range of topics in PE and KT, potentially attracting a wide range of readership. Future studies should more explicitly consider and compare the effects of variables such as post frequency and content on changes in exposure, reach, and engagement.

The findings related to characteristics of high- and low-profile posts have important implications for those planning online dissemination strategies in general and those specifically interested in building capacity for KT and PE practices. Among the blog characteristics tested, the only significantly different variable between high- and low-profile posts was word count. Notably, high-profile posts had significantly more words than low-profile posts. This finding is supported by some evidence suggesting longer blogs are more influential in terms of garnering reader attention and feedback [33]. We found no difference in KT or PE post topic, practice or conceptual type, number of tweets per post, or time period of publication between high and low-profile posts. Other metrics not captured in our study may help to explain differences between high- and low-profile posts. The finding that time period of publication was not significantly different does eliminate two important opposite influencing factors: first, that older posts might accumulate more views and reads compared with newer posts because of the former being posted for a longer period on the website, and second, that more recent posts might have higher views and reads compared with older posts because of recency bias [34].

Limitations

We acknowledge the limitations of this retrospective study and potential for continued evaluation to overcome them. First, we recognize that reliance on online use metrics provides only a proxy indicator of awareness and generally relies on the assumption that the reader is actively interacting with the content. Analysis of related indicators such as Medium comments or claps (Medium’s version of likes) may have provided additional evidence for active engagement and awareness with the KnowledgeNudge strategy, although the inherent difficulty of accessing, measuring, and interpreting social media metrics is recognized in the literature [35]. Retrospective use of standard online metrics also restricted data accessibility to some extent (particularly blog site-level metrics such as unique visitors), and this was compounded by the unanticipated effects of changing host sites during the study period. We recommend those planning similar evaluations ensure in advance that their anticipated metrics are accessible, relevant, and feasible to collect.

Future research opportunities for understanding the effects of the KnowledgeNudge dissemination strategy include (but are not limited to) additional analysis to explore factors influencing variation in individual post engagement (such as author and guest effects; social media influencer effects; tweet content such as hashtags, photos, or language; and timing), social network analysis based on KnowledgeNudge Twitter and/or Medium followers, and a prospective study examining the overall impact of KnowledgeNudge on knowledge, skills, and attitudes toward theory- and evidence-informed KT and PE practice. Recognizing the limitations of dissemination strategies on behavior [36] and given that multifaceted KT strategies have been shown to be more effective [37] the impact of KnowledgeNudge would likely be optimized when coupled with active training and practice-building strategies.

Conclusions

The KnowledgeNudge dissemination strategy demonstrated increased online blog site and Twitter exposure over an initial 2-year period. Growth of KnowledgeNudge resulted mostly from an increase in blog site and Twitter exposures. The outcomes included in this study, based on standard use data, provide evidence of a foundational component for increasing capacity for theory- and evidence-informed KT and PE practice: access to information. Critical next steps include ongoing evaluation to explore the effects of KnowledgeNudge on knowledge, skills, and behavior. Variation in individual post reach warrants further exploration and audience feedback to tailor content to user needs. Future work will include a prospective evaluation strategy to comprehensively explore the effect of KnowledgeNudge on knowledge, attitudes, and behavior, and opportunities to leverage KnowledgeNudge resources in an active training program will be explored.

Acknowledgments

This study was funded by the George & Fay Yee Centre for Healthcare Innovation. KMS is supported through the Canada Research Chairs Program. We acknowledge the leadership of Kristy Wittmeier and Sane Dubé in establishing the KnowledgeNudge dissemination strategy and contributions of the many authors who have developed content for the blog.

Abstract

Background: The use of digital technologies is increasing in health care. However, studies evaluating digital health technologies can be characterized by selective nonparticipation of older people, although older people represent one of the main user groups of health care.

Objective: We examined whether and how participation in an exergame intervention study was associated with age, gender, and heart failure (HF) symptom severity.

Methods: A subset of data from the HF-Wii study was used. The data came from patients with HF in institutional settings in Germany, Italy, the Netherlands, and Sweden. Selective nonparticipation was examined as resulting from two processes: (non)recruitment and self-selection. Baseline information on age, gender, and New York Heart Association Functional Classification of 1632 patients with HF were the predictor variables. These patients were screened for HF-Wii study participation. Reasons for nonparticipation were evaluated.

Results: Of the 1632 screened patients, 71% did not participate. The nonrecruitment rate was 21%, and based on the eligible sample, the refusal rate was 61%. Higher age was associated with lower probability of participation; it increased both the probabilities of not being recruited and declining to participate. More severe symptoms increased the likelihood of nonrecruitment. Gender had no effect. The most common reasons for nonrecruitment and self-selection were related to physical limitations and lack of time, respectively.

Conclusions: Results indicate that selective nonparticipation takes place in digital health research and that it is associated with age and symptom severity. Gender effects cannot be proven. Such systematic selection can lead to biased research results that inappropriately inform research, policy, and practice.

technology; exclusion; recruitment; self-selection; nonparticipation

Introduction

Increasingly more digital health technologies are evaluated for their potential use in the provision of health care services, with promising results at both individual and organizational levels [1-3]. It is expected that current health care service provision will be progressively restructured around the use of digital health technologies [4,5]. The use of digital technologies in health care service provision involves all users and hence, older people, as they represent one of the main user groups of health care services [6].

Although the number of older people using digital technologies is increasing [7], many are either nonusers or have little experience with using new technologies [8,9], even in countries that show high levels of internet and digital technology use [10].

Differences in the use of digital technologies exist not only between younger and older people but also within the older population [9]. Lower use and nonuse of digital technologies in old age are generally related to material, social, and individual resources [11]. Previous studies have found that lower education levels, less income, and poorer health status are associated with less use or nonuse of digital technologies [12-16]. Limited use or nonuse of digital technologies can also be determined by individual choices [17].

Such digital disparities can lead to disadvantages for some groups and hence contribute to increased risks of social exclusion and widened social inequality. Disparities can be reinforced by the participant selection strategies in studies evaluating new digital technologies [1,18,19]. Evaluations of digital health technologies typically follow the laboratory phases in which the digital technologies are developed and customized and focus on evaluating such tools with future target users via pilot trials or randomized trials [2]. However, such evaluations have some important shortcomings. Among others, the selection of study participants often results in samples that do not reflect the target population of interest [18,19] and hence, predetermines selective nonparticipation in the studies.

Selective nonparticipation in research prevents acknowledging, representing, and recognizing the interests and needs of different people [20,21], leading to biased research results [18,22] and generation of recommendations that are inaccurate for the entire population of interest. Underrepresented groups might be excluded or benefit less from the opportunities provided by the use of digital technologies in health care service provision and, most importantly, be disadvantaged by this change, compared with their digitally engaged counterparts. Such a disadvantage holds the potential to widen existing old-age inequalities [23,24].

Previous research has found that people who participate in studies on digital health technologies are typically younger, with better subjective health and overall quality of life; are more often men; are in better socioeconomic conditions; report more frequent digital access; and have higher digital skills [25-29]. Merkel et al [18] emphasized that vulnerable populations are less likely to be involved in such studies. In addition, refusal rates are often quite high [25,29,30]. Overall, people who agree to participate in studies can differ significantly from those who decline [29].

There are few studies that describe processes that result in selective nonparticipation of older people in digital health research [26,27,29]. Previous studies have mainly focused on individual decision making regarding whether to participate. However, less is known about selective nonparticipation resulting from the combination of two processes: (non)recruitment according to study requirements and self-selection as an individual decision.

The aim of this paper was to understand what predicts (non)participation of older people in digital health research. Here, participation is defined as being involved in digital health research as a study participant, and nonparticipation is defined as not being involved in digital health research. To study this, we conducted an analysis that deconstructs and examines (non)recruitment and self-selection occurring in a study evaluating exergame technology for patients with heart failure (HF); detailed descriptions of both the study and the intervention have been reported previously [31,32]. We investigated whether patients who were not eligible, those who declined, and those who accepted participation differed according to age, gender, and HF symptom severity. We hypothesized that age, gender, and symptom severity predicted individual participation in the HF-Wii study. We expected that participants would be younger, more likely to be men, and have less severe symptoms compared with those who were not eligible and those who declined to participate.

Methods

HF-Wii Study

This study was conducted within the research program “Supporting Self-Care by Information and Communication Technology for Older People with Long-Term Conditions” (ICT4Self-care; 2015-2018) conducted at Linköping University and funded by the Swedish Research Council for Health, Working Life and Welfare (FORTE; dnr 2014-4100). The analyses are based on data collected from the HF-Wii study [31,33], which contributed to this research program.

The HF-Wii study evaluated the impact of exergaming on the exercise capacity and daily physical activity of patients with HF. Exergame is a term that refers to video games that can be used for exercising, often at home. The HF-Wii study is based on a randomized controlled trial (RCT) approach. The HF-Wii study was developed based on the results obtained from a case study and a pilot study in which patients with HF were involved. Based on the experiences gained from these studies (ie, evaluating the results, experiences of patients with an exergame platform, and experiences of the research staff in conducting an exergame study), the RCT was developed [33,34]. Furthermore, a research partner (a patient with HF) from the Swedish Heart and Lung Foundation was involved in refining the instruction session, questionnaires, and recruitment and data collection strategies.

The target population of the HF-Wii study consisted of patients who were diagnosed with HF by a cardiologist according to

European Society of Cardiology guidelines [35] and who were older than 18 years. Exclusion criteria in the HF-Wii study were physical or balance problems, visual impairments, severe cognitive impairment(s) or psychiatric illness, a life expectancy shorter than 6 months, and not being able to speak or understand the language of the country where the study took place. Such criteria were assessed by a recruiter in each of the countries. Patients who were eligible according to the criteria were invited to participate in the HF-Wii study.

This study is based on data that refer to the study inclusion from four of the countries involved in the HF-Wii study: Germany, Italy, the Netherlands, and Sweden. Ethical approval for the HF-Wii study was obtained from local ethical committees (in Germany, GERS22(a)/2015; in Italy, IT:0052838/272/UVF/1; in the Netherlands, NL48647.068.14/METC141085; in Sweden, DNR 2012/247-31).

Data

The study population for this research in the four countries (Germany, Italy, the Netherlands, and Sweden) consisted of 1632 patients with HF who were screened in institutional settings between 2013 and 2017 for participation in the HF-Wii study. For these patients with HF, baseline information on age, gender, and HF symptom severity was completed by the recruiters in the four countries. Information on age was available for 1567 patients. Data on gender were retrieved for 1552 patients, and New York Heart Association (NYHA) class was recorded for 1180 patients.

Furthermore, data on (non)participation in the HF-Wii study based on the recruitment logs and reasons for nonparticipation were collected. No personal nor sensitive data were collected for this analysis.

Selective Nonparticipation

Selective nonparticipation was studied as resulting from two succeeding processes in the recruitment phase of the HF-Wii study: (non)recruitment according to the study requirements and self-selection as an individual decision [36]. The (non)recruitment process refers to the initial screening to select who is eligible to participate and excludes the others (ie, nonrecruited group). In contrast, self-selection is based on individual decision making that results in accepting or declining the invitation to participate and distinguishes between participants and decliners.

Outcome Variable

The outcome variable was constructed as a categorical variable with 3 categories, namely the 3 groups in which patients could alternatively be classified as a result of the recruitment phase: nonrecruited, decliner, or participant. The categories were constructed based on information from the recruitment logs that reported whether a patient was not recruited (ie, ineligible because of exclusion criteria), a decliner (ie, the patient declined the invitation to participate in the study), or a participant in the HF-Wii study.

Predictor Variables

Age, gender, and HF symptom severity were the predictor variables of this study. Age was included as a categorical variable: ≤64 years, 65-69 years, 70-79 years, ≥80 years, or missing. Gender was categorized as male, female, or missing. HF symptom severity was assessed by HF nurses according to the NYHA Functional Classification [37]. This classification is based on a subjective assessment of symptoms ranging between class I (ie, no symptoms and no limitation in ordinary physical activity, but presence of shortness of breath when walking or climbing stairs) and class IV (ie, severe limitations, experience of symptoms even while at rest). For the analyses, a missing value category was used.

Documented reasons for nonrecruitment and self-selection may further explain (non)recruitment and self-selection. Therefore, for those patients who were not eligible based on the HF-Wii study criteria, reasons for nonrecruitment were documented. For those patients who did not want to participate, reasons for declining the invitation were collected as free-text responses and coded into 10 categories: not having time, working or travelling a lot, unwilling to come to follow-up meetings, having other illnesses, already exercising a lot, unwilling to use technical equipment or the exergame device, already have a exergame device, living between different houses (unwillingness to move the exergame equipment from place to place), and shared living. Reasons for declining that did not fall into any of the above listed 10 categories were classified as “other.”

Analyses

First, descriptive analyses were performed to describe the predictor variables in the 3 groups and to illustrate nonrecruitment, declining, and participation rates. One-way ANOVA and Pearson’s chi-squared test were used for testing differences among the 3 groups.

Second, multinomial logistic regression was used to test the association between recruitment group membership (ie, nonrecruited, decliner, participant) and the predictors age, gender, and symptom severity. The participant group was the reference category.

Based on the regression model, we calculated the average marginal effects (AMEs) for each of the categories of the predictor variables. For each category of the predictor variables in the model, the AME showed the probability of being part of the nonrecruited, decliner, or participant groups for an individual who has the same values on every independent variable in the model except one [38]. AMEs were used because they could be compared more easily than odds ratios across groups in the sample [39].

In these analyses, we did not include patients for whom information on age and gender was missing. Inclusion of patients with missing data in the analyses was checked but did not result in a significant improvement of the model. However, we kept the missing value category for the variable NYHA as it concerns a larger number of cases. The sample size for these analyses consisted of 1489 patients (ie, net sample).

Third, to illustrate the selection processes, the reasons why patients were deemed ineligible, and why they decided not to participate in the HF-Wii study were evaluated. Reasons for ineligibility were investigated for all patients in the nonrecruited group, and reasons for individuals not to participate were described for patients in the decliner group.

Analyses were performed using SPSS Statistics version 25.0 (IBM Corp, Armonk, NY) and Stata software version 15 (StataCorp, College Station, TX).

Results

Patient Characteristics

Overall, 1632 patients with HF entered the recruitment phase of the HF-Wii study in the four countries. The mean age of the patients was 70 years (SD 11.9 years). More than half of the patients who entered the recruitment phase were ≥70 years old, representing 55.58% (907/1632) of the sample, and 13.30% (217/1632) of the patients were between 65 and 69 years of age. Around one quarter of the sample (443/1632, 27.14%) was ≤64 years old. No information on age was available for the remaining 3.98% (65/1632) of the patients. Of the 1632 patients screened, 64.83% (1058/1632) were men, and 30.27% (494/1632) were women. Information was missing for 4.90% (80/1632) of patients.

Of all the patients, 35.66% (582/1632) were classified as having mild HF symptoms and somewhat limited ability to exercise (NYHA class II), and 27.76% (453/1632) had marked limitations in activity due to symptoms (NYHA class III). Only 2.39% (39/1632) of patients had severe HF symptoms even at rest (NYHA class IV), and 6.50% (106/1632) had no HF symptoms (NYHA class I). Information on HF symptom severity was missing for 452 patients (452/1632, 27.70%).

Nonrecruitment, Declining, and Participation Rates

Overall, 71.45% (1166/1632) of all patients screened for the HF-Wii study did not participate in the intervention study (Table 1). Among those who did not participate, 37.99% (443/1166) were nonrecruited, and 62.01% (723/11166) declined to participate. The refusal rate for the HF-Wii study, based only on those patients who were invited to the study, was 60.81% (723/1189).

Mean ages were significantly different between the nonrecruited (73 years, SD 12.2 years), decliner (70 years, SD 11.8 years), and participant (67 years, SD 11.2 years) groups ($F_{2,1566}$=29.2, *P*<.001). Participants were significantly younger than patients in the decliner and nonrecruited groups.

Among the different age groups, the participation rate was lowest for patients 80 years old and older (59/361, 16.3%). The highest participation rate was found among patients 65-69 years of age (89/217, 41.0%). On the other hand, it was more common for patients 80 years old and older to be nonrecruited (155/361, 42.9%), compared with all the other groups (70-79 years, 127/546, 23.3%; 65-69 years, 40/217, 18.4%; and ≤64 years, 97/443, 21.9%). Declining to participate in the RCT was more common among patients 70-79 years of age (257/546, 47.1%), compared with the other age groups, for which declining varied from 40.6% to 42.9%.

On average, it was more common for men to participate in the HF-Wii study (332/1058, 30.38%) compared with women (134/494, 27.1%). In contrast, women were more often nonrecruited (168/494, 34.0%) than men (259/1058, 24.48%), while men more often declined participation (467/1058, 44.14%) compared with women (192/494, 38.9%). No information on gender was available for 16 patients in the nonrecruited group and for 64 patients in the decliner group.

On average, participation was lower among patients with marked limitations in activity due to HF symptoms and severe HF symptoms at rest (NYHA class III, 105/453, 23.2%; NYHA class IV, 4/39, 10.3%) compared with patients with no HF symptoms (NYHA class I, 55/106, 51.9%) or mild HF symptoms (NYHA class II, 280/582, 48.1%). Being ineligible for the HF-Wii study was more common among patients with NYHA class IV HF (28/39, 71.8%) than among the other groups for which the rate of nonrecruitment varied from 4.7% to 44.6%.

Table 1. Characteristics of the 1632 patients, by recruitment group.

Characteristics	Recruitment groups			Statistic	*P* value

[a] mean (SD).

[b] HF: heart failure.

[c] NYHA class I: no limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea (shortness of breath) [37].

[d] NYHA class II: slight limitation of physical activity. Comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea (shortness of breath) [37].

[e] NYHA class III: marked limitation of physical activity. Comfortable at rest. Less than ordinary activity causes fatigue, palpitation, or dyspnea [37].

[f] NYHA class IV: unable to carry on any physical activity without discomfort. Symptoms of HF at rest. If any physical activity is undertaken, discomfort increases [37].

Participation in the HF-Wii Study

A multinomial logistic regression was performed to test the association between recruitment group membership (ie, nonrecruited, decliner, participant) and the predictors age, gender, and HF symptom severity. The reference group consisted of patients who were recruited and agreed to participate (ie, participant group; Table 2).

The model shows that HF symptom severity, according to the NYHA functional classification, significantly predicted the likelihood of participation in the HF-Wii study. Patients with more severe symptoms, namely those in NYHA classes III and IV, had a decreased probability of participating and an increased probability of not being recruited, compared with patients with no or mild symptoms (ie, those in NYHA classes I and II). When compared with patients who displayed no symptoms (ie, NYHA class I), patients who had more severe HF symptoms (ie, NYHA classes III and IV) were significantly more likely to be nonrecruited to the HF-Wii study than to participate in it (NYHA class III, odds ratio [OR] 14.68, *P*<.001; NYHA class IV, OR 56.18, *P*<.001). Average marginal effects showed that more severe HF symptoms increased the probability of not being recruited by 63 percentage points for patients with NYHA class IV and by 35 percentage points for patients with NYHA class III (Figure 1). More severe HF symptoms decreased the probability of participation by 3 percentage points for patients with NYHA class I, by 25 percentage points for patients with NYHA class II, and by 39 percentage points for patients with NYHA class III.

Table 2. Multinomial logistic regression model of the relationship between recruitment group membership and predictors (ie, age, gender, and heart failure [HF] symptom severity) for all the patients for whom information on age and gender was available (n=1489) in the HF-Wii study. Pseudo R^2 (McFadden)=0.13.

[a] Reference category.

[b] AME: average marginal effect.

[c] N/A: not applicable.

[d] The missing value category was included in the analyses but is not reported in this table.

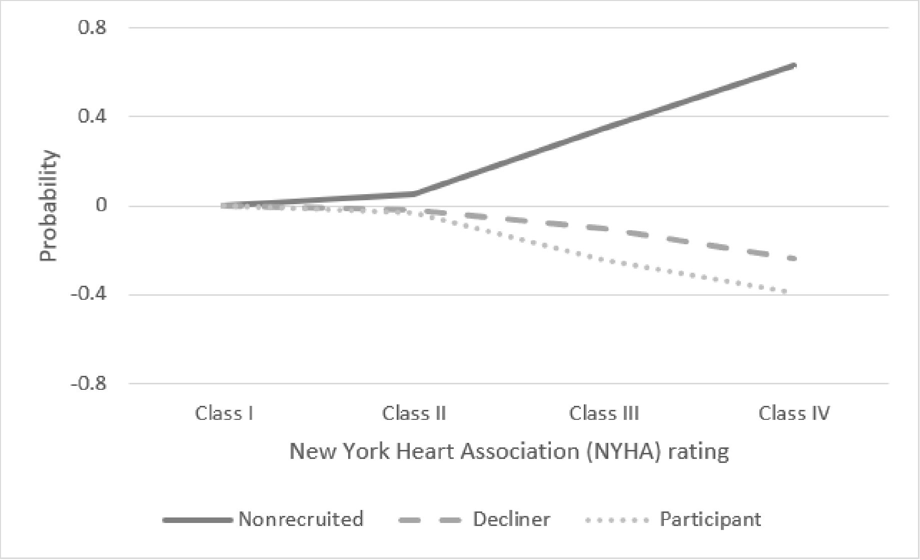
[e] NYHA class I: no limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnea (shortness of breath) [37].

[f] NYHA class II: slight limitation of physical activity. Comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea (shortness of breath) [37].

[g] NYHA class III: marked limitation of physical activity. Comfortable at rest. Less than ordinary activity causes fatigue, palpitation, or dyspnea [37].

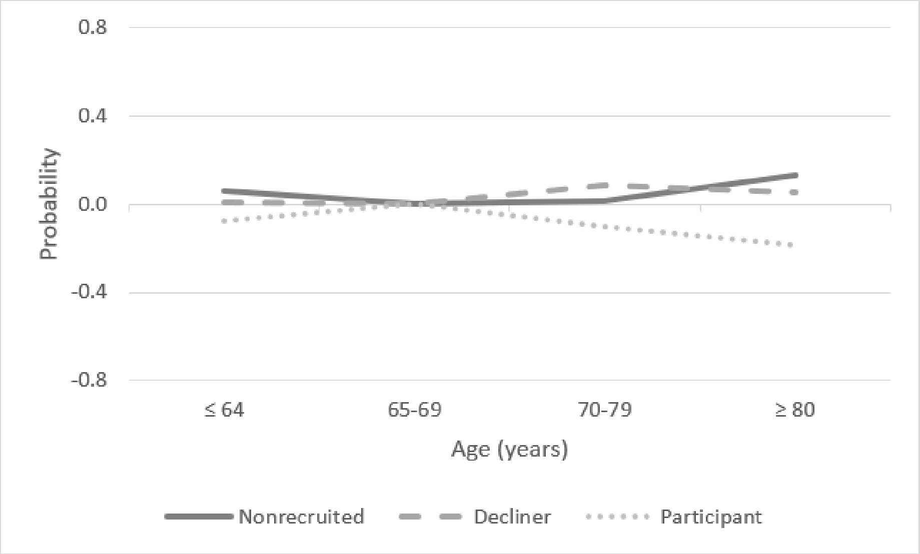
[h] NYHA class IV: unable to carry on any physical activity without discomfort. Symptoms of HF at rest. If any physical activity is undertaken, discomfort increases [37].

Figure 1. Probability of being in one of the 3 recruitment groups (ie, nonrecruited, decliner, participant) based on heart failure symptom severity.



The model also reveals that age was a significant predictor for participation in the HF-Wii study and contributed to explaining both (non)recruitment based on study requirements and self-selection as an individual decision. Being older reduced the probability of participating and of agreeing to participate. Compared with those 65-69 years of age, patients 80 years old and older were more likely to not be recruited than to be participants in the HF-Wii study (OR 3.86, *P*<.001). Probability of being not recruited increased by 13 percentage points for patients 80 years old and older, when compared with those 65-69 years of age (Figure 2). This was also found among patients 64 years of age and younger (OR 1.78, *P*=.03).

Figure 2. Probability of being in one of the 3 recruitment groups (ie, nonrecruited, decliner, participant) based on age.



Compared with the patients 65-69 years of age, people in the two older age groups (ie, 70-79 years and ≥80 years) were significantly more likely to decline the invitation to participate in the HF-Wii study than to participate in it (OR 1.74, *P*=.01; OR 2.44, *P*<.001, respectively). Being older increased the probability of declining participation in the study by 8 percentage points for patients 70-79 years of age and by 6 percentage points for those who were 80 years old and older, compared with patients 65-69 years of age.

Gender was not associated with the likelihood of participation in the HF-Wii study. It had no effect on the probability of being in the nonrecruited, decliner, or participant groups.

Reasons for Non-Recruitment and Declining to Participate

Of the patients, 27.14% (443/1632) were nonrecruited and thus were not invited to participate in the HF-Wii study. Patients were nonrecruited if they met at least one of the exclusion criteria.

The two most common reasons for being nonrecruited in the HF-Wii study were balance (223/443) and other physical problems (189/443; Table 3). Both reasons were more common among patients with marked and severe HF symptoms (ie, NYHA classes III and IV) than among the other patients. The least common reason for nonrecruitment was having a life expectancy <6 months (18/443). Age was a major factor for non-recruitment: 84% (187/223) of the nonrecruited patients with balance problems and 79% (149/189) of non-recruited patients with physical problems were 70 years old and older.

Table 3. Reasons for non-recruitment, based on the exclusion criteria and reasons for declining to participate in the HF-Wii study.

Reasons	n
Nonrecruitment (n=443)[a,b]	
Balance problems	223
Physical problems	189
Inability to fill in the questionnaire	107
Cognitive impairment(s)	79
Visual impairment	52
Life expectancy <6 months	18
Declining to participate (n=723)[c,d,e]	
Not having time	93
Working or travelling a lot	82
Unwilling to come to follow up meetings	48
Having other illnesses	41
Already exercising a lot	41

[a] Patients could be ineligible because of more than one criterion.

[b] Only the reasons given by at least 1 patient are reported.

[c] Multiple reasons for each patient were possible.

[d] Reasons were given by 569 patients (78.7%).

[e] Only reasons given by >30 patients are reported in the table.

Among the patients meeting the study criteria and invited to the HF-Wii study, 60.80% (723/1189) decided not to participate, and 79% percent (569/723) gave at least one reason for declining to participate (Table 3).

Among the reasons for declining, the 3 most often reported reasons were: “not having time,” “working or travelling a lot,” and “unwilling to come to follow-up meetings.” Not having time was the most common reason for declining participation in the HF-Wii study among patients 65-69 years of age and younger. It was more common among the youngest age group than among the other age groups to decline to participate in the HF-Wii study because they were already engaged in physical activities. Working or travelling a lot and not having time were the two most common reasons for declining to participate among patients 70 years and older.

Discussion

Evaluations of digital health technologies are affected by selective nonparticipation that can prevent the representation of needs and interests of parts of the target population, bias research results, and generate conclusions that lead to inefficient solutions and new inequalities. The aim of this paper was to understand the predictors of participation in digital health research. For this purpose, an analysis of selective nonparticipation in a study evaluating an exergame technology for patients with HF (ie, the HF-Wii study) was conducted to examine whether and how (non)participation is associated with age, gender, and symptom severity. Selective nonparticipation was deconstructed and analyzed as resulting from two consecutive processes: (non)recruitment based on study requirements and self-selection as the individual decision.

Overall, results show that participants, compared with nonparticipants, had less severe HF symptoms and were younger, but did not differ by gender. The main reasons for nonrecruitment were balance or physical problems, whereas the main reasons for declining participation in the HF-Wii study were related to lack of time and other commitments (ie, working or travelling a lot).

More severe HF symptoms predicted the nonrecruitment of patients in our sample. Patients with such severity of symptoms often show balance problems or severe comorbidities that more often make them ineligible according to study criteria. This result agrees with previous findings on participation in health-related research showing that patients with poorer health status, such as frail patients [40], patients with cognitive impairment [41], and patients with poorer physical functioning [42], are less likely to be participants.

However, among the patients in our sample, HF symptom severity did not significantly affect self-selection. This contrasts with findings of previous research describing individuals who decline participation as being more likely to show worse health than participants [43-45]. One possible explanation is that the patients with more severe HF symptoms were identified as ineligible to participate in the HF-Wii study already in the initial screening phase because of a higher incidence of balance or physical problems and, thus, were not invited to participate in the study.

Age significantly predicted participation in the evaluation of the exergame intervention. Belonging to an older age group reduced the probability of participating through both the processes of (non)recruitment and self-selection. This confirms previous findings on participation in health-related research

[46] and more specifically in both digital health [25,29] and HF research [47]. Such results are especially relevant in relation to the epidemiology of HF. As HF is more common among older people [48,49], it is crucial that the inclusion of older people in digital health research targeting HF is sustained.

Counter to expectations, patients 64 years old and younger were less likely to participate and more likely to be nonrecruited. This can be due to factors other than age and HF symptoms, which were, on average, not more severe than for other groups.

Gender did not affect the likelihood of participating. However, women represented less than one-third of the overall sample that entered the recruitment process and less than one-third of the participating group. This reflects difficulties in recruiting women with HF. Although the recruitment of women in HF studies has improved over time [50], the participation rate among women does still not reflect disease levels in the population [50,51]. In other studies, women were found to be more likely to decline the invitation to participate in digital health research [26,29]. This was not found for the sample in this study.

This study has some limitations. First, due to ethical clearance on collecting information about nonparticipants, only limited information on the patients was available. Such information did not include factors that can further explain participation in digital health research, such as level of education, digital skills, digital health literacy, and social participation. Future research should investigate the impact of such factors on both (non)recruitment and self-selection. On the other hand, it should be considered that collecting such detailed information, for example through a survey, might itself generate bias based on the nonresponse of some individuals. Therefore, although registered hospital information is limited, it can give an accurate description of selective non-participation. Second, for these analyses, reasons for refusal were only available grouped in main categories, which might have simplified the individual decision-making process for declining the invitation to participate in the HF-Wii study. Detailed reasons for declining the invitation to participate could have provided more insights into, for example, logistics-related and technology-related barriers to participation and allowed for a more elaborated description of the individual decision-making process. For example, in the full HF-Wii study it was found that 4% of the patients reported not wanting to participate because of the use of technology [32]. Future studies should further examine such reasons for refusal in combination with an analysis of the self-selection process. Third, as specific information on digital skills and technology-related aspects is not available, results from this study can also be relevant to the understanding of selective (non)participation in health research.

Selective nonparticipation in digital health research can prevent the production of results that appropriately inform research, policy, and practice on the impact of digital health technologies for the targeted populations. If participants and nonparticipants differ from one another, research results will not represent the target population of interest but rather a part of it. Groups that are often underrepresented in digital health research, such as people of older age and with poorer health, can be the most in need of accessing care and support [6] and can experience more barriers to using digital technologies [9,14]. Underrepresenting such groups implies overlooking their needs and interests, which are not necessarily expressed by their participating counterparts, and, as a result, miscalculating the impact of digital health technologies on the target population as a whole. Implementing digital health technologies that have been selectively evaluated might introduce further sources of exclusion and disadvantages to such groups with respect to their counterparts and contribute to widening old age inequalities.

We therefore recommend that a measure of selective nonparticipation is included in digital health research to identify overestimation and underestimation of the effects of digital health technologies due to the involvement of samples that do not reflect the target population. A measure of selective participation also allows researchers to employ further research strategies, such as focused recruitment of underrepresented groups or post-hoc adjustments of the results by weighting different groups depending on how well they are represented in the study sample.

Acknowledgments

Abstract

Background: Education and learning are the most important goals of all universities. For this purpose, lecturers use various tools to grab the attention of students and improve their learning ability. Virtual reality refers to the subjective sensory experience of being immersed in a computer-mediated world, and has recently been implemented in learning environments.

Objective: The aim of this study was to analyze the effect of a virtual reality condition on students' learning ability and physiological state.

Methods: Students were shown 6 sets of videos (3 videos in a two-dimensional condition and 3 videos in a three-dimensional condition), and their learning ability was analyzed based on a subsequent questionnaire. In addition, we analyzed the reaction of the brain and facial muscles of the students during both the two-dimensional and three-dimensional viewing conditions and used fractal theory to investigate their attention to the videos.

Results: The learning ability of students was increased in the three-dimensional condition compared to that in the two-dimensional condition. In addition, analysis of physiological signals showed that students paid more attention to the three-dimensional videos.

Conclusions: A virtual reality condition has a greater effect on enhancing the learning ability of students. The analytical approach of this study can be further extended to evaluate other physiological signals of subjects in a virtual reality condition.

(J Med Internet Res 2020;22(6):e17945) doi:10.2196/17945

KEYWORDS

virtual reality; learning ability; brain; facial muscle; fractal theory

Introduction

Virtual reality refers to the subjective sensory experience of being immersed in a computer-mediated world. Accumulating evidence [1,2] points to the exciting opportunity and potential of integrating virtual reality technology in education environments, which can add elements of reality to improve understanding of complex subjects such as the life sciences (eg, biology and anatomy) compared to traditional classes in which students must imagine the structures for comprehension. In addition, students have been shown to pay more attention to the lecturer when making direct eye contact [3]. However, a lecturer is only able to look at one or two students at a time during a lecture. Therefore, presenting a virtual image of a lecturer to students might increase their attention and consequently improve their learning ability, which can be applied to an electronic learning environment.

Along with the growing empirical evidence that virtual reality is a valuable learning tool, further investigations are needed to study how the use of virtual reality can improve the learning ability of students. In addition, few studies have focused on changes in physiological signals to understand the effect of virtual reality on the human body. Previous studies in this field have compared the brain reaction of anxious participants at rest and under a virtual reality condition [4], compared electroencephalogram (EEG) signals in virtual reality and the traditional display condition [5], analyzed brain activity in response to increasing levels of task complexity in virtual reality [6], employed a deep-learning approach to improve the rate of excitement to well above the 90% accuracy level [7], and analyzed reactions of the heart and brain in different virtual reality environments [8].

The aim of the present study was to investigate the attention and learning ability of students using virtual reality technology. We also investigated the variability of students' physiological state (facial reaction) under the virtual reality condition. To study the attention and learning ability of students, we recorded their brain signals (ie, EEG signals) and to study facial reactions, we recorded their electromyography (EMG) signals. For comparison, we also recorded the brain signals and facial reactions of the students in a traditional classroom learning condition. EMG was used to capture the engagement of facial muscles during visual perception, which we expected to be more strongly affected under the virtual reality condition.

Since both EEG and EMG signals have complex patterns, we adopted complexity theory for our analysis. In other words, the concept of complexity was employed to define the structure of EEG and EMG signals. Complexity theory can help to characterize the behavior of a system with many parts that interact with each other in highly variable manners [9]. Specifically, we analyzed the recorded EEG and EMG signals using fractal theory, which can be used to quantify the complexity of a system (EEG and EMG signals in this case). Fractals are self-similar or self-affine objects that have complex structures [10]. A self-similar fractal has the same scaling exponent at every scale, whereas a self-affine fractal has different values of the scaling exponent at different scales. EEG and EMG signals are self-affine fractals that have a nonlinear structure. An object with a greater fractal dimension (as a measure of complexity) has a greater level of complexity [11]. Several studies have analyzed different types of physiological signals using fractal theory to date, including analyses of magnetoencephalography [12], galvanic skin response [13], heart rate [14], respiration [15], speech-evoked auditory brainstem response [16], eye movement [17], and human DNA [18]. Similarly, many studies have applied fractal analysis to investigate the nonlinear structure of EEG signals under different conditions, including the influence of auditory [19,20], olfactory [21], and visual [22,23] stimuli; brain diseases [24]; body movements [25,26]; and aging [27].

Some previous studies have also applied fractal theory to analyze EMG signals, including a decoded finger [28,29], hand [29-31], and functional movements and force patterns [29], along with analysis of the effect of complexity of walking on a path with respect to the leg muscle reaction [32]. However, to our knowledge, only one study has employed fractal theory to analyze the facial muscle reaction to date [33].

To analyze and compare the physiological conditions of subjects in virtual reality versus traditional class conditions, we used fractal analysis to relate the complexity of EEG and EMG signals to the nature of the viewed videos.

Methods

Study Design

We aimed to analyze students' physiological state and learning ability under the three-dimensional (3D) virtual reality condition in comparison to those recorded under the traditional two-dimensional (2D) condition. For analysis of the physiological state, we chose EEG and EMG signals as indicators of the brain and muscle response, respectively. EMG signals were selected for the facial muscle reaction since the subjects were stimulated using visual stimuli. For this purpose, we used fractal theory to analyze the complexity of facial EMG and EEG signals. The fractal dimension, as the main quantitative measure of fractal theory, indicates the complexity of the process in which greater values of a fractal dimension reflect greater complexity of the object.

Various methods have been developed to calculate the fractal dimension, which are mainly based on the entropy concept. In this study, we used the box-counting method to calculate the fractal dimension [34]. In the box-counting algorithm, the object of interest is covered with boxes of the same size (ε). The number of boxes (*N*) required to cover the object is then counted. This process is repeated several times, while the box size keeps changing in each step. Finally, the slope of the regression line fitted to a log-log plot of the number of boxes versus the scale is calculated as an estimate of the fractal dimension for the object under consideration [35]:

Equation (2) defines the so-called generalized fractal dimension of order *c* [35]:

where is the Rényi entropy of order *c*, and the probability of occurrence (r_j) is defined as:

In Equation (3), the total time of the signal value occurrence within the jth value interval is denoted by t_j, whereas *T* represents the total duration of the recorded signal [36].

In this experiment, we showed the students 6 sets of videos (3 videos in the 2D condition and the same 3 videos in the 3D condition), and then investigated the reaction of the brain and facial muscle under both the 2D and 3D conditions using fractal theory to assess the students' attention to the videos.

In addition, to investigate the learning ability, we designed three questions based on the content of each video (9 questions in total for the 3 videos) that were asked to the students after watching each video in each condition. This questionnaire allowed for assessing the extent to which the students retained and learned the content of the videos.

Data Collection and Analysis

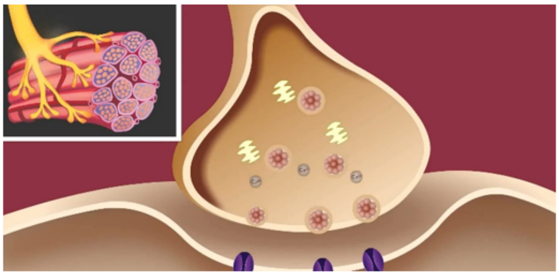
All procedures from recruiting subjects to conducting the experiment were approved by the Monash University Human Research Ethics Committee (MUHREC; approval number 20965). The study was carried out in accordance with the approved guidelines.

We conducted the experiment with 9 healthy students from Monash University Malaysia. We explained the experiment to the participants and then asked them several questions about their health conditions. Since mental disorders, some medications, as well as drinking beverages that contain alcohol or caffeine affect brain activity and cause inconsistent results, we excluded potential participants within these categories. In addition, participants were excluded if they had consumed beverages containing alcohol or caffeine within 24 hours before the experiments. The students who were deemed to be suitable for experiments signed the consent forms and were included in the study.

We conducted the experiment in a quiet room to isolate the participants from other external stimuli that could potentially affect the recorded EEG and EMG signals. The participants were asked to sit comfortably on a chair during the experiment, and were instructed to focus on watching the videos without engaging in any other task.

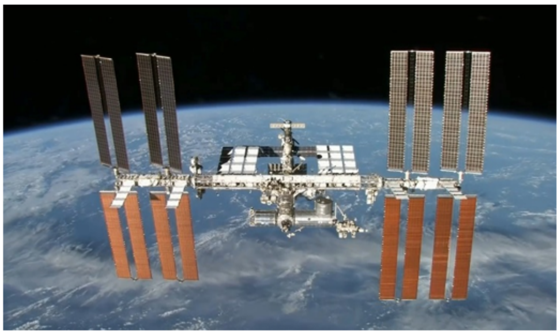
As mentioned above, we chose 6 sets of videos (3 videos in the 2D condition and the same 3 videos in the 3D condition) for our experiment. The 2D videos were selected from YouTube, which were then converted into 3D videos for our experiment. The first and second videos (same content) were about biology (Multimedia Appendix 1 and Multimedia Appendix 2), the third and fourth videos (Multimedia Appendix 3 and Multimedia Appendix 4) were about architecture, and the fifth and sixth videos (Multimedia Appendix 5 and Multimedia Appendix 6) were about space. Some screenshots from these videos are shown in Figure 1.

Figure 1. Representative screenshots of scenes from three different videos.



(a) Biology

(b) Architecture



(c) Space

The videos were displayed to the participants via a mobile phone. The participants watched the 2D videos with the naked eye, whereas the 3D videos were viewed through VeeR MINI VR Glasses (VeeR, Atlanta, GA, USA) (see Figure 2) in front of the mobile phone. We noninvasively recorded EEG and facial EMG signals from the participants using an EMOTIV EPOC+

14 Channel Mobile EEG headset (Emotiv, San Francisco, CA, USA) and Shimmer EMG device (Shimmer, Ireland) with a sampling frequency of 128 Hz and 256 Hz, respectively. As shown in Figure 2, the EEG device was placed on the participant's head and five electrodes of the EMG device were connected to the facial muscles.

Figure 2. Data collection from a participant.

First, we recorded EEG and EMG signals from the participants for 2 minutes while they watched the first 2D video. When the video was complete, we then asked the participants three questions related to the content. After a 1-minute rest period, the participants watched the first video again in the 3D condition for 2 minutes. The content of this video was identical to that of the 2D video, except that it was presented in 3D mode. Three questions were then asked about the content of the 3D video, followed by another period of rest for 1 minute. We continued this procedure to collect EEG and EMG signals from the participants (along with the responses to content-related questions) with the third, fourth, fifth, and sixth videos (each video lasted for 2 minutes), providing the participants with 1 minute of rest between watching the videos. The data collection was repeated for each participant in the second session to validate the repeatability of results.

Initially, we preprocessed the raw data to remove noise. For this purpose, we wrote a set of codes in MATLAB (MathWorks, Natick, MA, USA) based on the Butterworth filter. The frequency bands of 1-40 Hz and 25-125 Hz were chosen for filtering the EEG and EMG signals, respectively. Of note, two electrodes of the EEG device had some disconnection problems during data collection; therefore, we processed the collected data only from the other 12 electrodes.

After initial filtering, we proceeded with the analysis by computing the fractal dimension of the recorded EEG and EMG signals. The computation of the fractal dimension was based on the box-counting algorithm using boxes with sizes (1/2, 1/4, 1/8, etc) as the scaling factor. Although we recorded 120 seconds of data during each period of watching the 2D and 3D videos, we analyzed only 118.2 seconds of each dataset. This selection was due to the fact that the devices did not always have a consistent sampling frequency, which caused the data recording to be less than 2 minutes long, leading to a difference of a few seconds in the duration of collected data among some participants.

After confirming the normal distribution of the data, statistical analysis of the computed fractal dimension for EEG and EMG signals was performed to assess the effect of stimulation on variations of the fractal dimension of EEG and EMG signals using one-way repeated-measures analysis of variance (ANOVA). We also conducted the Student *t* test to compare the difference in mean values of EEG or EMG signals between the 2D and 3D condition. *P*<.05 was considered to reflect a statistically significant difference in our analysis.

Results

The variations of fractal dimensions of EEG signals for the first to the sixth visual stimuli are shown in Table 1. As mentioned above, the first, third, and fifth stimuli refer to the 2D condition, whereas the second, fourth, and sixth stimuli refer to the 3D condition.

Table 1. Fractal dimension of EEG[a] signals with the first to sixth stimuli.

Stimulus	Fractal dimension of EEG signal
First	1.7027
Second	1.7266
Third	1.7196
Fourth	1.7222
Fifth	1.6928
Sixth	1.7272

[a] EEG: electroencephalogram.

Based on the result of ANOVA (*F*=7.6334, *P*<.001), the effect of stimulation (2D and 3D) on variations of fractal dimensions of the EEG signal was significant. As shown in Table 1, for all stimuli, the EEG signal recorded from the participants in the 3D condition had a greater fractal dimension compared to that recorded in the 2D condition. Since the fractal dimension reflects the complexity of the signal, this result indicated that the EEG signal is more complex in response to 3D visual stimuli compared to 2D visual stimuli. In other words, the human brain becomes more engaged with a stimulus when it is presented in the 3D condition compared to the 2D condition. Differences between the mean values of the EEG signal from the first and second stimuli (*P*=.001) and from the fifth and sixth stimuli (*P*<.001) were greater than the difference between the third and fourth stimuli (*P*=.72). This suggested that the participants' brains were more engaged with the second and sixth stimuli compared to the third stimuli. This result is reasonable given that the second and sixth stimuli mainly contained animated scenes, whereas the fourth stimulus included more photos with less animated scenes. Therefore, the difference between the fractal dimension of the EEG signals in the third and fourth stimuli was lower than that observed under the other conditions.

The variations of the fractal dimension of the EMG signals for the first to the sixth visual stimuli are summarized in Table 2.

Table 2. Fractal dimension of EMG[a] signals with the first to sixth stimuli.

Stimulus	Fractal dimension of EMG signal
First	1.2361
Second	1.2594
Third	1.2554
Fourth	1.2580
Fifth	1.2488
Sixth	1.2675

[a] EMG: electromyography.

Based on the result of ANOVA (*F*=0.2468, *P*=.94), the effect of stimulation (2D and 3D) on variations of the fractal dimension of the EMG signals was not significant. Upon receiving a visual stimulus (2D or 3D), the brain processes the stimulus and then sends the impulses to the facial muscles. Therefore, the stimulus should have a greater effect on the brain than on the facial muscles, which explains why there was a significant effect of the stimuli on variations of EEG signals but not on the facial muscles.

As shown in Table 2, for all stimuli, the EMG signal had a greater value of the fractal dimension in response to 3D videos compared to 2D videos, indicating that the EMG signal is more complex in response to 3D videos compared to 2D videos. In other words, the facial muscles are more engaged with stimuli where they are presented in 3D rather than in 2D. In addition, the difference between the mean values of the EMG signal in the first and second stimuli (*P*=.43) and the fifth and sixth stimuli (*P*=.56) was greater than that between the third and fourth stimuli (*P*=.93). This indicates that the participants' facial muscles were more engaged with the second and sixth stimuli compared to the third stimuli. As mentioned above, this difference can be explained by the content of the videos, in which the second and sixth stimuli contained more animated scenes compared to the fourth video.

Despite these differences among videos, there was no significant difference in the fractal dimension of the EMG signal between each pair of stimuli. This suggests that although presenting the videos in 3D caused some changes in the muscle reaction, these changes were not substantial. Comparison of the results for EMG and EEG signals indicates that changing the visual stimulus from 2D to 3D could cause significant variations in the complexity of the EEG signal, but not in the EMG signal. Therefore, changes in the state of the brain are greater when changing a visual stimulus from 2D to 3D.

Moreover, evaluating the relationship between variations of EEG and EMG signals can provide further insight. The brain controls all parts of the human body, including the reactions of the facial muscle. When exposed to 2D or 3D videos as visual stimuli, the brain sends impulses to the facial muscles. Therefore, when the brain is more engaged with the stimuli, the muscle reaction will also be greater, which is reflected in the greater variations in the fractal dimension of the EMG signal.

The rate of correct responses to the questions posed after watching the 3D video was 92.60%, which was higher than that obtained after the 2D videos at 80.87%. This difference suggested that the 3D videos resulted in greater attention paid to the details of videos and therefore increased the learning ability of the students.

Discussion

In this study, we compared the effect of virtual reality on students' learning ability and physiological state with those recorded in a normal 2D condition based on watching 3 sets of videos each presented in 2D and 3D. We simultaneously recorded EEG and facial EMG signals of the participants during stimulation. Overall, the EEG and EMG signals had greater fractal dimensions in the 3D video condition, indicating that both the brain and facial muscles have a greater reaction to 3D videos compared to 2D videos. In addition, videos with more animated scenes resulted in a significantly greater brain reaction compared with that resulting from watching a video with less animated scenes, as reflected by the lack of a significant difference in the fractal dimension of EEG signals between 2D and 3D conditions. For the EMG analysis, although the 3D condition caused greater reaction in the facial muscle, there was no significant difference from the reaction recorded under the 2D condition.

We also examined the learning ability of the students after watching each video by asking them several content-related questions, demonstrating improved learning ability after watching 3D videos than 2D videos (92.60% vs 80.87% correct answers). These results clearly showed that students pay more attention to videos when they are presented in 3D. The present study offers a step forward compared to previous studies that only analyzed the learning ability or brain reaction [4-7] in a virtual reality condition without considering the reaction of facial muscles and investigating how that reaction correlates with brain activity.

The method of analysis employed in this study can be extended to investigate other physiological signals of students in a virtual reality condition. For instance, we can analyze how the heart rate changes in a 3D condition compared to a 2D condition. We can also expand this work by applying other types of stimuli, including olfactory stimuli, while students are watching videos in the virtual reality condition and investigate the effect of these additional stimuli on their learning ability. Developing a model between input (videos) and outputs (human physiological signals) is another important aspect of future work in this regard. For this purpose, we can benefit from different tools such as machine learning [37-39] and fractional-based mathematical equations [40]. Such analysis could allow for predicting human conditions (physiological signals) before exposure to different stimuli, providing guidance on the types of videos and characteristics of videos that are most likely to arouse the attention of students and facilitate learning. These efforts therefore have great importance in advancing research on students' learning ability and can provide strong recommendations to educational institutions.

Abstract

Background: A large Midwestern state commissioned a virtual driving test (VDT) to assess driving skills preparedness before the on-road examination (ORE). Since July 2017, a pilot deployment of the VDT in state licensing centers (VDT pilot) has collected both VDT and ORE data from new license applicants with the aim of creating a scoring algorithm that could predict those who were underprepared.

Objective: Leveraging data collected from the VDT pilot, this study aimed to develop and conduct an initial evaluation of a novel machine learning (ML)–based classifier using limited domain knowledge and minimal feature engineering to reliably predict applicant pass/fail on the ORE. Such methods, if proven useful, could be applicable to the classification of other time series data collected within medical and other settings.

Methods: We analyzed an initial dataset that comprised 4308 drivers who completed both the VDT and the ORE, in which 1096 (25.4%) drivers went on to fail the ORE. We studied 2 different approaches to constructing feature sets to use as input to ML algorithms: the standard method of reducing the time series data to a set of manually defined variables that summarize driving behavior and a novel approach using time series clustering. We then fed these representations into different ML algorithms to compare their ability to predict a driver's ORE outcome (pass/fail).

Results: The new method using time series clustering performed similarly compared with the standard method in terms of overall accuracy for predicting pass or fail outcome (76.1% vs 76.2%) and area under the curve (0.656 vs 0.682). However, the time series clustering slightly outperformed the standard method in differentially predicting failure on the ORE. The novel clustering method yielded a risk ratio for failure of 3.07 (95% CI 2.75-3.43), whereas the standard variables method yielded a risk ratio for failure of 2.68 (95% CI 2.41-2.99). In addition, the time series clustering method with logistic regression produced the lowest ratio of false alarms (those who were predicted to fail but went on to pass the ORE; 27.2%).

Conclusions: Our results provide initial evidence that the clustering method is useful for feature construction in classification tasks involving time series data when resources are limited to create multiple, domain-relevant variables.

Introduction

Background

According to the Centers for Disease Control and Prevention, motor vehicle crashes (MVC) are the leading cause of death in adolescents aged 12 to 19 years in the United States [1]. MVC risk is disproportionately high among novice drivers, particularly those aged 16 to 17 years, and peaks immediately after licensure during the first months of unsupervised driving [2,3]. Previous studies have demonstrated that the majority of these crashes early in licensure are attributed to critical driving errors because of skill deficits, inexperience, and inattention/distraction rather than recklessness and deliberate risk taking [4-7]. Research has demonstrated initial evidence for the ability of web-based screening tests (eg, web-based assessment of cognitive impairments) to predict poor driving simulator performance [8]. However, there remains a critical need for a screening test to quantify skill level at the time of licensure to identify those who are underprepared to drive safely.

In 2017, a large Midwestern state’s driver licensing agency aimed to address the need to identify underprepared license applicants (likely to fail the on-road examination [ORE]) by developing and deploying a new portable virtual driving test (VDT) as a potential prescreen tool for ORE [9]. The VDT was built on the Ready-Assess platform [10] (Diagnostic Driving, Inc) and was designed as a safe, reliable, and portable method for evaluating novice drivers’ preparedness to respond to common and serious potential crash scenarios [11-13]. Ready-Assess incorporates and expands on the scenarios and metrics of the previously validated simulated driving assessment (SDA) [14] to provide a variety of traffic situations to manage that go beyond what is feasible to assess during an ORE.

Objectives

The VDT assessment (which lasts approximately 7 min) includes both high-risk and common driving scenarios. The potential crash scenarios included in the VDT driving environments were determined by the National Highway Traffic Safety Administration [15,16], including intersections (3- and 4-way, stop sign, and traffic light), curved roads, rear-end events (lead car brakes suddenly), and hazard zones (construction zones, school zones, and pedestrian crosswalks). These typical driving scenarios were specified by subject matter experts from the state's licensing and motor vehicle safety body encompass a variety of settings (eg, urban and rural) and on-road elements (eg, school buses, ambulances, pedestrians, and hazards) to reproduce local driving environments. As a result, the VDT provides an opportunity for a wide variety of driving responses.

Consequently, a large quantity of applicant time series data was generated from the VDT assessment. To efficiently create a prediction (ORE pass/fail) scoring algorithm, steps must be taken to reduce the dimensionality of the data for analysis. Many traditional machine learning (ML) methods (*out-of-the-box*) require multiple domain-specific features that are well defined and created before being evaluated in an ML pipeline. Given the task of predicting the ORE outcome at the individual level, manually defining features with optimized predictive capabilities is an extremely resource-intensive task and often reliant on subject matter expertise (SME) and considerable domain knowledge.

Therefore, by leveraging data collected from the VDT pilot, this study aimed to develop and conduct an initial evaluation of a novel ML-based classifier using limited domain knowledge and minimal feature engineering to reliably predict applicant pass/fail on the ORE. Such methods, if proven useful, could be applicable to the classification of other time series data collected within the medical field and other settings.

Methods

Apparatus

The VDT used in this pilot was delivered by Diagnostic Driving, Inc [17] in collaboration with Children’s Hospital of Philadelphia (CHOP) and designated state-employed highly experienced driving examiners (SMEs). The VDT software evolved from a prior laboratory-based SDA into a highly scalable, portable, and self-directed tool (Figure 1) that could be delivered on ubiquitous hardware without the need for additional personnel to help facilitate its delivery (eg, research assistants and administrative personnel; Multimedia Appendices 1 and 2).

Figure 1. Workstation Setup: 1) Standard Monitor, 2) Standard Desktop Computer, 3) Off-the-shelf USB Steering Wheel and Pedals.

Virtual Driving Test Implementation Procedure

Applicants were directed to an available VDT workstation in the testing facility by state personnel, and applicants were asked to put on headphones (Multimedia Appendix 2) and enter the provided unique identification number that could be linked to their ORE results (Figure 2).

The VDT is a self-directed workflow (containing both on-screen and voice-directed instructions) that typically takes less than 15 min to complete after the applicant logs in to the VDT workstation with a unique identification number provided by state personnel. A short orientation video introduces the importance of safe driving and provides the applicant with an overview of the stages of the VDT workflow. This is followed by a simulated *practice drive*, a short orientation drive with built-in instructions to orient the applicant to all VDT controls (eg, turn signals, transmission controls, and navigation system) and to allow the applicant to test drive basic maneuvers (eg, steering, accelerating, braking, and 90° turns) on a course without additional traffic. This drive ends with a brief comprehension test that evaluates the driver applicant's ability to manage the controls and to follow basic instructions covered in it.

Next, the applicant begins the simulated *assessment drive*, a planned route through a randomly assigned environment selected from a bank of 10 possible environments (eg, *city 1*, *city 2*, ..., *city 10*), all of which contain variations of common and serious crash scenarios. In all the environments, driver applicants are never explicitly prompted to react to changing traffic conditions or traffic controllers (eg, *grant pedestrians in the crosswalk right of way* and *wait for the light to turn green*). They are, however, given navigational instructions to follow a planned route (eg, *turn left at the stop sign* and *shift into the right lane*). The assessment drive has no explicit time limit and finishes once the applicant brings his or her simulated vehicle to the end of the planned route.

On completion of the assessment drive, the applicant receives a series of 3 debriefing questions to answer on the screen (using a 5-point Likert scale: 1=strongly disagree and 5=strongly agree) to assess his or her ability to understand VDT directions and general comfort with the VDT controls.

Figure 2. Virtual driving test workstation.

Dataset

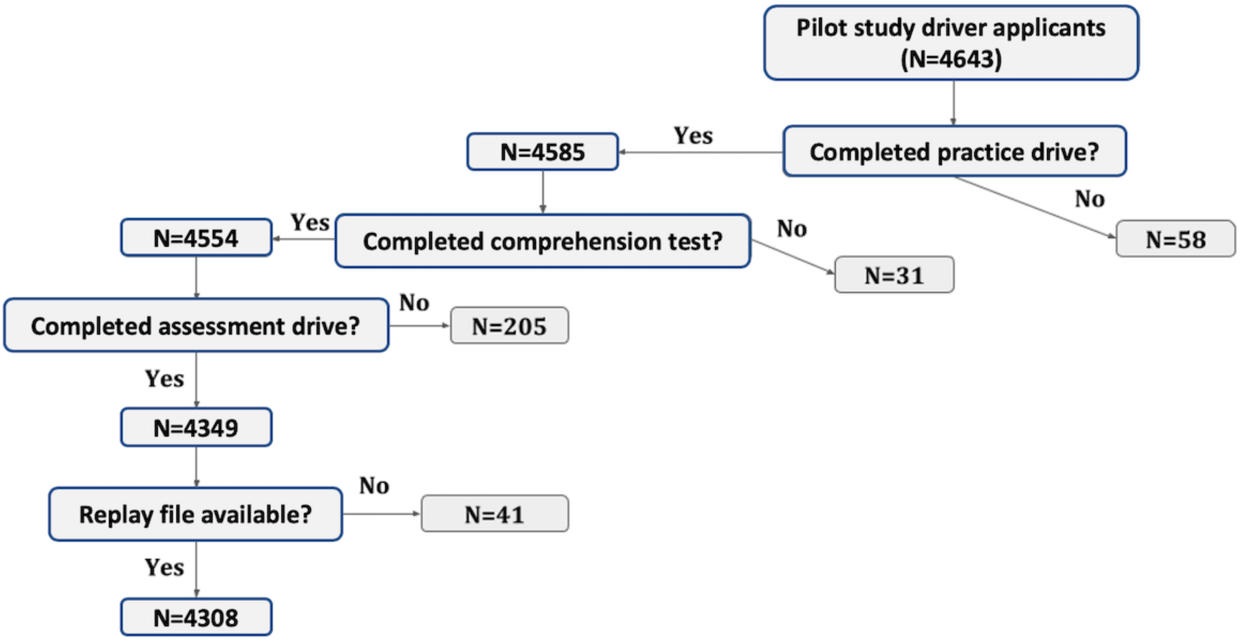
We received a deidentified dataset containing individually linked VDT and ORE performance data for 4643 driver applicants from 3 licensing facilities collected between July 2017 and March 2018. These data were collected by a large Midwestern state during a pilot phase of implementing the VDT in collaboration with Diagnostic Driving, Inc, and CHOP to test its utility as a screening tool in the context of a high-demand and established state government licensing workflow. During this pilot phase, no additional research or demographic information (eg, age and sex) was collected, and all driver applicants who completed the VDT went on to complete the ORE regardless of VDT performance.

In addition, neither the driver applicant nor the licensing examiner had access to the VDT results; therefore, no bias because of VDT performance was introduced when implementing the ORE. Driver applicant ORE outcomes were linked to VDT data and entered into a deidentified dataset that was shared with the research team. CHOP’s institutional review board determined that this study does not meet the criteria for human subjects research primarily because (1) data were not obtained by the researchers through intervention or interaction with the individual and (2) no identifiable private information was included in the dataset received.

Derivation of Sample

Figure 3 shows the derivation of the sample included in the analyzable dataset. Of the 4643 driver applicants who attempted the VDT in the pilot, the vast majority completed it: 58 (1.2%) applicants did not complete the practice drive, 31 (0.7%) did not complete the comprehension test, and 205 (4.4%) did not complete the assessment drive (descriptions of comprehension and assessment drives are given in the Virtual Driving Test Implementation Procedure section). Driver applicants who did not complete the entire VDT workflow, 6.3% (294/4643) were excluded from our analysis. SMEs from the licensing facilities provided information on why some applicants could not complete the workflow, and reasons included applicant had a language barrier, applicant did not understand the instructions, applicant was frustrated with the VDT software, applicant was called for their ORE earlier than expected, applicant walked away from the VDT workstation, applicant experienced symptoms of simulator sickness, and applicant elected not to continue (<1%). In addition to not completing the entire VDT workflow, an additional 41 (0.9%) applicants who completed the workflow did not have their replay files (raw time series information) successfully uploaded to the VDT cloud server (because of internet connectivity issues). These cases were also removed from our analysis, and the final analyzable sample included 4308 (92.8%) driver applicants.

Figure 3. Sample derivation: data from 335 (7.2%) enrolled driver applicants were excluded from the final sample of 4308 because they either did not complete the VDT workflow or their assessment replay file was unavailable for analysis. VDT: virtual driving test.



Data Collected: Time Series Channels

The VDT software is fully cloud based and collects raw time series–driving performance data, sampled at 60 Hz, including the driver's vehicle position; driver inputs (ie, steering wheel, brake, and throttle); additional driver attributes (ie, velocity); and information regarding ambient vehicles, pedestrians, and environmental objects. This raw and rich representation is then downsampled (for the purpose of storage) at approximately 10 Hz with the true elapsed time between contiguous frames recorded, with the added benefit of reducing the replay file size for permanent cloud storage while retaining the faithfulness of the time series representation. As each *replay file* (the downsampled recording of a VDT assessment) is stored as a multichannel sequence of frames averaging about 8 min in length downsampled to roughly 10 Hz, it provides more than 30,000 data points of information regarding driving performance.

Each frame of the recorded time series data includes several raw values regarding the applicant's physical interaction with the VDT workstation, including (1) the percentage of complete brake depression (with 1=full depression/stop) and throttle pedals (with 1=full depression/maximal acceleration), (2) the signed percentage of steering wheel rotations both left (negative) and right (positive) of its resting position, and (3) the position and heading of the applicant's vehicle within the simulated environment. Also recorded in each frame is the use of turn signals and steering wheel buttons that allow the driver to scan left or right to look for oncoming traffic.

The *lane offset* (sometimes referred to as lane position) [18] of the applicant's vehicle within its lane on the simulated road is computed for each frame and recorded as one of the time series channels. These channels comprise each applicant's VDT assessment recording and are used as the basis for feature set construction to represent driving performance.

Outcome Variable

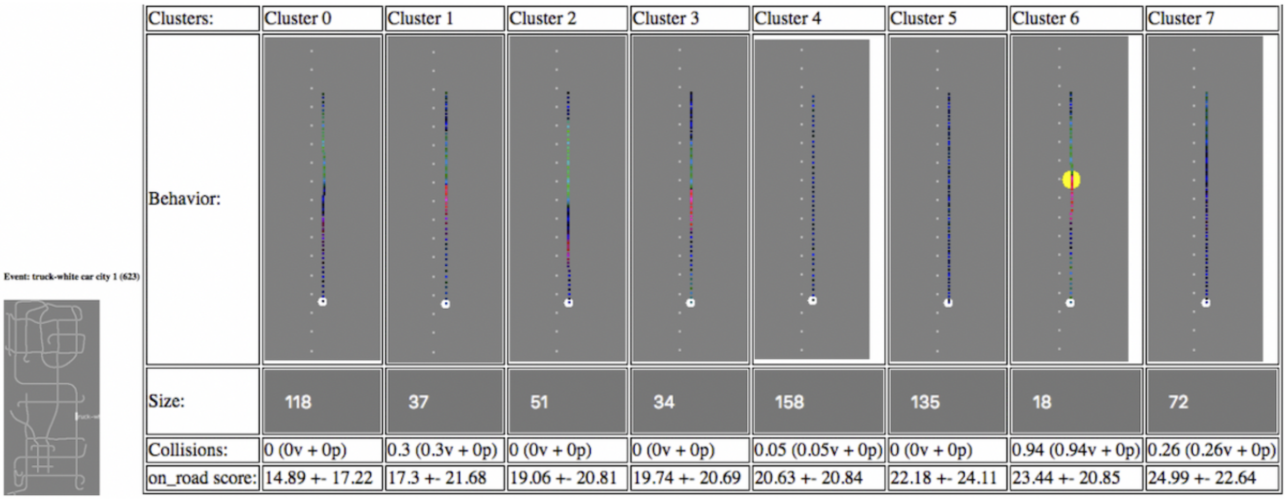
For all driver applicants who completed the VDT, the result of the ORE is provided in a numeric form (score), where a higher score indicates a more severe accumulation of infractions cited by the examiner during their ORE. According to the state licensing agency's ORE scoring protocol, any driver with a score greater than or equal to 26 fails the ORE and any driver with a score less than 26 passes the ORE (a score of 0 indicates a perfect score). These data (both numerical and dichotomous pass/fail representations) for each applicant are linked to the corresponding VDT record and added to the deidentified dataset. For the purposes of internal analysis, we define the *gray zone* of ORE scores between 20 and 35, where drivers either barely pass or accumulate just enough infractions to fail the ORE.

Analytical Procedure

To maximize our ability to reliably predict an applicant's likelihood of failing the ORE, we evaluated 2 alternative ways to represent the time series data. The first, standard approach (which we call the *variables* feature set) involves the reduction of the driver applicant's input time series data into manually created variables that represent driver behavior These variables further represent both continuous features (eg, velocity) and count/dichotomous data (eg, crash). The second method is novel and involves viewing the environments as a series of predefined *event zones* to which the applicant is exposed (eg, a crosswalk, an intersection, or a school zone). The corresponding applicant's input time series data (how the applicant responds to each of these event zones) are then partitioned according to these event zones. The range of applicant behaviors (combinations of steering, brake, and throttle on the simulated roadway) is then clustered for each segment without any preprocessing or manual reduction of the data. This *time series clustering* feature set has no shared features with the *variables* feature set.

To build classifiers of driver performance, we constructed these 2 feature sets as input for supervised ML algorithms (Figure 4).

Figure 4. Time Series Clustering for highlighted event zone with cluster centers representing prototypical driving behaviors in that zone.



Clusters:	Cluster 0	Cluster 1	Cluster 2	Cluster 3	Cluster 4	Cluster 5	Cluster 6	Cluster 7
Behavior:								
Size:	118	37	51	34	158	135	18	72
Collisions:	0 (0v + 0p)	0.3 (0.3v + 0p)	0 (0v + 0p)	0 (0v + 0p)	0.05 (0.05v + 0p)	0 (0v + 0p)	0.94 (0.94v + 0p)	0.26 (0.26v + 0p)
on_road score:	14.89 +- 17.22	17.3 +- 21.68	19.06 +- 20.81	19.74 +- 20.69	20.63 +- 20.84	22.18 +- 24.11	23.44 +- 20.85	24.99 +- 22.64

Standard Method for Data Reduction: Variables Feature Set

For every simulated drive, there are events corresponding to common and serious potential crash scenarios. Applicants' responses that have been tracked and tabulated in real time from within the VDT-simulated environment (eg, reduction of speed entering a construction zone) are augmented with manually created variables from the stored data, which indicate aberrant or hazardous driving behaviors (eg, number of instances applicant ran a red traffic light).

A summary of speed management within a sample is represented by the global maximum, mean, and median of the applicant vehicle velocities as well as the ratio of the applicant vehicle's velocity to the posted speed limit recorded. The same statistics on velocity and speed ratio are computed for the following event zones: crosswalks, school zones, construction zones, playground zones, and banking curves. To flush out adherence to the posted speed limit, the global percentages of each sample driven more than 10, 15, and 20 mph above and below the posted speed limit are used as potential predictors.

These values, along with other computed driving performance metrics, result in a representation of each sample as a vector of 67 engineered features plus the *outcome* variable (ORE pass/fail). With this representation of the tabulated data, supervised learning methods are deployed using standard 10-fold cross-validation; we examined the resulting confusion matrices. To evaluate the predictive power of this representation, we examined the resulting confusion matrices.

Novel Method for Automated Data Reduction: Time Series Clustering Feature Set

Each applicant's stored time series data were truncated to begin at the first downsampled frame with a simulated speed above 0.5 m per second to align replay files via a common starting condition. As assessment drives are of nontrivial length (on average, approximately 8 min in duration), relying on global measurements to compare driving behaviors may wash out highly predictive features from smaller segments of the assessment's planned route.

The *time series clustering* representation attempts to derive new features from sections of the drives that are designed to elicit specialized behaviors in response to environmental or traffic conditions. Unlike the standard variables approach, this new approach derives features automatically without the need for manual data reduction. Time series samples are grouped by the simulated environment to which the applicant is assigned, where each environment comprises a sequence of stationary event zones defined by *entry* and *exitwaypoints*. Given a sample that drives through a particular event zone, a *subinterval* of the time series is extracted that corresponds to the vehicle traveling between the zone's *entry* and *exit* waypoints. This subinterval is grouped in a set with all other subintervals from the drives that pass through the designated event zone.

The purpose of clustering is to reveal *prototypical behaviors* so that drivers can be categorized within each event zone (as defined by their lane position, throttle, brake, accelerator, and steering wheel usage in each frame). For example, at a crosswalk, there might be a cluster for those who slow to a stop and another for those who speed through the crosswalk without slowing. The variance in behaviors should be represented in the cluster centers, where all sample subintervals assigned to a given cluster have been determined to be most similar to the cluster center's *prototypical behavior*.

Speed and traffic conditions determine each driver's subinterval length in an event zone. Thus, to compare subintervals of unequal lengths, dynamic time warping [19,20] is used as the (dis)similarity measure, where the time steps of pairs of subintervals are aligned to minimize the time-warped aggregate difference between them. *k*-Medoids [21], a derivative of *k-means*, is used to pigeonhole the n samples into k clusters (*k*=8 in all the reported experiments) by electing k initial subintervals to act as *medoids*, cluster centers representing prototypical behaviors. A dissimilarity matrix is constructed, where each cell compares subintervals χ_i and numerically. The subinterval χ_i is assigned to cluster , with the most similar medoid at round *r* of iteration. The algorithm elects new medoids in each round by identifying the candidate subinterval within each cluster that maximizes the aggregate similarity (ie, minimizes dissimilarity) between it and all other cluster members.

At every round of clustering the *inertia*, the sum of squared residual dissimilarities between subintervals and their assigned medoids is computed. If the newly elected medoids reduce inertia from the round before, the cycle repeats itself, although we imposed a limitation of 100 repetitions. Once *k-Medoids* converge on a clustering that cannot be improved upon, the dissimilarities between each sample subinterval χ_i to medoids are arranged as a feature vector.

This method of reporting the medoid dissimilarities can be thought of as *soft clustering*, where we report the relative *membership* of each subinterval to all clusters. As the initial medoids are randomly selected, 20 initializations of clustering are run for each event zone, using the medoids that minimize the overall inertia to represent the range of prototypical behaviors for the given event zone. This is done to select the most *compact* clusters where samples grouped together minimize aggregate dissimilarity from the medoids, distilling the prototypical behaviors that best represent the range of behaviors observed.

Illustrated on the far-left side of Multimedia Appendix 3 is a bird's-eye view of 1 of the 10 simulated environments' track, with a specific event zone highlighted (eg, *prescripted traffic interaction and avoid collision response to white car ahead suddenly stops in roadway*). Depicted on the right side of Multimedia Appendix 3 is the range of prototypical behaviors exhibited by the identified medoids while navigating through the indicated event zone.Beneath the depictions of each prototypical behavior is recorded the number of subintervals in its cluster, the percentage of those subintervals that had collisions in the defined event zone (both with vehicles and pedestrians), as well as the means and standard deviations of ORE scores from all cluster members.

With 166 different event zones in our dataset, each sample was converted to a concatenated feature vector of 1328 medoid dissimilarity features ($k \times 166$). For samples that never encounter a given event zone, the dissimilarities to the generated medoids are left as *k* blank entries. With the data table of medoid dissimilarities constructed as features and every sample having an *actual* pass/fail *outcome label*, supervised learning is trained and tested on the dataset using standard leave-one-out 10-fold cross-validation.

Supervised Learning Methods

Supervised learning methods evaluated features (both observed and derived) to establish their ability to predict a given driver applicant's *outcome label* (ORE pass/fail). Specifically, all methods were evaluated using a standard 10-fold cross-validation in an attempt to minimize the overfitting of any model. We evaluated 2 classification methods within the Waikato Environment for Knowledge Analysis [22,23]: logistic regression and support vector machines (SVMs).

Logistic Regression

Logistic regression ML algorithms classify a given sample based on computing its probability of belonging to one of the binary classes defined by the pass/fail *outcome label*. Given the predicted probability that a sample has either passed or failed, a decision rule is used to classify the sample:

In this example, the outcome label is based on actual ORE pass/fail, and the probability threshold used in the decision rule is derived from 0.0 to 1.0, with a step size of 0.01, to explore the threshold parameter's effect on performance metrics.

Support Vector Machines

SVMs attempt to compute the optimal decision surface for partitioning datasets along with binary class values (in our case, *pass* and *fail*) by maximizing the margin of separation between samples known to be members of different classes [24]. The core assumption of an SVM model is that there exists a transformed space in which the dataset may be linearly partitioned via a hyperplane. As it is computationally costly to transform every sample, a *kernel function* was used to relate pairs of samples in the transformed space.

For all results using SVM classification, we elected to use the *radial basis function* (RBF) as our kernel because our initial experimentation suggested that our feature values resemble Gaussian distributions. A coarse grid search was used to narrow the ranges of parameters considered for building an effective classifier [25]. SVMs for binary classification are primarily configured using 2 different values: a *cost* parameter (which determines the degree of influence of data points far from the decision surface in the algorithm) and a *gamma* parameter (which controls the variance of the Gaussian functions that make up the RBF kernel). We dyadically iterated the *cost* from 2^{-5} to 2^{-15} by doubling. To perform a grid search in a 2-dimensional parameter space, we also dyadically iterated the *gamma* parameter from 2^{-10} to 2^{6} by doubling.

Evaluation Metrics

As previously described, the primary goal of the VDT pilot was to reliably assess applicant preparedness before taking the ORE, thereby maximizing the safety of driving examiners and providing an opportunity for prepared applicants to take the ORE. The evaluation metrics described in the following sections were used to evaluate a given model's predictive ability while addressing the goals of the VDT pilot.

Confusion Matrix and Evaluation Metrics

To predict a binary outcome of the ORE with confidence, a confusion matrix (see Table 1) for each classification model was generated to evaluate the predictive ability of our classifiers.

Our evaluation metrics included accuracy, algorithm fail rate, false alarm rate, ratio of false alarm, and risk ratio.

Accuracy was defined as the ratio of the total number of correctly classified cases to the total sample population:

Algorithm fail rate was defined as the percentage of total cases the classifier predicted as fail:

False alarm rate was defined as the percentage of total cases the classifier misclassified as fail:

The *ratio of false alarms* was defined as the ratio of cases of misclassified *fail* to the total cases where the classifier predicted *fail*:

The *risk ratio* was defined as the relative risk (RR) of failing the ORE when the classifier predicted *fail* versus predicting *pass*. The 95% CIs were also calculated for risk ratios:

SMEs within the licensing agency recommended that a satisfactory classifier would consist of a model that maximized both accuracy and risk ratio while minimizing the false alarm rate (applicants who failed the VDT but went on to pass their ORE).

Table 1. A confusion matrix, showing the 4 quadrants: FF (fail-fail), FP (fail-pass), PF (pass-fail), and PP (pass-pass).

Confusion matrix	Fail ORE[a]	Pass ORE
Fail VDT[b]	FF	FP
Pass VDT	PF	PP

[a] ORE: on-road examination.

[b] VDT: virtual driving test.

Fitness of Models

In addition to the evaluation metrics previously described, we also evaluated model fitness using *receiver operator characteristic* (ROC) curves to compare our predictions against a random binary classification. An ROC curve illustrates a model's performance using different parameterizations. Specifically, it plots the model's *true positive rate* (TPR) to its *false positive rate* (FPR). For our data, TPR (also known as sensitivity) is the ratio of driver applicants who are correctly predicted to fail the ORE to the overall population of applicants who went on to fail the ORE:

FPR is the ratio of driver applicants incorrectly predicted to fail the ORE to the overall population of applicants who went on to pass the ORE:

Classifiers that have equal TPR and FPR do not perform well, as there is less certainty that the classification of any particular sample is reliable. ROC curves that deviate significantly from the line TPR=FPR represent classifiers that perform better at distinguishing the 2 classes. A perfect classifier would have a TPR of 1.0 and an FPR of 0.0, where a random binary classifier would have these 2 values be the same. A common metric used to summarize the relationship between TPR and FPR over a range of model parameterizations is the *area under the curve* (AUC). AUC is the numerical integral of the ROC curve (FPR is the independent variable and TPR is the dependent variable), where a higher percentage of the total area coverable (TPR of 1.0 for all values of FPR) should indicate models that are more fit to reliably predict a class value (eg, ORE outcome) [26].

Results

Classifier Results

We summarize the classifier results with the evaluation metrics previously described in Table 2. In this table, results from 4 classifiers were reported: feature sets generated from 2 methods (*variables* and the novel approach) and *time series clustering*, used in 2 ML methods (logistic regression and SVM). Overall, the results from the *time series clustering* approach provided similar results to the *variables* approach. More specifically, logistic regression using the time series clustering approach to generate features produced the best classifier based on our evaluation metrics (highest accuracy: 76.2%; highest risk ratio: 3.07; 95% CI 2.75-3.43). In addition, this classifier minimizes the ratio of false alarms compared with the others (27.2%).

Table 2. Summary results of the evaluation metrics obtained from 4 classifiers: variables+logistic regression, variables+support vector machine, time series clustering+logistic regression, and series time clustering+support vector machine.

Classifier results	Standard method (variables)		Novel method (time series clustering)	
	Logistic regression	SVM[a]	Logistic regression	SVM
Accuracy, %	76.1	75.4	76.2	74.9
Fail rate, %	6.6	3.4	3.5	3.6
False alarm rate, %	2.6	1.3	1.0	1.7
Ratio of false alarms, %	38.5	37.7	27.2	45.9
Relative risk (95% CI)	2.684 (2.409-2.991)	2.581 (2.250-2.961)	3.071 (2.747-3.434)	2.223 (1.906-2.592)
True positive rate, %	15.9	8.3	10.0	7.8
False positive rate, %	3.4	1.7	1.3	2.2

[a] SVM: support vector machine.

Logistic Regression

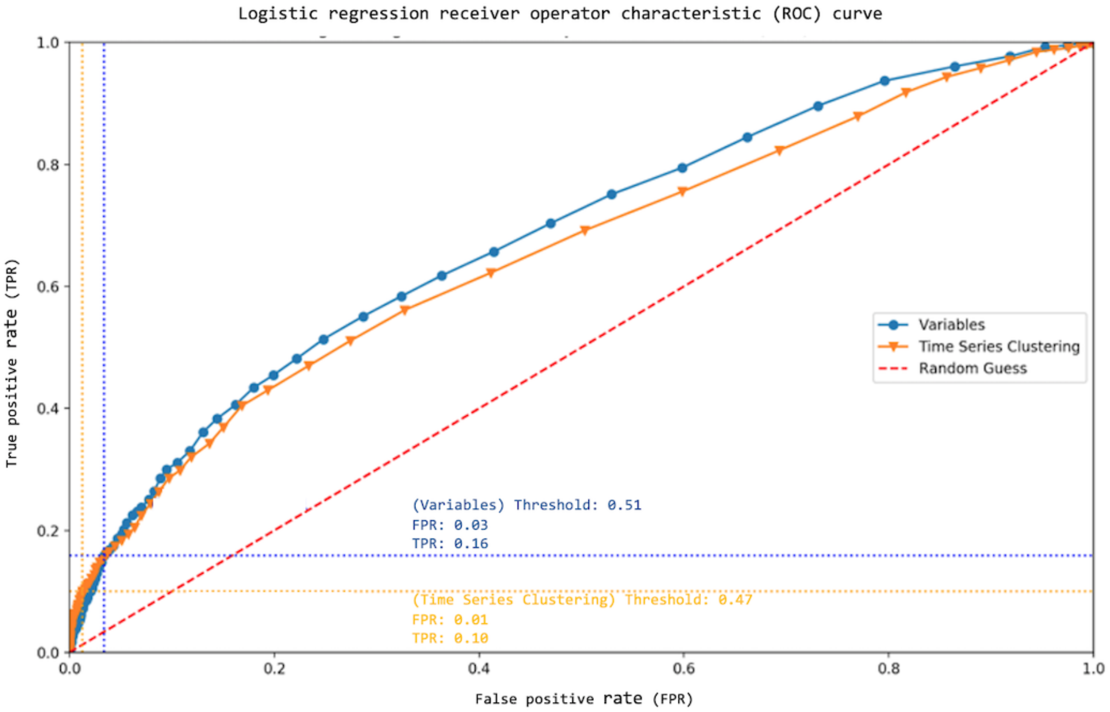
Figure 5 highlights the results for logistic regression with the highest observed classification accuracies for both representations (*variables* and *times series clustering*). The most promising parameterization of logistic regression using the *variables* representation as input for the VDT has an FPR of 3.4% and a TPR of 15.9%, whereas the most promising parameterization of logistic regression using the *time series clustering* representation as input for the VDT has an FPR of 1.3% and a TPR of 10.0%. Moreover, we observed that the *time series clustering* representation yielded a VDT classifier with a smaller ratio of false alarms (27.2%) than the most accurate VDT classifier using the *variables* representation (38.5%).

The threshold value yielding the model with the highest classification accuracy is highlighted in Figure 5. The highlighted parameterizations (yielding the highest classification accuracy, marked by the vertical dotted lines in the figure) demonstrate VDTs that show predictive promise, although there is room for improvement. Using logistic regression with different threshold values, the AUC for the *variables* feature set's ROC curve is 0.682, whereas the AUC for the *time series clustering* feature set's ROC curve is 0.656.

As seen in Figure 6 of Multimedia Appendix 4, logistic regression using the *variables* representation of the dataset produces a classifier that fails 6.9% of those taking the VDT, where 39% of those predicted to fail the ORE actually went on to pass (ratio of false alarms). The false alarms represent only 3% of all drivers, with 37% of the false alarms having an ORE score between 20 and 25, meaning these drivers nearly failed the ORE. Within the group of drivers misclassified (24% of all driver applicants), 30% of samples have an ORE score in the *gray zone* (20-35, with a score of ≤25 resulting in a pass). With this model, drivers failed by the VDT are 2.7 times more likely to fail the ORE (RR=2.68; 95% CI 2.41-2.97).

Using logistic regression, the *time series clustering* representation of the dataset produces a classifier that fails 4% of those taking the VDT, with a ratio of false alarms of 27%. Only 1% of all drivers are false alarms, where 25% of false alarms nearly fail the ORE with scores between 20 and 25. For all misclassified drivers (24% of all driver applicants), 25% of the samples had an ORE score in the *gray zone*. Using this model, drivers failed by the VDT are more than 3 times more likely to fail the ORE (RR=3.07; 95% CI 2.75-3.43). Overall, the *time series clustering* representation used as input for the logistic regression algorithm produces a more lax classifier that fails approximately half as many drivers as using the *variables* representation as input. However, when predicting failure on the ORE, logistic regression using the *time series clustering* representation is more often correct than with the *variables* representation (72% correct predictions of *fail* versus 62%).

Figure 5. Receiver operator characteristic curves for logistic regression using the variables and time series clustering feature sets for iterated logistic cutoff threshold values. Points in the bottom left represent models with the lowest thresholds (more people pass the virtual driving test), whereas points in the top right represent models with the highest thresholds (fewer people pass the virtual driving test).



Support Vector Machines

As Figure 7 in Multimedia Appendix 5 shows, the most accurate parameterization of SVM using the *variables* representation as input for the VDT has an FPR of 1.7% and a TPR of 8.2%, whereas the most promising parameterization of SVM using the *time series clustering* representation as input for the VDT has an FPR of 2.2% and a TPR of 7.8%. Moreover, we observed that the *time series clustering* representation yielded a VDT with a larger ratio of false alarms (45%) than the most accurate VDT using the *variables* representation (38%).

Loose grid search of SVM’s 2 parameters reinforces the notion that the 2 classes of ORE pass/fail are highly comingled within both feature spaces. Figure 8 in Multimedia Appendix 6 contains surface plots for both feature sets showing the interpolated landscapes of risk ratio and accuracy (vertical axis) over the SVM gamma and C (horizontal/lateral axes) parameters sampled in bivariate grid search.

The SVM parameterization with the highest observed classification accuracy using the *variables* representation of the dataset produces a classifier that fails 3.5% of those taking the VDT, with 38% of those predicted to fail the ORE being false alarms. The false alarms comprise 1.4% of all drivers, with 33% of the false alarms having nearly failed the ORE, where scores between 20 and 25 indicate nearly failing the ORE. Of the driver applicants misclassified (24% of all driver applicants), 26% of samples had an ORE score in the *gray zone* (20-35, with a score of ≤25 resulting in a pass). With this model, drivers failed by the VDT are 2.6 times more likely to fail the ORE, corresponding to the plateau of risk ratios illustrated in Figure 8 of Multimedia Appendix 6.

Using the *time series clustering* feature set, the SVM parameterization yielding the highest classification accuracy failed 3.6% of people taking the VDT, where 45% of those predicted to fail the ORE are false alarms. With 1.6% of all driver applicants being a false alarm, 13% of the false alarms nearly failed the ORE with scores between 20 and 25. This VDT misclassifies 25% of all driver applicants, where 26% of these drivers have an ORE score in the *gray zone*. With this model, drivers failed by the VDT are 2.3 times more likely to fail the ORE.

Discussion

Principal Findings

This study specifically aimed to evaluate a novel method for automatically classifying user-generated time series data versus a traditional and resource-intensive approach (classification by manually creating features [variables] using domain knowledge and SME). When compared with the standard method of feature selection (using manually created variables), the clustering method demonstrated a similar to higher accuracy in predicting ORE results. More specifically, it outperformed the standard method by accurately identifying the most underprepared applicants (those applicants who failed the ORE).

Although time series clustering is not a completely new idea, our particular application using a two-stage analysis of critical subintervals (our event zones) is novel. Moreover, our application does not suffer from the known problem of *sliding-window partitioningthen cluster* methods, which have been shown to be inconsistent in producing meaningful predictions [27]. In this study, we leveraged contextual similarities in scripted scenarios written to elicit specialized driving behavior in response to changes in the environment along the route, including ambient traffic [28]. Clustering the behaviors exhibited in these event zones leads to highly correlated clusters [29] that are quantifiably useful for the task of predicting ORE pass/fail.

The clustering is useful beyond simple binary prediction: Knowing how the data break down into groups allowed us to formulate a profile made of *prototypical behavior*, which represents the traits exhibited by the cluster members [30]. Only a small portion of the sample (433 of the 4308 drivers) had an ORE score greater than 45 (scores <26 result in passing). As we dealt with a heavily weighted distribution of ORE pass/fail (roughly 3 to 1), we carefully scrutinized the composition of the clusters formed; we also focused on identifying dangerous drivers (higher accumulation of critical driving errors) instead of optimizing overall predictive accuracy for ORE pass/fail.

Although the clusters did not cleanly separate all those who failed from those who passed, the features generated and then classified were able to identify outliers in the data rather easily. In many cases, these outliers presented aberrant driving behaviors, such as collisions with vehicles, collisions with pedestrians, and driving off the road. As it is meant to be a prescreening test, the purpose of VDT was never to identify all those who would go on to fail the ORE but rather to isolate the driver applicants who present a danger to themselves and others on the road. Operationally, the VDT should not restrict eligible driver applicants from taking the ORE; with that in mind, our novel approach shows promise in confidently classifying truly unprepared driver applicants. As a result, we considered evaluation metrics such as risk ratio instead of accuracy to keep state ORE examiners out of harm's way.

Limitations

This study had some limitations. First, the *variables* approach that we used did not represent the entire domain set of VDT performance metrics that could be derived and used. Many of the initial variables focused heavily on global measures (eg, measures across the entire simulated drive) rather than focusing on event-specific measures (eg, performance on curves and intersections). Owing to this, our analyses may not have taken into account the full variation in differential VDT performance (as we would expect that event-specific measures would be able to further explain this variability).

Second, the sample size available precluded model formulation specific to the simulated environment (eg, 10 separate models). Although assignment to clusters was performed for each of the 10 unique environments, only 1 dataset determined model formulation: each driver applicant record included a series of cluster assignments and their corresponding ORE score. Future research with larger samples will account for the different simulated environments and evaluate them individually.

Finally, because of restrictions placed on implementing the VDT in a busy licensing workflow, our limited dataset did not include demographic information and confounding variables collected for this sample. Age and sex are known risk factors for crashes among novice drivers [31] and may explain some variability in performances among new drivers seeking a driver's license.

Conclusions and Future Directions

This study provided initial evidence that the *time series clustering* feature set when used as input produced classifiers that performed just as well and, in some cases, better than those using the traditional *variables* approach. Future work will evaluate this method with larger sample sizes and potentially integrate it with other known methods to develop an optimized classifier. We also plan to explore more sophisticated variants of this approach, specifically expanding on a predefined number of clusters and using approaches such as the *silhouette method* [32] to determine an appropriate number of clusters for grouping behaviors exhibited by driver applicants in each event zone. Alternatively, we may attempt to maximize feature variance between clusters using a secondary *analysis of variance* clustering refinement procedure [33]. For the purpose of improved differential diagnostic capabilities in time series classification tasks, we intend to pursue several avenues of research that demonstrate potential for producing distinct prototypical user behaviors.

Acknowledgments

The authors would like to thank the individuals involved in the VDT pilot for collecting these data and providing our team with a deidentified dataset.

Conflicts of Interest

All authors had no contact with the driver license applicants and were not directly involved with data collection in the VDT pilot program. FW and VK disclose their intellectual property and financial interest in Diagnostic Driving, Inc and CHOP's institutional interest in Diagnostic Driving, Inc. Diagnostic Driving, Inc created the VDT. FW serves as the Chief Scientific Advisor, and VK serves as the Chief Executive Officer of Diagnostic Driving, Inc. FW operates under a Conflict Management Plan from CHOP and the University of Pennsylvania (Penn). EW also works at CHOP and Penn with FW. SO operates under a Conflict Management Plan from Drexel University. DG and ST are both nonshareholding employees of Diagnostic Driving, Inc.

Multimedia Appendix 3
Time Series Clustering for highlighted event zone with cluster centers representing prototypical driving behaviors in that zone. In the eight sub-plots, “prototypical behaviors” represent the derived cluster medoids for a specific event zone. Plots with more densely congregated and colorized pixels indicate the driver was moving more slowly through the given event zone than a plot with sparser, colorized pixels. The white dashes indicate the road median; time series subintervals begin at the white circle and the position of the driver applicant in each frame is a colorized pixel. Red corresponds to usage of the brakes, green corresponds to the throttle, light blue represents steering, and the spacing of these pixels are determined by the vehicle’s speed in the given zone. Collisions with other vehicle or pedestrians are indicated by red circles, collisions with static environmental objects are indicated by yellow circles. Displayed underneath are the means and standard deviations of actual ORE scores of samples in each cluster. In addition, displayed is the number of samples in each cluster and the average number of collisions with vehicles and pedestrians in a given cluster.

Multimedia Appendix 5
The most successful SVM parameterizations for both feature sets learn to distinguish data which is largely homogeneous with high “Cost” penalties for misclassification errors. The optimal trade-off observed between TPR and FPR occurs with a fail rate of approximately 3.5%, about 40% of samples failed are false alarms.
[DOCX File , 221 KB - jmir_v22i6e13995_app5.docx]

Multimedia Appendix 6
We consistently observed more SVM parameterizations that better predicted ORE pass/fail using the “Variables” feature set as input than for “Time Series Clustering”. Zero is imputed for undefined Risk Ratios in these plots, such results originate from VDTs with parameterizations that fail no one.

Abstract

Background: Apathy is a common symptom in neurological disorders, including dementia, and is associated with a faster rate of cognitive decline, reduced quality of life, and high caregiver burden. There is a lack of effective pharmacological treatments for apathy, and nonpharmacological interventions are a preferred first-line approach to treatment. Virtual reality (VR) using head-mounted displays (HMDs) is being successfully used in exposure- and distraction-based therapies; however, there is limited research on using HMDs for symptoms of neurological disorders.

Objective: This feasibility study aimed to assess whether VR using HMDs could be used to deliver tailored reminiscence therapy and examine the willingness to participate, response rates to measures, time taken to create tailored content, and technical problems. In addition, this study aimed to explore the immediate effects between verbal fluency and apathy after exposure to VR.

Methods: A mixed methods study was conducted in a sample of older adults residing in aged care, and 17 participants were recruited. Apathy was measured using the Apathy Evaluation Scale (AES), and verbal fluency was used as a proxy measure of improvements in apathy and debriefing interviews to assess feedback from participants. Side effects that can occur from using HMDs were also measured.

Results: We recruited participants from a high socioeconomic status setting with a high education level, and the participation rate was 85% (17/20); most responses to measures were positive. Access to a wide range of freely available content and the absence of technical difficulties made the delivery of a VR reminiscence intervention highly feasible. Participants had improved semantic scores (t_{14}=−3.27; *P*=.006) but not phonemic fluency scores (t_{14}=0.55; *P*=.59) immediately after the intervention. Those with higher levels of apathy demonstrated the greatest cognitive improvements after a VR reminiscence experience, which was indicated by a strong positive relationship between the AES and semantic verbal fluency change scores postminus pre-VR (*r*=0.719; 95% CI 0.327 to 0.900; *P*=.003). All participants enjoyed the experience despite 35% (6/17) of participants experiencing temporary side effects.

Conclusions: This study provides initial evidence that it is feasible to use VR with HMDs for therapy to treat symptoms of apathy in older adults in residential aged care. However, there is a need to closely monitor the side effects of HMD use in older adults. Further research is needed using an active control group to compare the use of VR with traditional forms of reminiscence therapy.

KEYWORDS

reminiscence; head-mounted display; apathy; cognitive aging; dementia; residential facilities; virtual reality

Introduction

Background

Apathy is one of the most common symptoms of neurological and psychiatric disorders such as dementia [1-3]. A lack of motivation is the defining feature of apathy, resulting in a reduction of goal-directed behavior [4]. Apathy contributes to a poorer quality of life and a faster rate of cognitive decline [5,6]. In addition, the risk of mortality in those with apathy increases 3-fold compared with those without apathy [7]. Those caring for people with apathy are also affected by reported higher caregiver burden compared with other neuropsychiatric symptoms [8,9].

A high prevalence of apathy of up to 84% has been reported in older adults in residential aged care with cognitive decline [10]. Healthy older adults can also experience symptoms of apathy in varying degrees [11,12]. Significant changes in life circumstances, for example, surviving natural disasters or being institutionalized, may reduce motivation, and increase symptoms of apathy [13]. Changes in specific brain regions have been associated with apathy, including frontal-subcortical structures [14,15]. However, the mechanisms of apathy are not fully understood.

Although symptoms of apathy may overlap with those of depression [16], apathy can also present as a separate clinical symptom [17], and there is increasing evidence supporting this distinction [18,19]. Symptoms of apathy can also differ depending on the type of dementia, with more severe symptoms found in the behavioral variant of frontotemporal dementia [20]. With little evidence supporting pharmacological treatment for apathy [21] and the side effects of current medications [22], alternative interventions are required.

Nonpharmacological approaches have demonstrated evidence in improving the levels of apathy, including music, art, cognitive stimulation, and reminiscence therapy [23]. Reminiscence therapy is commonly used in residential aged care and involves the discussion of a person’s past experiences involving the use of items including photographs, magazines, or music [24]. It can help maintain a person’s sense of identity and improve feelings of self-worth [25,26], an important aspect of improving apathy.

A recent Cochrane review found reminiscence therapy to be effective in some cases [27]. However, the effect sizes found were small and inconsistent. Little or no differences in cognitive outcomes were commonly found when comparing reminiscence therapy–treated groups with nontreatment groups (eg, standardized mean difference 0.11, 95% CI 0.00 to 0.23) [27]. Improving the delivery of tailored reminiscence therapy by increasing how realistic it is may increase the effectiveness of the therapy and the likelihood of attending sessions [28].

The use of technology in reminiscence therapy can provide access to a wide range of content via the internet and make it easy to tailor an intervention specifically for a person [29,30]. In a within-group study comparing the creation of a digital life storybook with a conventional life storybook for people with dementia, additional improvements were seen in the quality of life and autobiographical memory performance when the digital life storybook was used [30]. The traditional version in this study consisted of tangible prompts, including photos and other memorabilia, and the digital version consisted of a movie created and burned onto a DVD for playing on television. iPads have also been used in the delivery of individualized reminiscence therapy with positive results, including improvements in well-being [31,32]. Significantly higher levels of initiating speech and engagement were found using a touchscreen monitor compared with traditional reminiscence therapy using artifacts, including newspapers, books, and photos [33]. Virtual reality (VR) in the form of large-screen displays has also been used and provides an immersive experience [34]. The level of immersion can vary among technologies. iPads or computer screens are classified as nonimmersive, whereas large-screen displays are considered semi-immersive [35]. An increase in the level of immersion can increase the level of presence (the degree to which a person feels they are in the virtual environment) [36]. During a navigation task, an increased sense of presence using highly immersive 3D screens while wearing stereo glasses has been found to recruit additional brain areas compared with less immersive 2D screens [37].

VR using head-mounted displays (HMDs) provides a fully immersive, highly engaging, and realistic experience with the user closed off from external distractions. The use of HMDs is not limited to gaming and has infiltrated many areas, including medical training, rehabilitation, and therapy [38-41]. Advances in technology, production, and reduced costs have made HMDs widely accessible, with little training required to implement and use them. In patients who had previously not reported clinical benefits from other forms of psychotherapy, the use of VR using HMDs has been successful in treating post-traumatic stress disorder (PTSD), with a significant decrease in PTSD symptoms being found while comparing pretreatment symptoms with posttreatment symptoms (d=1.17) [42]. Other successful interventions using HMDs include reducing anxiety [43] and pain management of burn victims during wound care [44,45].

Recent research has found that older adults, including those with cognitive decline, can tolerate using HMDs and has reported positive experiences [46-49]. There has also been success in using HMDs for memory training in older adults with significant improvements in memory tests (d=.7) compared with a control group receiving music therapy [50]. Other uses of HMDs, including in older adults, have shown an increase in the performance of daily living activities in stroke victims [51] and success with vestibular rehabilitation in older adults with mild cognitive impairment [52]. These findings of HMD use in older adults suggest that expansion into other areas is possible. Research into the use of VR using HMDs in therapy for symptoms of neurological disorders is limited.

In addition to the lack of motivation in apathy [53], executive dysfunction has also been found to be associated with apathy [54,55]. Impairment in executive function is a key cognitive mechanism of apathy. Apathy is negatively associated with the performance of verbal fluency tasks [56]. Similarly, those with dementia and apathy have shown reduced performance on verbal fluency tasks, compared with those without apathy [57]. Specifically, associations have been reported between apathy and semantic fluency but not phonemic fluency [56,58]. Performance in verbal fluency tasks indicates executive control [59] and initiation [60]. These executive functions of control and initiation are reduced in those with apathy [61,62]. Apathetic participants demonstrated a preference for a VR task over a pen and paper task, as it provided a more engaging experience [63]. In addition, VR (using a projector screen with stereo glasses) has demonstrated the ability to stimulate autobiographical memories [34]. Therefore, VR may improve the performance of executive functions, both directly and indirectly.

Although there is evidence supporting the acceptability of using HMDs in older adults as previously mentioned, some people do experience side effects from using HMDs, including the occurrence of motion sickness such as that induced by air, sea, or land travel. Research on sickness symptoms while using HMDs in older adults has reported conflicting outcomes [64-66]. Many companies are starting to offer VR services for older adults in residential aged care [67-69]. However, the occurrence and prevalence of side effects of using VR HMDs with this age group are uncertain [70]. With the increased use of VR using HMDs in many areas, including older adults, awareness of any side effects from using this technology has become essential.

Objectives

This study aimed to evaluate the feasibility of using tailored content created for viewing in a VR HMD to deliver reminiscence therapy to older adults in residential aged care. Along with establishing the feasibility of this study, the following parameters were also examined: availability and willingness to participate, response rates to measures used, the time needed to create tailored content, and technical problems. Verbal fluency was used as a measure of immediate effects on executive function after exposure to tailored content in VR, and associations with verbal fluency and apathy were also examined. A debriefing interview was used to assess enjoyment and obtain feedback from participants. Side effects of using HMDs were also examined using the Simulator Sickness Questionnaire (SSQ) combined with feedback from the debriefing interview.

Methods

Participants

Participants were recruited from a residential aged care facility in Adelaide, Australia. Potentially suitable participants were identified by senior staff at the residential aged care facility following the inclusion and exclusion criteria. A list of identified participants was then given to the researcher, and the researcher approached participants to request their participation in the study. The current health status of each participant was obtained from the nursing staff on duty before the participants were contacted. Out of 20 participants who were requested to participate in this study, 3 declined; 10 women and 7 men, between the ages of 72 and 95 years with a mean age of 87.3 years (SD 6.3), agreed to participate. All the participants were Australian, of whom 11 were born in Australia, 2 in the United Kingdom, 2 in Africa, and 2 in Europe. The participants born in the United Kingdom, Africa, and Europe had spent most of their lives in Australia. The participants came from a high socioeconomic background and most were well educated; the mean years of education was 13 (SD 3). According to the Psychogeriatric Assessment Scale (PAS), 10 participants had no or minimal cognitive impairment, 3 presented with mild impairments, and 4 had moderate impairments [71]. The mean score for the Apathy Evaluation Scale (AES) was 31.5 (SD 6.3). Using a cutoff score of 36.5 [72], 3 participants met the criteria for a diagnosis of apathy with the highest score being 46; 5 participants scored between 34 and 36. Medication history was available for 14 participants. The most common medication used was for depressive symptoms in 6 out of 14 participants (43%). Participants were excluded if their score on the PAS was 16 or higher indicating severe impairment; had significant neurological disorders; had other conditions, including agitation and aggression at a level that would make assessment difficult; or if their vision could not be corrected by glasses or glass frames that could not fit into the HMD. Informed consent was obtained from all the participants, and no honorarium was offered for participation. Ethics approval was obtained from the University of South Australian Human Research Ethics Committee in accordance with the Australian National Statement on Ethical Conduct in Human Research (2007).

Materials

Virtual Reality Apparatus

The Oculus Go HMD was used [73] to deliver the VR experience to participants. This is a standalone HMD that does not require tethering to a computer or the use of a mobile phone.

Virtual Reality Content

YouTube VR (Google LLC) was used for the playback of 360-degree videos. This is an app that is specifically used for viewing YouTube videos in VR HMDs. All 360-degree videos were downloaded to the HMD to reduce reliance on the internet and improve the reliability of playback. Wander (Parkline Interactive) was used to navigate to places of interest tailored to the participant. This app uses data from Google Street View and has the feature of saving places visited for future access.

Questionnaire for Establishing Virtual Reality Content

An interview was conducted to develop tailored content for each participant and was based on reminiscence therapy guidelines [24]. Questions included the following: “What significant memories do you have from your childhood?” “What significant life events do you have positive memories of?” and “What memories do you have from working, including details about your first job, and work in the home?”

Psychogeriatric Assessment Scale

Cognitive status was obtained from the current records of the residential aged care facility using the PAS [74]. The PAS includes both a subject and informant interview and provides a summary of functioning related to cerebrovascular disease, cognitive status, and behavioral disturbance that can occur in dementia [74]. Scores range from 0 to 21 with a score of ≥4 indicating likely cognitive impairment [75] and the risk of further cognitive decline [76].

Apathy Evaluation Scale Self-Rated Version

Apathy was measured using the AES [4]. This was included to measure the participants' current level of apathy. The AES contains 18 items measured on a scale ranging from *not at all*, *slightly*, *somewhat*, and *a lot*. The AES scores range from 18 to 72, with higher scores indicating a higher level of apathy. Rating is based on the previous 4 weeks. The self-rated version of the AES has been found to have satisfactory test-retest reliability of .76 and good internal consistency (α=.86) [4]. The internal consistency for this study was α=.77. Questions included, "Are you interested in having new experiences?" and "Do you spend time doing things that interest you?"

Simulator Sickness Questionnaire

Side effects were measured using the SSQ [77]. This questionnaire is widely used in VR-related research [78]. It consists of 16 items that assess the symptoms in the VR environment using a 4-point rating scale from 0 (indicating *no symptoms*) to 3 (indicating *severe symptoms*). The SSQ has 3 subscales, including nausea, oculomotor, and disorientation, and has demonstrated good internal consistency (α=.87) [79]. Internal consistency for this study was α=.69. Both the total and subscale SSQ scores require weighting. The subscale scores were weighted as follows: nausea 9.54, oculomotor 7.58, and disorientation 13.92. Total scores were calculated by adding the 3 unweighted subscale scores and multiplying by 3.74. The 3 subscales include overlapping symptoms, for example, the symptom of *blurred vision* overlaps both the oculomotor and disorientation subscales. Symptoms measured included *headache*, *nausea*, *sweating*, and *eye strain*.

Slater-Usoh-Steed Presence Questionnaire

The Slater-Usoh-Steed Presence Questionnaire (SUS) was used to assess how realistic participants thought the VR environment was [80]. The SUS consists of 6 items scored from 1 to 7. Questions include "To what extent were there times during the experience when the virtual environment was reality for you?" and "During the time of your experience, did you often think to yourself that you were actually in the virtual environment?" This scale has demonstrated acceptable internal consistency (α=.75) [81]. Internal consistency for this study was α=.74.

Verbal Fluency

Both phonemic and semantic verbal fluency tasks were administered to the participants [82]. In the phonemic verbal fluency task, participants had to name as many words as possible starting with the letter *F* or *P*. In the semantic verbal fluency task, participants had to list as many words as possible in the category of either *animals* or *fruit/vegetables*. The tasks were timed for 1 min each.

Expectations/Enjoyment Measure

Participants were asked about their expectations before the VR experience "What are your expectations about the VR experience, in reference to overall enjoyment?" After the VR experience, they were asked, "How much did you enjoy the experience?" Each question was given a rating ranging from 1 to 10.

Debriefing Questionnaire

A debriefing interview consisting of 8 questions at the end of the VR session (session 2) assessed the feedback from the participants. Interview questions included "Did you find the experience enjoyable?" and "What did you like about the experience?"

Procedure

The study consisted of 2 sessions, with each session lasting for approximately 60 min. Before consent, to ensure that the participants were able to see images satisfactorily in the headset, a short demonstration was performed where participants viewed images in the HMD using the Wander app. Once it was established that the participants could satisfactorily see the images in the headset, and they consented to participate in the study, an appointment was made for the first session. In the first session, basic demographic data were collected. Participants were then asked a series of questions (questionnaire for establishing VR content) to establish topics for sourcing content to be viewed in the HMD. Finally, the participants completed the AES.

Once the researcher had sourced content based on data gathered from the interview in the first session for viewing in the HMD (approximately 3 days apart), an appointment was made for the second session. Before and after the VR session, 2 verbal fluency tests (phonemic and semantic), expectations/enjoyment rating, and the SSQ were administered. Alternate forms of verbal fluency tests were counterbalanced for each participant. Although the SSQ was designed to be used postexposure to VR, it was decided to follow the precondition of screening participants who may have health-related conditions [77]. The sourcing of content was completed between the first and second sessions and took approximately 90 min for each participant. Participants viewed the VR content that was timed for 20 min. The researcher determined the order of the content being viewed, and during the VR session, a conversation occurred between the participant and the researcher about the participant's past experiences with regard to the content. Participants were not given access to the controllers, and all navigation was performed by the researcher. This was done to minimize frustration and provide a seamless experience for each participant. The HMD image was mirrored to a laptop to enable the researcher to see what the participant was viewing and to allow the researcher to navigate within the apps. Participants remained seated during the VR content exposure, as standing has been found to increase the risk of motion sickness when using HMDs [83]. Remaining seated also reduced the risk of falls while wearing an HMD. A swivel chair was used to enable participants to turn freely when viewing the VR content, thereby limiting neck movement. One participant was restricted to a mobile chair, and the VR content was delivered while they were lying down at a 45-degree angle in the chair. The researcher turned the mobile chair during VR exposure to enable the participant to view the 360-degree videos. Another participant with mobility issues was seated in a lounge-type chair in their room. After VR exposure, the SUS was administered as a measure of presence, followed by the debriefing questionnaire.

Results

Separate Bonferroni corrections for multiple comparisons were applied for each family of tests. For the 2 fluency tasks, alpha was set at <.025 (.05/2). For the 4 SSQ scores, alpha was set at <.013 (.05/4). For the pre-expectations and enjoyment scale, alpha was set at <.05 (.05/1). Assumptions of normality using the Shapiro-Wilk test found both oculomotor and disorientation subscale SSQ scores to significantly deviate from a normal distribution; therefore, the Wilcoxon signed-rank test was performed for all SSQ comparisons. Two-tailed paired samples *t* tests were used for the remaining comparisons. Means and standard deviations for all pre- and postmeasures are shown in Table 1. Two-tailed paired sample *t* tests revealed that semantic verbal fluency scores were significantly higher post-VR, which was the only significant difference (Table 1).

Neither pre- nor post-VR comparison between phonemic and semantic fluency reached statistical significance in a two-tailed paired samples *t* test (pre-VR: mean 0.40 (SD 5.10); 95% CI −2.42 to 3.22; t_{14}=0.30; *P*=.77. post-VR: mean −2.47 (SD 5.21); 95% CI −5.35 to 0.42; t_{14}=−1.83; *P*=.09).

Bivariate (Pearson) correlations between the AES scores with either phonemic or semantic verbal fluency taken at baseline were not significant (AES and phonemic: *r*=0.309; 95% CI −0.241 to 0.709; *P*=.26; AES and semantic: *r*=−0.104; 95% CI −0.585 to 0.432; *P*=.71).

Bivariate (Pearson) correlations between the AES scores taken at baseline and phonemic verbal fluency change scores postminus pre-VR were not significant (*r*=−0.195; 95% CI −0.643 to 0.352; *P*=.49. There was a strong positive relationship between the AES and semantic verbal fluency change scores postminus pre-VR (*r*=0.719; 95% CI 0.327 to 0.900; *P*=.003; Figure 1).

Correlations between the AES scores and either phonemic or semantic change scores were significant (*P*=.03). Statistical differences between correlations were calculated using the Steiger method [84]. Figure 2 shows a breakdown of the SSQ scores for each participant pre- and post-VR using SSQ score cutoffs [85]. Figure 3 shows a summary of the total and subscale SSQ scores. Figure 4 shows a breakdown of the pre-expectation/postenjoyment scores for each participant.

Table 1. Means and standard deviations for all pre- and post-VR measures with statistics and effect size.

Measures	Pre-VR[a], mean (SD)	Post-VR, mean (SD)	*t* statistic (*df*)	*P* value	*d* value
Phonemic verbal fluency	10.13 (3.78)	9.73 (3.81)	0.55 (14)	.59	0.142
Semantic verbal fluency	9.73 (4.10)	12.20 (4.54)	−3.27 (14)	*.006* [d]	−0.843
SSQ total[b]	12.22 (13.07)	13.46 (11.38)	24.00[c]	.45	−0.230
SSQ nausea	15.90 (15.99)	17.17 (17.74)	14.00[c]	.62	−0.107
SSQ oculomotor	18.70 (21.98)	20.72 (20.75)	8.50[c]	.40	−0.174
SSQ disorientation	7.42 (15.67)	12.06 (14.76)	1.00[c]	.10	−0.408
Expectations/enjoyment	6.80 (2.18)	8.07 (1.87)	−2.02 (14)	.06	−0.520

[a] VR: virtual reality.

[b] SSQ: Simulator Sickness Questionnaire.

[c] Denotes the Wilcoxon signed-rank test. The remaining comparisons are paired samples two-tailed *t* tests.

Figure 1. Correlation between scores on the Apathy Evaluation Scale at baseline and postminus pre–virtual reality session semantic and phonemic verbal fluency. Two participants scored the same in the semantic verbal fluency correlation.

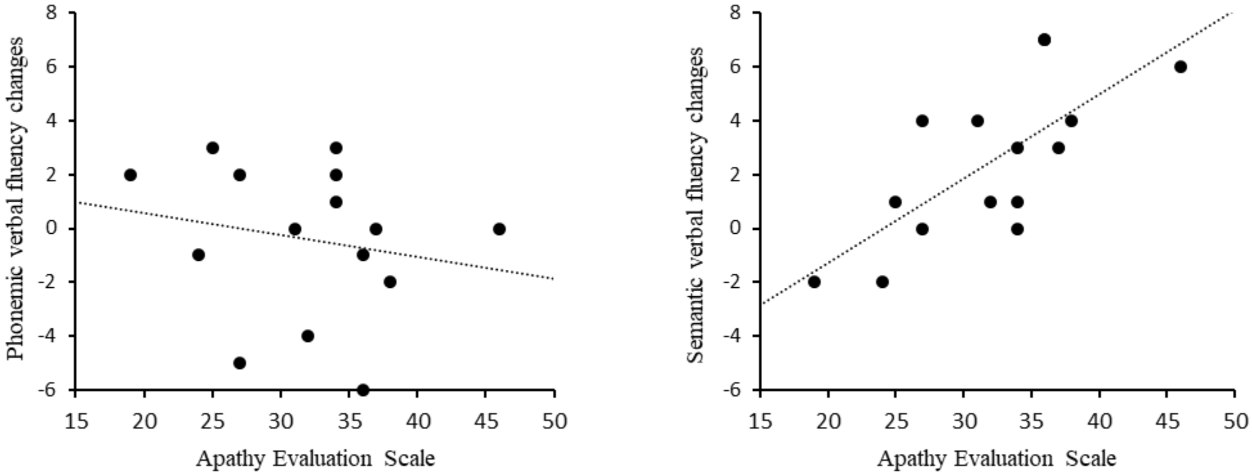

Figure 2. Pre– and post–Simulator Sickness Questionnaire scores with each line representing 1 participant. Shaded areas indicate Simulator Sickness Questionnaire score cutoffs of <5, 5 to 10, 10 to 15, 15 to 20, and >20. VR: virtual reality.

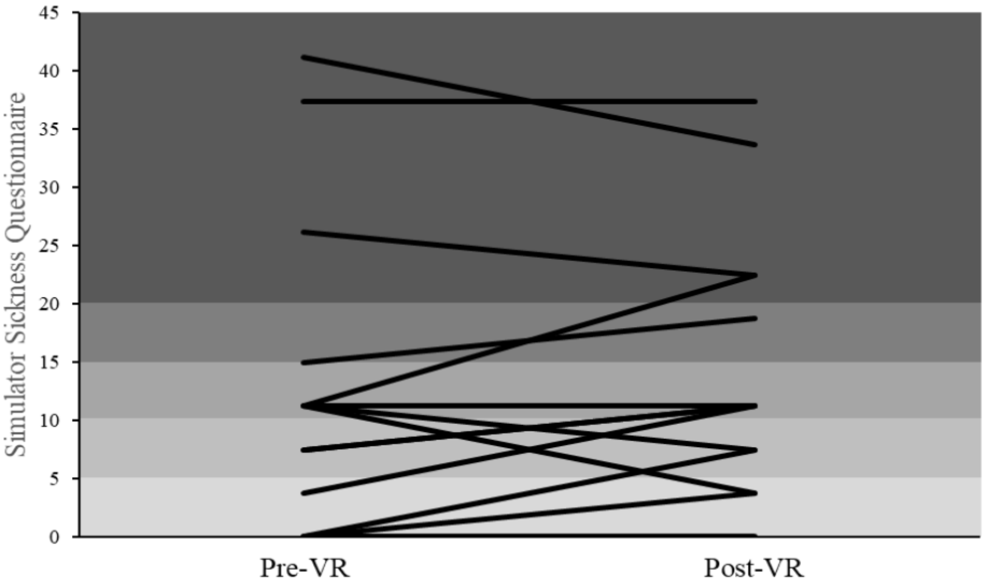

Figure 3. Distribution of Simulator Sickness Questionnaire total and subscale scores at pre- and post–virtual reality intervention, indicated by boxplots within violin plots, white dots represent medians.

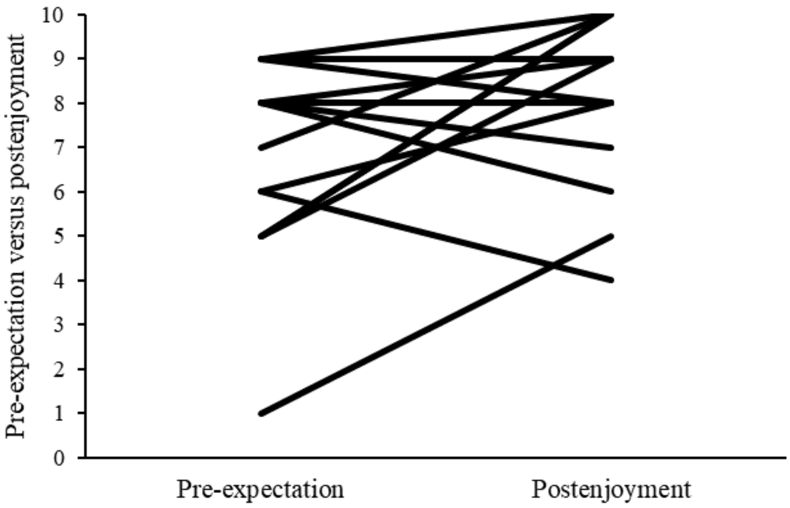
Figure 4. Pre–virtual reality expectations versus post–virtual reality enjoyment scores with each line representing one participant.



Most participants had some difficulty with the SUS questionnaire; question number 5 had to be repeated or further explained. Four participants did not attempt answering question number 5, and 2 participants could not complete any of the questions. Therefore, data from the SUS were not analyzed.

After the VR session, the participants were asked a set of 8 questions to gain feedback about their experiences. Although some of the questions could be answered with a yes or no response, participants were given the opportunity to elaborate on their answers, if required.

All the study participants found the experience enjoyable. When asked what they liked about the experience, 11 participants said they enjoyed reminiscing, 4 participants reported it was nice to do something different, 1 participant reported how realistic the experience was, and finally, 1 participant liked the colors and clarity of the images shown. Comments included “liked the accuracy, feeling of being there and sites that I wanted to see again,” “taken back to somewhere that I know I will never see again,” “better than looking at a computer,” and “I had a feeling of being there.”

In reference to acceptability, 1 participant reported that the HMD was heavy; however, this was rectified by adjusting the head strap. All remaining participants found everything acceptable. When asked if they would do it again, all responded yes, with 1 participant stating, “only for research purposes.”

There were instances where participants reported negative symptoms or side effects. This included 1 participant with discomfort around the cheekbone and forehead areas. Another participant reported dizziness and the feeling that they were “going to fall off the edge;” a further 2 participants reported the feeling that they were going to fall off the edge. One participant reported eyestrain, and another participant reported nausea 10 min after the VR session, which subsided within 10 min. Therefore, 6 out of 17 participants reported some type of negative symptoms or side effects.

Participants were asked to offer suggestions to improve their experience. One participant stated that they would have liked to use the controller to navigate in the virtual environment on their own; another participant suggested having some type of interaction; a third participant said it would have been good to “show the difference between then and now,” referring to the Wander app; and finally, one participant would have preferred to see the places that they had not been to before. All participants said they would recommend the VR experience to a friend.

Finally, the participants were asked what they thought about the questionnaires. A total of 12 participants reported that they were all acceptable; 1 participant did not like them without giving a reason; 1 participant could not remember enough to comment; 1 participant said there were too many questions; 1 participant thought there was not a lot of relevance; and 1 participant said that the pre-VR measures did “cause some tension.”

Discussion

This study found that VR using HMDs to deliver reminiscence therapy is feasible and may be beneficial for aged care residents with apathy. Of the 20 participants who were requested to participate, 17 agreed, indicating a willingness of residents in aged care to participate in research using VR technology. Therefore, the number of available participants for this study was easily achieved. The 3 participants who declined to participate were not interested. It is not known how often exclusion criteria had to be applied, as participants were selected by senior staff at the residential aged care facility following the exclusion criteria. A challenge for future research in apathy is a possible reluctance of those with high levels of apathy to participate because of a lack of interest and motivation, similar to reduced involvement in therapeutic activities found in those with higher levels of apathy [86]. The response rates to measures used in this study were positive. The SUS was the only measure that caused difficulties in understanding the questions, with 2 participants not completing any of the questions. The SUS was chosen because of the small number of items (6) and quick completion time compared with other measures of presence [81] to reduce participant burden. It was validated in a younger sample of university-based students with a technical background, who had no difficulties in completing the questionnaire [81].

As per the qualitative feedback received by this study, older adults may have difficulties in understanding some questions of the SUS. All other measures were fully completed, and all participants adhered to the procedure of the research. It should be noted that the reliability values for measures reported in the literature may not generalize to this study because of sample differences, that is, older adults with neurological and other chronic diseases.

The time taken to create content varied depending on the participant's previous experiences. In this study, the researcher prepared the content before the VR session. It was found that by using readily available apps, the content could easily be sourced for all participants for a VR exposure time of 20 min. This finding is of importance for this study, as individualized reminiscence therapy can be resource intensive [87]. The accessibility of content utilizing the apps in this study reduces the resources required for creating content and places fewer demands on staff if applied in aged care lifestyle activities.

In this study, the preparation of VR content took approximately 90 min for each participant. This time can be substantially reduced once a library of 360-degree travel or music videos has been created. In addition, in this study, the content was compiled before the VR session to maximize the amount of time the participant would reminisce. Sourcing of VR content could also be done during a reminiscence session, working together with the participant while they are viewing images in the HMD, and an area for future research. Working together with the participant not only reduces the preparation time but also allows sessions to be tailored and flexible depending on participants' responses [88]. Traditional methods, including making up a life history book, can require substantial resources and are also limited [88]. Using the Wander and YouTube apps reduces the preparation time and provides a wide range of content that can be easily changed. The use of a group reminiscence therapy format that is more generic can be a preferred approach because of the ability to improve social interaction [89] and can also be less resource intensive [90]. However, each person has a unique history, and using individualized content has been demonstrated to be more effective than using generic content [91]. In addition, an individualized approach is person-centered, focusing on a person's strengths, thereby helping maintain a sense of self and identity [92].

No technical problems with conducting the sessions were encountered. To enable successful delivery of the content, it is recommended that the VR headset be mirrored to an external screen and controlled by the person delivering the content. Thus, the focus is on viewing the content rather than trying to learn to navigate or use the controllers. Although 2 participants would have liked to interact in some form with the virtual environment, this study was designed to provide a seamless experience. As the VR exposure consisted of one session, the intention was to reduce any frustration that could occur because of pressing the wrong buttons on the controller. We cannot draw any conclusions about the extent to which aged care residents could navigate within the app and use the controllers themselves, as this was not attempted. However, the feasibility of controller usage and navigation in VR in this population is an avenue for future research for studies conducted over a longer period. Providing the ability to interact allows the user to act independently and may improve the sense of presence. Recent research has found that the use of VR in providing interaction may be an alternative way of delivering stimulation to people with dementia who do not participate in other lifestyle activities [93].

Verbal fluency was used as a proxy measure to assess improvements in apathy. Both semantic and phonemic verbal fluency results were similar at baseline, despite phonemic fluency being known to be more difficult [94]. This could be because of the level of education in this group of participants (mean 13 years, SD 3), as higher education has been correlated with increased performance in phonemic fluency [95]. In pre-VR sessions, both phonemic and semantic fluency scores were not associated with the participants' level of apathy. In post-VR sessions, not only did semantic fluency increase but the results were positively correlated with participants' level of apathy at baseline. This suggests that the greatest cognitive improvements were seen in participants with higher levels of apathy. What is unclear is why these differences were seen only in semantic fluency. Similar improvements in verbal fluency have been reported in a study using traditional reminiscence therapy in a sample of dementia patients [96] in a short number of sessions. However, in this study, increases were seen in both phonemic and semantic fluency, and apathy was not measured. The executive function of initiation required for verbal fluency may be low in persons with apathy [97], and the reliving of autobiographical memories in an immersive environment may have stimulated the process of initiation.

The results from the debriefing questionnaire were positive and in agreement with previous research, finding acceptance of using HMDs in older adults [46-48]. This study further expands the knowledge of acceptability by demonstrating that VR using HMDs can be used to deliver reminiscence therapy with participants of varying levels of cognitive impairment, including minimal, mild, and moderate impairment, as assessed by the PAS. All participants reported enjoying the VR experience, despite 6 participants reporting a side effect. Another indicator of positive response was that all participants stated they would do it again (although 1 said "for research purposes only"). The most common response about what the participants liked about the experience was related to reminiscence and the enjoyment of seeing places from their past, indicating that this is something this age group wants to experience in a VR environment. An important aspect of reminiscence is maintaining a person's sense of identity [87]. As loss of identity can be a key feature of Alzheimer disease that can increase apathy [98], participating in tailored reminiscence therapy may help in maintaining a person's sense of self and identity and therefore improve levels of apathy. The expectations questions asked pre-VR compared with the enjoyment level post-VR, although in a positive direction, failed to reach a significant level. There were 2 participants in pain because of pre-existing conditions during the VR session, which may have contributed to this result.

Although quantitative findings of short-term side effects from VR were not significant, the debriefing questionnaire raised some concerns. Six participants reported side effects, 4 of which were symptoms related to items measured by the SSQ, including nausea, eyestrain, and dizziness. These symptoms dissipated quickly. In one instance where a participant experienced nausea, it occurred 10 min after the VR experience with symptoms subsiding within 10 min. This after-effect highlights the importance of monitoring participants both during and after VR to avoid health and safety implications.

Moreover, 3 participants had the feeling of “falling off the edge” in VR. This symptom was not captured by the SSQ and did create some discomfort, with 2 of the participants requesting to be moved back to their original position, when they had not actually moved. This could not be associated with the type of content. One explanation could be that sometimes the camera shooting the VR content is elevated, and a high sense of presence may have given a realistic feeling of their position in the virtual environment. Another factor that may have contributed to this symptom is the common occurrence of balance problems in older adults with neurological diseases [99]. This symptom will need to be monitored in future studies when working with this population.

The importance of taking pre- and post-SSQ measures was demonstrated in this study, with some participants reporting symptoms before the commencement of VR. This was usually because of pain from existing conditions. It is also interesting to note that in 4 participants, the SSQ scores decreased post-VR; this included a participant with the highest pre-VR SSQ score. This reduction in the SSQ scores could be a similar effect seen in the successful use of VR for distraction-based therapies [44,45]. Despite all participants finding the experience enjoyable, it is important to consider that 6 out of 17 participants (35%) had some type of negative response when viewing the VR content and the importance of monitoring symptoms. When using cutoff scores for the SSQ (negligible symptoms: <5, minimal symptoms: 5-10, significant symptoms: 10-15, concerning symptoms: 15-20, and problematic symptoms: >20 [85]), it can be seen in Figure 2 that the majority of participants scored >5, with 4 participants experiencing problematic symptoms (>20). However, these cutoffs were created with military personnel using flight simulators, and how these cutoff scores relate to the general population and, in the case of this study, older adults is unknown.

This study aimed to assess feasibility; therefore, a control group was not included, and we could not compare results using a traditional reminiscence therapy approach. However, the aim was first to establish if HMDs could be used in this population for reminiscence therapy. Although alternate forms of both phonemic and semantic verbal fluency were used to reduce practice effects, the lack of a control group receiving no VR intervention warrants a caveat when interpreting the results. It must remain open to what degree the pre-post comparisons are the result of the VR exposure versus a pure retest effect. It is also not known how long the verbal fluency improvements would last and if other aspects of apathy were reduced. Anecdotally, staff members providing services to participants involved in the research reported positive mood changes during the research process, and there were also instances where positive changes in behavior were reported by family members of participants involved in the research.

As the self-rated version of the AES was used, it needs to be considered that people with apathy will normally underestimate their condition [4]. Therefore, true scores may be higher than reported. This study did not specifically recruit participants with apathy, and a challenge with future research is the difficulty of recruiting participants who do have apathy because of their lack of interest and motivation.

This study demonstrated that VR using HMDs can be used to deliver tailored content about a person’s past and that residents in aged care enjoyed this experience. The aged care site in this study was in an area of high socioeconomic status, and study participants had a relatively high education level. Higher levels of education have been associated with an increased willingness to participate in research [100]. The sample was also selected by the staff and therefore was not a random sample, possibly introducing a selection bias [101]. How these factors would generalize to a random sample with an average or lower education level is unknown and needs to be considered when determining generalizability as participation rates, adherence to sessions, and therefore feasibility may differ. Immediate effects on cognition for those with higher levels of apathy after 1 session is an interesting finding and highlights the importance of continuing this research. The VR experience can be implemented and incorporated into current lifestyle activities in aged care with the correct protocols in place. VR is being increasingly used in older adults in areas including assessment, cognitive training, and rehabilitation; therefore, it is critical to monitor side effects, particularly after the VR experience, to avoid any health and safety implications and assess whether the benefits of using HMDs outweigh the risk of side effects. This study provides initial evidence that it is feasible to use VR with HMDs for therapy to treat symptoms of apathy in older adults in residential aged care. Further research over multiple sessions using an active control group to compare with traditional reminiscence therapy will help establish the advantages of using VR with HMDs.

Abstract

Background: Technology is a potentially powerful tool to assist patients with transitions of care during and after hospitalization. Patients with low health literacy who are predisposed to poor health outcomes are particularly poised to benefit from such interventions. However, this population may lack the ability to effectively engage with technology. Although prior research studied the role of health literacy in technology access/use among outpatients, hospitalized patient populations have not been investigated in this context. Further, with the rapid uptake of technology, access may no longer be pertinent, and differences in technological capabilities may drive the current digital divide. Thus, characterizing the digital literacy of hospitalized patients across health literacy levels is paramount.

Objective: We sought to determine the relationship between health literacy level and technological access, use, and capability among hospitalized patients.

Methods: Adult inpatients completed a technology survey that asked about technology access/use and online capabilities as part of an ongoing quality of care study. Participants' health literacy level was assessed utilizing the 3-question Brief Health Literacy Screen. Descriptive statistics, bivariate chi-squared analyses, and multivariate logistic regression analyses (adjusting for age, race, gender, and education level) were performed. Using Bonferroni correction for the 18 tests, the threshold *P* value for significance was <.003.

Results: Among 502 enrolled participants, the mean age was 51 years, 71.3% (358/502) were African American, half (265/502, 52.8%) were female, and half (253/502, 50.4%) had at least some college education. Over one-third (191/502, 38.0%) of participants had low health literacy. The majority of participants owned devices (owned a smartphone: 116/173, 67.1% low health literacy versus 235/300, 78.3% adequate health literacy, *P*=.007) and had used the Internet previously (143/189, 75.7% low health literacy versus 281/309, 90.9% adequate health literacy, *P*<.001). Participants with low health literacy were more likely to report needing help performing online tasks (133/189, 70.4% low health literacy versus 135/303, 44.6% adequate health literacy, *P*<.001). In the multivariate analysis, when adjusting for age, race, gender, and education level, we found that low health literacy was not significantly associated with a lower likelihood of owning smartphones (OR: 0.8, 95% CI 0.5-1.4; *P*=.52) or using the internet ever (OR: 0.5, 95% CI 0.2-0.9; *P*=.02). However, low health literacy remained significantly associated with a higher likelihood of needing help performing any online task (OR: 2.2, 95% CI 1.3-3.6; *P*=.002).

Conclusions: The majority of participants with low health literacy had access to technological devices and had used the internet previously, but they were unable to perform online tasks without assistance. The barriers patients face in using online health information and other health information technology may be more related to online capabilities rather than to technology access.

When designing and implementing technological tools for hospitalized patients, it is important to ensure that patients across digital literacy levels can both understand and use them.

KEYWORDS

health literacy; digital literacy; hospitalization; technology

Introduction

Technology-based interventions have the potential to improve care transitions; however, they can also exacerbate existing health disparities. For instance, hospitalization represents a time of vulnerable care transitions [1] when technology-based interventions could improve patient engagement and outcomes. Examples include patient portals [2], educational videos [3,4], mobile apps [5], telehealth [6], and remote monitoring [7], which have the possibility of improving patient-provider communication and patient education at the time of hospitalization and discharge, when patients may be coping with a new diagnosis or needing assistance with controlling a chronic disease. However, these interventions can only be broadly effective if all patients are able to access, use and effectively understand them. Historically, the digital divide concept was characterized by differences in access to technology and largely driven by socioeconomic status (SES), age, and race [8]. Currently, with increasing access to technology-based devices, a shift to a digital capability divide may be even more salient [9].

Prior research has shown that health literacy is an important contributor to the digital capability divide, with patients with lower health literacy being 7%-47% less likely to access and have the ability to use technology [10,11]. At the same time, patients with low health literacy have worse health outcomes [12], increased risk of poor vision [13], longer hospital stays [14], increased hospital-to-home transitional care needs [15], and increased readmission risk, especially among older patients [16]. Therefore, technology-based interventions could be a mechanism to improve long-term outcomes for hospitalized patients with low health literacy, while adding complexity for some patients. Research investigating the relationship between health literacy and technology has been primarily conducted among community-dwelling and outpatient populations but has not been evaluated among hospitalized patients.

The relationship between health literacy and technology use may be particularly relevant for hospitalized patients, since many care transition interventions rely on technology. Prior research has also suggested that health literacy is dynamic, with hospitalization representing a period when health literacy may acutely decrease [17]. It is also very likely that technology access and capabilities are not static, but dynamic. Hospitalization provides an important assessment time point to understand if and how technology can be utilized to improve health. Finally, hospitalized patients likely differ from those in community-dwelling or outpatient settings, making them an important population to characterize. Therefore, we sought to determine the relationship between health literacy level and technology access, use, and digital capabilities among hospitalized adult general medicine patients.

Methods

We performed a cross-sectional observational study among adult inpatients at the University of Chicago Medicine as part of a large, ongoing study of inpatient quality of care [18]. Inclusion criteria included being hospitalized on a general medicine service, 18 years or older, and English-speaking. Exclusion criteria included an inability to provide consent and prior participation in the study. The University of Chicago Biological Sciences Division Institutional Review Board approved this protocol (#IRB16-0763).

We used a survey that was comprised primarily of national benchmarked Pew Research Center survey questions [19] that were categorized into 3 domains of technology: access, use, and capabilities. All variables in these domains were binary (yes/no). To assess technology access, participants were asked whether they owned a smartphone, computer, or tablet; whether they had a texting plan; and whether they had Wi-Fi at home. To assess technology use, participants were asked if they used the internet and whether they used the internet for health-related reasons. To assess digital capabilities, participants were asked if they knew how to perform a given online task or if they would need help. A summary measure was constructed for needing help with any online task, in which participants were categorized as needing help if they responded yes to needing help with one or more tasks. Participants were assigned as having either low or adequate health literacy based on the 3-question Brief Health Literacy Screen (BHLS). Each item in the BHLS is scored on a Likert scale from 0 to 4, with a score of 2 or less on any item identifying a participant as having low health literacy [20]. The BHLS and technology survey were orally administered.

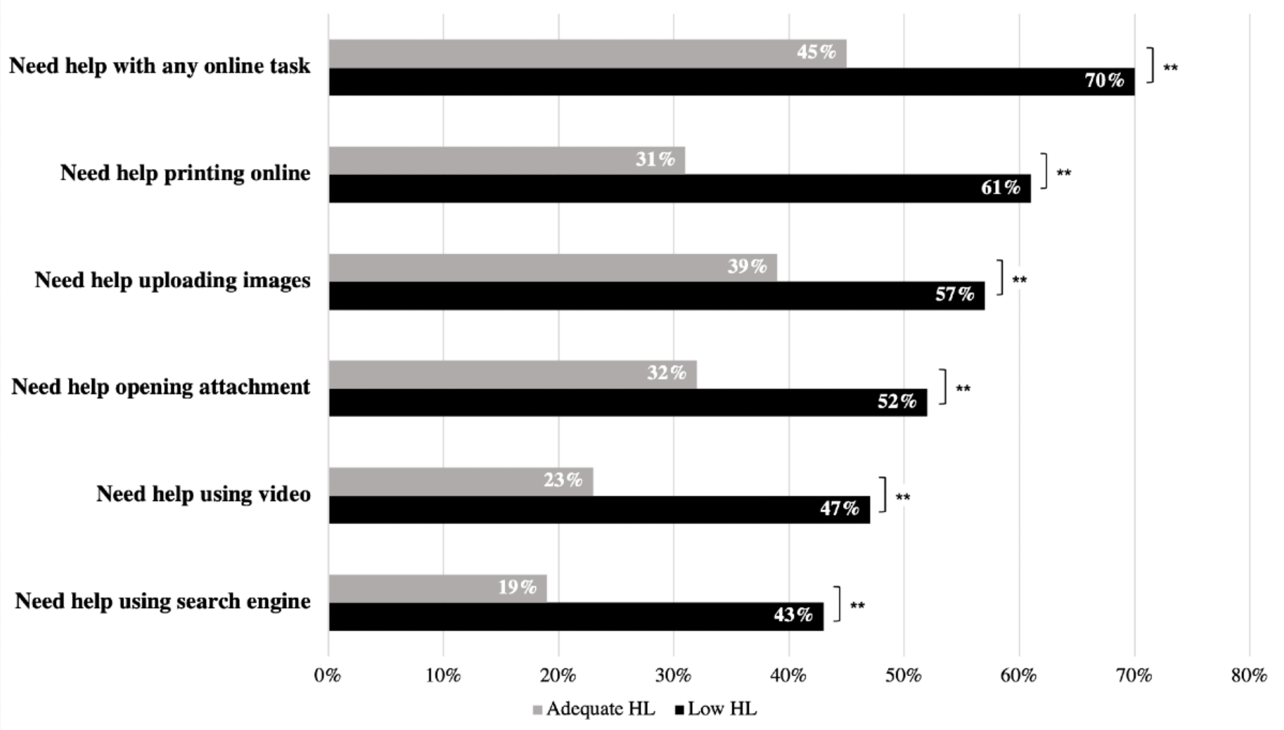
Differences in technology access, use, and capabilities by health literacy level were analyzed using chi-squared tests. Multivariate logistic regression analyses were conducted to determine differences in technology access, use, and capabilities adjusting for health literacy (binary), age (continuous), gender (binary), race (white, non-Hispanic black, other), and education (less than any college versus some college or more). All analyses were performed using STATA version 15.0 (StataCorp), with $P<.003$ defining statistical significance based on Bonferroni correction.

Results

From January 30, 2014 through May 10, 2018, 502 participants were enrolled in the study and completed the survey. Of these 502 participants, the mean age was 51 years, 358 (71.3%) were Black (non-Hispanic), 265 (52.8%) were female, and 253

(50.4%) had at least some college education. Out of 502 participants, 191 (38.0%) had low health literacy. Compared to participants with adequate health literacy, participants with low health literacy were less likely to own a desktop (49/191 [25.7%] low health literacy versus 130/311 [41.8%] adequate health literacy, *P*<.001) or laptop (63/191 [33.0%] versus 173/311 [55.6%], *P*<.001). In contrast, there was no significant difference in ownership of tablets (64/191 [33.5%] versus 139/311 [44.7%], *P*=.01) or smartphones (116/173 [67.0%] versus 235/300 [78.3%], *P*=.007) by health literacy level. Participants with low health literacy were less likely to report using the internet ever (143/189 [75.7%] versus 281/309 [90.9%], *P*<.001), daily internet use (91/189 [48.1%] versus 210/309 [68.0%], *P*<.001), or searching for health information online (95/155 [61.3%] versus 222/288 [77.1%], *P*<.001). Participants with low health literacy were more likely to report needing help for all online tasks queried (Figure 1).

Figure 1. Percent of participants that report needing help with online tasks by health literacy (HL) level. ** demonstrates significance of *P*<.003 for Bonferroni correction. Raw numbers of participants needing help with each task are as follows: Need help with any online task – adequate HL 135/303 (44.6%), low HL 133/189 (70.4%); Need help printing online – adequate HL 95/303 (31.4%), low HL 116/189 (61.4%); Need help uploading images – adequate HL 119/303 (39.3%), low HL 107/189 (56.6%); Need help opening attachment – adequate HL 96/303 (31.7%), low HL 99/189 (52.4%); Need help using video – adequate HL 61/257 (23.7%), low HL 81/172 (47.1%); Need help using search engine – adequate HL 59/303 (19.5%), low HL 82/189 (43.4%).



In multivariate analysis, we found that health literacy remained significantly associated with some aspects of technology access/use, but not others (Table 1). For example, low health literacy was still associated with a lower likelihood of owning a laptop (*P*<.001), but not with owning a smartphone (*P*=.50). Low health literacy level was not significantly associated with a lower likelihood of internet use (*P*=.02) or searching for health information online (*P*=.10). Low health literacy was associated with a higher likelihood of needing help with online tasks overall. Further results from multivariate logistic regression analyses are provided in Multimedia Appendices 1 and 2.

Table 1. The relationship of low health literacy and technology access, use, and capabilities[a].

Low health literacy[b]	OR[c] (95% CI)	*P* value	AOR[d] (95% CI)	*P* value
Technology access				
Own desktop	0.5 (0.3-0.7)	<.001	0.6 (0.4-0.98)	.04
Own laptop	0.4 (0.3-0.6)	<.001	0.5 (0.3-0.8)	.001
Own tablet	0.6 (0.4-0.9)	.01	0.8 (0.5-1.2)	.33
Own smartphone	0.6 (0.4-0.9)	.01	0.8 (0.5-1.4)	.52
Wi-Fi at home	0.4 (0.3-0.7)	<.001	0.7 (0.4-1.0)	.07
Text messaging plan-any	0.3 (0.2-0.6)	<.001	0.3 (0.2-0.7)	.002
Unlimited text plan	0.5 (0.3-0.8)	.007	0.6 (0.3-1.0)	.05
Technology use				
Ever internet use	0.3 (0.2-0.5)	<.001	0.5 (0.2-0.9)	.02
Daily internet use	0.4 (0.3-0.6)	<.001	0.6 (0.4-0.97)	.04
Search health info online	0.5 (0.3-0.7)	<.001	0.7 (0.4-1.1)	.11
Post health info online	0.6 (0.3-0.997)	.05	0.6 (0.4-1.0)	.07
Download app	0.6 (0.3-0.9)	.02	0.8 (0.5-1.4)	.40
Technology capabilities				
Need help with any online task[e]	3.0 (2-4.3)	<.001	2.2 (1.3-3.6)	.002
Need help to print online materials	3.5 (2.4-5.1)	<.001	2.7 (1.7-4.4)	<.001
Need help to upload images	2.0 (1.4-2.9)	<.001	1.4 (0.9-2.2)	.20
Need help to open attachment	2.4 (1.6-3.4)	<.001	1.7 (1.1-2.8)	.03
Need help to use video	2.9 (1.9-4.3)	<.001	2.5 (1.4-4.2)	.001
Need help to use search engine	3.2 (2.1-4.7)	<.001	2.1 (1.3-3.5)	.003

[a] Using Bonferroni correction for the 18 tests, the *P* value threshold for significance is <.003.

[b] Low health literacy is a binary variable where low HL = 0 denotes participants with adequate health literacy and low HL = 1 denotes participants with low health literacy.

[c] OR: unadjusted odds ratio.

[d] AOR: best fit adjusted odds ratio (adjusted for age [continuous], gender [binary], race [white, black, other], and education [less than any college versus some college or more]).

[e] Compilation of all items beginning with "Need help…", with participants categorized as needing help if they responded Yes to needing help with 1 or more of the online tasks listed.

Discussion

We found that despite most participants having access to smartphones and using the internet, hospitalized patients with low health literacy were significantly more likely to need help with online tasks. This raises the question of whether inpatients with low health literacy are able to effectively utilize technology, even if they have access to do so. Although our study suggests that certain devices, such as smartphones, may have appealing interfaces for patients across literacy levels, it also underlines that access is not synonymous with ability. This is consistent with a recent study showing disparities in hospitalized patients' interest in patient portals [21]. Patients who were older, African-American, non-English speaking, or homeless were less likely to want to use patient portals and the second most commonly cited reason for this was an inability to use the internet. If technology is to be implemented more broadly during and after hospitalization for patient use, we must do so in a way that is palatable, engaging, feasible, and equitable for diverse populations. It is not enough to design these resources in a health-literate manner; we must also ensure that patients have the necessary digital skills to utilize them. Interestingly, results from multivariate analyses suggested that in the cases where health literacy is no longer associated with certain technological capabilities (specifically, using a search engine and uploading images), age and education are significantly associated. This suggests that in years to come, as more people are raised with technology, the digital divide will likely shrink. Examining trends of digital capabilities over the period of our study would be interesting future work.

Some hospitals are measuring health literacy among their patients to identify those who may be at high risk for nonunderstanding and poorer health outcomes [22]. In addition, our findings suggest that it may be important to assess digital literacy if hospitals are promoting the use of technology for patients' self-care. It is also possible that a universal approach to digital literacy could be useful. Health literacy universal precautions have been proposed; they encourage providers and health care systems to approach all patients with the assumption that they may not understand health information. This is based on the idea that health literacy is a dynamic process that is not only determined by individuals' abilities but also the complexities of the system [17]. In the same manner, hospitals could approach all patients with universal digital literacy precautions, ensuring that interventions are designed to be accessible and usable for patients across literacy levels and that patients have the ability to utilize technology as part of implementation. Although this requires up-front increased personnel to educate patients, long-term, technological resources could be cost-saving [23].

Recently, electronic health (eHealth) literacy has gained traction as an important aspect of patients' ability to obtain and use information from online sources. eHealth literacy represents a complex interplay between multiple literacies, including health literacy and digital literacy [24], which we measured in this study. However, these two literacies alone likely do not adequately encompass all the skills necessary to effectively utilize technology-based health resources. Future studies could use eHealth literacy assessment tools to determine if and when eHealth literacy should be assessed prior to prescribing technology-based interventions in the hospital setting. Additionally, a recent study found that health literacy and eHealth literacy were not significantly correlated [25], suggesting that both may need to be studied to determine patients' abilities to use technology-based health resources. Future studies could aim to examine eHealth literacy among hospitalized patients and whether health literacy, digital literacy, and eHealth literacy are correlated.

Limitations of our study include being a single-site study and using self-reported measures of technology access, use, capabilities, and health literacy. Further, our study did not measure eHealth literacy directly. Future studies could focus specifically on the eHealth literacy of hospitalized patients and how it relates to their ability to use health technologies during and after hospitalization.

In summary, our results indicated that health literacy is an important contributor to the digital capability divide among hospitalized patients and helped to identify areas of future research. Technology provides both opportunities for improvement during care transitions and potential pitfalls. To mitigate these pitfalls, health literacy and digital literacy should be accounted for when considering how best to implement technology-based interventions across hospital-to-home transitions of care.

Abstract

Background: Increased access to the internet has facilitated widespread availability of health information. Thus, electronic health (eHealth) literacy—the ability to seek, find, understand, and appraise health information from electronic resources and apply that knowledge in making a health-related decision—is a crucial skill. Despite the increasing use of the internet as a source of health information in developing countries, only a few studies have examined the eHealth literacy of young adults, who frequently use the internet to access health information in these developing countries.

Objective: The aim of this study was to assess the patterns of internet use and eHealth literacy levels among university students pursuing a non–health-related degree in Pakistan. We also examined the association of the eHealth literacy levels of these young adults with their physical activity levels and dietary supplement intake.

Methods: Students from 2 leading engineering universities in Pakistan were invited to participate in a cross-sectional anonymous web-based survey in order to collect data on their internet use, eHealth literacy, and dietary supplement intake. Of the 900 eligible university students who were invited to participate, 505 (56.1%) students who completed the questionnaire were included in the analysis. The findings were converted to median values and frequency analyses were performed. The associations between the variables were determined using the chi-square test; $P \leq .05$ was considered significant.

Results: In this study, the median eHealth literacy scale (eHEALS) score was 29, which did not vary across gender. The most common type of health-related information that was searched by the participants was that related to maintaining a healthy lifestyle (305/505, 60.4%). Participants with high eHEALS scores were those who used the internet frequently for finding people with similar health issues ($P<.001$). The use of specific social media platforms was not associated with the perceived eHealth literacy levels. Neither the frequency of physical activity nor the dietary supplement use was associated with the eHealth literacy of the participants.

Conclusions: University students in non–health-related disciplines in Pakistan expressed high confidence in their skills to find health-related information on the internet, as indicated by the aggregate eHEALS scores. However, the findings of our study show that the perceived eHealth literacy was not associated with health behaviors such as physical activity and dietary supplement intake. Further research is necessary to investigate the extent to which eHealth literacy can be considered as a panacea for solving public health challenges in developing countries.

Introduction

The role of internet and smartphone ubiquity in health care improvement, particularly in a resource-constrained developing world, has gained global interest in the past decade [1]. Under the umbrella terms of electronic health (eHealth) and mHealth, researchers have investigated possible ways in which the proliferation of smartphone devices and internet platforms can be used to improve health education and health outcomes in the developing world [2].

In developed countries such as the United States and Japan, more than 70% of the population has reported the use of internet as the primary source of information, especially for self-care management; similarly, in developing countries, the use of internet for accessing health information has been rapidly increasing [3,4]. This trend is not surprising, considering the tech savviness of young adults and the easy accessibility to the internet. However, these web-based health interventions or programs cannot be executed as technical programs in a vacuum, ignoring the complex contexts in which they are implemented [5]. Therefore, in digital health literacy, it is important that consumer-focused electronic resources are designed such that they are aligned with the literacy levels of the intended audience. eHealth literacy is identified as an important skill set for eHealth users, and it refers to the ability of an individual to seek, find, understand, and appraise health information from electronic resources and apply such knowledge to addressing or solving a health problem [6]. The eHealth literacy scale consists of several levels, which show the set of skills that are required to effectively engage the use of information technology for improving health. The lower levels of the scale comprise operational and navigational skills, while the higher levels require the ability to choose and critically evaluate the available information [7]. eHealth literacy can help developing countries access web-based health information resources effectively. Studies examining eHealth literacy [4,8-11] have largely been performed in developed countries such as the United States, Finland, China, and Japan—with particular emphasis on young adults and college students. However, only a few studies have identified an association between eHealth literacy and health behaviors, while even fewer studies have examined the association between eHealth literacy and the health behaviors of young adults in developing countries [12].

Despite the increasing use of the internet as a source of health information in developing countries, eHealth literacy is an unexplored entity, which has been created and refined by the developed world [13]. While technology-based health information is being proposed as the solution to elevate the health literacy levels of the Pakistani population [14], there is very limited investigation of the eHealth literacy of the health seekers—with focus only on those seeking health-related education [15]. The latest National Human Development Report of Pakistan [16] highlighted that only little is known about the health literacy and the health behaviors of Pakistani youths—especially among those who are well-educated and frequent users of the internet.

Therefore, in this study, we aimed to examine the association between the patterns of internet use for seeking health information and the eHealth literacy of university students in Pakistan. Further, we investigated the possible association of eHealth literacy with the health behaviors (physical exercise and dietary supplement intake) of these university students.

Methods

Participants

Eligible participants in this study were Pakistani university students aged 18 years or above and they were enrolled in an undergraduate or a postgraduate course primarily in any degree other than in medical or health sciences. The convenience sample of the participants was approached using the university group email lists (N=900) of 2 leading engineering universities in Pakistan by one of the investigators (AB). Participants were expected to have adequate computer skills as they studied in engineering universities with sophisticated technical infrastructure.

Measurements

A quantitative cross-sectional design was used to conduct this research. Students enrolled in the universities had to meet the English language requirements prior to admission, as the mode of instruction in the anonymous web-based survey was English. Therefore, all the participants had to comprehend and answer the questions in English. The survey instrument was developed based on a review of previous studies consisting of validated items [8,17,18]. The questionnaire consisted of the following key items.

1. Demographic data and patterns of internet use: This item consisted of questions on participant age, gender, and education level. The internet use patterns were explored by asking questions on the frequency of internet use for browsing health information and common health-related topics. These questions were designed on the basis of previous studies exploring the patterns and reasons for seeking web-based health information [17]. Finally, participants rated their frequency of using Google and other social media platforms as a venue for seeking health information on a scale of 1 to 5 (1=Never, 5=Very Often). The participants rated the following social media platforms: Google, WhatsApp, Twitter, Snapchat, Instagram, and Facebook [8].
2. Perceived eHealth literacy: eHealth literacy was measured using the English version of the eHealth literacy scale (eHEALS) [18], which is an 8-item instrument measured on a 5-point Likert-type scale ranging from 1 (strongly disagree) to 5 (strongly agree). The eHEALS scores ranged from 8 to 40, wherein a high score indicates high perceived eHealth literacy and a low score indicates low perceived eHealth literacy.
3. Health behaviors: Physical activity was assessed through questions on the weekly frequency of moderate physical activity. Supplement intake was assessed through questions on the use of dietary supplements. For those who used dietary supplements, further information was requested on the type of supplement used.

The ethical approval for this study was obtained from the Human Research Ethics Committee (Approval number: 1700000897) of Queensland University of Technology. This study has been reported in accordance with the Checklist for Reporting the Results of Internet E-Surveys [19].

Survey Validation and Administration

A pilot test of the survey was completed with a sample of 14 undergraduate university students in Pakistan to ensure that the target audience understood the meaning of each question and response. The pilot feedback was used to edit the survey accordingly. The revised survey was administered using the web-based Key Survey tool. We believed that a web-based survey would be appropriate for this study because responders to such surveys can use the computer and internet effectively. The identified eligible participants were sent the link to the web-based survey via their university group email and 1 reminder was sent to give them the opportunity to complete the survey if they had not already done so. The participation in this survey was voluntary and no incentives were offered for participation. The survey remained open for 6 weeks (December 2017 to January 2018).

Data Analysis

A data matrix was produced from the completed questionnaires by using SAS 9.4 for Windows (SAS Institute Inc). Qualitative variables were expressed as numbers and percentages. The percentages were calculated based on the valid cases only. The chi-square test was performed to determine the association between the variables. $P \leq .05$ was considered significant. The total scores of the eHEALS were summed to a range from 8 to 40, with high scores representing high self-perceived eHealth literacy. We divided the eHEALS score into one of the 2 categories (high or low) relative to the median group value (median 29, IQR 26-32); we did this in accordance to that done in previous studies [4,8] that used eHEALS to analyze the associations between the frequency of seeking health information, eHealth literacy, and health behaviors.

Results

Participants’ Demographic Data and Internet Use Patterns

Of the 900 eligible students invited to participate, 559 (62.1%) students logged onto the web-based questionnaire platform and 505 (56.1%) students completed the questionnaire by providing all the demographic information; thus, 505 students were included in the final analysis (Table 1). Of these 505 students, 211 (41.8%) students were females; 88.1% (445/505) of the participants were younger than 25 years and 85.3% (431/505) of them were pursuing an undergraduate degree. We found that 79.6% (402/505) of the participants were identified as frequent users of the internet (almost every day); 11.1% (56/505) of the participants reported using the internet for searching health-related information almost every day, while 46.1% (233/505) used it once a week or more.

Table 1. Demographic data and internet use patterns of the participants (n=505).

Demographic data and frequency of internet use	Value, n (%)
Age (years)	
16-25	445 (88.1)
26-30	38 (7.5)
30+	22 (4.2)
Gender	
Male	294 (58.2)
Female	211 (41.8)
Education level	
Undergraduate degree	431 (85.3)
Postgraduate	74 (14.6)
Frequency of internet use	
Almost everyday	402 (79.6)
Several days a week (≥1 day)	88 (17.5)
Less than once a week or never	15 (3.0)
Frequency of internet use for health-related information	
Almost everyday	56 (11.1)
Several days a week (≥1 day)	233 (46.1)
Less than once a week or never	216 (42.7)

Internet Use Patterns and eHealth Literacy

With regard to eHealth literacy, only 399 participants who used the internet for finding health-related information answered the 8 standard eHEALS questions. The median eHEALS score was 29 and this value did not vary with gender or the education level. Based on the eHEALS score, the participants were divided into 2 groups: the first group had scores higher than the median eHEALS score (191/399, 47.8%) while the second group had scores lower than the median eHEALS score (208/399, 52.1%). The most common type of health-related information searched by the participants (305/505, 60.4%) was that related to healthy lifestyle (weight, exercise, etc)—this was common among both high and low eHealth literacy groups. However, those with high perceived eHealth literacy reported that they used the internet over the last 12 months more often for finding people with similar health issues (*P*<.001) (Table 2). Google was the most widely used search engine. Of the 401 participants who reported frequent use of Google, 365 (91.0%) used Google to obtain health-related information. With regard to other social media platforms, 64.0% (199/311) of the participants who used Facebook, 59.6% (171/287) of the participants who used Wikipedia, and 15.0% (40/265) of the participants who used Twitter reported that they used these platforms to obtain or share health-related information. The use of any of these specific social media platforms was not associated with the perceived eHealth literacy.

Health Behaviors and eHealth Literacy

Overall, 25.9% (119/459) of the participants reported engaging in moderate physical activity more than five times a week, while 23.5% (108/459) of the participants engaged in moderate physical activity less than once a week. The perceived level of eHealth literacy was not associated with the reported levels of physical activity (Table 3). Some form of supplement was taken by 48.7% (220/452) of the participants. Vitamin D supplements were reported as the most commonly used supplement (177/413, 42.9%). Dietary supplement use was significantly associated with gender (*P*=.002), with females more likely to use supplements as compared to males. The perceived level of eHealth literacy was not associated with the reported supplement use patterns (Table 3).

Table 2. Association between internet use patterns and eHealth literacy (n=399).

Internet use patterns and eHealth literacy	Value, n (%)		*P* value
	eHEALS[a] Low	eHEALS High	
Frequency of internet use for health-related information			.02
Several days a week or more	62 (44.3)	78 (55.7)	
Once a week or less	146 (56.4)	113 (43.6)

Multivitamins (not containing vitamin D)	8 (42.1)	11 (57.9)	.37

[a] eHEALS: eHealth literacy scale.

Discussion

To our knowledge, this study is one of the very few studies that have examined the eHealth literacy levels among young adults in developing countries and the association of eHealth literacy with internet use patterns and health behaviors. After controlling for the sociodemographic variables, we found that eHealth literacy was not associated with health behaviors such as physical activity and dietary supplement intake. Although there is evidence that eHEALS may consist of several subscales, we analyzed the eHEALS as a unidimensional factor, following Hyde's recommendation [20]. Therefore, our analysis considers the full eHEALS, which also allows us to compare our results with those of other studies [8].

Our population consisted of university students pursuing an engineering degree in Pakistan; the median eHEALS score in our study was similar to that reported among young adults seeking a health-related degree in Pakistan [15]. Further, the median eHEALS score in this study was comparable to that reported previously in an adult population in the United States (mean eHEALS score, 29.0), slightly higher than that reported in the adult populations of Korea, Iran, and Kuwait (mean eHEALS scores, 28.0, 28.2, and 28.6, respectively), and much higher than that reported in an adult population in Japan (mean eHEALS score, 23.4) [4,8-10]. Similar to that reported in previous studies, most sociodemographic variables (eg, gender, age) examined in this study were not significant predictors of eHealth literacy [4,8-10]. As reported previously [4,10], it is possible that the geographical location and cultural and language barriers could affect the eHEALS scores because of limited availability of health-related information in languages other than English. This may not be the case for the population in this study as English is the official medium of instruction in the Pakistani university educational system and participants in this study are frequent users of the internet.

Unlike the findings of recent studies from the United States and Japan [4,21] that showed a significant association between eHEALS scores in young adults and health behaviors such as exercise, we found no association between eHEALS scores and the reported physical activity levels. In Pakistan, very few studies have investigated how digital health literacy can improve health behaviors. In 2018, Saeed et al [22] evaluated the digital health literacy of patients with type 2 diabetes (N=204) in Lahore, Pakistan, and they reported that patients with high socioeconomic status agreed that access to digital medical content via smartphones and tablets helped them improve their health. However, only the use of internet and the high eHealth literacy levels among educated young adults cannot translate into health behavior improvements (eg, increase in the physical activity levels) if the communities that they live in lack the needed infrastructure to facilitate the required physical activity programs. It is important to note that developing countries such as Pakistan—unlike Japan and the United States—lack culturally suitable infrastructure (eg, safe outdoor facilities for young women) and civic amenities such as playgrounds, parks, and gyms (even within universities) [23,24]. The lack of such facilities inhibits the realization of positive health behaviors and encourages indoor sedentary lifestyles [16].

We also found that there was no significant association (P=.25) between eHealth literacy and dietary supplement intake. Recent studies from developed countries have reported internet as the primary source of information to inform attitudes toward the use of dietary supplements among young adults [25,26]. Recent evidences have shown that eHealth literacy influences the food choices of adolescents [27]. In the last few years, Pakistan has witnessed a rise in the demand for nutraceuticals; dietary supplements attained a compound annual growth rate of 14% in 2016 [28]. These nutraceuticals are mostly used by the educated population [29]. In light of these interesting preliminary trends, future research should focus on the effects of the patterns of internet searches and social behaviors on supplement intake. The aspects around eHealth literacy and its association with health behaviors such as dietary supplement use have not been reported in any developing country to date, to the best of our knowledge. This study presents a valuable contribution to establish evidence, in particular, for a country facing pressures to improve health literacy and public health outcomes.

This study has several limitations. First, the participants were recruited from a convenience sample of university students in Pakistan; thus, the relationships assessed may have been biased because of the potentially non-representative nature of this sample. However, this approach was viable because it provided us with a sizable sample in a reasonable amount of time for a population wherein such investigations have not been performed previously. Our study presents the needed ground to build on future studies that explore the eHealth literacy of broad population groups so that the findings can be applied to other developing countries. Second, as in previous studies, health behavior and eHealth literacy were examined using a self-administered questionnaire. Thus, inaccuracies in estimating the health behavior and eHealth literacy level were unavoidable, and data of some of the participants were missing. In addition, we did not investigate the specific health status of the participants or whether they were searching for health-related information for another family member. Moreover, this study was limited to only examining supplement use as a dietary behavior. Future studies should explore additional dietary behaviors (eg, nutritional intake, smoking) and the context for using the internet for health-related information. Our findings revealed high eHEALS scores among the participants. This high confidence shown by the university students presents a myriad of opportunities to better engage people digitally and conveniently. As internet is being increasingly used as a source of health information, further research is needed to identify the mechanisms linking eHealth literacy with health behaviors toward designing contextually effective strategies for improving self-care in developing countries.

Acknowledgments

This research was financially supported by Queensland University of Technology Early Career and Research Development grant. We thank the administration staff in the participating universities for their assistance in questionnaire distribution and collection throughout the study period.

Authors' Contributions

AT and SK conceived and designed this study. AB and AT conducted the data collection. All authors contributed to the analysis and interpretation of data. AT wrote this manuscript with all co-authors commenting on the drafts of the paper. All authors gave their approval for the final version to be published.

Abstract

Background: Although online physician rating information is popular among Chinese health consumers, the limited number of reviews greatly hampers the effective usage of this information. To date, little has been discussed on the variables that influence online physician rating from the users' perspective.

Objective: This study aims to investigate the factors associated with the actual behavior and intention of generating online physician rating information in urban China.

Methods: A web-based cross-sectional survey was conducted, and the valid responses of 1371 Chinese health consumers were recorded. Using a pilot interview, we analyzed the effects of demographics, health variables, cognitive variables, and technology-related variables on online physician rating information generation. Binary multivariate logistic regression, multiple linear regression, one-way analysis of variance analyses, and independent samples *t* test were performed to analyze the rating behavior and the intentions of the health consumers. The survey instrument was designed based on the existing literature and the pilot interview.

Results: In this survey, 56.7% (778/1371) of the responders used online physician rating information, and 20.9% (287/1371) of the responders rated the physicians on the physician rating website at least once (posters). The actual physician rating behavior was mainly predicted by health-related factors and was significantly associated with seeking web-based physician information (odds ratio [OR] 5.548, 95% CI 3.072-10.017; *P*<.001), usage of web-based physician service (OR 2.771, 95% CI 1.979-3.879; *P*<.001), health information-seeking ability (OR 1.138, 95% CI 0.993-1.304; *P*=.04), serious disease development (OR 2.699, 95% CI 1.889-3.856; *P*<.001), good medical experience (OR 2.149, 95% CI 1.473-3.135; *P*<.001), altruism (OR 0.612, 95% CI 0.483-0.774; *P*<.001), self-efficacy (OR 1.453, 95% CI 1.182-1.787; *P*<.001), and trust in online physician rating information (OR 1.315, 95% CI 1.089-1.586; *P*=.004). Some factors influencing the intentions of the posters and nonposters rating the physicians were different, and the rating intention was mainly determined by cognitive and health-related factors. For posters, seeking web-based physician information (β=.486; *P*=.007), using web-based medical service (β=.420; *P*=.002), ability to seek health information (β=.193; *P*=.002), rating habits (β=.105; *P*=.02), altruism (β=.414; *P*<.001), self-efficacy (β=.102; *P*=.06), trust (β=.351; *P*<.001), and perceived ease of use (β=.275; *P*<.001) served as significant predictors of the rating intention. For nonposters, ability to seek health information (β=.077; *P*=.003), chronic disease development (β=.092; *P*=.06), bad medical experience (β=.047; *P*=.02), rating habits (β=.085; *P*<.001), altruism (β=.411; *P*<.001), self-efficacy (β=.171; *P*<.001), trust (β=.252; *P*<.001), and perceived usefulness of rating physicians (β=.109; *P*<.001) were significantly associated with the rating intention.

Conclusions: We showed that different factors affected the physician rating behavior and rating intention. Health-related variables influenced the physician rating behavior, while cognitive variables were critical in the rating intentions. We have proposed some practical implications for physician rating websites and physicians to promote online physician rating information generation.

KEYWORDS

online physician rating; user-generated content; physician rating website; behavioral intention; actual behavior

Introduction

With the development of user-generated content and prevalent use of mobile devices, some industries (ie, food service, travel, and e-commerce) have begun gathering web-based reviews, because of which many websites of these industries have now become reliable and effective [1]. The health care system has also started garnering web-based reviews, even though the development of the review platform was slow in the initial years. Similar to how people review products, health consumers can post their opinions on the health care received and have access to other patients' opinions on the care they received from physicians. In particular, information on physician rating websites seems to play an increasingly important role in the life of health consumers and has attracted the attention of medical practitioners. A study [2] showed that in 2007, only 3%-7% of the health consumers in the United States used physician rating websites, but the proportion increased to 23% in 2012 [3], 25% in 2013 in Germany [4], 42% in 2014 in the United States [5], and 43.6% in 2016 in Germany [6]. Online physician rating information is an important factor that seems to increasingly influence a patient's choice of medical practitioners [7]. On the contrary, physicians have always reported a negative attitude toward online physician rating information [8-10] because they fear that limited reviews could produce bias and negative web-based reviews could ruin their reputation [11,12]. Previous studies have shown the content analyses of physician rating websites in different clinical specialties [13-16], and the average number of reviews per physician was found to be low [17-19], even though the number of reviews has increased rapidly in the past few years [20]. Emmert et al [4] reported that only 11.03% of the Germans had posted ratings on a physician rating website in 2013, while this percentage increased to 23% in 2016 [6]. The limited number of reviews is the key factor that has affected the adoption of online physician rating information by both physicians and consumers. Thus, it is important to investigate the factors that predict the generation of online physician rating information from the perspective of health consumers.

Previous studies have mainly focused on the usage of online physician rating information and the related factors. Terlutter et al [21] reported that women, young adults, and people with higher education levels or chronic diseases used physician rating websites more than their counterparts. Galizzi et al [22] found that white British people and people with high incomes were less likely to use physician rating websites. Further, female participants, widows, and those with high health care utilization showed a significantly high likelihood of being aware of physician rating websites [4]. In China, due to the promotion of the "internet + health care" strategy by the government, physician rating websites are becoming increasingly popular among urban citizens. Hao et al [23-25] conducted a content analysis of Chinese physician rating websites and identified factors that were related to physician ratings. Zhang et al [26] analyzed the negative comments on physician rating websites to identify the possible solutions for improving patient satisfaction. Li et al [27] developed a hierarchical topic taxonomy to uncover the latent structure of the physician reviews and illustrated its application in mining data on patients' interests. Deng et al [28], Han et al [29], and Li and Hubner [30] investigated how web-based ratings and other factors influence the selection of physicians by the Chinese consumers. However, studies on physician rating websites in the Chinese context are still limited and little is known about the factors influencing the generation of online physician rating information.

To fill this research gap, we first conducted a web-based pilot interview and recruited 30 Chinese citizens with different education levels, occupational backgrounds, and hometowns. We introduced several Chinese physician rating websites at the beginning of the interview; thereafter, the participants reported their experience of using the physician rating websites. Only 5 of the 30 participants generated online physician rating information. Finally, participants were asked why they did or did not generate online physician rating information. Following the procedure of qualitative analysis, 3 researchers transcribed and coded the data, and we finally identified the factors related to the generation of online physician rating information. These factors were divided into three dimensions, namely, health and habit-related factors (ie, usage of web-based physician service, ability to seek health information, health conditions, experience of medical service, and rating habits in the e-commerce context), cognitive factors (ie, altruism, self-efficacy, and trust in online physician rating information), and technology-related factors (ie, perceived usefulness and perceived ease of use). Cognitive factors were often reported to be associated with knowledge-sharing behavior [31], and technology-acceptance factors were often associated with system adoption [32]. The use of physician rating websites to rate physicians signifies knowledge-sharing and system-adoption behavior. In this study, we applied a similar procedure used by Terlutter et al [21], Galizzi et al [22], and Emmert et al [4] to empirically explore the significant factors that predict the actual behavior and intention of rating the physicians on the physician rating websites. The results of this study will be useful for understanding the web-based rating behavior of health consumers and for further promoting the development of physician rating websites.

Methods

Participant Recruitment

Since physicians in rural areas are seldom rated on physician rating websites [23], our study focused on physicians in the urban regions of China. We used the snowball sampling method to recruit participants through web-based social networking. First, we selected 160 WeChat friends with varying gender, education levels, and occupational backgrounds to complete the web-based questionnaire. Second, we requested these participants to invite friends with varying genders, education levels, and occupational backgrounds to participate in the web-based survey. In total, we received 1556 responses from September 2018 to October 2018 and from August 2019 to October 2019. Among the total number of responders, 185 were excluded from the analysis because of inconsistent answer patterns (eg, flatliners, contradictions) or because the participants tried to complete the questionnaire quickly with incomplete answers in a short span of time. Finally, this study considered the responses of 1371 valid respondents. We paid each participant 2 RMB (US $0.3) to compensate for their time.

Questionnaire Design

The researchers designed a survey based on the existing literature [21,22] and their pilot interview. All items, except categorical variables, were measured using a 7-point Likert scale, with the options ranging from “strongly disagree” to “strongly agree” (Multimedia Appendix 1). To ensure the validity of the scale in our questionnaire, we adopted measurement items from the existing literature and we modified some items to adapt to the online physician rating scenario based on our first pilot study with 30 Chinese citizens. We calculated the mean values of the multiple items as predictor scores after checking the measurement’s internal reliability.

The questionnaire was created in English. One researcher translated it into Chinese, and then another researcher translated it back into English to ensure the consistency of the content. After developing the Chinese questionnaire, 3 researchers in health informatics were invited to assess the ease of understanding, logical consistencies, item sequence, and contextual relevance of the items in the questionnaire. We made some minor modifications based on their suggestions. Furthermore, a pilot test was conducted with 20 participants, and the items were modified slightly.

Measurements

Rating Behavior, Rating Intention, and Demographic Variables

To ensure that the respondents understood the online physician rating system, a screenshot of a physician rating website was presented in the introductory phase before the respondents answered the questions. The actual behavior of rating a physician was assessed by asking if the respondents had rated physicians on physician rating websites previously (0=no, 1=yes). We defined participants as posters if they had rated a physician on a physician rating website at least once and we defined participants as nonposters if they had never rated a physician on the physician rating website. The intention of rating a physician was assessed using a 3-item scale adapted from the study of Ajzen [33]. This scale was found to be reliable (mean 5.064, SD 1.189; Cronbach α=.949). Additionally, data on demographic variables such as age, gender, education level, marital status, monthly income, daily internet use, and the number of vulnerable family members were also collected (Multimedia Appendix 1).

Health and Habit-Related Variables

The usage of web-based physician information was assessed by asking respondents if they had ever sought physician information on the internet (0=no, 1=yes). The usage of web-based physician service was assessed by asking participants if they had ever booked or consulted a physician on the internet (0=no, 1=yes). The ability to seek health information was assessed using 2 items adapted from the model developed by Richard et al [34]. The scale (mean 4.649, SD 1.350; Cronbach α=.890) assessed the participant’s ability to search for web-based health information. The health conditions of the participants or their family members were measured using the following 2 questions: “Did you or your family members develop any chronic disease in the past 2 years?” and “Did you or your family members develop any serious disease in the past 2 years?” (0=no, 1=yes). Medical experience was measured using the following questions: “I had a very good medical experience in the past 2 years” and “I had a very bad medical experience in the past 2 years” (0=no, 1=yes). In the e-commerce era, some consumers have the habit of posting reviews after performing web-based transactions, and the habit was found to be effective in the online physician rating scenario in our pilot interview. The following rating habit in the e-commerce context was assessed using an item adapted from a previous study [35]: “Rating the product after a web-based transaction has become a habit for me” (1=strongly disagree, 7=strongly agree).

Cognitive Variables

Altruism is a behavior intended to benefit another, even when this action may involve sacrificing one’s welfare [36]. A 3-item scale on altruism was adapted from previous studies [37,38] and applied in our pilot interview. This scale was found to be reliable (mean 5.438, SD 1.042; Cronbach α=.910). Self-efficacy refers to the belief or the estimate of an individual about his/her own ability to perform a particular task [39]. The self-efficacy scale was adapted from prior studies and applied in our pilot interview [40,41], and the scale was found to be reliable (mean 4.594, SD 1.202; Cronbach α=.770). Trust refers to a situation in which one party willingly relies on the actions of the other party [42]. The scale for trust in online physician rating information was adapted from a previous study [43], and this scale was also found to be reliable (mean 4.711, SD 1.224; Cronbach α=.885).

Technology-Related Variables

Perceived usefulness refers to the usefulness of using physician rating websites to rate physicians, and perceived ease of use refers to the ease of using physician rating websites to rate physicians. Based on our pilot interview and previous studies [44,45], we adapted reliable scales for perceived usefulness (mean 5.147, SD 1.162; Cronbach α=.842) and perceived ease of use (mean 4.405, SD 1.127; Cronbach α=.742).

Data Analysis

Data were downloaded from the web-based questionnaire database to computers in our laboratory in Nanjing University, China. Two independent research assistants examined the data and removed 185 unqualified cases. Data analyses were conducted using the SPSS 23.0 software (IBM Corp). We examined the descriptive statistics for all the variables. Since we focused on participants who were aware of physician rating websites before completing our survey, binary logistic regression analysis was performed to examine the effect of the variables on the likelihood of generating online physician rating information. Multiple linear regression, one-way analysis of variance (ANOVA), and independent samples *t* test (two-tailed) were performed to investigate the different factors influencing the physician rating intentions of the posters and nonposters. We applied data screening procedures to identify problematic patterns within the data set before performing linear regression. Linear relationship, multivariate normality, multicollinearity tested by variance inflation factors (VIFs), autocorrelations tested by Durbin-Watson, and homoscedasticity were tested, and we found that the data could be used for further linear regression. A bootstrapping procedure (with 5000 bootstrap samples) was used in our regression models.

Results

Demographic Data of the Participants

The demographic characteristics of the participants are presented in Table 1. The age range of most of the participants was between 25 and 40 years. Out of the 1371 participants, 789 (57.6%) were women and 980 (71.5%) were married. The monthly income of 69.1% (947/1371) of the participants ranged between 3000 RMB (US $435) and 12,000 RMB (US $1740). With respect to the education level, 68.5% (939/1371) of the participants had completed college or higher level of education. Of the 1371 participants, 778 (56.7%) used online physician rating information and 287 (20.9%) rated the physicians on physician rating websites.

Factors Associated With the Actual Behavior of Rating Physicians on Physician Rating Websites

We focused on participants who were aware of physician rating websites before our survey (n=972), and Table 2 and Table 3 show the results of 4 binary logistic regressions. In the first step, a binary logistic regression between having rated a physician or not (yes=1, no=0) as the criterion and demographic variables was performed (Model 1). Model 1 was significant. Age (β=.146; *P*=.06), monthly income (β=.197; *P*=.003), and education level (β=–.308; *P*=.02) were significantly associated with the likelihood of rating a physician on physician rating websites. However, we also noticed that Nagelkerke R^2 (.041) was quite low, and –2 log-likelihood (1130.138) was high. The results indicated that demographic variables only explained a small part of the actual rating behavior.

Then, we entered the health- and habit-related variables into regression Model 2. The model improved with a Nagelkerke R^2 change of 0.238. The regression coefficients were significant for the following variables: experience of seeking physician information on the internet (β=1.713; *P*<.001), usage of web-based physician service (β=1.019; *P*<.001), ability to seek health information (β=.129; *P*=.04), development of serious diseases (β=.993; *P*<.001), and good medical experience (β=.765; *P*<.001). We also noticed that gender (β=.410; *P*=.02) and marital status (β=–.441; *P*=.047) were significant factors associated with the actual rating behavior, while age (β=.116; *P*=.16) was not significant after health-related factors were considered.

Following Model 2, cognitive variables were entered into Model 3, which were also significant (*P*<.001). Furthermore, Model 3 showed a minor improvement over Model 2, with increased Nagelkerke R^2 change of 0.035. The significant factors in Model 2 mentioned above were still significant. Altruism was negatively (β=–.492; *P*<.001) related to the likelihood of rating physicians. Self-efficacy (β=.374; *P*<.001) and trust in online physician rating information (β=.274; *P*=.004) were significantly and positively related to the likelihood of the rating behavior.

Based on Model 3, technology-related variables were entered into Model 4. However, no improvement was observed in Nagelkerke R^2 and the regression coefficients of perceived usefulness (*P*=.42) and perceived ease of use (*P*=.33) were not significant. Significant variables in Model 2 and Model 3 were also significant in Model 4.

Besides the reliability indices mentioned above, collinearity statistics using VIF and tolerance values were tested. The results showed that VIF scores did not exceed 2.479, and tolerance values were not lower than 0.411. According to the criteria proposed by Montgomery and Peck [46] that VIF should be lower than 10 and tolerance value should be more than 0.1, our results indicated that multicollinearity was not a big concern.

Table 2. Binary logistic regressions for online physician rating behavior (Model 1-2).

Predictive Factors for the Intention of Rating a Physician on Physician Rating Websites

To investigate how the variables influence the rating intention of the participants differently, we divided the samples into 2 groups, namely, posters group and nonposters group. Using hierarchical multiple regression analyses, we tested the effects of different dimensions of the factors on the rating intention. By controlling the demographic variables, we found that health-, cognitive-, and technology-related variables explained 21.3%, 38.1%, and 5.5% of the increased variance in the rating intention of the posters and 12.8%, 48.1%, and 0.4% of the increased variance for nonposters, respectively. The VIF and tolerance values showed that multicollinearity was not a concern in any model.

Table 4 displays the final models. For posters who rated the physicians on the physician rating websites, health and habit-related variables, that is, seeking physician information on the internet (β=.486; *P*=.007), using web-based medical services (β=.420; *P*=.002), ability to seek health information (β=.193; *P*=.002), and habits of ratings (β=.105; *P*=.02) were found to be significantly and positively related to the rating intention. The cognitive variables, that is, altruism (β=.414; *P*<.001), self-efficacy (β=.102; *P*=.06), and trust in online physician rating information (β=.351; *P*<.001) were also significant predictors of the rating intention. Perceived usefulness was not significantly associated with the rating intention (β=–.031; P=.63), while perceived ease of use (β=.271; P<.001) was a significant predictor.

For nonposters who did not rate the physicians on the physician rating websites, usage of web-based medical service (β=.077; P=.003), development of chronic disease (β=.092; P=.06), bad medical experience (β=.047; P=.02), and habits of ratings (β=.085; P<.001) were found to be significantly associated with the rating intention. Similar to that observed in the posters group, altruism (β=.411; P<.001), self-efficacy (β=.171; P<.001), and trust (β=.252; P<.001) were also found to be the predictors of the rating intentions of nonposters. Since nonposters did not post web-based physician reviews, perceived ease of use (β=.017; P=.505) was not significantly associated with the rating intention, but perceived usefulness (β=.109; P=.001) was a significant predictor of the rating intention.

[c] Sig.: significance probability.

Furthermore, we used one-way ANOVA and independent samples t test to compare the differences between posters (n=287) and nonposters (n=1084) on the rating intention and related factors. Following the suggestion by Fritz et al [47], Cohen d was used to estimate the effect size. It can be seen from Table 5 that posters had a higher level of rating intention than nonposters (t_{1369}=5.569; P<.001). Regarding self-efficacy, the 2 groups differed as expected (t_{1369}=5.771; P<.001), with posters ascribing higher self-efficacy than the nonposters. Table 5 also indicated that posters trusted the information on physician rating websites to a greater extent than nonposters (t_{1369}=5.549;

$P<.001$). The 2 groups did not differ significantly in altruism at $P<.05$ level ($t_{1369}=1.697$; $P=.09$). Additionally, posters perceived higher levels of usefulness ($t_{1369}=3.020$; $P=.003$) and ease of use ($t_{1369}=3.928$; $P<.001$) than nonposters. With regard to the effect size, a Cohen *d* value of 0.2 indicated a small effect and a value of 0.5 indicated a medium effect. Thus, the effect sizes for rating intention, self-efficacy, and trust were found to be medium, while the effect sizes for perceived usefulness and perceived ease of use were found to be small.

Table 5. Differences between posters and nonposters in the rating intention and related factors.

Variables	Poster, mean (SD)	Nonposter, mean (SD)	*t (df)*	*P* value	Cohen *d*
Rating intention	5.495 (1.120)	5.064 (1.189)	5.569 (1369)	<.001	0.373
Altruism	5.556 (1.074)	5.438 (1.042)	1.697 (1369)	.09	0.112
Self-efficacy	5.052 (1.229)	4.594 (1.202)	5.771 (1369)	<.001	0.377
Trust	5.150 (1.058)	4.711 (1.224)	5.549 (1369)	<.001	0.358
Perceived usefulness	5.380 (1.150)	5.147 (1.162)	3.020 (1369)	.003	0.202
Perceived ease of use	4.700 (1.085)	4.405 (1.127)	3.928 (1369)	<.001	0.267

Discussion

Principal Findings

Previous studies on online physician rating information mainly focused on the usage of online physician ratings and related factors [2-4,21], and only 2 studies [4,6] have shown the proportion (11% and 23%) of people who rated the physicians on physician rating websites. Our study focused on the urban Chinese population and found that 20.9% (287/1371) of the respondents rated the physicians on physician rating websites at least once. An important aspect of our study was that we investigated the factors that predicted the actual behavior of rating the physicians on the physician rating websites. Since only 56.7% (778/1371) of the participants had used online physician rating information, we examined the effects of different factors on the rating intentions of the posters and nonposters. Our results also show that the factors affecting the actual rating behavior and rating intention were different, even though the rating behavior was positively related to the rating intention in our partial correlation analysis ($r=.148$; $P<.001$).

Our study shows that only sociodemographic variables cannot produce a satisfying model to predict the actual behavior of rating physicians on the physician rating websites. Even though monthly income and education level were significantly correlated with the rating behavior (Model 1 in Table 2), the Nagelkerke R^2 (0.041) of the logistic regression model was low. We also found that gender and marital status were significantly associated with the rating behavior when health and cognitive variables were included. The change in Nagelkerke R^2 indicated that it was necessary to integrate additional health and cognitive variables to predict the rating behavior to a more satisfying extent. Health-related factors played an important role in predicting the likelihood of the rating behavior. In our study, participants with the experience of seeking physician information on the internet, who used web-based physician service, and who had higher ability to seek health information were more prone to rate physicians on the physician rating websites. Since there have been incidents of poor physician-patient relationships and severe cases of vicious attacks on medical professionals particularly in China [48], many health consumers choose to check physician information on the internet and seek web-based health information to avoid unpleasant medical experiences. Seeking web-based health information increased their awareness of the online physician rating information and motivated them to rate physicians. Development of serious diseases and good medical experience were also predictors of the rating behavior. This result corroborated that of previous studies that showed a large number of positive reviews on physician rating websites [49-52]. Further, altruism was negatively related to the rating behavior, indicating that egoistic motivation played a role, and nonposters showed exaggerated level of altruism in their behavior of generating online physician rating information. Self-efficacy reflects an optimistic self-belief that one can perform a task, and it was found to be positively related to the rating behavior. In a web-based context, trust is always a big concern, and it was found to be positively related to the usage of online physician rating information [21]. In our study, trust in online physician rating information was also positively related to the rating behavior. However, as most participants had not used physician rating websites, perceived usefulness and perceived ease of use were not significantly associated with the rating behavior.

Regarding the rating intention, cognitive factors explained the largest variance in the rating intention, and factors influencing the rating intention of posters and nonposters were different. The common factors were health information-seeking ability, rating habit, altruism, self-efficacy, and trust in online physician rating information. However, most health- and technology-related variables that predicted the rating intentions of the posters and nonposters were different. For health-related variables, the rating intention of the posters was mainly predicted by the usage of web-based health information or service, while the rating intention of the nonposters was associated with the health status and medical experience. Although the results in Table 2 indicated that serious disease development and good medical experience predicted the actual rating behavior, our linear regression model demonstrated that chronic disease and bad medical experience were associated with the rating intentions of the nonposters after they became aware of physician rating websites. Additionally, perceived usefulness was associated with the rating intention of the nonposters and perceived ease of use was associated with the rating intention of the posters. Further, we noticed that the posters judged the rating intention, altruism, trust in online physician rating information, perceived usefulness, and perceived ease of use higher than the nonposters.

Practical Implications

Based on the results in our study, we have some recommendations for physician rating websites and physicians who are the stakeholders of online physician rating information generation. Commercial physician rating websites are the main sources for health consumers to access online physician rating information; thus, a large amount of online physician rating information is necessary and critical for the development of physician rating websites. Large amount of online physician rating information can be generated as follows. First, physician rating websites need to cooperate with widely used search engines and social media to increase the awareness of these websites among health consumers, since our results indicated that many consumers were unaware of these websites, and usage of web-based physician information could improve online physician rating information generation behavior and rating intention. Although Chinese physician rating websites have provided services for many years and are top-ranked in the search engine results page, most health consumers are still unfamiliar with these physician rating websites and are uncertain about their reliability. Second, physician rating websites need to cooperate with hospitals officially. Health consumers have high levels of trust in public hospitals. Thus, cooperation with hospitals would enhance consumers' trust and improve the usability of commercial physician rating websites. Our findings suggested that trust was positively related to the physician rating behavior and intention. In fact, reviews on some physician rating websites in China increased greatly after physician rating websites provided booking services for hospitals. These physician rating websites are becoming increasingly popular among health consumers in cities. Third, physician rating websites must provide additional incentives for health consumers to generate online physician rating information. Knowledge sharing is an altruistic behavior. However, our results indicated altruism to be negatively related to the actual rating behavior. Egoism may play an important role in the actual rating behavior. Thus, a better incentive mechanism is needed for attracting health consumers to rate physicians on the physician rating websites. Fourth, physician rating websites need to cooperate with physicians and provide web-based medical services, besides online physician rating information. In the past 2 years, many physicians in China have begun to use physician rating websites to provide web-based medical services, which have greatly increased the number of reviews and the usability of these websites.

The results of our study could also be interesting for physicians. Online physician rating information is important for physicians to boost their reputation and to enjoy success in their careers. Thus, physicians need to actively encourage patients to generate online physician ratings by performing the following measures. First, physicians should be concerned about patients' medical experiences. We found that good medical experience predicted the actual behavior of rating the physician on the physician rating websites. This finding is consistent with that reported in previous studies that showed positive reviews for physicians [20,48]. Physicians need not worry about negative reviews ruining their reputation, even though a bad medical experience was positively related to the rating intention of nonposters. Physicians are encouraged to show empathy to their patients, who may consequently provide positive reviews about them. Second, physicians should recommend physician rating websites to their patients and encourage them to provide online physician ratings after receiving the medical service. Physician recommendations would increase patients' trust in online physician rating information and directly lead to the generation of more reviews. Even though it is embarrassing to be rated by patients, physicians should accept that online physician rating information could lead to their medical service improvement.

Limitations and Future Direction

This study has some limitations. First, we used a snowball sampling method and focused on well-educated people who were younger than 46 years in China. There is a possibility of selection bias among respondents, even though they are the potential online physician rating information users. Thus, a large randomized sample would certainly be desirable in future studies. Second, we only tested the altruistic motivation, which was found to be negatively related to the rating behavior. Future studies should analyze how egoistic motivation directly affects the rating behavior. Third, we did not differentiate people with bad medical experience from people with good medical experience. Medical experience could be an interesting variable to focus on, considering the special patient-physician relationship in China. Researchers should explore if the kind of medical experience has nuanced the effect on the intention to post online physician rating information with regard to the unsatisfying physician-patient relationships in China. Finally, factors influencing the actual behavior and intention of rating physicians were quite different in our study. Since many participants were unaware of physician rating websites before our survey, it would be better to examine how these factors affect their actual rating behavior. Even though the intention is predictive of future behavior, the self-reported intention might be exaggerated. A long-term follow-up study is needed in the future to investigate how different factors affect the actual rating behavior after health consumers become aware of the online physician rating information.

Conclusion

Since the limited number of web-based reviews greatly hampers the effective usage of physician rating information, it is important to discuss the variables that influence the generation of physician rating information from the health consumer's perspective. Our cross-sectional study shows that factors affecting the physician rating behavior and rating intention are different. We found that health-related variables influenced the physician rating behavior while cognitive variables were critical in the rating intentions. Based on our findings, we have provided some practical suggestions for physician rating websites and physicians to promote the generation of online physician rating information.

Abstract

Background: In today's society, commercial physical activity apps (eg, Fitbit and Strava) are ubiquitous and hold considerable potential to increase physical activity behavior. Many commercial physical activity apps incorporate social components, in particular app-specific communities (allowing users to interact with other app users) or the capacity to connect to existing social networking platforms (eg, Facebook or Instagram). There is a growing need to gain greater insights into whether commercial physical activity apps and specific components of these apps (social components) are beneficial in facilitating physical activity.

Objective: This study aimed to examine the relationship between the use of commercial physical activity apps and engagement in physical activity. The social components of commercial physical activity apps (app-specific communities and existing social networking platforms) were also explored. This involved isolating specific features (eg, sharing, providing, and receiving encouragement, comparisons, and competitions) of app-specific communities and existing social networking platforms that were most valuable in facilitating physical activity.

Methods: A cross-sectional web-based survey was conducted. Participants were 1432 adults (mean age 34.1 years, 1256/1432, 88.00% female) who completed measures assessing physical activity, the use of commercial physical activity apps, and engagement with app-specific communities and existing social networking platforms.

Results: Overall, 53.14% (761/1432) of the sample reported engaging with a commercial physical activity app. The most commonly used apps were Fitbit (171/761, 22.5%), Strava (130/761, 17.1%), and Garmin (102/761, 13.4%). The use of physical activity apps was significantly associated with physical activity. Notably, the use of app-specific communities and existing social networking platforms facilitated significantly greater engagement in physical activity. The features of app-specific communities that were most beneficial in promoting engagement in physical activity were providing encouragement to a partner, receiving encouragement from close friends and family, and engaging in competitions with members of public app-specific communities. In relation to existing social networking platforms, sharing physical activity posts predicted engagement in physical activity.

Conclusions: The findings indicate that app-specific communities and existing social networking platforms are components of apps that are fundamental in facilitating physical activity. They further suggest that commercial physical activity apps afford high population level reach and hold great potential to promote engagement in physical activity, an important public health consideration.

KEYWORDS

physical activity; mobile applications; social networking

Introduction

Background

Physical activity confers many health benefits, including a reduced risk of cardiovascular disease, hypertension, osteoporosis, diabetes mellitus, obesity, mental illness, and premature mortality [1-3]. Despite this, globally, 1.4 billion adults (28%) are not meeting physical activity guidelines (150 min of moderate to vigorous physical activity per week), a figure that continues to rise [4]. This highlights the need to develop scalable interventions to increase physical activity.

Physical activity mobile apps present an innovative approach to promote engagement in physical activity due to their widespread reach, accessibility, and convenience. Recently, there has been exponential growth in the availability of commercial physical activity apps (eg, Fitbit, Strava, and Garmin) [5]. However, much of the previous research examining physical activity apps has focused on apps developed by researchers as opposed to commercially available apps [6,7]. This presents a shortcoming of research to date, such that despite the accessibility and ubiquity of commercial apps, there is limited literature exploring their use and influence on physical activity. This indicates the need to gain greater insight into the use of commercial apps to ascertain their capacity to increase levels of physical activity and, thus, improve public health.

A growing body of research examining the content of commercial apps has identified that social features are an increasingly ubiquitous component [6,8-10]. That is, many commercial apps incorporate app-specific communities, allowing users to interact with other app users by sharing physical activity data, receiving or providing encouragement (eg, likes and comments), and engaging in competitions or comparisons [8]. However, to date, there has been little examination of app-specific communities, and, in particular, the association between engagement with the features of these communities (eg, sharing and competitions) and physical activity. Insights into app-specific communities is important to ascertain their value in promoting engagement in physical activity and crucial for the development of future physical activity interventions.

Content analyses of commercial apps have identified that many physical activity apps also have the capacity to connect to existing social networking platforms such as Facebook or Instagram [6,8-10]. This has been suggested to be an important component of an app, given that a recent review [7] identified that the use of existing social networking platforms in conjunction with apps enhances engagement [11]. However, the review [7] also documented that this research area is in its infancy, and there is a need to gain greater insights into how to optimally harness existing social networking platforms in conjunction with physical activity apps. This requires identifying the features of existing social networking platforms (eg, social interaction and comparisons) that are associated with app engagement and, thus, physical activity.

Objectives

To our knowledge, no previous study has comprehensively examined commercial physical activity apps and specifically, how the social components of these apps (app-specific communities or existing social networking platforms) may be associated with physical activity. This is important given the increasing prevalence of commercial physical activity apps together with the need to isolate components of apps that are linked to physical activity engagement. Thus, the first aim of this study was to gain a comprehensive understanding of the use of commercial physical activity apps and their relationship with physical activity. The second aim was to explore the value of app-specific communities and existing social networking platforms in facilitating physical activity. More specifically, we sought to ascertain the features of app-specific communities and existing social networking platforms that were used and how these were associated with frequency of app use and engagement in physical activity.

Methods

Study Design and Participants

A web-based cross-sectional survey was conducted. Participants were recruited via the Discipline of Psychology's web-based research participation system, paid Facebook advertising, and free advertisements placed on social networking platforms (eg, Facebook, Instagram, and Twitter) for a study on *Physical Activity and Online Social Networking*. Ethical approval was obtained from the University Social and Behavioral Research Ethics Committee (protocol no. 8232). All participants provided informed consent electronically. Participants were adults, ≥18 years, and proficient in English.

Procedure

Participants completed a web-based survey through the Qualtrics platform between February and April 2019. The survey took approximately 30 min to complete and incorporated the measures listed below in the order of presentation. As a token of appreciation, participants could enter a raffle to win 1 of 5 AUD $25 (USD $15) shopping gift vouchers.

Measures

Demographics

Participants were invited to report their age, gender identity, and ethnicity.

Regular Structured Physical Activity

Regular structured physical activity was assessed following the methods of Prichard and Tiggemann [12]. Participants were invited to self-report the type, duration, and frequency of structured physical activity or sports they generally engaged in on a weekly basis. The total number of minutes of physical activity engaged in per week was then calculated by multiplying each activity's frequency by its duration. Separate physical activity totals were calculated according to the type of physical activity listed, specifically individual physical activities (eg, walking or running), gym-based activities (eg, gym classes), or sports-based activities (eg, netball or football).

Current Physical Activity App Use

Participants were asked to self-report their current use of physical activity apps, defined as apps that have the capacity to track or monitor physical activity (eg, steps or distance) or provide guided training or workouts. In particular, participants were asked to self-report using an open-ended response format, the name of the physical activity app they were currently using most frequently (main physical activity app, eg, Strava), the physical activity or sport they were using the app for, and their level of engagement with the app (number of times used per week). The apps were categorized according to their capabilities, including tracking, providing guided workouts, tracking plus providing guided workouts, or other (eg, scheduling gym classes or immersive games). The types of physical activity the apps were used for were classified as all daily activities, individual activities (eg, running, cycling, or walking), group-based activities (eg, netball, soccer, or football), gym-based activities (eg, fitness classes or personal training), or a combination of different activities (individual, group-based and gym-based activities).

Engagement With an App-Specific Community

In relation to the main physical activity app participants were currently using, they were asked to self-report their engagement with the features of the app-specific community. This included specifying how frequently on a 6-point Likert scale ranging from 0 (*never*) to 5 (*very often*) they engaged with specific features of the app community, such as sharing physical activity posts, liking and/or providing positive comments on others' posts, receiving likes and/or positive comments, comparing their physical activity performance with others, and engaging in competitions. Furthermore, participants were asked to indicate the frequency that they engaged with the aforementioned features with specific members of their app community, including partners, family, close friends, peers, public app-specific community members, and work colleagues. Example items include *Within the main physical activity app you are currently using, how often do you share posts relating to your physical activity performance with a partner?* and *Within the main physical activity app you are currently using, how often do you Like/Kudos/Cheer and/or provide positive comments on physical activity posts from close friends?* As the networks within each feature were highly correlated (α=.74), a composite score was calculated for the use of each specific feature of the app community (eg, sharing) across the different networks (eg, peers and family) while also examining the independent influence of engaging with specific networks in relation to each feature.

Participants who specified that the main physical activity app they were using incorporated an app-specific community but reported that they did not engage with it were provided with an open-ended question to determine the underlying rationale for this. Preliminary themes were established by the first author, and the responses were subsequently categorized by 2 independent coders.

Engagement With Existing Social Networking Platforms in Relation to Physical Activity

Participants were also asked to self-report their physical activity-related use of existing social networking platforms on measures developed for this study. Specifically, participants were asked to specify on a 6-point Likert scale how frequently (from *never*=0 to *very often*=5) they share physical activity posts, like and/or provide positive comments on others' posts, receive likes and/or positive comments, and compare their physical activity performance with others' physical activity posts on Facebook, Instagram, and Twitter (plus the option to specify other platform(s)). Example items included *How often do you share physical activity posts on the following social networking platforms?* and *How often do you like and/or provide positive comments on physical activity posts from other people on the following social networking platforms?* A composite score was calculated for the use of each specific feature (eg, sharing) across the different social networking platforms (eg, Facebook and Instagram).

Statistical Analysis

Data were analyzed using Statistical Package for the Social Sciences version 25 (IBM, Corp). Significance for all analyses was set at *P*<.05 (2-tailed). Overall, the study variables (with the exception of app engagement) did not deviate substantially from normality based on skewness, kurtosis, or histogram examination. Therefore, parametric tests were used for all analyses, except those that included the variable app engagement for which a nonparametric test (Kruskal-Wallis test) was used.

Descriptive statistics were used to generate demographic information. A series of independent samples *t* tests and chi-square analyses were conducted to determine differences between app users and nonusers in age, gender identity, ethnicity, and minutes of physical activity per week. Chi-square analyses were used to identify differences in app use (ie, the most commonly used apps, the capabilities of the apps used, and the activity app is used for) based on demographics (age and gender identity). A Kruskal-Wallis test with pairwise comparisons using the Dunn-Bonferroni correction was conducted to examine the relationship between app engagement (frequency of app use per week) and physical activity.

Kruskal-Wallis tests were also conducted to examine the relationships between the use of specific features of app-specific communities and app engagement among app users. In addition, 1-way analyses of variance were performed to determine differences in engagement with features of app-specific communities based on age, capabilities of the app used, and activity the app was used for, but not for gender identity (because of the small proportion of men). The aforementioned analyses were repeated using specific features of existing social networking platforms. Independent samples *t* tests and chi-square analyses were also used to determine differences between users and nonusers of the app-specific communities and existing social networking platforms.

Finally, a multiple linear regression was conducted to explore the predictors of physical activity among app users. The regression model incorporated the frequency of app usage and all features of both app-specific communities (including specific networks) and existing social networking platforms. Demographic characteristics (age, gender identity, and ethnicity) were incorporated as control variables.

Results

Sample

In total, 1640 individuals began the survey, 208 of whom did not complete it (a response rate of 87.3%), resulting in a final sample of 1432 participants. The sample had a mean age of 34.1 years (range 18-83 years) and comprised predominately female participants (1256/1432, 88.00%). Overall, the sample engaged in high levels of structured physical activity (mean 266.8 min per week, SD 219.8), and 53.14% (761/1432) reported currently engaging with a physical activity app. Table 1 presents the demographic characteristics of app users and nonusers. There were no significant differences between the 2 groups (app users and nonusers) in relation to age, gender identity, or ethnicity. However, app users engaged in significantly more structured physical activity per week than nonusers (Table 1). Overall, among those who reported engaging in physical activity, participants predominately engaged in individual physical activities (eg, walking or running, 619/858, 72.2%), followed by gym-based activities (eg, gym classes, 324/620, 52.2%), and sports-based activities (eg, netball or football, 88/324, 27.2%). This did not differ based on whether participants used an app. Relatedly, participants spent the most time engaging in individual activities per week (mean 133.6 min, SD 176.5), followed by sports-based activities (mean 113.5 min, SD 110.7), and gym-based activities (mean 83.2 min, SD 94.9). Again, this was consistent across app users and nonusers (Table 1).

Table 1. Sample characteristics of physical activity app users and nonusers (n=1432).

Characteristic	App users (n=761)	Nonusers (n=671)	*P* value[a]	Effect size, Φ	Effect size, Cohen *d*

[a] Statistical significance is represented by *P*<.05.

[b] N/A: not applicable.

Physical Activity App Use

Multimedia Appendix 1 presents the physical activity apps that were most commonly used. Fitbit (171/761, 22.5%), followed by Strava (130/761, 17.1%) and Garmin (102/761, 13.4%) were the most popular apps, and this did not differ by age or gender identity. Participants most commonly engaged with apps that had the capacity to exclusively track behaviors and predominately used apps for individual activities (eg, running or walking). This was consistent across age and gender identities.

The greatest proportion of participants reported using their physical activity app on 7 occasions per week (296/761, 39.0%), followed by use on 3 occasions (102/761, 13.4%) and more than 7 occasions (70/761, 9.2%) per week. A Kruskal-Wallis Test comparing weekly physical activity duration revealed a statistically significant difference (*P*=.006) across levels of app usage. Specifically, pairwise comparisons identified that participants who used the app on 6 occasions per week engaged in significantly higher levels of structured physical activity (median 491.9 min) than those who used the app on 2 occasions per week (median 297.4 min; *P*=.003). Overall, participants who used an app 6 times per week engaged in the highest levels of structured physical activity.

Use of Social Components of Physical Activity Apps

Among app users, 3.4% (26/761) used app-specific communities exclusively, 59.9% (456/761) used existing social networking platforms exclusively, and 22.0% (167/761) used both app-specific communities and existing social networking platforms. This did not differ significantly by age, gender identity, ethnicity, capabilities of the app used (eg, tracking), the type of physical activity the app was used for, or frequency of app usage per week.

Physical Activity App Use in Conjunction With an App-Specific Community

Among app users, 59.0% (447/761) reported that the physical activity app they were currently using incorporated an app-specific community. Of these, 43.1% (193/447) reported engaging with the community. Participants who reported engaging with the app-specific communities predominantly used Strava (80/193, 41.5%), Fitbit (40/193, 20.7%), and Garmin (13/193, 6.7%). Table 2 shows that the distribution of age was significantly different between app community users and nonusers. Specifically, app community users were predominately >30 years. App community users also engaged in significantly more structured physical activity per week than nonusers (t_{445}=2.62; *P*=.009; *d*=0.25). However, there were no significant differences between users and nonusers of the app-specific community in relation to gender identity, ethnicity, capabilities of the app used (eg, tracking), the type of physical activity the app was used for, or app usage per week. Among participants who reported not engaging with the app-specific community (254/447, 57.0%), the reasons identified were privacy or security concerns, negative attitudes toward the use of the community, considered unnecessary, lack of support, beliefs regarding the nature of physical activity, disinterest in others' physical activity performance, and use of an alternative social network. Of these, the most commonly cited reasons were that the use of the community was considered unnecessary (83/249, 33.4%), disinterest in others' physical activity performance (50/246, 20.3%), and privacy or security concerns (43/246, 17.5%).

Among participants who engaged with the app-specific community (n=193), users most frequently used features that allowed the sharing of physical activity performance, providing encouragement to others' physical activity posts (eg, likes or positive comments), and receiving encouragement on one's own posts. These features were most frequently reported to be used with networks that were close friends or peers. There were no significant differences in engagement with features of app-specific communities across age, levels of app usage or according to capabilities of the app used, or the activity the app was used for.

Table 2. Sample characteristics of app-specific community users and nonusers (n=447).

Characteristic	Community users (n=193)	Nonusers (n=254)	*P* value[a]	Effect size, Φ	Effect size, *Cohen d*

Physical Activity App Use in Conjunction With Existing Social Networking Platforms

Among app users, 82.0% (624/761) reported using existing social networking platforms (Facebook, Instagram, or Twitter) in relation to physical activity. There were no significant differences between users and nonusers of existing social networking platforms in relation to age, gender identity, or ethnicity. Participants who used existing social networking platforms engaged in significantly more structured physical activity than those who did not (t_{672}=2.9; *P*=.004; *d*=0.44). The features of existing social networking platforms that were most frequently used were providing encouragement on others' physical activity posts, followed by receiving encouragement on one's own physical activity posts (eg, likes or comments). Notably, there were significant differences in the frequency of engagement with features of existing social networking platforms based on age, both in terms of sharing physical activity posts ($F_{3,666}$=5.37; *P*=.001) and engaging in comparisons ($F_{3,666}$=19.0; *P*<.001). Specifically, participants aged 18-25 years shared posts to existing social networking platforms significantly less frequently than all other age groups. In addition, participants >40 years made significantly fewer comparisons relative to all other age groups. However, there were no significant differences in the frequency of engagement with features of existing social networking platforms across the frequency of app usage or according to the capabilities of the app used, or the activity the app was used for.

Exploring Predictors of Physical Activity

The regression model accounted for 42.6% of the variance in structured physical activity (R^2=0.426) and was significant ($F_{38,96}$=1.87; *P*<.01). The following variables were significant positive predictors of structured physical activity: frequency of app use (β=.25; *P*=.009), providing encouragement to a partner (β=.52; *P*=.005), receiving encouragement from close friends (β=.59; *P*=.01) and family (β=.48; *P*=.02), engaging in competitions with members of a public app-specific community (β=.38; *P*=.001), and sharing posts to existing social networking platforms (β=.31; *P*=.004). In addition, the following variables were significant negative predictors of structured physical activity: sharing physical activity posts with a partner (β=−.40; *P*=.007), providing encouragement to close friends (β=−.57; *P*=.01), receiving encouragement from members of a public app-specific community (β=−.35; *P*=.04), and engaging in competitions with a partner (β=−.30; *P*=.04, Table 3).

Discussion

Principal Findings

This study aimed to provide a comprehensive examination of the use of commercial physical activity apps and the relationship between app usage and physical activity. In addition, we sought to explore the use of social components of apps (app-specific communities and existing social networking platforms) and their value in facilitating engagement in physical activity. This study is timely, given the ubiquity of commercial physical activity apps coupled with the need to understand how specific components of these apps may be beneficial in facilitating physical activity.

Overall, the findings demonstrate that the use of physical activity apps is common, with over half of the participants reporting that they currently use a physical activity app. Our findings are consistent with Krebs and Duncan [13], who reported that in a large, diverse US sample (50% female), 58.2% had downloaded a health-related app, of which 52.8% used the app to track physical activity. This reflects both the omnipresence of commercial physical activity apps and their capacity to have high-population level reach. Notably, physical activity app users engaged in significantly more structured physical activity, consistent with findings from a previous study documenting that physical activity app users were 27% more likely to engage in physical activity than nonusers [14]. In this study, app users predominantly used Fitbit, Strava, and Garmin, with the primary function of these apps being to track or monitor behavior. This may explain the higher levels of physical activity among app users, given that self-monitoring is a behavior change technique consistently associated with increased physical activity [15,16]. These findings suggest that commercial physical activity apps may have great potential to influence physical activity. However, it must be acknowledged that the causality of the relationship between app use and physical activity is presently unclear, in that those who engage in high levels of physical activity may be attracted to apps to monitor their behavior. Longitudinal research examining app use and physical activity over time is needed to ascertain the direction of this relationship.

This study identified that participants most commonly engaged with physical activity apps on 7 occasions per week, and in line with previous research, the frequency of app usage was significantly associated with physical activity [11]. Interestingly, participants who used the apps on 6 occasions per week engaged in the highest duration (minutes) of structured physical activity per week. This indicates that relatively high app use is associated with high levels of physical activity, reflective of the previously cited dose-response relationship between app use and behavioral outcomes (eg, physical activity) [17]. The present findings further highlight that app usage is an important consideration in appropriately leveraging apps to promote engagement in physical activity. This emphasizes the importance of examining specific components of apps that may be harnessed to increase app usage, namely social components.

A novel aspect of this study was its comprehensive examination of the social components (app-specific communities and existing social networking platforms) of commercial physical activity apps. Interestingly, the use of the social components of apps differed markedly, such that most app users engaged exclusively with existing social networking platforms (in relation to physical activity, 456/761, 59.9%), whereas far fewer engaged with both app-specific communities and existing social networking platforms (167/761, 22.0%) or app-specific communities exclusively (26/761, 3.4%). This is perhaps not surprising given that existing social networking platforms are immensely popular, afford widespread reach, and achieve high levels of sustained engagement [18]. Age is another factor that may have contributed to the difference in the use of the social components of apps, such that users of app-specific communities were predominately >30 years (66.8%); by contrast, age was not associated with the use of existing social networking platforms. This suggests that app-specific communities are most appropriate for a specific subgroup of the population (>30 years), whereas existing social networking platforms could be harnessed for the population more broadly. Relatedly, future research could consider examining other factors that may influence the use of app-specific communities and/or existing social networking platforms, such as one’s presence on social networking platforms (ie, those with vs without an established social networking presence).

Despite the differences in the usage of app-specific communities and existing social networking platforms, the social features across both were used similarly, with providing and receiving encouragement the most popular features. Interestingly, the findings also indicate that demographic characteristics may be linked to the likelihood that individuals will utilize specific features. For example, in relation to existing social networking platforms, those aged 18-25 years shared posts less frequently than all other age groups, whereas those aged >40 years engaged in comparisons less frequently relative to all other age groups. This is consistent with a recent review [19] of mobile health interventions documenting that preferences for social features that facilitated comparisons, competitions, or social support varied among participants and purported that this may be linked to individual differences (eg, competitiveness). When leveraging the features of social components of physical activity apps (eg, existing social networking platforms), a 1-size-fits-all approach is not appropriate, and individual differences must be considered. Future research may usefully extend this understanding by examining whether other individual difference factors such as psychological characteristics (competitiveness and social comparisons) may influence the use of specific features.

Notably, the use of app-specific communities and existing social networking platforms was associated with significantly higher engagement in structured physical activity. This is a novel finding given that it suggests that the social components of apps may play a fundamental role in facilitating engagement in physical activity. This may be attributed to the unique capacity of app-specific communities and existing social networking platforms to generate social support [20], an important determinant of engagement in physical activity [21,22]. Another explanation is that individuals who engage in more physical activity have more content to share and are more likely to engage with the social components of apps, which, in turn, may foster supportive interactions. This study demonstrates the value of social components of apps in facilitating physical activity and the need to further examine app-specific communities and existing social networking platforms in future research.

Finally, the regression analysis revealed that the frequency of app usage was a significant predictor of structured physical activity, indicating the need to determine strategies that will facilitate app use. Interestingly, in relation to app-specific communities, providing encouragement to a partner, receiving encouragement from close friends and family, and engagement in competitions with members of public app-specific communities were positive predictors of physical activity. Conversely, sharing physical activity posts and engaging in competitions with a partner, providing encouragement to close friends, and receiving encouragement from members of public app-specific communities were negative predictors of physical activity. These findings indicate that receiving encouragement from strong ties (close friends and family) is beneficial in facilitating engagement in physical activity, whereas receiving encouragement from weak ties (public app-specific communities) is not. This is consistent with previous research showing that strong ties provide emotional support (encouragement, empathy) [23,24], which is linked to improvements in health outcomes [25], and an increased likelihood that one will initiate and maintain engagement in physical activity [26]. Conversely, weak ties often only provide informational support (advice or suggestions) [23,24], shown to be negatively associated with health behavior [27], and this has been attributed to receiving information or advice that is unwanted or in surplus [28]. The findings do, however, suggest that engaging in competitions with weak ties (public app-specific communities) is advantageous in promoting physical activity, whereas engaging in competitions or behaviors that may generate competitions (sharing physical activity posts) with strong ties (eg, partner) is negatively associated with physical activity. This is in line with existing research documenting that comparisons (generating competitions) with strong ties elicits greater pressure and fear of experiencing shame and embarrassment, ultimately decreasing the likelihood that one will engage in the behavior [29,30]. Together, these findings provide an important understanding of the specific features (and networks) of app-specific communities that are most beneficial in facilitating physical activity, and thus should be leveraged in future app-based interventions.

The regression analysis also showed that in relation to existing social networking platforms, sharing physical activity posts positively predicted engagement in physical activity. This is perhaps not surprising given that a recent study [27] found that sharing posts related to tracked health information (eg, physical activity, sleep, or calories) to existing social networking platforms is positively associated with social support, and this, in turn, predicts engagement in the associated health behavior. This highlights the need for future research to further explore the use of existing social networking platforms in relation to physical activity apps and physical activity behavior. In addition, future studies could explore how different social networking environments (eg, network size or composition) may interact with apps to influence physical activity.

Implications

Our findings have important implications for informing the design of future app-based interventions. They demonstrate that commercial physical activity apps, in particular, those that facilitate self-monitoring (eg, Fitbit, Strava, and Garmin) hold great potential to promote engagement in physical activity. The convenience, accessibility, and affordability of commercial apps coupled with their capacity to facilitate physical activity highlight that future app-based interventions should harness commercial apps, as opposed to previous interventions that have predominately incorporated researcher-developed apps [7]. The findings also indicate that the social components of apps are important in promoting physical activity and, thus, fundamental in the development of effective app-based interventions. More specifically, in relation to app-specific communities, receiving encouragement from close friends and family, providing encouragement to a partner, and engagement in competitions with members of public app-specific communities were shown to be the most beneficial features in facilitating physical activity and, thus, should be leveraged to maximize effectiveness. However, relatively few app users engaged with app-specific communities (193/447, 43.1%), with commonly cited barriers to using the communities, including disinterest and privacy or security concerns. Nevertheless, app-specific communities show great potential in facilitating physical activity, and thus, these barriers must be considered and overcome in the design of future apps and app-based interventions. The findings also suggest that existing social networking platforms are commonly used in relation to physical activity, and notably, sharing physical activity posts to these platforms predicts engagement in physical activity. Thus, existing social networking platforms will be an important component of future app-based interventions given their capacity to achieve high levels of use and promote engagement in physical activity.

This study also has important implications for guiding future research. Experimental evidence is now needed to isolate the influence of the social components of apps and their associated features on physical activity. Future research should also endeavor to ascertain the mechanisms (eg, social support and self-efficacy) underlying the capacity of app-specific communities and existing social networking platforms to facilitate physical activity. Finally, longitudinal research is needed to determine the value of app-specific communities and existing social networking platforms in promoting sustained app use, and thus prolonged engagement in physical activity.

Limitations

As with all studies, there are a number of limitations that need to be acknowledged. First, the sample consisted predominantly of white women, and the participants' origin (country/region) was unknown. These 2 sample characteristics limit the generalizability of the findings to the population more broadly. Nevertheless, app usage rates were similar to those previously reported in a large, diverse US sample [13]. Second, the sample as a whole engaged in high levels of structured physical activity, indicative of self-selection bias, and, thus, may not be representative of the general population. Third, participants self-reported structured physical activity, which may have resulted in under- or overreporting. In addition, the assessment of structured physical activity did not capture incidental physical activity, which is often recorded by apps that track or monitor daily or individual physical activities. Thus, future research should consider using accelerometer-derived measures of physical activity in conjunction with self-report measures that have the capacity to capture both structured and incidental physical activity. Finally, there are a number of factors that may influence app use and/or the association between app use and physical activity such as socioeconomic status (SES), fitness device ownership, and overall engagement with the app-specific community, which were not measured in this study. Many physical activity apps are often used in conjunction with fitness devices (eg, Fitbits and Apple Watches), which may be too expensive for some individuals. As such, future research could examine potential interactions between SES, fitness device ownership, app use, and physical activity.

Conclusions

Notwithstanding these limitations, this study provides an important contribution to existing literature by comprehensively exploring the use of commercial physical activity apps and their associated social components in a large cross-sectional sample. The findings indicated that the use of commercial physical activity apps facilitates engagement in physical activity and, therefore, have great potential to disseminate scalable interventions to improve health behavior. This study also provided a nuanced insight into app-specific communities and existing social networking platforms, identifying that they are components of apps that are valuable in promoting physical activity, and should be harnessed in the development of future app-based interventions. Together, these findings highlight the importance of further examining the social components of apps and gaining an understanding of the mechanisms underlying their influence on physical activity. In so doing, this study has demonstrated that commercial physical activity apps afford high population level reach and hold great potential to facilitate engagement in physical activity. Thus, future interventions aimed at increasing physical activity should further explore commercial physical activity apps and their associated social components.

Abstract

Background: Both body mass index (BMI) and the perceived importance of health have received a lot of attention, but few studies have fully investigated the interaction of their effects on health behaviors.

Objective: This study investigates the effects of BMI and the perceived importance of health on health behaviors (patterns of eating, sleeping, and exercising) among college students in Taiwan.

Methods: A survey was conducted with 334 students to assess their perception of the importance of health (using indicators) and their health behavior (using the Health Behaviors Scale). Respondent BMI was calculated from self-reported body weight and height. Descriptive statistical analysis, independent t test analysis, two-way analysis of variance (ANOVA), and one-way ANOVA were conducted.

Results: The results showed a significant difference between genders in health behaviors among college students (eating: t_{332}=2.17, P=.03; exercise: t_{332}=5.57, P<.001; sleep: t_{332}=2.58, P=.01). Moreover, there was an interaction between BMI and perception (of the importance of health) for exercise behaviors ($F_{2,328}$=3.50, P=.03), but not for eating behaviors ($F_{2,328}$=0.12, P=.89) or sleep behaviors ($F_{2,328}$=1.64, P=.20).

Conclusions: This study establishes, for the first time, the interaction of BMI and the perceived importance of health on health behaviors. The perception of health was found to have a significant effect on exercise behaviors. Thus, the perception of health plays a significant role in the exercise behaviors of college students in Taiwan. This finding provides researchers, policy makers, and practitioners with evidence, and consequently, opportunities for focusing on preventive actions. The findings suggest that increasing the importance of health in the perception of college students, should be the focus of efforts to help students exercise more regularly.

KEYWORDS

body mass index; college students; health behavior; perceived importance of health

Introduction

Both identity and health habits are formed during a young person's transition from adolescence to adulthood [1]. The period during which one attends college is the ideal time to establish positive healthy behavior and eliminate unhealthy ones [2]. Although these years provide personal freedom and opportunities for new experiences, there is also the potential to adopt unhealthy and risky behavior [3]. Common health issues that affect young people at the start of college are poor sleep quality and lack of sleep [4]. In particular, students in the first year of college face several stressors and experience changes in their dietary and exercise patterns [5]. In its 2018 annual report, Taiwan's Health Promotion Administration highlighted the increase in the number of overweight and obese students over 18 years of age [6]. The findings of their Changes in

National Nutrition and Health Survey suggest the need for a deeper understanding of the health behaviors of Taiwanese college students [6].

Healthy behavior, such as making good dietary choices, exercising regularly, and maintaining regular sleep patterns, consists of positive actions that maintain or enhance health [7]. In general, healthy eating, sleeping, and exercise habits are each related to individual factors [8]. Scholars have argued that the perception that health is important prompts an individual to adopt a health-promoting lifestyle [9]. Previous studies have shown that individuals who place the utmost importance on health tend to adopt healthy behavior with respect to diet and nutrition, exercise [7-9], and sleep [7,8].

The link between body mass index (BMI) and health behaviors has also been the focus of research. Diet-related behaviors [10], dietary fat intake, amount of physical activity, amount of sedentary leisure time [11], and unhealthy behaviors [12] were all found to be associated with BMI. Students with a low BMI were less likely to snack and more likely to eat breakfast regularly [13]. In contrast, a high BMI was associated with unhealthy dietary patterns [14], eating irregularly [15], or eating a diet low in fiber-density [16]. Obesity and being overweight have been associated with being less likely to exercise regularly [17]. A U-shaped curvilinear association was found between sleep duration and BMI [18]—being overweight [19] or being underweight [20] was associated with poor sleep quality.

The roles of BMI and the perceived importance of health have received a lot of attention, but few studies have fully investigated the interaction of their effects on health behaviors. Because an in-depth study of these aspects would be useful in guiding the development of an effective educational program that promotes healthy behavior among college students, the aim of this study was to investigate the interaction of their effects. We hypothesize that there is an interaction between the effects of the perceived importance of health and BMI on the health behaviors of college students. Additionally, we hypothesize there is a difference between male and female health behaviors. Gender has been found to be a strong predictor of health behaviors [21] and studies have shown that female college students are more likely than male college students to have poor eating habits [22,23], poor exercise habits [23], and poor sleep habits [8].

Methods

Respondents

A questionnaire was administered to 360 college students from 12 colleges of which 334 valid questionnaires were returned (334/360, 92.8%). Of the total respondents, 50.0% were male (167/334) and 50.0% were female (167/334); 47.9% (160/334) attended college in the northern region, 23.1% (77/334) attended college in the central region, and 29.0% (97/334) attended college in the southern region of Taiwan; and the mean age was 20.70 (SD 1.35) years.

Questionnaire

Data collected through the questionnaire included age, gender, height, weight, an item indicating perceived importance of health, and the 12-item Health Behaviors Scale. Using the reference standard of Taiwan's Ministry of Health and Welfare [24], respondents were classified into three groups according to their BMI: values less than 18.5, values under 24 and greater than or equal to 18.5, and values greater than or equal to 24.

To assess respondents' perceived importance of health, we employed an item designed by Beşer et al [9]. The degree of importance assigned to health was measured by a 5-point Likert scale ranging from "none" (coded as 1) to "very much" (coded as 5) in response to the question: "To what degree do you give importance to your health?" [9]. To avoid group divisions that were not meaningful, respondents were classified into two groups according to their scores: scores less than or equal to 3 (low importance) and scores greater than or equal to 4 (high importance).

The respondents' health behaviors were evaluated using Chiang et al's [8] Health Behaviors Scale which consists of 12 items that address three aspects of health behavior: exercise (four items), eating (four items), and sleep behaviors (four items). Using item analysis, exploratory factor analysis, and confirmatory factor analysis, Chiang et al [8] showed that the Health Behaviors Scale is a valid and reliable measure of health behaviors for Taiwanese college students (Cronbach α=.83). Respondents answered the 12-item Health Behaviors Scale on a 5-point Likert scale with scores ranging from 1 (never) to 5 (always). Higher scores indicated that respondents have regular physical activity and exercise, healthy eating habits, healthy sleep habits, and good quality sleep. In terms of internal consistency, the exercise (Cronbach α=.79), eating (Cronbach α=.77), and sleep (Cronbach α=.80) showed good reliability.

Data Analysis

Statistical analysis was performed using SPSS software (version 20.0; IBM Corp). First, for a better understanding of the respondents' characteristics, descriptive statistical analysis was performed. Second, an independent *t* test (two-tailed) was used to identify if a gender difference in health behaviors existed. A *P* value less than .05 indicated that there was a statistically significant difference between genders. Finally, a two-way analysis of variance (ANOVA) was used to determine the effects of BMI and perceived importance of health on exercise, eating, and sleep behaviors among respondents. If the interaction of BMI and the perceived importance of health was significant ($P<.05$), then a one-way ANOVA was performed to assess the simple effects of the perceived importance of health and BMI.

Results

Descriptive Statistics

Table 1 presents a descriptive summary of each health behavior for the corresponding perceived importance of health and BMI groups. The mean scores were 13.46 (SD 3.06) for eating behaviors, 13.75 (SD 3.61) for exercise behaviors, and 10.66 (SD 3.56) for sleep behaviors.

Table 1. Descriptive summary for each health behavior by perceived importance of health and BMI.

Respondent groupings, n (%)		Health behavior scores		
		Eating, mean (SD)	Exercise, mean (SD)	Sleep, mean (SD)
Low perception of health importance	156 (100)	12.31 (2.98)	12.81 (3.41)	9.51 (3.21)
BMI<18.5	21 (13.5)	11.38 (2.78)	11.86 (3.77)	8.05 (2.29)
18.5≤BMI<24	88 (56.4)	12.32 (3.17)	13.25 (3.49)	9.57 (3.35)
BMI≥24	47 (30.1)	12.72 (2.63)	12.43 (3.01)	10.06 (3.15)
High perception of health importance	178 (100)	14.47 (2.78)	14.57 (3.60)	11.67 (3.55)
BMI<18.5	20 (11.2)	13.75 (2.10)	11.90 (2.40)	11.70 (2.96)
18.5≤BMI<24	121 (68.0)	14.48 (2.66)	14.60 (3.62)	11.76 (3.69)
BMI≥24	37 (20.8)	14.84 (3.40)	15.89 (3.32)	11.38 (3.43)
All	334 (100)	13.46 (3.06)	13.75 (3.61)	10.66 (3.56)
BMI<18.5	41 (12.3)	12.54 (2.72)	11.88 (3.14)	9.83 (3.19)
18.5≤BMI<24	209 (62.6)	13.57 (3.07)	14.03 (3.62)	10.84 (3.70)
BMI≥24	84 (25.1)	13.65 (3.15)	13.95 (3.58)	10.64 (3.32)

Gender Differences in Health Behaviors

Table 2 reveals gender differences in college students’ eating, exercise, and sleep behaviors indicating that male students have healthier eating behaviors (*P*=.03), better exercise habits (*P*<.001), and better sleep quality (*P*=.01) than female students.

Table 2. Health behavior scores showing gender differences.

Health behaviors	Gender, mean (SD)		*t* test (*df*)	*P* value
	Male (n=167)	Female (n=167)		
Eating	13.83 (3.10)	13.10 (2.99)	2.17 (332)	.03
Exercise	14.80 (3.69)	12.69 (3.21)	5.57 (332)	<.001
Sleep	11.16 (3.51)	10.17 (3.54)	2.58 (332)	.01

Effects of BMI and Perceived Importance of Health on Eating, Exercise, and Sleep Behaviors

As shown in Table 3, for eating behaviors, there were statistically significant main effects for BMI ($F_{2,328}$=3.66, *P*=.03) and for the perceived importance of health ($F_{1,328}$=29.44, *P*<.001); however, the interaction effect between BMI and the perceived importance of health was not statistically significant ($F_{2,328}$=.12, *P*=.89).

For exercise behaviors, there were statistically significant main effects for BMI ($F_{2,328}$=6.91, *P*=.001) and for the perceived importance of health ($F_{1,328}$=14.66, *P*<.001) as well as a statistically significant interaction between BMI and the perceived importance of health ($F_{2,328}$=3.50, *P*=.03).

For sleep behaviors, there was a statistically significant main effect for the perceived importance of health ($F_{1,328}$=26.99, *P*<.001); however, there was no statistically significant main effect for either BMI ($F_{2,328}$=1.03, *P*=.36) or the interaction between BMI and the perceived importance of health ($F_{2,328}$=1.64, *P*=.20).

As indicated by the simple effects analysis of the perceived importance of health and BMI on exercise behaviors shown in Table 4, respondents who considered health to be important and whose BMI was greater than or equal to 18.5 had significantly higher exercise behavior scores than respondents who did not consider health to be as important and whose BMI was greater than or equal to 18.5. In addition, respondents whose BMI was greater than or equal to 18.5 and who considered health to be important had significantly higher exercise behavior scores than respondents whose BMI was less than 18.5 and who considered health to be important.

Table 3. Statistical results of the two-way analysis of variance for the effects of perceived importance of health and BMI on health behaviors.

Health behaviors	BMI		Importance of health		BMI × Importance of health	
	F test (*df*)	*P* value	*F* test (*df*)	*P* value	*F* test (*df*)	*P* value
Eating	3.66 (2,328)	.03	29.44 (1,328)	<.001	0.12 (2,328)	.89
Exercise	6.91 (2,328)	.001	14.66 (1,328)	<.001	3.50 (2,328)	.03
Sleep	1.03 (2,328)	.36	26.99 (1,328)	<.001	1.64 (2,328)	.20

Table 4. Simple effects of the perceived importance of health and BMI on exercise behaviors.

Exercise behaviors scores, mean (SD)	Perception groups		Perception effect	
	Low	High	*F* test (*df*)	*P* value
BMI groups				
BMI<18.5	11.86 (3.77)	11.90 (2.40)[a,b]	0.002 (1,39)	.97
18.5≤BMI<24	13.25 (3.49)	14.60 (3.62)[a]	7.34 (1,207)	.007
BMI≥24	12.43 (3.01)	15.89 (3.32)[b]	25.03 (1,82)	<.001
BMI effect				
F test (*df*)	1.87 (2,153)	8.72 (2,175)	N/A[c]	N/A[c]
P value	.16	<.001	N/A[c]	N/A[c]

[a] Indicates belonging to the a pair, and statistically significant difference between the pairings (*P*=.006)

[b] Indicates belonging to the b pair, and statistically significant difference between the pairings (*P*<.001).

[c] N/A: Not applicable.

Discussion

Principal Findings

This study aimed to identify the interaction the effects of BMI and perceived importance of health on eating, exercise, and sleep behaviors. Moreover, there were significant gender differences in health behaviors among Taiwanese college students. Finally, there was an interaction between the effects of BMI and perceived importance of health for exercise behaviors, but not for eating or sleep behaviors. The effect of the perceived importance of health on exercise behavior was only true for those with BMI greater than 18.5; for underweight individuals, the perceived importance of health had no effect on exercise behaviors. Thus, the research hypothesis was partly supported.

Previous studies have found that being overweight is associated with physical inactivity and sedentary daily habits [17]. Thus, overweight and obese students may require encouragement to undertake physical activity. This study found an interaction between the effects of BMI and the perceived importance of health on exercise behaviors. College students with normal and above normal BMI who placed importance on health were more likely to exercise regularly than those with below normal BMI. Consistent with previous studies [7-9], we found the perceived importance of health plays a significant role in adopting healthy exercise behavior. Therefore, increasing the perception of health among overweight students may encourage them to participate more in physical activities.

This study found that the mean score of sleep behaviors was 10.66 (range 4-20). Previous studies have shown that college students have poor sleep quality and irregular sleeping habits [8,25,26]. College students with higher stress levels experience poor sleep quality [25,26]. Many health education programs are focused on improving knowledge and skills related to regular exercise and a healthy diet. However, sleep quality and problems related to sleep are overlooked [27]. School and government authorities need to be more proactive in designing appropriate sleep and stress management strategies to help college students improve their sleep quality and maintain positive sleep habits.

This study showed that male students have healthier eating behaviors, better exercise habits, and better sleep quality than female students supporting the findings of previous studies [8,22,23]. These results suggest that gender-specific eating, exercise, and sleep intervention programs for college students are necessary.

Finally, this study found that the interaction between the effects of BMI and perceived importance of health did not affect health behaviors related to eating and sleeping; however, the study also revealed that the eating behaviors of college students with different BMI show significant differences but sleep behaviors do not. College students with different levels of perceived importance of health also have significant differences in their eating and sleeping behaviors. These findings reveal that college students' eating behaviors are influenced by their BMI and both eating and sleeping behaviors are influenced by perceived importance of health.

Limitations

The study sample consisted of respondents in a higher education setting and was restricted by age to college students and by place to Taiwan. Consequently, the findings should not be overgeneralized and must be interpreted with consideration of the sample's homogeneity. Finally, the perceived importance of health was measured using only one item. Future studies should include respondents of different ages as well as develop further instruments to measure this construct (the perceived importance of health).

Conclusions

This study found that the interaction between the effects of BMI and the perceived importance of health does not affect the health behaviors of eating and sleeping. Previous studies have shown that college students' choice to major in medicine and their self-rated health were related to their health behaviors [7,8]. Future studies should consider the effects of the interactions of these individual factors as well as BMI on eating and sleeping behaviors, to investigate how best to help students adopt regular eating habits and improve their sleep quality.

This study established, for the first time, the interaction between the effects of BMI and the perceived importance of health on health behaviors. This finding provides researchers, policy makers, and practitioners in the field with evidence and opportunities for focusing on preventive action. The findings of the study suggest that increasing the perceived importance of health should guide efforts to help students adopt better exercise habits. There were also significant gender differences in health behaviors among college students suggesting that health education practitioners should design gender-specific health behavior intervention programs for college students.

Abstract

Background: There is currently a lack of comprehensive, intuitive, and usable formative evaluation frameworks for health information technology (HIT) implementations. We therefore sought to develop and apply such a framework. This study describes the Technology, People, Organizations, and Macroenvironmental factors (TPOM) framework we developed.

Objective: The aim was to develop and apply a formative evaluation framework for HIT implementations, highlighting interrelationships between identified dimensions and offering guidance for implementers.

Methods: We drew on an initial prototype framework developed as part of a literature review exploring factors for the effective implementation of HIT. In addition, we used qualitative data from three national formative evaluations of different HIT interventions (electronic health record, electronic prescribing, and clinical decision support functionality). The combined data set comprised 19 case studies of primarily hospital settings, and included 703 semistructured interviews, 663 hours of observations, and 864 documents gathered from a range of care settings across National Health Service (NHS) England and NHS Scotland. Data analysis took place over a period of 10 years and was guided by a framework informed by the existing evidence base.

Results: TPOM dimensions are intimately related and each include a number of subthemes that evaluators need to consider. Although technological functionalities are crucial in getting an initiative off the ground, system design needs to be cognizant of the accompanying social and organizational transformations required to ensure that technologies deliver the desired value for a variety of stakeholders. Wider structural changes, characterized by shifting policy landscapes and markets, influence technologies and the ways they are used by organizations and staff.

Conclusions: The TPOM framework supports formative evaluations of HIT implementation and digitally enabled transformation efforts. There is now a need for prospective application of the TPOM framework to determine its value.

health information technology; evaluation; sociotechnical

Introduction

Health systems worldwide are prioritizing the implementation of health information technology (HIT) in the quest to address some of health care's greatest challenges, including aging populations living with long-term conditions, persistent variations in the quality of care, and rising health care costs [1,2]. Although there is general agreement that HIT has the potential to improve safety, quality, and efficiency [3], large-scale HIT implementations require significant upfront investment, benefits are likely to materialize slowly, and those who put in most of the effort are often not those who benefit directly [4].

Such social and organizational challenges, which vary across contexts and technological functionalities, are often hard to navigate and predict for those managing change [5,6]. Despite efforts to identify success factors to guide implementation efforts, there is no simple recipe for success [7].

Formative evaluations can help to navigate these challenges. They can assist decision makers in moving from reactive to proactive strategies and identifying appropriate metrics to establish baselines and measure progress. In addition, they can help decision makers learn lessons more rapidly within the time frame of a project life cycle [8-10]. Formative evaluations can identify emerging unintended consequences and thereby, for instance, help to avert potential adverse outcomes for patient safety (eg, those arising from shortcomings in design, implementation strategy, and work practices) [11,12]. Evaluators should ideally work closely with strategic decision makers to keep projects on track and identify potential risks and mitigation strategies as early as possible.

However, despite these potential benefits, there is limited expertise in health services in conducting such formative evaluations. Existing organizational implementation evaluations, if conducted at all, often take place after an implementation has gone wrong, and use suboptimal methodologies.

Evidence-based frameworks to guide organizations in conducting HIT implementation evaluations have the potential to be helpful. A number of health informatics scholars have recently recognized this gap and developed various frameworks, some of which are summarized in Table 1 [13-19]. Some factors, such as user engagement and leadership, are well established in the change management literature. Other factors, such as political and market dimensions, have more recently received increasing recognition in shaping HIT implementations. The proliferation of frameworks poses a challenge for implementers seeking to navigate the literature and this paper seeks to integrate these frameworks.

Table 1. Examples of existing health information technology evaluation frameworks.

Framework	Key characteristics	Reference
Nonadoption, abandonment, scale-up, spread, and sustainability (NASSS) framework	This framework includes the following domains: the condition or illness, the technology, the value proposition, the adopter system, the organization(s), the wider context, and the interaction and mutual adaptation between all these domains over time.	Greenhalgh et al [13]
Framework for Evaluation of Informatics Tools	This framework includes the following stages: specification and needs requirements, component development, integration of system into a clinical setting, and routine use of a system.	Kaufman et al [14]
Health Information Technology Evaluation Toolkit	This framework includes the following dimensions: articulating goals of the project, understanding stakeholders, and benefits measurement.	Cusack and Poon [15]
Health Information Systems: human, organization, and technology-fit factors (HOT-fit)	This framework focuses on the fit between technological, human, and organizational dimensions.	Yusof et al [16]
Health Information Technology Reference-based Evaluation Framework (HITREF)	This framework includes 6 dimensions: structural quality, functional quality, effects on quality processes, effects on outcome quality of care, unintended consequences, and barriers and facilitators.	Sockolow et al [18]

Based on over 10 years of experience, we set out to update current thinking about formative evaluation frameworks. Drawing on the existing literature, our aim was to develop and apply a formative evaluation framework for HIT implementations that would offer guidance for implementers. In this study, we will present our experiential conclusions and highlight interrelationships between identified dimensions.

Methods

Description of the Data Set

We have led a series of qualitative, theoretically informed case studies of different HIT implementations in the context of national formative evaluations. These included electronic health records (EHRs), clinical decision support (CDS) systems, and a combination of CDS and computerized physician order entry (CPOE) systems [4,20,21]. Our ongoing involvement as principal investigators and researchers in these various formative evaluations provided a platform for understanding HIT implementation challenges.

Table 2 shows our data set, consisting of qualitative data collected between 2009 and 2018 by our research teams that included 11 social scientists. AS was the principal investigator on two of these projects [4,20], KC was the principal investigator on one [21], and RW was a senior adviser on all three [4,20,21]. We have published several papers from these evaluations, including both primary research and sets of evaluation recommendations based on the literature [4,20,21].

KC collected some primary data (approximately 100 interviews and 60 hours of observations on [20], 40 interviews on [4], and 14 interviews on [21]). The majority of case study sites (18 of 19) included hospital settings implementing EHR and CDS/CPOE functionality in the English National Health Service (NHS).

Table 2. Data set informing the development of the evaluation framework.

Project	Data set	Timeline
National evaluation of the implementation of electronic health records in secondary care in England	12 longitudinal qualitative case studies: 431 interviews, 590 hours of observations, 234 sets of field notes, and 809 documents	February 2009 to January 2011
National evaluation of the implementation of clinical decision support/computerized physician order entry systems in English hospitals	6 longitudinal qualitative case studies: 242 interviews, 32.5 hours of observations, and 55 documents	December 2011 to March 2016
National evaluation of a pilot decision support platform in Scottish primary care	30 interviews and 8 nonparticipant ethnographic observations	May 2018 to October 2018

Sampling Overview

We defined a case as an organization implementing relevant functionality within the boundaries of an organizational setting. We sampled hospitals for maximum variation in relation to geographical location, size, implementation strategy, technological systems, and governance structures [22].

We sampled individual participants through a combination of convenience and snowball approaches with key local gatekeepers facilitating initial contacts [23]. Participants in case study settings included representatives with varying degrees of seniority from a range of clinical professions (medical, nursing, pharmacy, and allied health care professionals), managerial, and IT support staff. We also collected data from relevant policymakers and system vendors, in order to gain insights into the wider market and policy dynamics in which local implementations took place.

Data Collection Overview

We collected data between February 2009 and October 2018. The majority of data consisted of digitally audio-recorded semistructured qualitative interviews (mainly face-to-face, some by telephone). These interviews explored expectations and experiences of implementing, using, and developing the new technology (depending on the background of the interviewee). Although interview guides varied with the specific focus functionality examined, key issues explored included the following: current systems, strategies, and organizational setup; views on potential system benefits and barriers to achieving these; and future directions and visions.

In many cases (18 of 19 case studies), we sought to interview participants longitudinally (ie, before the implementation of the system, during the implementation, and once they had time to get used to the HIT system).

Observations were nonparticipant in nature, opportunistic, and involved attending relevant strategic meetings (where the researcher took notes) or following a particular activity (eg, doctors using a specific system). Observations explored technological deployments in real-world contexts.

Documents consisted of minutes of strategic meetings, summaries of lessons learned, and business cases. These provided insights into planned activities and local narratives surrounding implementation.

Development of the Framework

We began by conducting a review of existing frameworks and undertook a systematic literature review to explore which factors are important for the effective implementation of HIT [24]. The resulting prototype coding framework was iteratively refined over time and throughout projects. It included a number of dimensions and factors that formed the basis for coding qualitative data collected throughout case studies. In this process, we also allowed additional categories to emerge inductively [25]. Case studies were initially coded separately and then integrated iteratively across functionality (EHRs, CDS/CPOE in hospitals or what is known as ePrescribing in the United Kingdom, and CDS). This resulted in development of the prototype coding framework into a more comprehensive evaluation framework, which was synthesized to reflect the most pertinent categories and updated in light of the current literature. Here, our focus was on breadth rather than depth, aiming to produce a comprehensive overview of various stakeholder perspectives. We gave particular attention to stakeholders who were underrepresented (eg, vendors and administrative staff).

Our analysis and development of the novel framework was informed theoretically by the sociotechnical approach, structuration theory, the social shaping of technology, and the theory of the diffusion of innovations [26-29]. The final framework was agreed upon through iterative discussion.

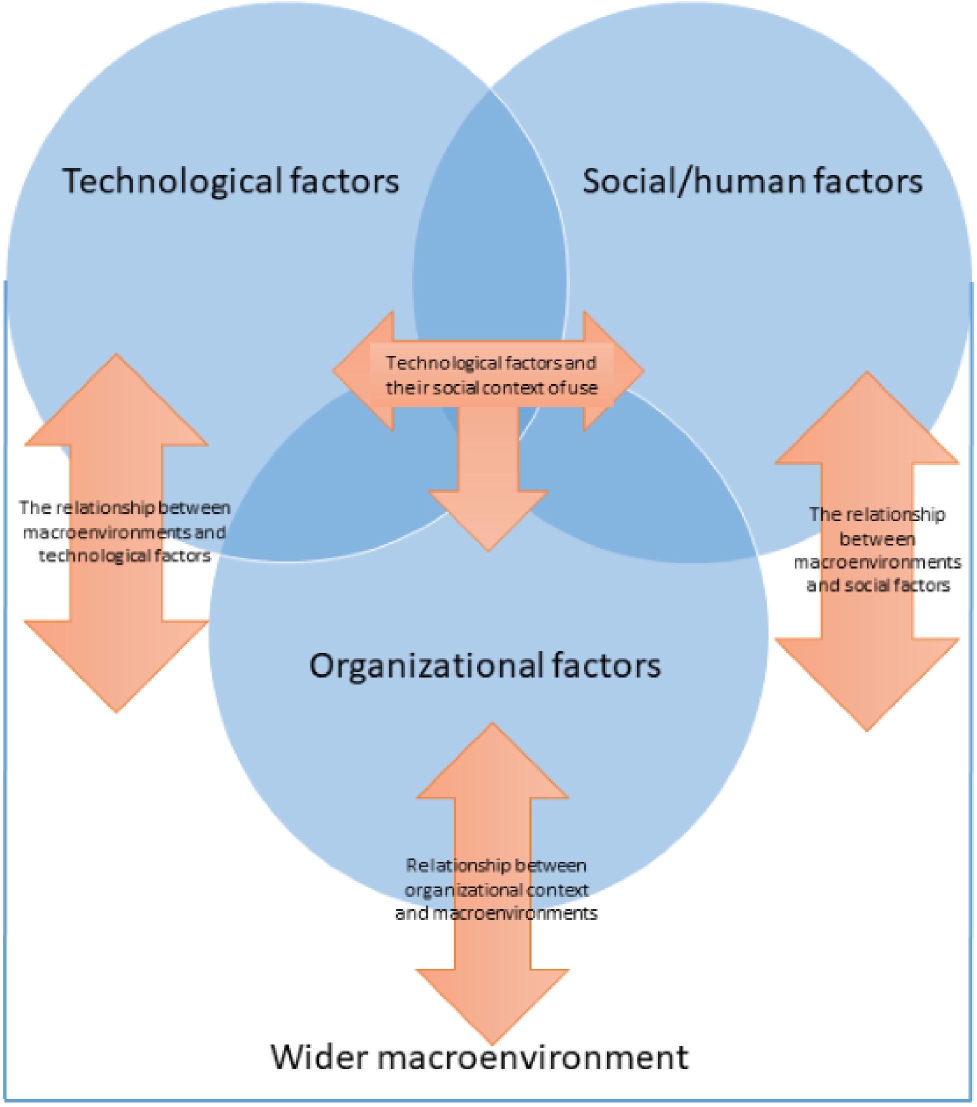
Results

We observed some commonalities across diverse settings and technological functions. The evaluation framework that has emerged from this work (Table 3, Figure 1) tackles important characteristics of the implementation landscape, where a range of technological, people (social/human), organizational, and wider macroenvironmental factors play an important role. Table 3 illustrates the key considerations in each of the dimensions. Figure 1 shows the interrelationship between the dimensions (technology, people, organizational, and macroenvironmental) and the various subcategories within each of these that need to be considered when implementing HIT.

Table 3. The Technology, People, Organizations, and Macroenvironmental factors (TPOM) framework, with example descriptions of dimensions.

Factor and dimension	Description
Technological factors	
Usability	What is the ease of use and learnability of the technology?
Performance	Does the technology function as intended by developers?
Adaptability and flexibility	Can system design be changed to suit emerging needs?
Dependability	Is the system reliable and stable?
Data availability, integrity, and confidentiality	Is data in the system available, accessible, and usable for those who need it?
Data accuracy	Is the data in the system accurate?
Sustainability	Is use of the technology sustainable?
Security	Is the system secure?
Social/human factors	
User satisfaction	Who are the users? Are users satisfied with the technology?
Complete/correct use	Are features and functionality implemented and used as intended?
Attitudes and expectations	What benefits do users expect from using the technology and how can these be measured?
Engagement	Are users actively engaged in implementation, adoption, and optimization?
Experiences	Do users have negative experience with previous technologies?
Workload/benefits	Are the benefits and efforts relatively equal for all stakeholders?
Work processes	Does the system change relationships with patients, patterns of communication, and professional responsibilities (eg, increase of administrative tasks)?
User input in design	Is there effective communication between designers, information technology staff, and end users, as well as between management and end users?
Organizational context	
Leadership and management	Are management structures to support the implementation adequate?
Communication	Are aims, timelines, and strategy communicated?
Timelines	Are implementation timelines adequate?
Vision	What benefits do organizations expect from implementing the technology and how can these be measured? Is a coherent and realistic vision driving developments?
Training and support	Is the training adequate and realistic?
Champions	Are champions and boundary spanners utilized?
Resources	Is implementation adequately resourced? (includes technology, change management, and maintenance)
Monitoring and optimization	Is system performance and use monitored and optimized over time? Are lessons learned captured and incorporated in future efforts?
Wider macroenvironment	
Media	How is the technology viewed by the media and by the public? How does the organization view/manage media relations?
Professional groups	How is the technology viewed by professional groups?
Political context	What benefits do policymakers expect from the technology and how can these be measured? What is the national approach to achieving interoperability and does the system align with this? Is there a coherent vision, consistent approach, and a clear direction of travel, allowing a degree of local input?
Economic considerations and incentives	Are there clear incentives for organizations and users to implement? (eg, improvements in quality of care) Is sufficient funding in place to support the initiative?
Legal and regulatory aspects	Have legal and regulatory frameworks been established?
Vendors	Is vendor management effectively organized?
Measuring impact	Are various stakeholders working together to define, validate, test, and refine outcome measures and measurement strategies? Are outcome measures important, clinically acceptable, transparent, feasible, and usable?

Figure 1. Diagram illustrating the evaluation framework.



None of these dimensions outranks the others. The relationship between dimensions influences how implementation, adoption, optimization, and maintenance processes unfold over time. Below, we illustrate some examples of the interrelationship between the different overarching TPOM dimensions (technology, people, organizational, and macroenvironment; Figure 1). The dimensions identified are not intended to provide detailed support for the different components of the framework, but rather to illustrate the relationships and interdependencies of the framework components.

Technological Factors and their Social Context of Use

We observed that, irrespective of the technology, systems needed to be usable, stable, and reliable (dependability), hold data securely (security), and only allow those with appropriate access rights to view confidential data (confidentiality). If systems and data within them were not dependable, users and implementers tended to lose confidence in their system choice.

> *…we are now questioning whether [name] is the right solution for our high secure service…* [Manager, EHR Evaluation]

However, it was also apparent that the design of technologies never occurred in isolation of the social and organizational context of use. This was exemplified through the many different ways in which technologies transformed how users worked in often unanticipated ways (eg, by making data entry more cumbersome; see the Social/human dimension, which includes “User satisfaction,” “Workload/benefits,” and “Work processes,” in Table 3), but also by how different technologies were optimized to suit organizational and user requirements over time (“Adaptability” in Table 3).

> *We had customized the system over a significant period of time to make it usable...* [Clinical Lead, EHR Evaluation]

System usability was the most important prerequisite for successful adoption. If users had to navigate a large number of interfaces and had difficulty finding relevant data, and if there was a general lack of intuitiveness, this slowed down their work (“Workload” and “Work processes” in Table 3).

> *All our doctors and nurses are having to work harder now, because we are having to see the same number of patients with less time, because you are spending*

> *more time on a computer now.* [Consultant, EHR Evaluation]

As a result, to not disrupt everyday delivery of care, staff had to employ workarounds ("Complete/correct use" in Table 3).

> *The staff just create workarounds of the system and some of them are ingenious and have gone on to change the system in a good way, but some aren't as helpful.* [Pharmacist, CDS/CPOE Evaluation]

Although changes to system design could address these issues, modifications were in many instances cumbersome and lengthy ("Adaptability and flexibility" in Table 3). Vendors, in turn, struggled to find a balance between tailoring of applications to local needs (achieved through local configuration) and developing commercially viable generic system versions ("Vendors" in Table 3).

> *So when [vendor] deliver the product it will have a form designer so you will be able to go in the back end […]so the focus is to, for most of it make sure that it's done through configuration not through software changes.* [Manager, CDS/CPOE Evaluation]

The Relationship Between Organizational Context and Macroenvironments

Organizations tended to employ two distinct strategies to approach system implementation. These involved both "top-down" and "bottom-up" management approaches, as well as technology strategies that involved transformative change combined with automating existing processes. "Top-down" and "bottom-up" strategies occurred at two different levels. These included the following: (1) technology design/procurement (in the English National Programme for IT (NPfIT) characterized by centralized procurement; "Political context" in the Wider macroenvironment dimension); and (2) technology implementation strategy within the organization ("Leadership and management" in the Organizational dimension).

Balancing these tensions was instrumental for the perceived success of initiatives; this is not recognized in many existing frameworks. For example, although there was a perceived need for clinicians to be heavily involved in strategy, implementation, and deployment ("Communication" and "Vision"), stakeholders also recognized that some decisions at an organizational level had to satisfy the needs of diverse stakeholders, including those outside the immediate hospital environment ("Adaptability and flexibility" in Table 3).

> *Everybody wants their own changes so some of the changes are the [management] have decided to do it that way but that doesn't mean Consultant A thinks that's the right way, so there is often not acceptance.* [Pharmacist, CDS/CPOE Evaluation]

The Relationship Between Macroenvironments and Technological Factors

It was very clear throughout our work that wider structures had a significant impact on organizational processes, ways of working, and technologies (see the Macroenvironmental dimension in Table 3). These included tensions between the long time frames needed to achieve transformation (5 to 10 years) and the episodic funding schemes (2- to 3-year programs; "Timelines" in Table 3). We also observed changing policy landscapes that involved a high turnover in senior staff and accompanying changes in visions of digital care and available funding (see "Political context" in Table 3). For example, when we began our work, England's national strategy of implementing centrally procured systems had just started [30]. However, during the CDS/CPOE evaluation, there was an increasing focus on local involvement in decision making, driven by the demise of the NPfIT and increased economic pressures resulting from the global recession. When we completed data collection, there was again a growing recognition that national guidance was crucial for promoting implementation progress and interoperability [31].

> *I've got a concern that if one of those two parties come into power and it seems highly likely that they will, that the National Programme might be closed and [system] might be shut down and what then happens…do they close the whole of the National Programme in which case, do we go back to where we were eight years ago?* [Manager, EHR Evaluation]

In addition, we observed shifts in market and vendor structures and the technologies themselves. These are not sufficiently accounted for in existing frameworks (see "Vendors" in the Wider macroenvironment dimension in Table 3). During the NPfIT, we observed a limited number of large vendors pushing other players out of the English/UK market, although the dynamics changed after the demise of NPfIT and the termination of associated contracts. This gave way to a more vibrant vendor landscape (although the market is still not very open to new vendors), which has important implications for organizations and users as they can only procure technologies from those that are currently available.

> *With the breakdown of [NPfIT] we are now seeing a lot more [hospitals] looking to take advantage of electronic prescribing and we're seeing an increased level of interest at this time to see if they can do this because effectively they've put the infrastructure in…* [Vendor, CDS/CPOE Evaluation]

We also saw how technologies were refined "in use" and through close working relationships between vendors and users over long periods ("Adaptability" in the Technology dimension in Table 3), which helped vendors/system designers overcome their limited knowledge of the social context of use. We have repeatedly seen the formation of vendor/user groups and observed how these helped to actively shape designs and markets ("User input in design").

Discussion

Summary of Findings

We have developed an evaluation framework for implementers of HIT initiatives to guide implementation and optimization of functionality (Table 3). Although this draws on formative work, it can also guide summative evaluations. The TPOM framework includes key issues to consider in relation to technological, social/human, organizational, and wider macroenvironmental dimensions. Our ongoing work has shown that these dimensions are intimately related. Technologies never exist in isolation; it is therefore critical to appreciate that technological change will be accompanied by transformations in social groups, organizations, and the wider landscapes in which these are situated, including health policy, economic climates, and the development of markets.

Strengths and Limitations

This work has drawn on a substantive composite qualitative data set collected over a long time frame. Therefore, it helped us to assess which dimensions were relatively stable over time, and only these were included in the TPOM framework. Insights presented here are views derived following careful critical reflections on a series of evaluations.

Although we acknowledge that many dimensions could be included, we deliberately attempted to keep the themes and subthemes manageable, thereby addressing a key issue in health technology evaluation: the usability of evaluation tools. We do not claim to capture all factors that play a role in implementation, adoption, and optimization of HIT, nor do we claim that our TPOM framework will provide a recipe for success. However, its pragmatic use in implementation and evaluation activity is likely to improve processes by prompting implementers to consider the most important dimensions influencing outcomes, thereby reducing unintended consequences and maximizing value. The framework now needs to be applied prospectively to confirm its utility across settings and regions. As such, we hope that it will provide a solid foundation for other countries to develop their own evaluation frameworks.

A key challenge faced by most existing evaluation frameworks, including ours, is that they neglect to account for the dynamic relationship between social and technological dimensions of change. As this relationship is a process, it does not lend itself well to presentation in 2D pragmatic evaluation tools. We have illustrated this dynamism in the Results section, drawing on concrete examples.

Integration of Findings with the Current Literature

Many empirical studies of HIT implementation are primarily concerned with evaluating impact and therefore emphasize quantitative measurements guided by benefits realization frameworks [32,33]. Recent evaluation frameworks have expanded this limited focus to include a more in-depth appreciation of the interplay of social and technological factors shaping implementations. However, although acknowledging the complexity of the process, these nuanced frameworks tend to concentrate on one particular local and situated aspect of technology implementation, thereby neglecting the role of wider structuring conditions in shaping developments [16,34-37].

Others have considered wider structuring conditions, but the tools developed lack intuitiveness, usability, and practical applicability. For example, some frameworks that are designed to shed light on sociotechnical processes can become abstract and difficult to apply by those without academic backgrounds (which arguably includes the vast majority of those implementing change in health system settings) [38]. Others have become so complex that they may include a myriad of relevant dimensions, but this attempt to capture everything may result in a level of complexity that undermines the usefulness of the framework as a tool [13,26]. The challenge is to avoid Lewis Carroll's cartographer's dilemma of needing to make a comprehensive map on the same scale as the mapped landscape, which then no longer helps users navigate [39]. Our framework has sought to address this dilemma.

There are several commonalities with existing frameworks, including a recognition of key technology, human and organizational dimensions, and their interrelationship [13-16,18]. However, TPOM is not condition- or illness-specific [13]. It is not concerned with the likelihood of the technology being adopted and its spread [13], but it is designed to help implementers of technology consider how implementation is progressing, the potential emerging risks, and what aspects therefore need attention to facilitate adoption. Implementers can apply TPOM to any HIT project at any stage of implementation. It builds on other evaluation frameworks that take into account the microcontext of use [14-16,18], to include consideration of wider macroenvironment dimensions that influence implementation and adoption. It is not concerned with management tools, but with alignment of perspectives [15]. As such, it does not provide a "recipe for success"; rather, it is a tool designed to help implementers navigate a complex landscape with many conflicting agendas and considerations. When problems or risks are identified with the help of the framework, these can be systematically targeted to facilitate implementation and adoption.

Policy Recommendations and Implications for Practice Emerging From This Work

Pragmatic formative evaluation frameworks can help to understand areas for potential improvement, benefits, and ways to streamline processes associated with technology implementation in health care settings. Evaluations need to move away from simple benefit realization approaches (that attempt to identify and measure benefits at the end of an implementation) toward formative evaluations that help the stakeholders involved adjust strategy along the way. Formative evaluations are part of a shift toward an evolutionary model where evaluation is a resource for faster and more effective learning.

Our proposed framework is a guide for implementers of technological change initiatives, to assist in planning, or during implementations of HIT initiatives in health care settings. We invite those who use it to suggest changes in both content and usability, as this will help to maximize its use and application. In due course, we hope to be able to draw on a range of data collected through the lens of the framework in different settings, refine it, and develop new insights in relation to each of the dimensions.

Large transformative policy programs aimed at facilitating technology implementation beyond hospitals are likely to require different evaluation frameworks, as their effects may be harder to trace and attribute.

Conclusions

We have drawn on a substantial body of data to develop the TPOM framework (Table 3), which stakeholders can use to monitor change processes and, if necessary, adjust the direction of HIT implementation projects. Going forward, a key challenge is likely to be the ongoing tension between attempts to capture the dynamics, processes, and interrelationships involved in technological change; the large number of these dimensions and their complexity; and the usability of evaluation tools by those delivering care, which is linked to their potential to have impact. We encourage prospective application of the TPOM framework to determine its value.

Acknowledgments

This article has drawn on a range of programs of independent research funded by the NHS Connecting for Health Evaluation Programme, The National Institute for Health Research, the Digital Health and Care Institute, and Scottish Government. The views expressed are those of the authors and not necessarily those of the funders.

Abstract

Background: Cancellations and rescheduling of doctor's appointments are common. An automated rescheduling system has the potential to facilitate the rescheduling process so that newly opened slots are promptly filled by patients who need and can take the slot. Building on an existing online patient portal, a large health care system adopted an automated rescheduling system, Fast Pass, that sends out an earlier appointment offer to patients via email or SMS text messaging and allows patients to reschedule their appointment through the online portal.

Objective: We examined the uptake of Fast Pass at its early stage of implementation. We assessed program features and patient and visit characteristics associated with higher levels of Fast Pass utilization and the association between Fast Pass use and no-show and cancellation rates.

Methods: This study was a retrospective analysis of Fast Pass offers sent between July and December 2018. Multivariable logistic regression was used to assess the independent contribution of program, patient, and visit characteristics on the likelihood of accepting an offer. We then assessed the appointment outcome (completion, cancellation, or no-show) of Fast Pass offered appointments compared to appointments with the same patient and visit characteristics, but without an offer.

Results: Of 177,311 Fast Pass offers sent, 14,717 (8.3%) were accepted. Overall, there was a 1.3 percentage point (38%) reduction in no-show rates among Fast Pass accepted appointments compared to other appointments with matching characteristics ($P<.001$). The offers were more likely to be accepted if they were sent in the evening (versus early morning), the first (versus repeated) offer for the same appointment, for a slot 1-31 days ahead (versus same-day), for later in a day (versus before 10am), for a primary care (versus specialty) visit, sent via SMS text messaging (versus email only), for an appointment made through the online patient portal (versus via phone call or in-person), or for younger adults aged 18-49 years (versus those aged 65 years or older; all at $P<.001$). Factors negatively associated with offer acceptance were a higher number of comorbidities ($P=.02$) and visits scheduled for chronic conditions (versus acute conditions only; $P=.002$).

Conclusions: An automated rescheduling system can improve patients' access by reducing wait times for an appointment, with an added benefit of reducing no-shows by serving as a reminder of an upcoming appointment. Future modifications, such as increasing the adoption of SMS text messaging offers and targeting older adults or patients with complex conditions, may make the system more patient-centered and help promote wider utilization.

KEYWORDS

access to care; health information technology; appointment scheduling; patient-centered care

Introduction

Physicians and health care systems have long struggled with two concomitant but discordant conditions with regard to patient access to care. Many health systems simultaneously report long wait times for patient appointments and available appointment slots that are underutilized. Common contributing factors to this are last-minute cancellations and appointment no-shows by patients, leaving unfilled appointment slots in a physician's schedule. No-show rates have been variably reported to be as low as 2% to more than 50% of scheduled appointments [1-6], and represent an estimated annual cost to the health care system of $150 billion [6-8]. These schedule holes disrupt clinic workflows and reduce efficiency, reduce access for other patients who could have filled the slot, represent lost revenue for the health care systems, result in worse patient health outcomes, and ultimately cause dissatisfaction for patients and health care providers [9-13]. Typical countermeasures are often clinician-centric. For example, clinicians may maintain long wait queues to increase the probability of full schedules. Clinicians have relied on staff to manage waitlists of patients, but this approach is time- and labor-intensive, as clinic staff spend time calling patients to try to fill open slots [1,14,15].

Health information technology (HIT), particularly electronic health records (EHR), is often cited as a source of physician burnout, with clinical documentation requirements and other administrative tasks associated with EHR use in the United States being major contributing factors [16-18]. However, this literature often fails to recognize the counterbalancing beneficial aspects of HIT, such as enabling patients to access their health records electronically, schedule and reschedule appointments, and actively participate in shared decision-making, potentially resulting in improved care experiences and satisfaction [19-22]. An automated HIT system that leverages digital patient engagement to take advantage of available care options presents an opportunity to create a mutually beneficial scenario, addressing the need to improve practice efficiency and the patients' desire for more timely access.

In 2015, Sutter Health began piloting an automated appointment offer and fulfillment program called Fast Pass, a module developed by Epic Systems Corporation, and subsequently completed an enterprise-wide implementation in ambulatory primary care and specialty practices in 2018. Fast Pass allows a waitlisted patient to receive an automated message when an earlier appointment slot is available, and accept it or keep the original appointment. Fast Pass has significant potential to improve access and patient experience, in addition to promoting efficiency by filling clinic slots.

We therefore conducted a rigorous evaluation of the Fast Pass system. We evaluated the implementation of the system in 2018 after it had been rolled out across the Sutter Health system. The current paper describes the program features and identifies patient and visit factors associated with higher levels of Fast Pass utilization, as well as the association between Fast Pass implementation and no-show and cancellation rates. To our knowledge, this is the first study to systematically evaluate the implementation and effectiveness of an automated rescheduling system across ambulatory primary and specialty care settings.

Methods

Setting

Sutter Health is a large, not-for-profit health care system in Northern California serving more than 3 million people across 100 rural, suburban, and urban communities. The health care population represents high diversity in insurance coverage and race/ethnicity (eg, 17% Asian, 11% Hispanic/Latino), socio-demographics, and cultural backgrounds, mirroring the larger underlying catchment area. The health care system has a long history of utilizing HIT, with one affiliate becoming the first health system in the nation to implement Epic Systems Corporation's MyChart patient portal, My Health Online (MHO), in 2001.

Features of Fast Pass

In late 2015, Sutter implemented a pilot program, Fast Pass, to allow patients to be notified via email of an earlier appointment slot should one become available. Then, in early 2018, along with implementation of SMS text messaging reminders for appointments, Fast Pass was rolled out across the organization and patients were allowed to opt in to receiving Fast Pass notices via email, SMS text messaging, or both.

To use Fast Pass, a patient must first opt into the program via MHO (the online patient portal) and elect to receive notifications via email, SMS text messaging, or both (Figure 1). After a patient schedules an appointment, they can elect to be added to the waitlist for an earlier appointment slot. Once notified of an earlier slot, the patient must log on to MHO to respond. After several modifications during the initial pilot phase, the current Fast Pass system is scheduled to offer alternative appointment slots 9 times per day (Table 1). Two of these batches are sent early in the morning between 6 AM and 7:30 AM for same-day appointments and they expire after 30 minutes. One batch is sent midday (11:30 AM), also expires after 30 minutes, and is for appointment slots either that same day or up to 7 days ahead. The final six batches are all sent in the evening between 6 PM and 8:30 PM for appointments the next day up to 31 days ahead, and these offers all expire at 5:30 AM the following day. For each batch, an appointment slot was offered to 5 patients simultaneously; the offer expired automatically once it was taken on a first come, first served basis or when the time expired.

Table 1. Fast Pass offer characteristics.

	Batch 1	Batch 2	Batch 3	Batch 4	Batch 5	Batch 6	Batch 7	Batch 8	Batch 9
Time sent	6 AM	6:30 AM	11:30 AM	6 PM	6:30 PM	7 PM	7:30 PM	8 PM	8:30 PM
Time before expiration	30 minutes	30 minutes	30 minutes	11.5 hours	11 hours	10.5 hours	10 hours	9.5 hours	9 hours
Offered appointment date	Same day	Same day	Same day to 7 days ahead	1-31 days ahead	1-31 days ahead	1-31 days ahead	1-31 days ahead	1-31 days ahead	1-31 days ahead
Minimum days saved	1	1	1	3	3	3	3	3	3
Number of offers sent per slot	5	5	5	5	5	5	5	5	5

Statistical Analysis

Factors Associated With the Likelihood of Accepting a Fast Pass Offer

We used Fast Pass offers sent between July and December 2018 for this retrospective analysis. First, we examined the distribution of responses to Fast Pass offers, classified into the following: accepted, declined, viewed on time (while the offer was active) but did not respond, viewed too late (after expired or taken by another person), and did not view.

We then assessed differences in acceptance rates based on Fast Pass feature, visit type, and patient demographic and clinical characteristics. *T* test and analysis of variance (*F* test) were used to examine differences in the unadjusted proportion of accepted offers across subgroups. Multivariable logistic regression was used to assess the independent contribution of each factor on the likelihood of accepting the offer.

Fast Pass and the Likelihood of No-Shows

We assessed whether outcomes of an appointment (ie, completed, canceled, or no-show) with a Fast Pass offer (whether the appointment was rescheduled through Fast Pass or the original appointment was kept) differed from appointments without an offer. We considered a canceled appointment as happening any time prior to the scheduled appointment time. Recognizing that the impact of Fast Pass would depend on patients' responses to the offer, we analyzed two types of responses to the offer separately: "accepted" and "viewed but not accepted". For each Fast Pass offer that was accepted or viewed, we randomly selected 5 matched appointments from the pool of patients who were actively using MHO but were not offered a Fast Pass alternative for an upcoming appointment. The Fast Pass offer appointments and 5 matching no-offer appointments were exactly matched on the following characteristics: age group (0-17, 18-39, 40-54, 55-64, 65 years or older); primary care versus specialty care; scheduled appointment time (before 10 AM, 10 AM to 11:59 AM, noon to 2:59 PM, 3 PM and later); and days between appointment made and visit date (0, 1-7, 8-24, 29 days or longer). We chose the 1:5 ratio to make the best use of available data while also reducing bias, as there were very few appointments with an offer relative to those without an offer that had the same observed characteristics [23,24].

Analyses were conducted with Stata 14.2 (StataCorp). The study was reviewed and deemed to be quality improvement by the Sutter Health Institutional Review Board.

Results

Responses to Fast Pass Offers

Of 177,311 Fast Pass offers sent for 44,792 appointment slots to 38,361 patients, 8.3% (n=14,717) were accepted, 11.1% (n=19,682) were declined, 8.0% (n=14,185) were viewed on time but with no response, 53.3% (n=94,507) were viewed after the offer expired or became unavailable, and 19.4% (n=34,398) were never viewed.

Characteristics of Fast Pass Offers

Out of the 177,311 Fast Pass offers sent, most were for same-day appointments (n=48,502, 27%), appointments the next day (n=28,370, 16%), or appointments 2-7 days ahead (n=62,059, 35%), with the remainder (n=37,235, 21%) for appointments 8-31 days ahead (Table 2). If they were accepted, Fast Pass offers would have saved 8-30 days from the originally scheduled appointment in most cases (n=83,891, 47%), followed by 0-7 days (n=51,469, 29%), and 31-358 days (n=42,196, 24%). Those who accepted an offer saw their clinician on average 14.8 (SD 14.6) days sooner than initially scheduled for primary care, and 23.7 (SD 23.0) days sooner for specialty care. A quarter of offers (n=40,992, 23%) were sent during the early morning, 64,005 (36%) were sent midday, and 72,313 (41%) were sent in the evening. Fast Pass offers can be sent repeatedly for the same appointment slot, and 59,238 (33%) of appointment slots had an offer 5 or more times. See Table 2 for other patient and visit characteristics.

Table 2. Program, visit, and patient characteristics of Fast Pass offers.

[a] E/M: evaluation and management coding.

[b] This category includes visits with no diagnosis falling into acute or chronic conditions and appointments later canceled or no-shows.

Bivariate Analysis of Characteristics of Accepted Fast Pass Offers

The first offer for an appointment slot was far more likely to be accepted than subsequent offers for the same original appointment (17.7% versus 2.1%-10.1% of acceptance rates, respectively; *P*<.001; Table 2). Offers sent in the evening were more than twice as likely to be accepted (13.1%) than morning offers (3.5%-6.0%; *P*<.001). There was a higher acceptance rate when the offered slot was more than one week ahead (12.4%-13.5%), 2-7 days ahead (9.2%), or the next day (8.2%), as compared to the same day (3.7%; *P*<.001). The acceptance rate was higher for offers with potentially fewer days saved (9.0% for 0-7 days versus 6.9% for 31-358 days; *P*<.001) and when the offered slot was in the afternoon (8.6%-8.8%) rather than in the morning (8.0%; *P*<.001). Acceptance rates were higher when the appointment was scheduled through MHO versus offline (10.3% versus 7.4%; *P*<.001) and among patients who opted to be contacted through SMS text messaging versus email only (10.4% versus 7.4%; *P*<.001). Compared to non-Hispanic whites, Asians were more likely to accept an offer (9.0% versus 8.1%; *P*<.001).

Patients with a high comorbidity burden were less likely to accept offers (Charlson Comorbidity Index [CCI]=0, 8.5%; CCI≥2, 6.7%; *P*<.001). Acceptance rates were highest among people aged 18-49 years (9.7%) and lower for those aged 0-17 years (6.4%; their guardian received the messages) or 50-64 years (8.1%; *P*<.001). Male patients were more likely to accept an offer than female patients (8.5% versus 8.2%; *P*<.001). Accepted visits were more likely to be for acute conditions only (16.5%) rather than for chronic conditions only (13.6%) or both acute and chronic conditions (12.4%; *P*<.001). Specialty care visits were slightly more likely to be accepted (8.4% versus 8.1%; *P*=.009), and there were no differences in acceptance rates across specialties (eg, dermatology, ob-gyn, orthopedics).

For same day or next-day offers only (N=60,206), offers sent in the evening (of the day before the opened slot) rather than in the morning (of the appointment day) were three times more likely to be accepted (11.5% versus 3.5%; *P*<.001), and patients with acute conditions only (12.2%) were more likely to accept the offer (*P*<.001) than those with both chronic and acute conditions (8.5%).

Factors Associated With Offer Acceptance in Multivariable Analysis

After controlling all other factors, findings from the adjusted, multivariable analysis (Table 3) were similar to those from the unadjusted, bivariate analysis, with a few exceptions. Preventive visit, older age (aged 65 years or older), and specialty visit were negative predictors of Fast Pass acceptance (*P*<.001). In addition, the following factors no longer had a significant association with offer acceptance in the adjusted model: potentially saved at least 31 days (versus 7 days or fewer; *P*=.33), CCI≥2 (*P*=.24), visit for chronic conditions (versus both acute and chronic conditions; *P*=.48), female (*P*=.04), aged 50-64 years (versus 0-17; *P*=.17), and Asian (versus non-Hispanic white; *P*=.08).

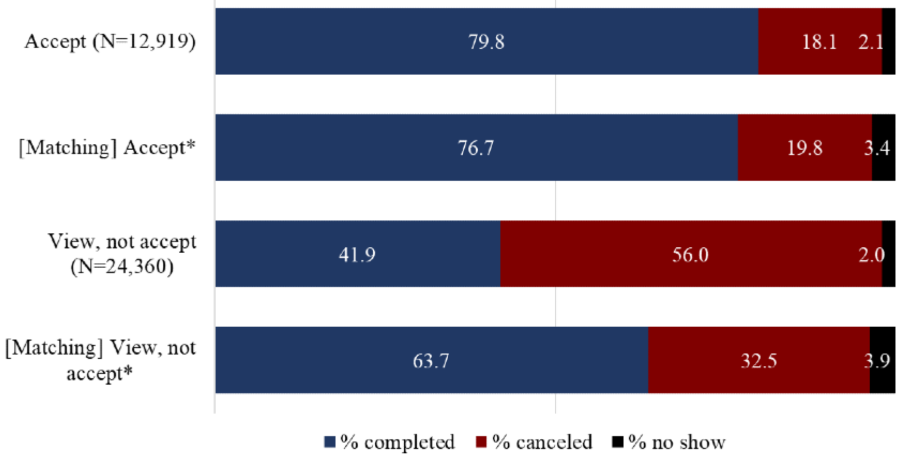
Fast Pass and the Likelihood of Appointment Completion, Cancellation, and No-Shows

As compared to appointments with matched characteristics but without a Fast Pass offer, accepted Fast Pass appointments were more likely to be completed (79.8% versus 76.7%) and less likely to be canceled (18.1% versus 19.8%) or result in no-shows (2.1% versus 3.4%; *P*<.001; Figure 2). Additionally, Fast Pass offers viewed but not accepted were less likely to be completed (41.9% versus 63.7%) and more likely to be canceled (56.0% versus 32.5%) but less likely to be no-shows (2.0% versus 3.9%; *P*<.001).

Figure 2. Appointment outcomes by Fast Pass offer status. * indicates matching comparison groups of "accept" and "view, not accept" groups, respectively.



Discussion

Principal Findings

Fast Pass, a patient-centered application of HIT, mutually benefits patients and providers. Patients who accepted a Fast Pass offer experienced more timely access to care, with time to see a doctor reduced by 15 days in primary care and 24 days in specialty care, on average. From the provider perspective, Fast Pass offers facilitated efficient management of office visit slots by automating rescheduling processes and filling gaps in provider schedules in a timely manner.

The Fast Pass system also serves to remind the patient about an upcoming appointment, reducing no-shows by 1.3 percentage points (a 38% relative reduction or 168 appointments) and facilitating timely cancellation of appointments that are no longer needed by 1.7 percentage points (a 9% relative reduction or 219 appointments), when the offer was accepted. Even when the original appointment was kept, those who viewed the offer had almost half the no-show rate as their matched comparisons (2.0% versus 3.9%). Other studies have found that patients often miss an appointment simply because they have forgotten about it, because of long delays between scheduling an appointment and the actual visit date, or because patients have no means of cancelling [1,4,6,25,26]. Using SMS text messaging to send reminders for upcoming appointments has been shown to reduce no-show rates and increase cancellation rates, providing time for the health care system to fill that slot with another patient [1,14,15]. Though the change in no-show rates seems relatively modest, if all patients in the health care system opt into the program, it would have significant clinical implications. Applying the rate to the volume of appointments in this health care system, approximately 20 million in 2018, it translates to 260,000 no-shows that could have been avoided annually if all patients were reminded through the Fast Pass system.

Despite the potential benefits, the acceptance of Fast Pass offers was 8% of the total early appointments offered. Notably, Fast Pass offers were more likely to be accepted when the initial notification was received via SMS text messaging. The alternative to SMS text messaging of Fast Pass offers is email, which may explain the high rate of Fast Pass offers (53.3%) that were viewed after the offer expired or became unavailable. In light of protections provided by the Telephone Consumer Protection Act, which implements consumer protections from unwelcome solicitations via phone and text messaging, the organization has offered this feature to patients who have individually enrolled and consented to receiving reminders via SMS text messaging. Balancing the activation inertia of enrolling in a new program and the desire to advocate for robust consumer protections versus the desire to maximize the potential patient benefits comes with the cost of increased socio-behavioral and technical barriers to adoption. Alternative approaches not being tested here (eg, more automated enrollment for digital waitlists and SMS text messaging as well as tighter integration with conditions of registration workflows) should also be considered and evaluated in future modifications.

There are several potentially modifiable program features to improve the benefits realized from Fast Pass for those who opted into the program. Our findings suggest that offer acceptance can improve by increasing the rate of patients enrolled to receive offers delivered by SMS text messaging; sending next-day offers in the evening rather than same-day offers in the early morning; sending an offer once per appointment slot and, if not accepted, not sending another one, but instead offering it to another person; allowing more time to respond for same-day slots; and focusing on users of the online patient portal, who are more likely to view and respond to the offer. A potential modification that might help improve the acceptance rate and make the system more patient-centered is to ask patients their preference for alternative slots at the time they sign up for the waitlist. This may become feasible as more patients sign up for Fast Pass and the volume of waitlist participants is large enough to identify matching between available and preferred slots.

It is unclear, though, whether Fast Pass offers are currently utilized by those who need it most. Patients who perceive their conditions as urgent may be more likely to accept the offer, as shown with the higher acceptance rate among patients with acute conditions only and a lower rate for preventive visits. On the other hand, the acceptance rate was lower for those with multiple comorbid conditions and higher disease burdens and for older patients whose medical needs are typically greater. One potential explanation is that older adults and patients with multiple comorbidities are less likely to opt for SMS text messaging than email. To improve overall uptake of the system as well as to reduce disparities in the utilization, more outreach efforts may be necessary, especially to those who could benefit most from the system, eg, patients with higher comorbidity burdens.

Limitations

Our study has several limitations that future extended studies should address. First, though we were able to quantitatively measure the rates of acceptances and declines of Fast Pass offers, we do not understand facilitators and barriers to using the Fast Pass program from the perspective of the patient. Focus groups or patient surveys would better examine the factors that impact adoption of the program. Second, we have yet to assess whether the system reduced the workload related to rescheduling for front desk staff and schedulers, as intended. Finally, we investigated one form of an automated rescheduling system, suggesting potential modifications for improvement. A prospective study, preferably with natural experiments, should address whether such modifications would help facilitate better utilization of the system by patients who could benefit most.

Conclusions

Fast Pass, an innovative automated rescheduling system embedded in the EHR, improves patient access to care by reducing wait time for an appointment, with an added benefit of reducing no-shows and increasing timely appointment cancellation by serving as a reminder of an upcoming appointment. Future modifications, such as allowing more time to respond to the offer and targeting patients with complex conditions, may help enhance the value of the system and wider adoption of the model beyond the Sutter Health system. Identifying opportunities for the implementation of interventions such as Fast Pass can provide evidence of the full range of benefits of HIT by simultaneously improving clinician practice efficiency and patient experience and access to care.

Acknowledgments

SC had full access to all of the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. All the analytical work and the initial manuscript was completed during her employment at Sutter Health. SC, ASC,

VGJ, and DLF, and MCM conceived of the study concept and design, and reviewed and provided critical feedback on manuscript drafts. SC and MCM led data interpretation, and framing and writing of the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared. The authors are employees of the health care system where the study was conducted. The organization had no influence on the conduct or reporting of this study.

Abstract

Background: Recent advances in natural language processing and artificial intelligence have led to widespread adoption of speech recognition technologies. In consumer health applications, speech recognition is usually applied to support interactions with conversational agents for data collection, decision support, and patient monitoring. However, little is known about the use of speech recognition in consumer health applications and few studies have evaluated the efficacy of conversational agents in the hands of consumers. In other consumer-facing tools, cognitive load has been observed to be an important factor affecting the use of speech recognition technologies in tasks involving problem solving and recall. Users find it more difficult to think and speak at the same time when compared to typing, pointing, and clicking. However, the effects of speech recognition on cognitive load when performing health tasks has not yet been explored.

Objective: The aim of this study was to evaluate the use of speech recognition for documentation in consumer digital health tasks involving problem solving and recall.

Methods: Fifty university staff and students were recruited to undertake four documentation tasks with a simulated conversational agent in a computer laboratory. The tasks varied in complexity determined by the amount of problem solving and recall required (simple and complex) and the input modality (speech recognition vs keyboard and mouse). Cognitive load, task completion time, error rate, and usability were measured.

Results: Compared to using a keyboard and mouse, speech recognition significantly increased the cognitive load for complex tasks ($Z=-4.08$, $P<.001$) and simple tasks ($Z=-2.24$, $P=.03$). Complex tasks took significantly longer to complete ($Z=-2.52$, $P=.01$) and speech recognition was found to be overall less usable than a keyboard and mouse ($Z=-3.30$, $P=.001$). However, there was no effect on errors.

Conclusions: Use of a keyboard and mouse was preferable to speech recognition for complex tasks involving problem solving and recall. Further studies using a broader variety of consumer digital health tasks of varying complexity are needed to investigate the contexts in which use of speech recognition is most appropriate. The effects of cognitive load on task performance and its significance also need to be investigated.

speech recognition software; consumer health informatics; ergonomics

Introduction

Recent advances in natural language processing and artificial intelligence have led to improvements in and widespread adoption of speech recognition technologies [1]. Speech recognition is an input modality that translates human speech into computerized text [2]. In consumer applications, speech recognition is usually applied as a way to interact with conversational agents, which are systems that mimic human conversation using text or spoken language [3,4]. Consumer conversational agents (such as Amazon Alexa and Google Assistant) can improve patient workflow by allowing patients to call nurses [5]. In health care, conversational agents have been utilized for a variety of purposes, including data collection, decision support, and patient monitoring [5-8].

Problems with the use of digital health technology represent a well-documented safety concern in the literature [9,10]. However, little is known about the problems associated with conversational agents that pose actual or potential risks of harm to consumers [9]. One study in which the participants were asked to interact with conversational agents identified significant safety concerns arising from the quality of information provided in response to health-related questions [11]. For example, incorrect information provided by a conversational agent in response to a question about the amount of alcohol that could be consumed while taking oxycodone could lead to severe harm, including death. However, few studies have evaluated conversational agents in the hands of consumers [3,4].

In other consumer-facing tools, cognitive load has been observed to be an important factor affecting the use of speech recognition technologies. Users reported finding it more difficult to think and speak at the same time when compared to typing, pointing, and clicking [12,13]. However, the effects of speech recognition use on cognitive load when performing health tasks has not yet been explored. Cognitive load is the amount of workload imposed on the brain's working or short-term memory, which has limited capacity [14,15] and a short duration [16], particularly when performing tasks requiring problem solving and recall [14,17]. An example of a problem-solving task is using basic arithmetic to calculate nutritional information, whereas recall involves memorizing and reporting exercise information. Due to the cognitive load, certain tasks may be more difficult to perform because speaking shares the same cognitive resources in the brain as those required for problem solving and recall (ie, working memory) [12]. Therefore, a possible challenge with the use of speech recognition is that it can increase the cognitive load in tasks requiring more problem solving and recall.

Although studies in other domains have investigated the effects of speech recognition use on cognitive load, to our knowledge, no study has measured its effects in digital health tasks [12,18,19]. Thus, the aim of the present study was to evaluate the use of speech recognition for documentation in consumer digital health tasks such as recording diet and exercise information in comparison to using a conventional keyboard and mouse. The following hypotheses were tested: (1) cognitive load is higher for speech recognition compared to keyboard and mouse use in complex tasks requiring more problem solving and recall; (2) the percentage of errors is higher for speech recognition compared with keyboard and mouse use in complex tasks requiring more problem solving and recall; (3) task completion time is lower for speech recognition compared with keyboard and mouse use in simple tasks requiring less problem solving and recall; and (4) speech recognition is less usable than a keyboard and mouse for both simple and complex tasks requiring more problem solving and recall.

These findings will shed light on the characteristics of consumer digital health tasks that make them most suitable for using speech recognition as an input modality.

Methods

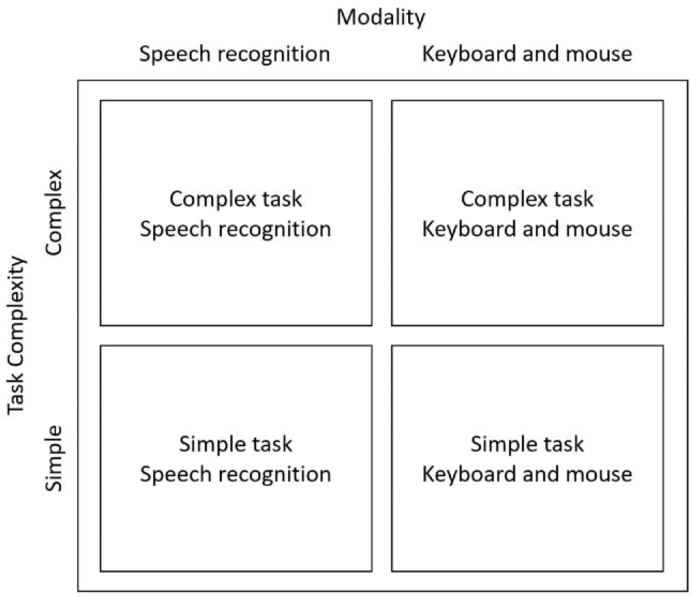
Participants

Fifty-two university students and staff participated in this study (see Results for a summary of the participant demographics). The participants were either students or staff who met the minimum English language proficiency for admission to a university program or workplace. These participants also had working knowledge of computer technology and systems as required for their degree or profession. Hence, there were no requirements regarding level of English language, health literacy, or technology proficiency for inclusion. The participants responded to advertisements sent by email or published in a university newsletter. Consenting adults aged 18 years or older were eligible to participate. Ethical approval was granted by Macquarie University's Human Research Ethics Committee to recruit people within the Faculty of Medicine and Health Sciences. Participants were not offered any remuneration or gifts to incentivize participation.

Experimental Design and Tasks

The study included two within-subject factors: human-computer interaction modality (speech recognition vs keyboard and mouse) and task complexity (simple vs complex) providing four experimental conditions (Figure 1).

Figure 1. Experimental design.



Each participant was asked to complete four consumer digital health tasks to document nutritional and exercise information: two simple and two complex tasks, using speech recognition and a keyboard and mouse to interact with a simulated conversational agent (Figure 1). For each documentation task, participants were asked to adopt a persona within a hypothetical scenario focusing on physical activity and diet, and to answer the conversational agent's questions (see Multimedia Appendix 1). The tasks were designed to assess problem solving and recall using the information provided within the scenario.

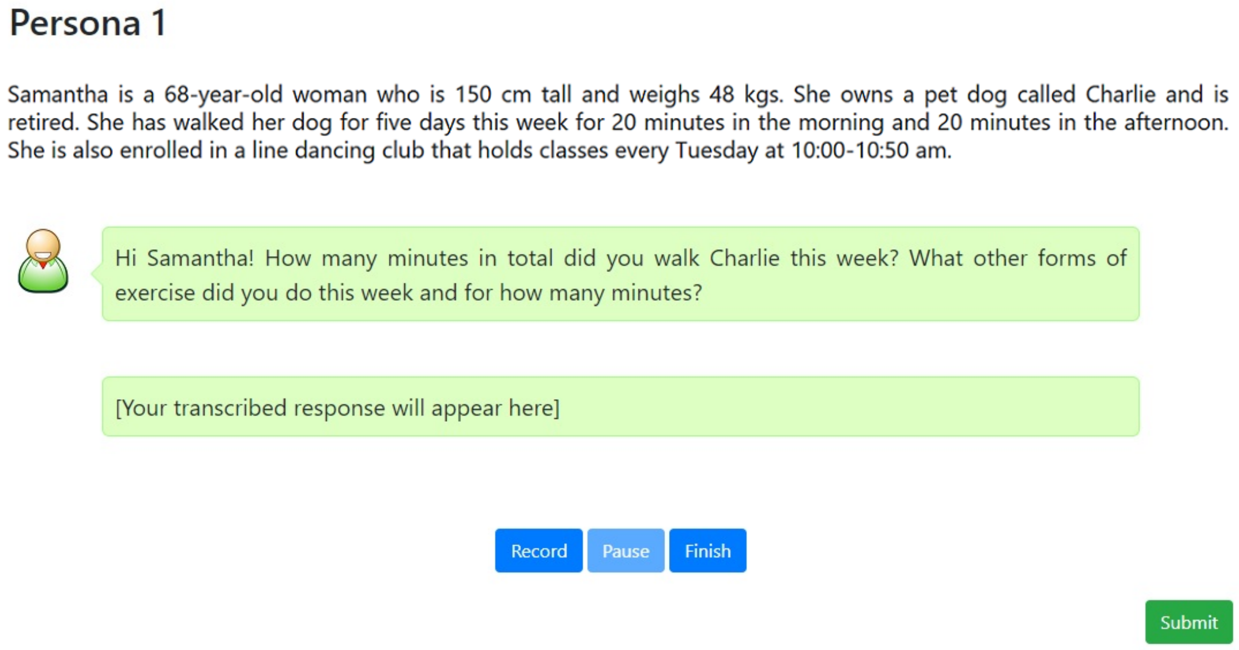
Complexity was measured by the number of information items that participants needed to manipulate in working memory. The relationship between the number of information items requiring manipulation in working memory and cognitive load has been well established in the literature [20]; that is, human performance is affected when the cognitive load is too high or exceeds the limits of working memory [21,22]. For simple tasks, the conversational agent displayed the hypothetical scenario on the same screen as the questions. Complex tasks were designed to impose a higher cognitive load by increasing the number of pieces of information needed to perform arithmetic and commit to memory (6 total items for simple tasks vs 17 total items for complex tasks; see Multimedia Appendix 1). Simple tasks required participants to problem solve using 5 items of information, including 5 days, 20 minutes, line dancing, 10:00-10.50 am, whereas complex tasks required participants to recall the same 5 items and were provided with 12 items for problem solving. A higher cognitive load was also imposed by displaying the scenario in a pop-up modal window, requiring participants to commit key information in the scenario to working memory when transferring between the windows [23]. Participants could not copy and paste their answers.

The tasks were developed in consultation with a health informatics researcher (DL) and a primary care physician (LL). Pilot testing was performed by asking 7 individuals to complete the tasks using a prototype of the system and provide feedback. Any issues were iteratively fixed before the next pilot test. This pilot testing ensured that the prescribed tasks and the system were understandable and functional. Individuals who assisted with pilot testing were excluded from participating in the experiment. The correct answers to tasks were predetermined and validated by the health informatics researcher.

Simulated Conversational Agent

Participants attended a computer laboratory at the university where a workstation was set up with the tasks running on a web app connected to a keyboard, mouse, and microphone. Presented as a text message conversation, user responses could either be typed using the keyboard and mouse or transcribed using speech recognition depending on the experimental condition (Figure 2). Participants were able to view their responses before submitting. Web Speech API, a JavaScript-based general purpose speech recognition application programming interface, was used to implement a live audio transcription function for this system [24]. To activate speech-to-text using speech recognition, the participants were instructed to press the "Record" button. The system was launched using Google Chrome on a local machine.

Figure 2. Graphical user interface of the simulated conversational agent on Google Chrome.



Persona 1

Samantha is a 68-year-old woman who is 150 cm tall and weighs 48 kgs. She owns a pet dog called Charlie and is retired. She has walked her dog for five days this week for 20 minutes in the morning and 20 minutes in the afternoon. She is also enrolled in a line dancing club that holds classes every Tuesday at 10:00-10:50 am.

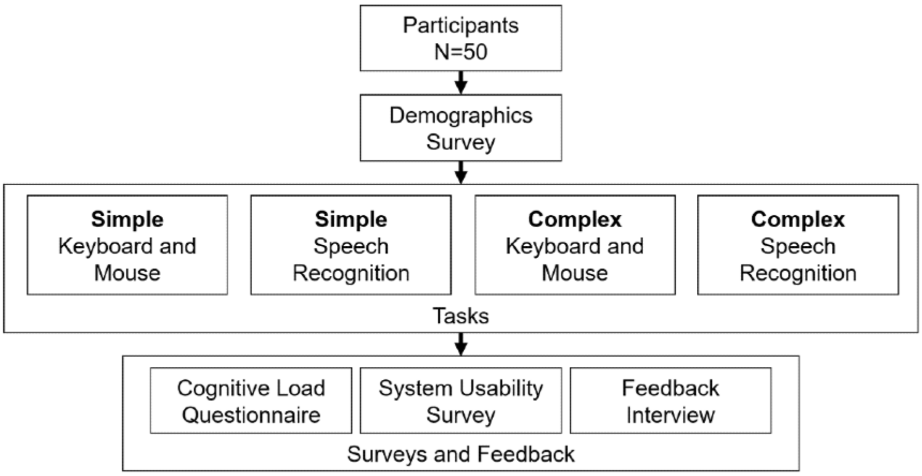
Hi Samantha! How many minutes in total did you walk Charlie this week? What other forms of exercise did you do this week and for how many minutes?

[Your transcribed response will appear here]

Procedure

After obtaining informed consent, the participants completed a short survey about use of speech recognition technology and provided demographic information. They were then briefed that the tasks consisted of problem solving and recall and given instructions about how to use the speech recognition interface before commencing the experiment. Training continued until the participant clearly understood all aspects required to perform the experimental tasks; no practice tasks were undertaken. Participants completed two simple and two complex tasks, half of which were randomly assigned to using speech recognition (Figure 3). At the end of each task, cognitive load was assessed. To avoid order effects, the assignment of simple and complex tasks for the two modalities and task sequence were randomized. All voice recordings for the speech recognition tasks were captured independently to determine errors. At the end of all four tasks, the System Usability Scale (SUS) questionnaire [25] was completed for each modality followed by a feedback interview.

Figure 3. Experimental flow diagram.



Outcome Measures and Analysis

Participants' responses to the lifestyle management tasks with speech recognition and keyboard and mouse were compared using data extracted from the computer log, audio recordings of participant responses, and paper surveys.

Cognitive load was measured using a cognitive load inventory that was adapted from a validated instrument to reflect the nature of the tasks in the present study [26] (Multimedia Appendix 2). Self-ratings of using this inventory have shown it to be reliable, unobtrusive, and sensitive to small differences [23]. This inventory has been widely used [23,26,27], including in controlled studies of clinical decision making [28]. The inventory was administered on paper at the end of each condition.

Task completion time was measured in seconds and calculated from computer logs as the difference between the task start and end time.

The error rate for a given task was defined as the number of failed recall and problem-solving responses, calculated as a percentage of the maximum score for the task. Participants were asked to answer each of the conversational agent's questions correctly by recalling information or solving for numerical answers. Each task had predefined correct answers along with numbers associated with correct problem-solving and recall responses (Multimedia Appendix 1). For example, if the correct answers to a task were "line dancing" and "50 minutes," then the maximum score was 2. If a participant incorrectly recalled "line dancing" but correctly answered "50 minutes," then the error rate would be calculated as 50%. To ensure that transcription errors were not mistakenly attributed to participants, the voice recording on each response was used to validate the answers for tasks that were completed with speech recognition.

Usability was assessed using the SUS, a validated 10-item questionnaire [25], resulting in overall usability scores and scores of subelements (usability and learnability).

Statistical Analyses

The effects of speech recognition on cognitive load, task completion time, error rate, and SUS scores were tested using repeated-measures analysis to control for individual differences. The Wilcoxon signed-rank test was used because the results were not normally distributed. We compared speech recognition and keyboard and mouse across both levels of complexity. Cohen criteria were used to calculate and interpret effect sizes (*r*), where 0.1 indicates a small effect, 0.3 indicates a medium effect, and 0.5 indicates a large effect [29]. We estimated that a sample size of 42 was required to detect a difference of 25% and a standard deviation of 20% for each outcome measure for all tasks with 90% power and *P*<.05 [30]. No baseline measures could be derived from the literature. Descriptive statistics were used to summarize demographic information. All statistical analyses were undertaken using SPSS v24.0.0.0 software (IBM Corp, Armonk, NY, USA).

Results

Participants

Fifty-two university staff and students participated in the experiment. One participant did not complete the experiment and data from another was lost due to a technical error, leaving a total of 50 participants for inclusion in the analysis. The participants were aged 18-64 years, 30% (15/50) were 25-34 years and 54% (27/50) were women. More than half of the participants (56%, 28/50) reported never using speech recognition in their daily lives, 28% (14/50) reported using it once or twice a week, 14% (7/50) reported using it more than multiple times a week, and 4% (2/50) used speech recognition multiple times a day.

Effects of Speech Recognition on Cognitive Load

Participants experienced a significantly higher cognitive load when using speech recognition to perform the prescribed tasks (Table 1). These findings were consistent across both levels of task complexity, although the effect size increased from medium for simple tasks to high for complex tasks.

Table 1. Comparison of cognitive load between keyboard and mouse and speech recognition use by task complexity.

Task complexity	Keyboard and mouse, median (IQR)	Speech recognition, median (IQR)	*Z* value[a]	*P* value	Effect size (*r*)
Complex	3.2 (2.1-4.2)	5.2 (3.6-6.3)	–4.22	<.001	0.60
Simple	2.2 (2.2-4.4)	3.3 (2.2-5.6)	–2.24	.02	0.32

[a] Wicoxon signed-rank test.

Task Completion Time and Error Rate

Participants took significantly longer to complete tasks using speech recognition than the keyboard and mouse for complex tasks; however, there was no difference observed for simple tasks (Table 2). For complex tasks, there was a statistically significant increase in task completion time with a medium effect size (*r*=0.36); however, there was no difference for simple tasks.

There was no difference in error rates for both simple and complex tasks (Table 2). For complex tasks, we examined error rates by their type and found no difference for both problem solving (*Z*=–1.96, *P*=.05) and recall error rates (*Z*=–1.55, *P*=.12).

Table 2. Comparison of task completion time and error rates between keyboard and mouse and speech recognition use by task complexity.

Task complexity	Keyboard and mouse	Speech recognition	*Z* value[a]	*P* value
Complex, median (IQR)				
Completion time (seconds)	162 (124-192)	173 (136-223)	2.52	.01
Error rate (%)	11 (0-25)	11 (0-36)	1.80	.07
Simple, median (IQR)				
Completion time (seconds)	90 (74-124)	83 (68-11)	7.90	.43
Error rate (%)	0 (0-33)	0 (0-33)	–0.33	.74

[a] Wilcoxon signed-rank test.

Usability and Participant Perceptions About Speech Recognition

Participants found speech recognition to be significantly less usable than the keyboard and mouse. This was consistent with the SUS factor analysis, which revealed that speech recognition was perceived to be significantly less usable and harder to learn with medium and large effect sizes, respectively (Table 3).

Table 3. Usability (SUSa scores) of speech recognition compared to keyboard and mouse.

SUS category	Keyboard and mouse, median (IQR)	Speech recognition, median (IQR)	*Z* value[b]	*P* value	Effect size (*r*)
Overall	85 (72-90)	75 (62-85)	–3.30	.001	0.47
Usability	100 (97-100)	100 (75-100)	–2.98	.003	0.42
Learnability	81 (68-88)	72 (59-84)	–3.54	<.001	0.50

[a] SUS: System Usability Scale.

[b] Wilcoxon signed-rank test.

Overall, participants commented that the simulated conversational agent was “very straightforward” to use. Some reported that not having to think about spelling and grammar was an advantage of speech recognition. Although the participants found speech recognition to be a possibly more convenient way to enter free-text information, many observed that the major pitfalls of speech recognition were any transcription errors generated by the software, an inability to retract and edit answers once a sentence was uttered, and unwanted filler utterances such as “um” and “er” appearing in their responses. Participants also commented about the extra time taken to check and correct the output of speech recognition for transcribing errors when such errors could be prevented by using a keyboard and mouse in the first place. Others raised privacy issues as they were self-conscious about strangers eavesdropping on their responses.

When commenting on difficulties, some participants stated that they had struggled to formulate answers for scenarios and construct sentences to dictate to the conversational agent via speech recognition at the same time. They also commented that this action consumed more time to complete the task. By contrast, typing was perceived to be easier because it was “what we do every day.” This also allowed for using the textbox input to record answers as opposed to “keeping more in the brain” when storing information in cognitive, working memory. Speech was also perceived as a novelty because many were familiar with using a keyboard and mouse and saw it as a standard mode for human-computer interaction.

Discussion

Main Findings

When using speech recognition, participants reported a higher cognitive load for both simple and complex tasks compared to using a keyboard and mouse. Some participants reported an inability to think while speaking, which is consistent with previous observations [12,13]. A possible reason is due to an extra step introduced in processing the information and then having to form complete sentences before speaking. This extra processing step, which occurs once participants begin to formulate responses to the simulated conversational agent’s questions, may have involved working memory and contributed to participants experiencing a higher cognitive load while using speech recognition.

The higher cognitive load also provides a potential explanation for the more time required to complete complex tasks when using speech recognition and for it to be perceived less usable. Participants also noted a time delay required for speech recognition to process responses. It is thus possible that the extra time was introduced by the system and the time participants spent in checking the live transcription provided by speech recognition. If this was true, a consistent increase in time across all conditions would be expected. However, there was no significant time difference found for simple tasks. This could mean that the difference more likely arose from the task characteristics themselves. Further experiments are required to examine the interaction effect of modality and task complexity on cognitive load.

Despite previous reports about higher error rates with speech recognition for clinical documentation tasks [31], we found no difference in error rates between the two modalities for both simple and complex tasks. One possible reason that the second hypothesis was not supported is that most participants were observed to formulate their responses with caution by double-checking their answers when using speech recognition. For simple tasks, this meant looking at the scenario section that was on the same screen. For complex tasks, participants repeatedly clicked the “review scenario” button until they were satisfied with their answer.

Speech recognition was perceived to be less usable than a keyboard and mouse because it was harder to learn. A major factor contributing to this effect is that many participants reported being more comfortable with typing because it was an everyday human-computer interaction, especially in their profession. In addition, 56% of the participants did not use speech recognition in their daily lives, which possibly meant that they are less proficient in using speech recognition. Another possible factor is that the conversational agent was purposely designed to limit participants by not allowing users to correct transcription errors. This may be a common source of frustration that affects perceptions of usability for conversational agents. However, the error rate was unaffected because we used independent voice recordings to determine errors and the impact on usability was captured in the overall score.

Some participants reported lack of privacy as another major factor for speech recognition being less usable than a keyboard and mouse. A major advantage with typing was that a third party could not eavesdrop on interactions with the conversational agent. Thus, less confidence was placed on using the conversational agent with speech recognition compared with a keyboard and mouse. Although there was no difference in error rates, the increased cognitive load and task completion time may also have affected user experience.

Implications

Our findings suggest that speech recognition may not be uniformly suitable for the different contexts of health care. An important implication is for system designers to consider task characteristics and the resulting impact on cognitive load when selecting modalities for humans to interact with computers. In general, lower cognitive load, fewer errors, less time, and better usability are desirable. Speech recognition may be more suitable for frequent tasks such as documentation of notes in electronic health records (EHRs), which may generally not involve problem solving and recall (eg, when a doctor has already established a diagnosis during the patient consultation and uses the EHR to record their notes). However, it may not be suitable for occasional tasks such as incident reporting, which involves problem solving and recall, requiring clinicians to recollect the sequence of events and identify problems that led to an incident [32]. For such complex documentation tasks, the higher cognitive load and greater time required to use speech recognition, along with the lower usability, suggest that a keyboard and mouse may be a better input modality. By contrast, speech recognition may be necessary for contexts that require use of the hands and eyes.

One practical strategy for designers to assess the suitability of speech recognition as an input modality is to test user interfaces in the prototype stage with the cognitive load inventory, which is readily applicable to different modalities and systems. Importantly, designers need to consider privacy requirements when using speech recognition for busy health care settings, especially when sensitive health information is being handled. Our findings also suggest that privacy requirements may present a barrier for the use of speech recognition in some contexts such as health apps that require users to document their personal health information. These considerations will need to be evaluated on a case-by-case basis.

Comparison With the Literature

To the best of our knowledge, no previous studies have measured the effects of speech recognition in consumer digital health tasks. In clinical applications, the use of speech recognition for clinical documentation was found to increase error rates and task completion time in a controlled laboratory setting [31,33,34]. One possible reason for the disparity with our results may be the difference in the source of complexity. In the previous studies, complexity was distributed between the clinical scenario and the user interactions with an EHR, which required users to navigate to different sections of the record. By contrast, in our study, the type of user interaction remained the same for the different task types. The complexity instead arose from the scenario itself, which required users to problem solve and recall information from memory.

Limitations

There are several limitations to the design of the current study. We focused on the use of speech recognition as an input modality within a computer laboratory, which may not be representative of a real-world setting where environmental factors such as background noise and interruptions affect consumer interactions with digital health technologies. A general-purpose speech recognition engine that was not specifically optimized for the consumer health domain was tested on a desktop computer. This may have affected participant perceptions about usability and time required to use speech recognition. Participants were university students and staff, almost half of whom reported not using speech recognition technology in their daily lives. Therefore, our sample may not be representative of the general population of health consumers who might use conversational agents. However, because the participants were from a cohort that regularly used a keyboard and mouse, we were able to undertake a realistic assessment of the effort to learn and use speech recognition in the context of the conversational agent. For regular speech recognition users, expectations about the robustness and accuracy could have affected SUS scores. Although it is possible that individual differences such as health literacy, native language, pronunciation, fluency, and experience with speech recognition and a keyboard and mouse may have impacted the outcome variables, we attempted to control for these differences by using a within-subjects design. Further studies are needed to explore the influence of health and nutritional literacy. It is also possible that the quality of the speech recognition could have affected task completion time, but the effect would be consistent across experimental conditions. The error rate was unaffected because we used independent voice recordings to determine correct answers; therefore, the risk of the speech recognition mistranscribing speech by recording responses was controlled.

Despite these limitations, this study has contributed evidence related to the use of speech recognition as an input modality in human-computer interaction, particularly in a consumer digital health context. These results provide baseline measures of cognitive load in using speech recognition. Further studies using a more representative population of conversational agent users are needed to investigate the effects of cognitive load on task performance when speech recognition is integrated with consumer digital health technologies in real-world settings, including mobile devices such as smartphones and tablet computers.

Conclusions

This study found that using a keyboard and mouse was preferable to speech recognition for complex tasks involving problem solving and recall. This may be due to the higher cognitive load reported when using speech recognition and that the participants were more comfortable using a keyboard and mouse. Our results suggest that task characteristics need to be considered by designers when selecting the most appropriate input modality for human-computer interaction. Further studies using a broader variety of consumer digital health tasks of varying complexity are needed to investigate the contexts in which use of speech recognition is appropriate. The effects of cognitive load on task performance and its significance also need to be investigated.

Acknowledgments

We thank the participants who gave up their time to participate in this study. We thank Vitaliy Kim and Owen Sun for sharing their expertise to build the simulated conversational agent.

Authors' Contributions

FM conceptualized the study design. JC conducted the research and primary analysis, and drafted the paper. LL helped to formulate the scenarios and DL helped to adapt the cognitive load inventory. JC is responsible for the integrity of the work as the guarantor of the study. All authors participated in writing and revising the paper. All aspects of the study (including design; collection, analysis, and interpretation of data; writing of the report; and decision to publish) were led by the authors.

Abstract

Background: Dialog agents (chatbots) have a long history of application in health care, where they have been used for tasks such as supporting patient self-management and providing counseling. Their use is expected to grow with increasing demands on health systems and improving artificial intelligence (AI) capability. Approaches to the evaluation of health care chatbots, however, appear to be diverse and haphazard, resulting in a potential barrier to the advancement of the field.

Objective: This study aims to identify the technical (nonclinical) metrics used by previous studies to evaluate health care chatbots.

Methods: Studies were identified by searching 7 bibliographic databases (eg, MEDLINE and PsycINFO) in addition to conducting backward and forward reference list checking of the included studies and relevant reviews. The studies were independently selected by two reviewers who then extracted data from the included studies. Extracted data were synthesized narratively by grouping the identified metrics into categories based on the aspect of chatbots that the metrics evaluated.

Results: Of the 1498 citations retrieved, 65 studies were included in this review. Chatbots were evaluated using 27 technical metrics, which were related to chatbots as a whole (eg, usability, classifier performance, speed), response generation (eg, comprehensibility, realism, repetitiveness), response understanding (eg, chatbot understanding as assessed by users, word error rate, concept error rate), and esthetics (eg, appearance of the virtual agent, background color, and content).

Conclusions: The technical metrics of health chatbot studies were diverse, with survey designs and global usability metrics dominating. The lack of standardization and paucity of objective measures make it difficult to compare the performance of health chatbots and could inhibit advancement of the field. We suggest that researchers more frequently include metrics computed from conversation logs. In addition, we recommend the development of a framework of technical metrics with recommendations for specific circumstances for their inclusion in chatbot studies.

Introduction

Background

The potential of human-computer dialog to provide health care benefits has been perceived for many decades. In 1966, Weizenbaum's ELIZA system caught the public imagination with its imitation of a psychotherapist through the relatively simple linguistic token manipulation possible at the time [1]. From the mid-1990s, a family of interventions based on automated telephone sessions (telephone-linked care) demonstrated effectiveness in promoting health adherence across a range of behaviors including medication, diet, and physical activity [2]. As mobile phones have become commonplace, a range of SMS text messaging–based interventions have been developed and trialed, with particular success in smoking cessation [3]. At the same time, internet/web-based interventions have shown the ability to promote positive health behavior change [4,5], and the interaction components associated with users sticking with an internet intervention are increasingly well understood and include the inclusion of dialog elements [6].

With the advent of smartphones, the distribution of highly interactive chatbots has been greatly facilitated, particularly with the ubiquitous use of app stores and wide installation of chat apps that can include chatbots, notably Facebook Messenger. Chatbots, as with other electronic health (eHealth) interventions, offer scalability and 24-hour availability to plug gaps in unmet health needs. For example, Woebot delivers cognitive behavior therapy and has been tested with students with depression [7]. The students who used Woebot significantly reduced their symptoms of depression over the study period as measured by the depression questionnaire PHQ-9, while those in the information control group (who instead read a self-help book) did not [7]. In recent years, artificial intelligence (AI) based on deep learning has created waves with its ability to outperform physicians at some diagnostic tasks [8,9]. XiaoIce is a social chatbot that emphasizes emotional connection and it has communicated with over 660 million active users since its launch in 2014 [10]; its performance shows that deep learning can be successfully applied to meaningful dialog tasks. Combining the factors of ease-of-distribution, successful applications, and AI methods to improve health chatbot performance, it is reasonable to expect health chatbots in increasing numbers and variety to take an increasingly serious role in the health care system.

Research Problem and Aim

To be an evidence-based discipline requires measurement of performance. The impact of health chatbots on clinical outcomes is the ultimate measure of success. For example, did the condition (eg, depression, diabetes) improve to a statistically significant degree on an accepted measure (eg, PHQ-9 [11] or hemoglobin A1c [12], respectively), as compared to a control group? Such studies, however, may require large sample sizes to detect the effect and provide relatively little insight into the mechanism by which the chatbot achieves the change; additionally, studies may provide particularly little insight if the result is negative.

As an alternative and useful precursor to clinical outcome metrics, technical metrics concern the performance of the chatbot itself (eg, did participants feel that it was usable, give appropriate responses, and understand their input?). Appropriateness refers to the relevance of the provided information in addressing the problem prompted [13]. Furthermore, this includes more objective measures of the chatbot interaction, such as the number of conversational turns taken in a session or time taken, and measures that require some interpretation but are still well-defined, such as task completion. These technical measures offer a potential method for comparison of health chatbots and for understanding the use and performance of a chatbot to decide if it is working well enough to warrant the time and expense of a trial to measure clinical outcomes.

Previously, we had introduced a framework for evaluation measures of health chatbots to provide guidance to developers [14]. The framework development, however, was based on a relatively informal process vulnerable to the authors' biases in terms of what studies were considered in its formulation. Therefore, the aim of this study is to use a rigorous review methodology to identify the technical metrics used by previous studies to evaluate health care chatbots. The final goal of these efforts is to be able to make recommendations for an evaluation framework for health chatbots.

Methods

Overview

To achieve the aforementioned objective, a scoping review was conducted. To conduct a transparent and replicable review, we followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) Extension for Scoping Reviews (PRISMA-ScR) guidelines [15]. This research was conducted by an interdisciplinary team of researchers with backgrounds in nursing, computer science, and mental health applications.

Search Strategy

Search Sources

For this review, we searched the following bibliographic databases November 1-3, 2019: MEDLINE (via EBSCO), EMBASE (Excerpta Medica Database; via Ovid), PsycINFO (via Ovid), CINAHL (Cumulative Index of Nursing and Allied Health Literature; via EBSCO), IEEE (Institute of Electrical and Electronics Engineers) Xplore, ACM (Association for Computing Machinery) Digital Library, and Google Scholar. We screened only the first 100 hits retrieved by searching Google Scholar, as it usually retrieves several thousand references ordered by their relevance to the search topic. We checked the reference list of the included studies to identify further studies relevant to the current review (ie, backward reference list checking). Additionally, we used the "cited by" function available in Google Scholar to find and screen studies that cited the included studies (ie, forward reference list checking).

Search Terms

The search terms were derived from previously published literature and the opinions of informatics experts. For health-related databases, we used search terms related to the intervention of interest (eg, chatbot, conversational agent, and chat-bot). In addition to intervention-related terms, we used terms related to the context (eg, health, disease, and medical) for non–health-related databases (eg, IEEE and ACM digital library). Multimedia Appendix 1 details the search strings used for searching each electronic database.

Study Eligibility Criteria

The intervention of interest in this review was chatbots that are aimed at delivering health care services to patients. Chatbots implemented in stand-alone software or web-based platforms were included. However, we excluded chatbots operated by a human (Wizard-of-Oz) or integrated into robotics, serious games, SMS text messaging, or telephone systems. To be included, studies had to report a technical evaluation of a chatbot (eg, usability, classifier performance, and word error rate). We included peer-reviewed articles, dissertations, and conference proceedings, and we excluded reviews, proposals, editorials, and conference abstracts. This review included studies written in the English language only. No restrictions were considered regarding the study design, study setting, year of publication, and country of publication.

Study Selection

Authors MA and ZS independently screened the titles and abstracts of all retrieved references and then independently read the full texts of included studies. Any disagreements between the two reviewers were resolved by AA. We assessed the intercoder agreement by calculating Cohen, which was 0.82 for screening titles and abstracts and 0.91 for reading full texts, indicating a very good agreement [16].

Data Extraction

To conduct a reliable and accurate extraction of data from the included studies, a data extraction form was developed and piloted using 8 included studies (Multimedia Appendix 2). The data extraction process was independently conducted by two reviewers (MA and ZS) and a third reviewer (AA) resolved any disagreements. Intercoder agreement between the reviewers was good (Cohen κ=0.67).

Data Synthesis

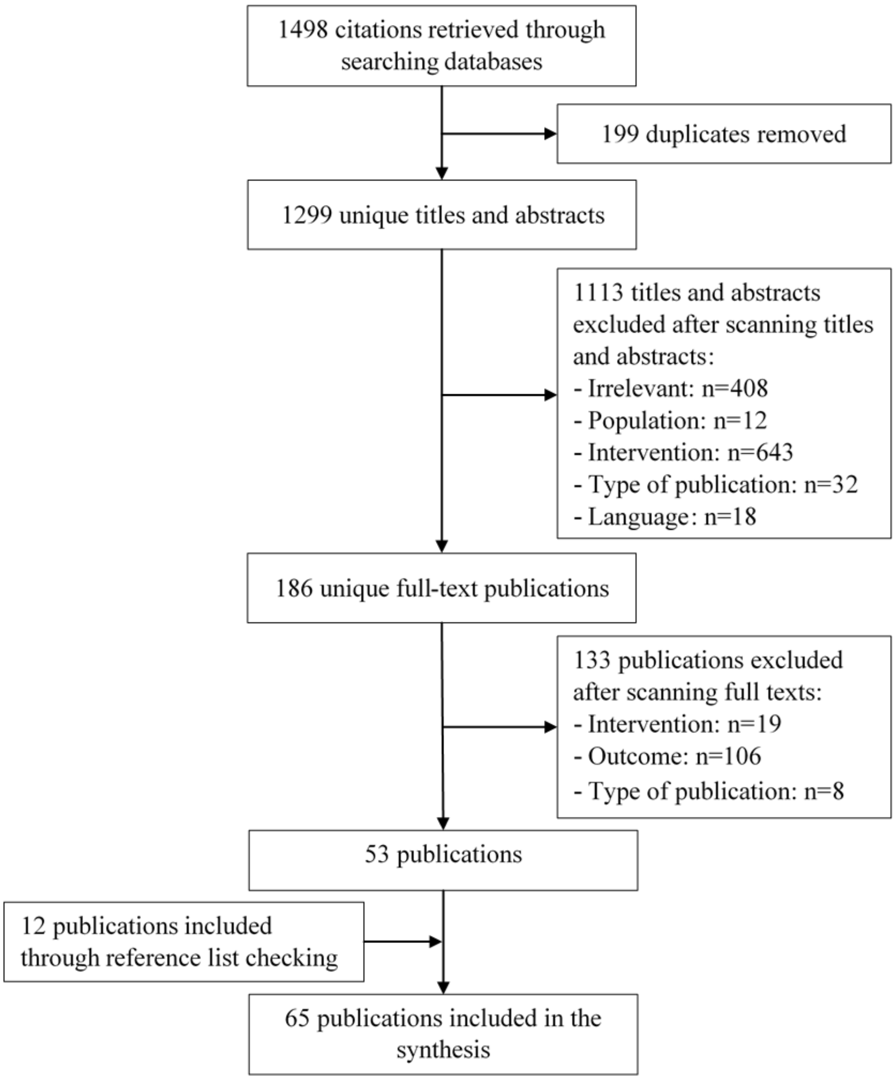
A narrative approach was used to synthesize the extracted data. After identifying all technical metrics used by the included studies to evaluate chatbots, we divided them into 4 categories based on the aspect of chatbots that the metrics evaluate. The 4 categories were formed after a discussion by the authors in which consensus was reached. For each metric, we identified how the studies measured it. Data synthesis was managed using Microsoft Excel (Microsoft Corporation).

Results

Search Results

By searching the 7 electronic databases, 1498 citations were retrieved. After removing 199 (13.3%) duplicates of these citations, 1299 (86.7%) titles and abstracts were screened. The screening process resulted in excluding 1113 (74.3%) titles and abstracts due to several reasons detailed in Figure 1. When we read the full text of the remaining 186 (12.4%) citations, a further 133 (8.9%) citations were excluded (Figure 1). In total, 12 studies were found by backward and forward reference checking. We included 65 studies in the review.

Figure 1. Flowchart of the study selection process.



Description of Included Studies

Characteristics of the included studies are detailed in Table 1. Cross-sectional survey was the most commonly used study design (n=41, 63%). About 57% (n=37) of the included studies were published as journal articles. Half of the studies (n=33, 51%) were conducted in the United States. Approximately 70% (n=45) of the studies were published between 2015 and 2019.

The sample size was reported in 61 studies, and 38 studies (62%) had 50 or fewer participants. In 44 studies, the age of participants was reported; the mean age of participants was 39 years, with a range of 13-79 years. Sex of participants was reported in 54 studies, where the mean percentage of males was 48.1%. Of the 62 studies that reported participants' health conditions, 34 (54.8%) studies recruited participants from a clinical population (ie, those with health issues). Participants were recruited from clinical settings (n=30, 49.2%), community (n=20, 32.8%), and educational settings (n=18, 29.5%). Metadata and population characteristics of each included study are presented in Multimedia Appendix 3.

Chatbots were used for self-management (n=17, 26.2%), therapeutic purposes (n=12, 18.5%), counselling (n=12, 18.5%), education (n=10, 15.4%), screening (n=9, 13.8%), training (n=7, 10.8%), and diagnosing (n=3, 4.6%). Although chatbots were implemented in stand-alone software in about 62% (n=40) of studies, chatbots were implemented in web-based platforms in the remaining studies (n=25, 39%). Chatbot responses were generated based on predefined rules, machine learning approaches, or both methods (hybrid) in 82% (N=53), 17% (n=11), and 2% (n=1) of the included studies, respectively. In the majority of studies (n=58, 89%), chatbots led the dialogue. In about 62% (n=40) of studies, users interacted with chatbots only by typing in their utterances (texts). The most common modalities used by chatbots to interact with users were a combination of text, voice, and nonverbal language (ie, facial expression and body language; n=21, 32%), text only (n=20, 31%), and a combination of voice and nonverbal language (n=19, 29%). The most common disorders targeted by chatbots were any health condition (n=20, 31%) and depression (n=15, 23%). Multimedia Appendix 4 displays characteristics of the intervention in each included study.

[a] Percentages were rounded and may not sum to 100.

[b] Sample size was reported in 61 studies.

[c] Mean age was reported in 44 studies.

[d] N/A: not applicable.

[e] Sex was reported in 54 studies.

[f] Sample type was reported in 62 studies.

[g] Setting was reported in 61 studies.

[h] Numbers do not add up as several chatbots focused on more than one health condition.

[i] Numbers do not add up as several chatbots have more than one purpose.

[j] Numbers do not add up as several chatbots target more than one health condition.

Results of Studies

Overview

The included studies evaluated chatbots using many technical metrics, which were categorized into 4 main groups: metrics related to chatbots as a whole (global metrics), metrics related to response generation, metrics related to response understanding, and metrics related to esthetics. More details about metrics are presented in the following sections.

Global Metrics

The included studies evaluated chatbots as a whole using the following metrics: usability, classifier performance, speed, technical issues, intelligence, task completion rate, dialogue efficiency, dialogue handling, context awareness, and error management.

Usability of chatbots was assessed in 37 (56.9%) studies [17-53]. Usability was evaluated using a single question in a self-administrated questionnaire [17,20-25,29-31,33,34,36,37,40,42,44,45,47-51,53], multiple questions in a self-administrated questionnaire [28,41,43], a specific questionnaire (eg, system usability scale [SUS] questionnaire) [18,26,27,32,35,38,39,46,52], or observation [19].

Classifier performance of chatbots was evaluated in 8 (12.3%) studies [54-61]. Many metrics were used to measure the classifier performance, namely: area under curve [54,55,60,61], accuracy [56-58,61], sensitivity [55,57,59,60], specificity

[55,57,59,60], positive predictive value [55,57,60], and negative predictive value [55,60]. The speed of chatbots was examined in 4 studies [29,35,53,62]. The speed was evaluated using a single question in a self-administrated questionnaire [29,35], multiple questions in a self-administrated questionnaire [53], and interviews [62].

Technical issues (eg, errors/glitches) in chatbots were examined in 4 studies (6.2%) [7,36,51,63]. Technical issues were assessed through interviews [7,51,63], a single question in a self-administrated questionnaire [36], and checking staff logs [51]. In addition, 3 studies assessed the intelligence of chatbots using either multiple questions in a self-administrated questionnaire [41,64] or a single question in a self-administrated questionnaire [27]. In 3 studies, the task completion rate was examined by checking the conversation logs [38,53,65].

Of the reviewed studies, 2 (3.1%) studies examined chatbot flexibility in dialogue handling (eg, its ability to maintain a conversation and deal with users' generic questions or responses that require more, less, or different information than was requested) using interviews [27] and multiple questions in a self-administrated questionnaire [38]. Dialogue efficiency of chatbots, which refers to the number of dialogue steps required to finish a task, was assessed in 1 study by reviewing transcribed conversation logs [38]. The same study examined the chatbot's context awareness (ie, its ability to utilize contextual knowledge to appropriately respond to users) using multiple questions in a self-administrated questionnaire [38]. Error management, which refers to a chatbot's ability to detect and understand misspelled words in users' replies (eg, "anious" instead of anxious), was examined in only 1 study [27].

Metrics Related to Response Generation

The following metrics were utilized by the included studies to evaluate response generation by chatbots: appropriateness of responses, comprehensibility, realism, speed of response, empathy, repetitiveness, clarity of speech, and linguistic accuracy.

Of the reviewed studies, 15 (23.1%) examined the appropriateness and adequacy of verbal [18,19,27,28,31,34,38,39,51,58,66-69] and nonverbal responses of chatbots [32]. Appropriateness of responses was assessed using interviews [18,19,31,34,51,66,68], a single question in self-administrated questionnaire [27,32,39,67], conversation logs [38,58,69], and multiple questions in self-administrated questionnaire [28].

Comprehensibility of responses, which refers to the degree to which a chatbot generates responses understandable by users, was evaluated by 14 (21.5%) studies [20,23,31,34,36,39,42,44,51,52,59,60,63,69]. Comprehensibility of responses was evaluated using a single question in a self-administrated questionnaire [20,23,31,36,39,42,44,52,59,60,63,69] and interviews [34,51].

In total, 14 (21.5%) studies assessed how human-like chatbots are (realism) [17,18,21,34,39,41,46,50,63,66,68,70-72]. Realism of chatbots was examined in terms of verbal responses only [17,21,34,39,46,63,68,70], nonverbal responses only [66], or both verbal and nonverbal responses [18,41,50,71,72]. The included studies evaluated realism using a single question in a self-administrated questionnaire [17,18,21,39,46,50,63,70], multiple questions in a self-administrated questionnaire [41,72], and interviews [18,34,66,68,71].

Altogether, 11 (16.9%) studies assessed the speed of a chatbot's responses [18,19,28,30,34,36,38,68-70,73]. The speed of responses was examined using a single question in a self-administrated questionnaire [18,30,36,69,70,73], interviews [19,34,68], multiple questions in a self-administrated questionnaire [53], and system logs [38]. Empathy of a chatbot, which refers to its ability to show empathy to users, was examined in 10 studies [7,35,41,42,64,66,67,71,73,74]. Those studies evaluated empathy using a single question in a self-administrated questionnaire [7,35,41,42,67,71,73], interviews [66,71], and multiple questions in a self-administrated questionnaire [64].

Repetitiveness of a chatbot's responses was examined in 9 (13.8%) studies [7,20,27,53,57,66,73,75,76]. Repetitiveness of responses was evaluated using a single question in a self-administrated questionnaire [7,20,27,53,57,73] and interviews [66,75,76]. We found that 6 (9.2%) studies evaluated clarity or quality of speech using either interviews [51,62,75] or a single question in a self-administrated questionnaire [27,69,77]. Linguistic accuracy of a chatbot's responses was evaluated in 2 (3.7%) studies using a single question in a self-administrated questionnaire [31,35].

Metrics Related to Response Understanding

The included studies evaluated chatbot understanding of users' responses using the following metrics: understanding as assessed by users, word error rate, concept error rate, and attention estimator errors.

Chatbot understanding, which refers to a chatbot's ability to adequately understand the verbal and nonverbal responses of users, was assessed by 20 (30.8%) studies [7,18,20,23,27,32,33,36,39,41,42,53,57,59,63,64,68,73,78,79]. Of those studies, 2 studies assessed understanding of both verbal and nonverbal responses [18,79], 1 study assessed understanding of nonverbal responses only [32], and the remaining studies assessed understanding of verbal responses only. The understanding of responses was evaluated using multiple questions in a self-administrated questionnaire in 4 studies [42,64,78,79], interviews in 2 studies [18,68], and a single question in a self-administrated questionnaire in the remaining studies.

Word error rate, which assesses the performance of speech recognition in chatbots, was examined in 2 (3.7%) studies using conversational logs [65,69]. Concept error rate, which depends on the correct recognition of the semantic result of a user utterance, was evaluated in 1 study by checking conversational logs [65]. Attention estimation, which refers to a chatbot's ability to determine whether the user is gazing toward the screen or away from it, was examined in 1 study by checking conversational logs [69].

Metrics Related to Esthetics

The included studies evaluated the esthetics of chatbots using the following metrics: appearance of the virtual agent, background color and content, font type and size, button color, shape, icon, and background color contrast.

In total, 5 (7.7%) studies assessed the appearance of the virtual agent using a single question in a self-administrated questionnaire [69,77,80], interviews [51], and focus groups [45]. In addition, 1 (1.5%) study evaluated background color, color contrast, and content; font type and size; and button color, shape, and icon using a survey [80].

Discussion

Principal Findings

It became clear that there is currently no standard method in use to evaluate health chatbots. Most aspects are studied using self-administered questionnaires or user interviews. Common metrics are response speed, word error rate, concept error rate, dialogue efficiency, attention estimation, and task completion. Various studies assessed different aspects of chatbots, complicating direct comparison. Although some of this variation may be due to the individual characteristics of chatbot implementations and their distinct use cases, it is difficult to see why metrics such as appropriateness of responses, comprehensibility, realism, speed of response, empathy and repetitiveness are each only applicable to a small percentage of cases. Further, objective quantitative metrics (eg, those based on log reviews) were comparatively rarely used in the reported studies. We thus suggest continuing research and development toward an evaluation framework for technical metrics with recommendations for specific circumstances for their inclusion in chatbot studies.

Jadeja et al [81] introduced 4 dimensions for chatbot evaluations: the information retrieval (IR) perspective, the user experience (UX) perspective, the linguistic perspective, and the AI (human-likeness) perspective. In earlier work [14], we adapted and broadened this categorization, modifying the IR perspective to a task-oriented perspective since health chatbots are not necessarily designed only to retrieve information; additionally, we included system quality and health care quality perspectives. Excluding the health care quality perspective, which is outside the definition of technical metrics, the findings of this scoping review show that all these dimensions are indeed represented in health chatbot evaluations. Rather, the issue appears to be the inconsistency in what is measured and how, along with the skew toward self-reporting and the UX perspective. Additional work is still required to come up with standard metrics and corresponding assessment tools specifically addressing quality in health chatbots.

We found usability to be the most commonly assessed aspect of health chatbots. The system usability scale (SUS [82,83]) is a well-established usability instrument that we observed was used repeatedly, although it was not used in the majority of the studies assessing usability; in many cases, a single survey question was used instead. The SUS is nonproprietary, technology-agnostic, and designed to support comparison across products [82]. As such, global assessment of the user experience of health chatbots could be enhanced in quality and comparability by researchers standardizing on inclusion of the SUS in their evaluations. However, studies by Holmes et al [84] showed that conventional methods for assessing usability and user experience may not be as accurate when applied to health chatbots. As such, there remains research to be done toward appropriate metrics for health chatbots.

Conversational-turns per session (CPS) has been suggested as a success metric for social chatbots as exemplified by XiaoIce [85]. Although the aims for health chatbots are not identical to those of social chatbots, if CPS gains acceptance as a standard measure in the social chatbot domain, it would make it a leading candidate for a standard measure to include in health chatbot evaluations to assess their social engagement dimension. An alternative or supplementary measure related to the social dimension would be to have users score the chatbot on empathy; however, CPS has the advantage of being an objective and quantitative measure. Other objective and quantitative measures such as interaction time or time on task could be alternatives to CPS, but might be less representative of engagement than CPS if for instance the user was multitasking chatbot interaction with other tasks. Beyond social engagement, task completion (often assessed by analyzing conversation logs) is another promising global measure.

A further area for standardization would be in the quality of responses. We observed response generation to be widely measured but in very diverse ways. Emergence of standard measures for response generation and understanding would greatly advance the comparability of studies. Development of validated instruments in this area would be a useful contribution to chatbot research.

We commend the inclusion of classifier performance in health chatbot studies where this is applicable and practical to assess. It could be less meaningful to compare raw performance (eg, as area under the curve) across domains due to differences in difficulty; ideally, chatbot performance would be compared to the performance of a human expert for the task at hand. Further, we perceive the opportunity for a progression of performance measures in health chatbot studies as a given product gains maturity. Good early-stage metrics would be those that assess response quality and response understanding to establish that the product is working well. Subsequent experiments can advance the assessment of self-reported usability and metrics of social engagement. Where applicable, classifier performance can round out technical performance evaluation to establish whether trials to assess clinical outcomes are warranted.

Strengths and Limitations

Strengths

This study is the first review that summaries the technical metrics used by previous studies to evaluate health care chatbots. This helps readers explore how chatbots were evaluated in health care. Given that this review was executed and reported in line with PRISMA-ScR guidelines [1], it could be considered a high-quality review.

To retrieve as many relevant studies as possible, the most commonly used databases in the fields of health and information technology were searched. Further, we searched Google Scholar and conducted backward and forward reference list checking to retrieve gray literature and minimize the risk of publication bias.

As two reviewers independently selected the studies and extracted the data, the selection bias in this review was minimal. This review can be considered a comprehensive review given that we did not apply restrictions regarding the study design, study setting, year of publication, and country of publication.

Laranjo et al [86] reviewed the characteristics, current applications and evaluation measures of health chatbots. In contrast to our work, they did not solely concentrate on the technical metrics used for chatbot evaluations. The metrics they reviewed included task completion or word accuracy. In contrast to Laranjo et al [86], who included only 17 papers reporting on 14 different conversational agents, our work is more comprehensive as it included 65 publications. Further, we had a different research question in mind while conducting the review.

Limitations

This review focused on chatbots that are aimed at delivering health care services to patients and work on stand-alone software and web browsers; it excluded chatbots that used robotics, serious games, SMS text messaging, Wizard-of-Oz, and telephones. Thus, this review did not include many technical metrics used to evaluate chatbots for other users (eg, physicians, nurses, and caregivers), in other fields (eg, business and education), or with alternative modes of delivery (eg, SMS text messaging, Wizard-of-Oz, and telephones). The abovementioned restrictions were applied by previous reviews about chatbots as these features are not part of ordinary chatbots [87-90].

Due to practical constraints, we could not search interdisciplinary databases (eg, Web of Science and ProQuest), conduct a manual search, or contact experts. Further, the search in this review was restricted to English-language studies. Accordingly, it is likely that this review missed some studies.

Conclusion

From this review, we perceive the need for health chatbot evaluators to consider measurements across a range of aspects in any given study or study series, including usability, social experience, response quality, and, where applicable, classifier performance. The establishment of standard measures would greatly enhance comparability across studies with the SUS and CPS as leading candidates for usability and social experience, respectively. It would be ideal to develop guidelines for health chatbot evaluators indicating what should be measured and at what stages in product development. Development of validated measurement instruments in this domain is sparse and such instruments would benefit the field, especially for response quality metrics.

Authors' Contributions

AA developed the protocol and conducted the search with guidance from and under the supervision of KD and MH. Study selection and data extraction were carried out independently by MA and ZS. AA solved any disagreements between the two reviewers. AA synthesized the data. AA and KD drafted the manuscript, and it was revised critically for important intellectual content by all authors. KD and JW reviewed the related literature and interpreted the results. All authors approved the manuscript for publication and agree to be accountable for all aspects of the work.

Conflicts of Interest

Abstract

Background: In the homeless population, barriers to housing and supportive services include a lack of control or access to data. Disparate data formats and storage across multiple organizations hinder up-to-date intersystem access to records and a unified view of an individual's health and documentation history. The utility of blockchain to solve interoperability in health care is supported in recent literature, but the technology has yet to be tested in real-life conditions encompassing the complex regulatory standards in the health sector.

Objective: This study aimed to test the feasibility and performance of a blockchain system in a homeless community to securely store and share data across a system of providers in the health care ecosystem.

Methods: We performed a series of platform demonstrations and open-ended qualitative feedback interviews to determine the key needs and barriers to user and stakeholder adoption. Account creation and data transactions promoting organizational efficiency and improved health outcomes in this population were tested with homeless users and service providers.

Results: Persons experiencing homelessness and care organizations could successfully create accounts, grant and revoke data sharing permissions, and transmit documents across a distributed network of providers. However, there were issues regarding the security of shared data, user experience and adoption, and organizational preparedness for service providers as end users. We tested a set of assumptions related to these problems within the project time frame and contractual obligations with an existing blockchain-based platform.

Conclusions: Blockchain technology provides decentralized data sharing, validation, immutability, traceability, and integration. These core features enable a secure system for the management and distribution of sensitive information. This study presents a concrete evaluation of the effectiveness of blockchain through an existing platform while revealing limitations from the perspectives of user adoption, cost-effectiveness, scalability, and regulatory frameworks.

Introduction

Background

According to Austin's Ending Community Homelessness Coalition (ECHO), more than 7100 people in Austin experienced homelessness and needed housing and other supportive services in 2016 [1]. One of the many barriers to housing for persons experiencing homelessness (PEH) is the lack of access to their own documentation and the time and money required to replace lost or stolen documents. Client data are often distributed between service providers, causing a deterioration in health and delays in service when accessing data from multiple sources. Existing database systems such as Homeless Management Information System (HMIS) to manage documentation for the PEH lack interoperability for different document formats and organizations outside the system, do not facilitate data ownership for clients, and cannot guarantee data privacy and security.

The Mayor's Challenge Competition, sponsored by Bloomberg Philanthropies, is designed to facilitate innovative and scalable solutions for city leaders to tackle urgent local challenges. Austin, Texas, was one of the 35 cities selected to prototype and test their ideas over 6 months with a grant support of US $100,000. Through a partnership between Dell Medical School, the City of Austin government, Austin Travis County Emergency Medical Services, and community organizations, a pilot study was conducted to test the first use of blockchain technology to validate identities and improve access to services for the PEH in the country.

Objectives

To solve these problems of *transaction identity*, we previously proposed the use of distributed ledger technology (DLT), or blockchain technology, to provide a validated, immutable identity and record of service transactions [2]. The literature shows promise using blockchain for data control in electronic health records, public health surveillance, disease management, genomic and biomedical data, and clinical trials [3-9]. Blockchain is currently used in rural Indonesia, Syrian refugee camps, and the slums of Kenya for similar identity management applications. Key life events such as birth registration, immunizations, health provider visits, and agricultural harvests are securely recorded and maintained on a blockchain, creating an immutable, accessible, and portable identity for displaced and marginalized people. Following this model, we explored the use of a true *economic passport* for the homeless, working toward the goal of ending homelessness. This technology was chosen as a solution over other methods of storing and sharing information such as a digital wallet or a relational database because its features met the requirements of our use case. We have continued this study, and here, we provide results from our testing of the deployment of this approach.

Blockchain is a technology for shared databases used by multiple writers in which each organization's entries must be verified and cannot be modified by an outside party. When transactions from one entity are needed by another to provide a service or verify a document, storing transactions in a single shared database promotes expedient exchange of information. A regular shared database can reliably manage the permissioning of multiple authorized users to view data. However, a relational database system in which various entities update and write information can result in unrecoverable errors. Maintenance of a health and social service information system involves backup storage services, recovery mechanisms, and updating information [7]. In the event of a database server failure, the entire system is affected, and information can be lost if it has not been backed up and stored. Ownership of the master file by a centralized user also accords control to a single party; thus, there is no inherent safeguard against data tampering, and the integrity of data cannot be guaranteed [10].

Blockchains organize data so that secure transactions are approved and recorded through consensus from entities on the chain [10,11], providing greater error checking and transactional validity than relational shared databases [10-12]. A blockchain distributes data across the network, with data copied on each node of the chain [13]. Each node installs the genesis block or the first block in the chain [10]. A group of validated transactions is added to a new block with the file attachment, sender, receiver, timestamp, and cryptographic hash of the previous block [14]. A hash is a one-way encryption function, which is used to generate a public and private key for each user [15]. Information sent over the blockchain is secured by a user's private key and cannot be viewed or modified without the key [12,13]. Data are encrypted and unintelligible to protect private information stored on the blockchain or in the event of a security breach [14]. An individual block's hash depends on the hash of the previous block, locking transactions together [12,14]. Modifying data in one block would alter all subsequent blocks, making the blockchain an immutable and authoritative record of transactions [10,12-14]. Blockchain also uses a consensus validation mechanism replacing a trusted third-party intermediary or a manual offline reconciliation process with peer-to-peer protocols, allowing organizations to agree upon submitted entries without a singular point of failure or control [10-12,16]. A network of users collectively adheres to previously agreed upon rules automatically implemented to verify the authenticity of transactions and ordering of records added to the chain [12,16].

A *public* blockchain is completely decentralized, and transactions depend on consensus from a majority of nodes. In a *private* blockchain, users are granted access by permission from the owner of the blockchain [10]. For sensitive data such as personal identity records, private blockchains limit transaction visibility to authorized users and promote scalability because of greater user and transactional control [12]. A private blockchain is only partially decentralized because nodes are limited to trusted users with varying degrees of access and sharing permissions. If a conflict or security breach arises, the system can be recovered from any user and timestamp [10]. The only security issue is that a majority of nodes could collude to rewrite the chain, as there is a partially centralized authority controlling the nodes in the chain. However, in a permissioned system, it is unlikely that users aim to violate the immutability of the blockchain, as they are trusted entities using the blockchain for organizational or personal benefit [12,16-18].

Lack of interoperability between service providers arises from nonuniform data formats and storage methods [13]. Blockchain creates an accessible and authoritative ledger of diverse document types, acting as a method for storing and gathering information from multiple independent systems [6]. Off-blockchain data storage can be integrated for large files or extensive data storage in a variety of formats and is scalable to include a larger health and social service ecosystem. The blockchain can also be used to facilitate communication for application programming interfaces (APIs), which can restructure, aggregate, and merge data from various sources in a standardized format. A blockchain-based API model allows for decentralized and authoritative data exchange between systems, user identification, a validated transaction history, and proof of transaction legitimacy [19].

In this study, we describe the results of a pilot test using a blockchain solution to mitigate the current challenges in service access for the homeless and data exchange between providers. The potential for blockchain in various health care settings has been examined in several studies [3,4,6-9,14,20,21]. However, these studies are theoretical in nature, and to our knowledge, no published studies have examined the feasibility, effectiveness, or performance of blockchain in a real-life public setting. In this study, we used a private, permissioned blockchain system for secure storage and transmission of documents with planned API integration for intersystem data access and transmission from legacy databases. This model additionally permits individuals to access and control their own data by uploading official documents and sharing self- or provider-uploaded records with select organizations. Our approach in this study aimed to increase agency, motivation, and control while reducing service barriers for the homeless and supplying more complete and accurate information for service providers.

Methods

Generating Testable Assumptions

Austin, Texas, was 1 of the 35 cities selected by the 2018 Mayor’s Challenge Competition, sponsored by Bloomberg Philanthropies. The competition was designed to facilitate innovative and scalable solutions for city leaders to tackle urgent local challenges. Each Champion City selected in the Mayor’s Challenge Competition was to prototype and test their ideas over 6 months. Through a partnership between Dell Medical School, the City of Austin’s Office of Technology Innovation, Austin Travis County Emergency Medical Services, and community organizations, a pilot study was conducted to test the use of blockchain technology to validate identities for the homeless.

Participation in the Mayor’s Challenge Competition required a series of steps to design and implement testing. First, we identified assumptions underlying the idea, which will be required for stakeholder participation. We found that the following set of assumptions must be tested and shown to be valid for the successful implementation of our solution (see Textbox 1): (1) our prototype platform would be appropriate for PEH in Austin, (2) PEH will be able to understand its features and will consent to participate in such a system, (3) providers will be able to access and trust the information on the platform, (4) blockchain technology is essential to manage identity for PEH, (5) privacy and confidentiality of data will be protected, (6) service delivery will be facilitated, and (7) interorganizational efficiency will increase by sharing data in a standardized manner with shared governance on the platform. After determining how to test and evaluate these assumptions, we developed and modified prototypes and tests based on real-life findings, user feedback, and an evolving understanding of our idea. For prototype testing, we used an existing blockchain technology platform that had been implemented outside the United States to manage the identities of refugees.

Second, we identified markers for what constitutes an appropriate test of a platform based on blockchain technology (see Table 1). To be effective, the platform needs to be able to allow individuals to enter the system by creating an account. They need to be able to upload documents and then share those documents with others, with control over which documents get shared with which other participants. Service providers need to be able to additionally conduct transactions, especially transactions of identity validation, and to share information with each other. All these actions and pieces of information need to be recorded and available, to be differentially accessible based on user-controlled permissions, and to remain securely protected and immutable. The system overall needs to be easily understood by users.

Before testing our assumptions, initial engagement with the homeless population was performed to determine their needs and concerns. Two-hour meetings were held biweekly over a period of 12 months. Attendees included 20 homeless individuals in the City of Austin and 1 to 2 staff members from the City of Austin Office of Innovation who regularly interacted with the homeless population. The homeless participants were rotated monthly to include a larger subset of the population, and each participant was compensated for their time at a rate of US $20 per hour. Meetings consisted of open-ended questions regarding difficulties those with lived experience of homelessness face in daily life, interacting with service providers, maintaining documents, and filling out applications.

On the basis of these discussions and the answers we received to the questions in Table 2, we developed a list of documents that are most useful for testing our solution. Figure 1 lists types of documents and types of organizations and gives a sense of how difficult it is to reobtain a particular document. The figure provides insight into what a person experiencing homelessness needs to be able to manage to prove their identity to receive services, especially those that provide health care and potential housing.

As can be seen, the documents required for identity verification varied across types of organizations. Every organization, though, needed an official photo ID; yet, about one-third of clients lacked such a basic identity document when first entering the system. Replacing a photo ID is a time-intensive effort. Approximately half of the presenting users lacked insurance cards, which were required by many organizations. Looking at the entirety of the figure, though, it becomes clear that managing identity involves managing a significant number of identity documents across a wide audience of service organizations.

As some of the assumptions had overlapping aspects, we describe our methodology in testing all 7 assumptions in the subgroups below.

Textbox 1. Testable assumptions for solution implementation.

1. Given that our blockchain platform is modified from a pre-existing platform for refugees, the use case of refugees must be nominally equivalent to the use case of people experiencing homelessness
2. To gain user participation, people experiencing homelessness must understand the functionality and features of the platform, and consent to participate.
3. Stakeholder participation requires providers to access, accept, and trust information shared through the blockchain network.
4. Blockchain is necessary to meet our goals.
5. Privacy and confidentiality of personal data needs to be protected.
6. Enabling access to information facilitates service transactions.
7. The technology enables a shared data standard and governance that increases inter-organizational efficiency.

Table 1. Blockchain components needed for a successful prototype.

Test	Elements needed
(1) Allow individuals to create accounts and upload documents	• Profiles • Ability to connect profiles • Individual document repository • Ability to grant repository and asset level access
(2) Allow individuals to share documents with differentiated permissions	• Ability to find other profiles in the system • Ability to send a document • Ability to share a document • Profile user-controlled permission • Data level permission
(3) Allow service providers to share documents and conduct transactions, including verification of service use	• Ability to see a validated document • Ability to share a document • Ability to see permissions by individuals
(4) Allow service providers to share with each other	• Ability to find other verifiable users/profiles
(5) Capture all transactions/records	• Ledger with varied permissions • All actions write to a ledger • Inability to delete from ledger

Table 2. Research questions.

Particpants	Questions
For persons experiencing homelessness:	• Which things on your to-do list frustrate you the most? • Which records or documents are you in most need of accessing? • If you could reduce a barrier to a daily goal, what would it be?
For community health paramedics, when you help the homeless:	• Where do you see the most missed opportunities? • What common miscommunications could be prevented if you had direct information or document access? • What information is lacking that would help you the most?

Testing Assumptions 1 and 5: Usability and Security of the Platform

Assumptions 1 and 5 regarding the viability of an existing private, permissioned blockchain platform for our use case and the security and privacy of data were tested in 2 sessions on June 14, 2018, and July 13, 2018. In the first session, our testing plan was for the homeless clients to set up an account, upload a document onto the blockchain, deny a request to connect from an organization, accept a request to connect from an organization, and participate in a 3-party transaction between the client and 2 service providers. All tests were performed with platform provider staff, our team members, and 2 homeless individuals. Members of our team created mock provider accounts before testing with our homeless participants. For our second testing session, we modified the user interface so that an account profile contained the user's picture and name with categories for general profile information, identity documents, medical documents, and dependents or emergency contacts.

Testing Assumption 2: User Participation and Understanding of the Technology

We tested our assumption regarding user participation (assumption 2) at 2 pop-up resource clinics, where the homeless could access multiple health, social, and other service interventions. Our group of 8 city officials and 5 individuals from our team engaged a total of 34 homeless residents. Of the 34 homeless residents, 15 agreed to participate, 11 indicated interest when more information and a working platform were available, and 8 either declined to participate or did not finish the discussion.

Attendees were offered the opportunity to discuss and provide feedback on a technology designed to securely store and share their documents. In our discussions with homeless participants, we used 3 different prototypes of our platform with increasing levels of fidelity to a real-life DLT platform. At the lowest level, to explain the concept of DLT in a nontechnical manner, we created a prototype of the platform using several journals with a lock and key (Figure 2). Each journal represented the record of a user or a service provider. In a DLT, when a document (or other record) is written in the journal or uploaded onto the blockchain, none of the other users in the individual's network can see its contents until permission is granted, even if they are aware that there is an existing entry in the ledger (or block on the chain). In our testing analogy, granting permission is represented by the key that opens the lock to a specific physical journal. We also demonstrated distributed data storage by tearing up a piece of paper from a user's journal and spreading the pieces into buckets representing different institutions. In this scenario, when a document was accessed with permission, the pieces were reassembled.

Increasing the fidelity of the prototypes, we next showed screenshots of the platform prototype with sample transactions, and then, at the highest fidelity level, a digital prototype on a mobile phone with uploaded data was presented. These 2 prototypes were used to further explain the technology and platform concepts. The static screenshot-based prototype showed prospective categories (eg, identity, residency, medical profile, employment history, education, and children/preferred contacts) for the different types of documents. We also showed screenshots of a request from a provider for permission to see a user's data, accepting and giving the provider permission to view specific documents, and a transaction history showing that a document was shared with a provider.

At this stage in our project, the high-fidelity prototype platform was then used to demonstrate uploading and viewing a picture of a driver's license via the platform. The prototype platform for refugees had not been modified at all for our use case. Thus, our demonstration was performed in a sandbox or in a closed, nonlive testing environment to safely experiment with Web or software projects. We additionally decided to conduct further tests with sample documents until the technology was fully configured and free of errors.

Understanding and acceptance of metrics were measured with participation consent forms and qualitative feedback through open-ended questions.

Figure 2. Distributed ledger technology prototype.

Testing Assumptions 3, 6, and 7: Stakeholder Participation and Organizational/Data Standards

We tested assumptions 3, 6, and 7 regarding stakeholder participation and organizational and data standards through interview questions with representatives of the Downtown Austin Community Court, Central Health, and ECHO who interact with and provide services to PEH regularly (Multimedia Appendix 1). The participants were initially explained the technology platform, its relevant features, and our assumptions to test its practicality in addressing PEH identity management for health care and social services. Each representative was provided an opportunity to respond to the semistructured, facilitated discussion.

Results

Test of Assumptions

As was clear in the Methods section, multiple assumptions were tested in each of the approaches. As such, we note which assumption(s) was being tested, where appropriate. In particular, note that assumption 6 about data availability facilitating service transactions permeates most aspects of the testing process. The assumptions are listed in Textbox 1, and more detailed testing results are listed in Multimedia Appendix 2.

Assumptions 1 and 5

In testing assumptions 1 and 5, both of our homeless participants were able to set up a user account, accept a connection request, deny and accept a provider connection request, and exchange transactions to and from providers. Specific observations, difficulties encountered, and their relevance to our project and testing assumptions are displayed in Multimedia Appendices 2 and 3. During the second session, with modifications to the test, some of the onboarding workflow resulting from entering extensive personal information created a more streamlined user experience in terms of finding and categorizing types of documents. However, testers still experienced several challenges (Multimedia Appendices 2 and 3) in addition to those previously documented in Multimedia Appendix 2 regarding platform features and functionality. In general, the problems that users experience tend to fall into 5 buckets: trusting self-uploaded documents, understanding blockchain concepts, platform performance issues, confusion about the workflow, and privacy concerns. We return to this in the discussion below.

Overall, users on the platform were able to accomplish the tasks expected of them even if guidance was required, but there were definite issues that need to be solved. Trying to use an existing platform developed to assist refugees without modification did not translate to the use case of working with those experiencing homelessness. Furthermore, privacy and security did indeed turn out to be of paramount importance to end users.

Assumptions 2 and 6

The results of our tests showed that the homeless can understand the platform and its potential benefits, and a majority of individuals consented to participate immediately or at a later date. Feedback from our PEH test participants included the need for a wider variety of documents that can be validated and authenticated on the platform, leading us to consider possibilities for future expansion, such as involving state or federal institutions. We also planned to create benchmark documents facilitating services such as housing, disability benefits, Supplemental Nutrition Assistance Program (SNAP), medical, court documents, and insurance. Each benchmark document would consist of validation from multiple providers that the documents necessary for a service have been obtained and authenticated, increasing efficiency for service providers and improving access to services for their homeless clients.

Assumptions 3 and 6

The results showed that providers will accept data shared through the blockchain platform, but permissible document fidelity varies across organizations. Specifically, the requirements of what would be considered a certified document varied (see Table 3). Transactions requiring hard copies included employment documents, bank transactions, social security, and vital records, which would be difficult to include without altering the standards for data. The Medical Access Program Card (a local health insurance card), SNAP application documents, and housing applications permit document copies and can easily facilitate transactions without adjusting data standards.

The need for interorganizational records or documents from clients also varied. Many providers kept internal digital copies of client records and provided services to the homeless without proof of identity because of flexible policies for this population. Identification documents are unnecessary for social security, disability benefits, transitional housing, or rehabilitation services, but the lack of identification documents can delay medical care at hospitals. These providers envisioned a role for a distributed ledger system when clients did not grant permission for document storage and for time-sensitive documents such as a current utility bill needed to prove residency. In these cases, system-level efficiency could be improved if provider employees knew what type of documents were available and if documents of interest could easily be located without looking through extraneous information.

Table 3. Level of document certification

Certification level	Definition	Requirements to meet level of certification	Examples
Validated	Approved to be valid document and belong to the holder (platform user)	Documents coming directly (digitally and physically) from the originating Source	• Birth certificate uploaded and sent by Vital Records • Medical record sent by a doctor • Medical Assistance Program (MAP) card sent by the issuing entity
Verified	Verified that document belongs to the holder (platform user) and document is what it claims to be	Physical document must be seen by the certifying entity	• ID that is seen in person by Austin Police Department (APD) and uploaded or sent to a user
Uncertified	Exists as a document/asset, but not marked as validated or verified	None	• A self-uploaded form, such as a Homelessness Statement

Assumption 4

Potential changes in the organizational workflow to accommodate a new system, such as our platform, was another area of friction. The HMIS provided by the US Department of Housing and Urban Development (HUD) is already widely used across the country as a centralized database to confidentially aggregate data on the homeless and housing provisions provided to these individuals. Copies of documents and IDs can be stored via HMIS, and organizations funded by HUD are required to use HMIS for client data. From the service provider perspective, blockchain is most useful for documents not currently stored in the HMIS database or for client personal use to keep track of future appointments and pending documents needed for services. This showed that the blockchain platform may, for the time being, work complementary to other existing databases or information systems, adding new features that are difficult to establish using legacy systems.

Assumptions 5 and 6

Technological concerns included the privacy and confidentiality of indelible and immutable client data for a service that might not be successful in the long term. Providers agreed that the technology showed value for the nonhomeless population as well, but opinions on whether the technological barriers were surmountable for the homeless were mixed. The most vulnerable members of the homeless population struggle to keep a phone and remember their email IDs and passwords, complicating platform access and use. There will always be a level of tension between ease of use and privacy/security concerns. However, adequately addressing the latter may help facilitate more practical solutions for the former. The readiness to overcome any specific requirements for the use of the solution by PEH seemed to be determined by how many of their problems were being solved effectively by using such a platform.

Assumption 7

Analysis of interview feedback elucidated the requirement of clearly defined roles for each organization. Not all providers wanted responsibility or additional work processes of account creation, document validation, and resolution of transactional or account legitimacy. Legal issues and worries regarding Health Insurance Portability and Accountability Act (HIPAA) compliance to share personal health information and other client data between organizations were further constraints on stakeholder roles, participation, and interorganizational efficiency. The questions around governance and standardized processes for onboarding and managing roles remained unresolved. It was not clear whether the City of Austin had the capacity to manage a blockchain platform or if there was another organization in the city, which had the capacity and trust of all other stakeholders and general citizens, including the PEH.

Assumptions 1 and 4

The results of our tests demonstrated that the platform we had chosen to use lacked core functionality and configuration specifically needed for our particular use case. The user experience was time consuming and not intuitive for tasks such as account creation and sharing of data, which will likely hinder client and provider understanding, acceptance, and adoption of the platform. Validated data could not be securely shared while protecting privacy and confidentiality; thus, data transactions on the blockchain platform cannot facilitate services or increase interorganizational efficiency. The nature of sharing and transacting data on this platform was specific to the original use case of small farmers and refugees and was not suitable for our purpose of securely sharing and storing documentation. As our contract with the platform provider was constrained to limited modifications because of the time frame and budget of the project, we were unable to make the necessary changes to continue testing this platform for our use case. Given these findings, testing assumption 4 on the equivalence of the 2 platform use cases was invalidated.

Discussion

Principal Findings

Secure, fast, and reliable sharing of validated health and identity data is crucial to improve the quality of life and health outcomes of the general population, particularly vulnerable populations such as those experiencing homelessness. Our project tested whether a blockchain-based platform had the functionality to manage permissioned access and distribution of data while empowering patients with control over their own records. This study also showed the need to address challenges in establishing and operationalizing a blockchain system before trial or full-scale production.

Although broader and timely access to health and identity records can be achieved through blockchain, there are costs in transferring to a new system and training professionals and patients on the best methods of use to improve efficiency and outcomes. In the underserved populations, initial adoption depends on a user-friendly interface and an end user experience accounting for varying levels of technological access and ability. Unfamiliarity with blockchain technology and usage also creates challenges in adoption for service providers. Understanding the basic principles of blockchain technology is necessary to confer trust in the system and allow changes in workflow, promoting organizational efficiency and preventing the burden of additional verification of authorized documentation. Institutions participating in a blockchain system must also mutually agree upon the size of data that may be stored or transferred on the blockchain to maximize system performance [7,12].

Our research showed that a blockchain can be used to manage personal and health data by facilitating interoperability, patient control of documents, and a record of consented document access while maintaining data privacy and security. A validated, immutable, and decentralized ledger promotes system and transactional trustworthiness but cannot guarantee the absence of falsifications or errors from the point of origin. These mistakes are perpetuated in the blockchain without a manual content verification procedure [10,22,23]. Our results show that a private, permission-based blockchain might be suitable for sensitive personal and health information with regulatory guidelines and standards to ensure appropriate use of data. In a permissioned system, participating organizations need to decide who is responsible for the creation of new accounts [10]. Individual users may also request for their data to be erased [11]. If the data are protected health information (PHI), HIPAA mandates its deletion in the event of unauthorized access. PHI must also be destroyed when a data storage device is decommissioned. This is only possible when documents are not stored in the blockchain. If data are stored in an off-blockchain data repository or database, a record of the existence of deleted data may still be maintained within the chain [24]. There is ambiguity regarding whether metadata of PHI are considered PHI [25], but legal counsel with respect to the application of HIPAA and data privacy standards is vital to ensure compliance with regulatory frameworks [24,26]. A potential limitation regarding these data and use standards arises with respect to a private, partially centralized blockchain. To achieve compliance and vendor neutrality, an outside enforcing authority may be required [12].

Limitations

Timeline and budgetary constraints from the Mayor’s Challenge Project limited our ability to fully modify the platform for our use case. We were unable to develop an end user experience promoting homeless client adoption or develop changes in workflow, policy, and data sharing agreements for the best use of blockchain technology. The significant security and usability issues with our original platform prevented large-scale implementation in an empirical setting.

Further research is required to compare the efficacy and costs of an approach based on blockchain technology with other alternative approaches. Although the research presented here shows the potential of a blockchain-based approach, we need to better understand the comparative benefits and costs. For example, the City of Austin could have created a central database to which all partners and collaborators would agree to add their data. Questions on whether all participants would adopt the use of standard data types and a centralized, city-owned database would need to be addressed. Experience has shown that not all advocacy groups or people experiencing homelessness fully trust the city government, for example. The purpose here, however, was to show whether a blockchain-based approach could work, and it was not to address the question of comparative effectiveness.

Comparison With Prior Work

Several studies to date have explored the potential applications of blockchain to solve key issues in the health care sector. This study demonstrates a methodology and rigor that may be needed to test if a blockchain can be used to securely store and track verified documentation, promote client ownership of data, and improve interoperability by facilitating permission-based data sharing. This study paves the way for future studies by detailing specific organizational, logistical, and system considerations for successful and scalable implementation.

Conclusions

Blockchain may provide a means for consented access to validated personal and health data, thus increasing interoperability without compromising the security or privacy of data [12,24]. Existing solutions need to be put through rigorous testing before being adopted at scale. We developed assumptions based on feedback from end users, PEH, and service providers on important aspects to be tested. We engaged these groups actively to test the assumptions using a preexisting platform and found that many of the assumptions could not be validated, given the constraints of the platform, limitations on time and resources in the pilot, and lack of clarity on legal and compliance implications of this new technology. On the basis of our learnings through this pilot study, we opine that using an off-blockchain data lake or extant provider databases for PHI storage and systematic storage of an index of health records and associated metadata on the chain can permit the management of access and data control while complying with privacy and regulatory standards [24,27]. Maintaining limited personal data on the blockchain maximizes the speed of transactions and scalability of the blockchain system [11,12,20]. Through an API, organizations can integrate data and receive accurate, updated information in a usable format [19]. Faster availability of real-time data reduces delays in service [10,11,28] and promotes coordinated health care and specialized treatment based on outcomes and efficacy. Shifting data ownership and control to the individual optimizes access to health and social services and engages a patient in their own care through selective sharing of information and data with providers or researchers [29-31]. Patient-reported measurable outcomes and data from mobile apps or on-person sensors may also be integrated, creating a single access point for all real-time health data and improving personalized health care [12,13]. These benefits outweigh the challenges in adoption, employment, and investment of a blockchain system. The application of current recommendations and continued research into blockchain implementation is crucial to develop cost-effective strategies for the operationalization of blockchains while ensuring efficiency, data privacy, and scalability in the health care ecosystem [24].

Acknowledgments

The authors would like to thank Bloomberg Philanthropies for their financial support through the Mayor’s Challenge Program, City of Austin’s Office of Technology Innovation, Austin Mayor’s Office, Austin/Travis County Emergency Medical Services, Central Health, and PEH who participated in the study.

Authors' Contributions

AK and VR designed the study along with City of Austin partners. AK, SA, and VR wrote the manuscript. AK, SA, and VR reviewed and approved the final version of the manuscript.

Abstract

Background: Personal health record (PHR) security, correctness, and protection are essential for health and medical services. Blockchain architecture can provide efficient data retrieval and security requirements. Exchangeable PHRs and the self-management of patient health can offer many benefits to traditional medical services by allowing people to manage their own health records for disease prevention, prediction, and control while reducing resource burdens on the health care infrastructure and improving population health and quality of life.

Objective: This study aimed to build a blockchain-based architecture for an international health record exchange platform to ensure health record confidentiality, integrity, and availability for health management and used Health Level 7 Fast Healthcare Interoperability Resource international standards as the data format that could allow international, cross-institutional, and patient/doctor exchanges of PHRs.

Methods: The PHR architecture in this study comprised 2 main components. The first component was the PHR management platform, on which users could upload PHRs, view their record content, authorize PHR exchanges with doctors or other medical health care providers, and check their block information. When a PHR was uploaded, the hash value of the PHR would be calculated by the SHA-256 algorithm and the PHR would be encrypted by the Rivest-Shamir-Adleman encryption mechanism before being transferred to a secure database. The second component was the blockchain exchange architecture, which was based on Ethereum to create a private chain. Proof of authority, which delivers transactions through a consensus mechanism based on identity, was used for consensus. The hash value was calculated based on the previous hash value, block content, and timestamp by a hash function.

Results: The PHR blockchain architecture constructed in this study is an effective method for the management and utilization of PHRs. The platform has been deployed in Southeast Asian countries via the Asia eHealth Information Network (AeHIN) and has become the first PHR management platform for cross-region medical data exchange.

Conclusions: Some systems have shown that blockchain technology has great potential for electronic health record applications. This study combined different types of data storage modes to effectively solve the problems of PHR data security, storage, and transmission and proposed a hybrid blockchain and data security approach to enable effective international PHR exchange. By partnering with the AeHIN and making use of the network's regional reach and expert pool, the platform could be deployed and promoted successfully. In the future, the PHR platform could be utilized for the purpose of precision and individual medicine in a cross-country manner because of the platform's provision of a secure and efficient PHR sharing and management architecture, making it a reasonable base for future data collection sources and the data analytics needed for precision medicine.

Introduction

Background

Traditionally, standard clinics have offered medical services focused on disease treatment. However, with the world's current aging populations, there is a growing gap between what services clinics offer and patients' actual needs. This means that clinics may not be equipped to offer the complete range of care required by patients, resulting in preventable medical harm. The National Institute for Health and Care Excellence's 2016 Multimorbidity Clinical Assessment and Management Guidelines Report [1] emphasized the importance of integrating patient-centered decision-making methods for multiple problems, with a focus on precision medicine. Precision medicine is a disease treatment and prevention strategy formulated with reference to individual variability in terms of genes, environment, and lifestyle, which is used to determine necessary dynamic changes and personalized treatment for preventative health care and clinical care. The core elements of precision medicine are historical disease data, daily vital signs data, personal health management, and medical record exchange, and it aims to stop potentially harmful or unnecessary medical behavior, integrate care, reduce treatment burden, and help patients select meaningful treatment and care goals through accurate assessment. With the requirements of precision medicine mentioned earlier, there is a need to not only maintain patients' electronic medical records (EMRs) in hospitals but also to establish personal health records (PHRs) by combining medical records from different health institutes and functions of precision medicine, which patients can use to save, manage, use, and exchange with health care practitioners.

PHRs are highly private data, and this sensitivity means that there are significant security challenges involved in their management and exchange. Any system that seeks to manage and exchange such records must ensure that health records are exchanged appropriately, that they are not leaked, and that protected data are not tampered with. A good way to achieve the secure exchange of health records is by using blockchain architecture. A decentralized storage management architecture based on blockchain would be able to meet the security requirements. In a 2016 study, Ford [2] predicted that 75% of the adults worldwide will be using PHRs by 2020 without any external incentives. The importance of a PHR is that it allows a health care provider to examine a patient's history of illnesses and medications and it provides a basis for medical decision making. More importantly, PHRs offer a basis for personal health management. PHRs include various health information such as medical information, vital signs (heartbeat, blood pressure, blood sugar, and body temperature), family disease history, and blood test reports [3-5]. Most countries today, however, still use the EMR system. In 2013 in Taiwan, a total of 502 hospitals had a comprehensive EMR system for accessing medical records, inspection reports, medical images, medication information, and so on. However, these data only exist in hospitals and are exchanged between other hospitals or clinics via the EMR exchange center. To achieve the goals of precision medicine and health care, a *patient-centered* approach to record management and exchanges is required; the traditional centralized PHR repository in hospitals does not meet the requirements to achieve this. A patient-centered approach would involve PHRs being managed by the patients themselves, while providing those records to various health care providers as needed. This kind of system would require a very secure architecture to protect PHR data.

According to the National Health Insurance (NHI) Administration of the Ministry of Health and Welfare in Taiwan, the average number of outpatient visits, not including Chinese medicine or dentists, is 13 per year for people in Taiwan. Most of these people visit different hospitals for treatment of the same condition over a short period of time. With the PHR system, people can manage their own health records and conditions, and doctors can also view their past medical records and medication status.

Blockchain technology was proposed by Nakamoto in 2008 [6] in a white paper titled "Bitcoin: A Peer-to-Peer Electronic Cash System." A blockchain has the characteristics of decentralization, and its encryption mechanism can be designed to verify the data content to ensure that the data have not been tampered with. In this paper, the blockchain concept was used to solve the problem of data security and third-party authentication in the transaction process. A blockchain is a decentralized public account that records all money transactions and how much money everyone owns. John et al [7] proposed that the use of blockchain technology in electronic health care records can avoid the need to add another organization between the patient and the records. It is not a new repository for data but rather implies a decentralized control mechanism in which all users have an interest, but no one exclusively owns the data. This technology can improve data safety and remove privacy issues. Pouyan et al [8] stated that regarding the trust in health information exchange competency and exchange integrity, the blockchain architecture is more trustworthy than other exchange mechanisms for exchanging highly sensitive information.

This design differed from previous work on blockchain infrastructures and associated consensus mechanisms in that, while they operate in a decoupled manner from other blockchain frameworks, Fast Healthcare Interoperability Resource (FHIR) Chain [9] focuses on designing the decisions of smart contracts to be compatible with any existing blockchain architecture that supports the execution of smart contracts. However, this architecture remains vulnerable to the 51% of cyber attacks and does not provide complete data security.

Objectives

This study proposed a blockchain-based architecture for storing, sharing, and protecting sensitive personal information. In the proposed architecture, the blockchain manages the authorization of data exchanges between patients, health care providers, and other users. The blockchain does not physically replace the electronic health record system, as most hospital information systems store detailed EMRs in a secure database on site or on a duplicate site located outside the hospital. Therefore, the blockchain architecture simply helps to ensure the security, confidentiality, integrity, and availability of the data. Combined with FHIR's data format standards, stakeholders can read and write data into their own electronic health record systems that can be exchanged securely with other systems using the blockchain. The computational strength of the encryption built into the blockchain ensures that the data are correctly and safely transferred during PHR exchange transactions. However, a blockchain is not a data repository, rather it is a ledger of data integrity. This technology can be used to exchange records, verify data, and protect sensitive data. It can ensure that medical records will not be modified by unauthorized third parties. The uploading time of the data to the blockchain can also be recorded. Thus, the enabling of the collection of a patient's more complete longitudinal data and the ability to share it remotely with professionals can allow for better decision making and reduce medical errors and medical malpractice.

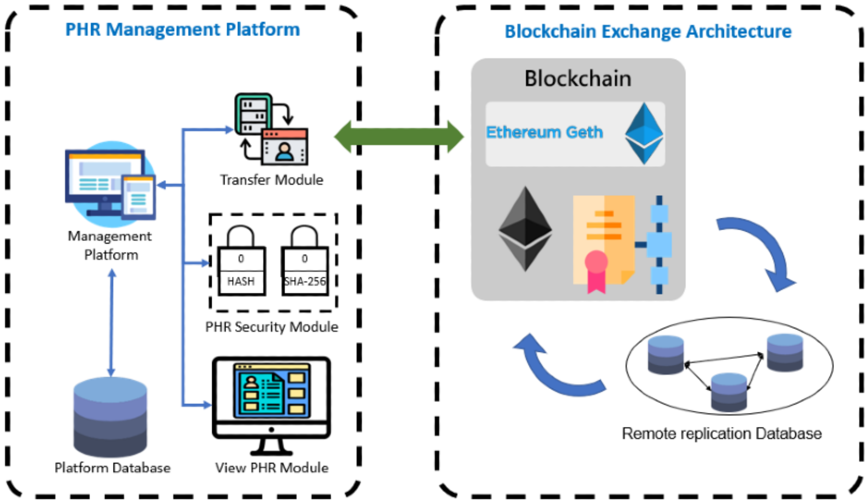
Methods

The blockchain-based exchange architecture for PHR management proposed in this study comprises 2 main components. The first component is the PHR management platform, on which users can upload PHRs, view their record content, authorize PHR exchange with doctors or other medical health care providers, and check their block information. When a PHR is uploaded, the hash value of the PHR is calculated by the SHA-256 algorithm, and the PHR is encrypted by the RSA (Rivest-Shamir-Adleman) encryption mechanism before being transferred to a secure database. The second component of the architecture is the blockchain exchange architecture, which is based on Ethereum to create a private chain. Proof of authority (PoA), which delivers transactions through a consensus mechanism based on identity, is used for consensus. The hash value is calculated based on the previous hash value, block content, and timestamp by a hash function.

The architecture of the platform is shown in Figure 1. The PHR management platform consists of the transfer module, the security module, and the view PHR module. The transfer module allows users to connect to the blockchain exchange architecture to create or search for blocks. The security module is used to encrypt and confirm the PHR content. The view PHR module displays the PHR content for personal health management or for doctors to view the record.

The blockchain architecture in this study is designed based on Ethereum, including elliptic curve digital signature, PoA, and the new block creation function. The blockchain architecture ensures that the PHR content remains secure and confirms that the PHR content is correct.

Figure 1. Personal health record management platform and blockchain architecture. PHR: personal health record.



Personal Health Record Management Platform

The major goal of this study was to build a cross-area health information exchange platform that could fulfill the needs of international medical services. This study used My Health Bank (MHB) as an initial example of PHRs. In Taiwan, MHB is issued by the NHI and contains a majority of the clinical data collected from different health care services. MHB not only includes the necessary clinical data chronically arranged by time for a single patient but also contains the information entered by the patient, such as blood pressure measured at home. Therefore, there was a good reason for this study to choose MHB for the PHRs in the Asia eHealth Information Network (AeHIN). Detailed items of the MHB are provided in this manuscript. Basically, PHRs refer to individual-centric personal health data from different medical service providers or devices, while EMRs represent the data of a patient in a single hospital.

Multiple simulated computers are used as blockchain nodes in this study to emulate the encryption and secure storage of a PHR in this study. As health records are private data, the blockchain must be built in a secure environment as a private chain, increasing the efficiency and stability of data transmission and sharing.

MHB was used as a PHR example in this study. MHB was launched by the Ministry of Health and Welfare of Taiwan in 2015. It allows Taiwan's NHI members to download their own health records from its website.

The MHB data contain all the necessary clinical information because they are generated by the hospital when it applies for health insurance payments.

The entire PHR of any single patient was uploaded in our platform. For authority management and confidentiality, we used a variety of tags in the contents to specify the function levels to different uses through a carefully designed user interface, through which patients could assign which data would not be revealed to others as well as assign tags to the data. Our design to keep the whole data is for the purpose of future use of the data, as the PHR platform could also become a clinical data repository and the data could be used for further analysis of precision medicine in the future.

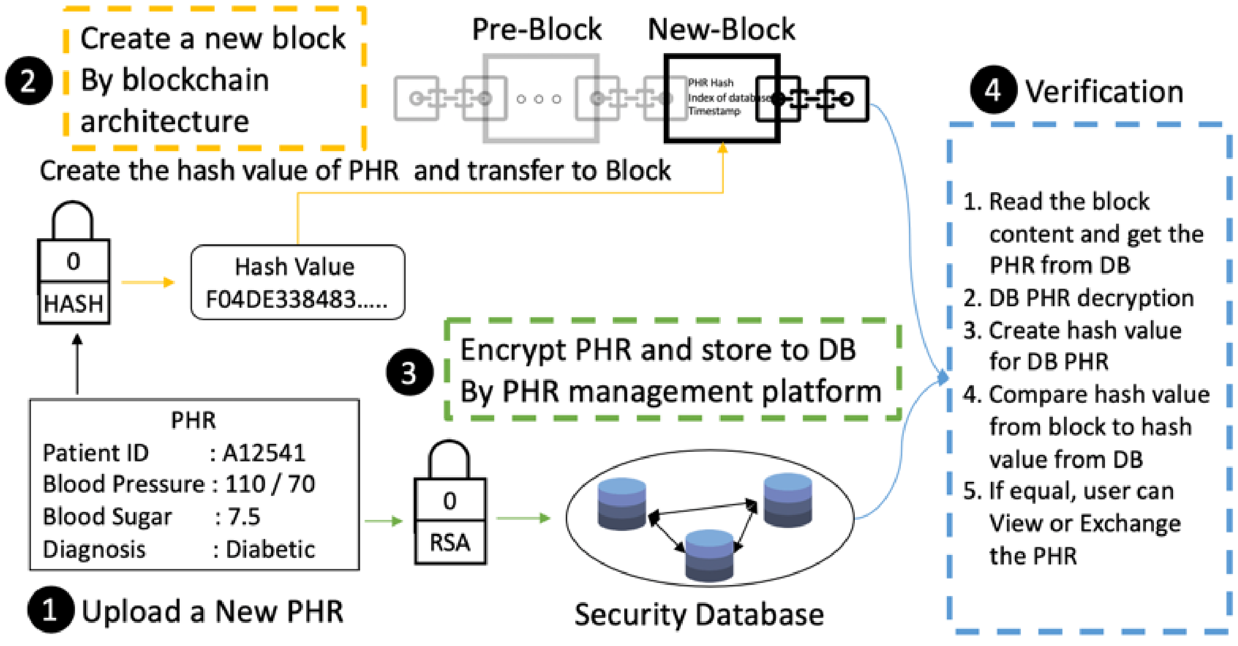
The MHB data include (1) outpatient information for Western medicine, traditional Chinese medicine, and dentistry; (2) hospitalization information; (3) allergy information; (4) images and information for pathological exams and tests; (5) patients' discharge record abstract; (6) patients' intention for organ donation and palliative care; (7) preventive health data; (8) preventive vaccination information; (9) patients' health insurance card information; (10) premium and charging specific information; and (11) insurance premium payment specific information. The MHB file format can be selected as either XML or JSON. This study used the XML format.

Hash Value for Data Integrity Confirmation

To ensure that PHRs are not modified when they are transferred between platforms, this study designed a hash function to confirm the integrity of PHR data. SHA-256 was used to create a hash value for each PHR. SHA-256 is a cryptographic hash function, which takes an input and produces a 256-bit (32-byte) hash value known as a message digest, typically rendered as a hexadecimal number, 40-digit long. It was designed by the United States National Security Agency and is a US Federal Information Processing Standard [10,11]. If the PHR data have not been altered during transfer, the SHA-256 hash value would remain the same. Unlike encryption, which converts text into reversible cipher texts of different lengths, the hash function converts text into irreversible hash strings (or message digests) of the same length.

When users upload their PHRs to the platform, the PHR hash value is created and transferred to the blockchain architecture as block content. Then, when the PHRs are viewed by the owner, or exchanged with other users, the platform obtains the hash value from the block and calculates the PHR hash value by SHA-256 again. If the hash value from the PHR is equal to the hash value from the block, the PHR data have not been modified. The procedure of PHR management is shown in Figure 2.

Figure 2. Personal health record creation, uploading, and verification procedure. DB: database; PHR: personal health record.



Data Encryption for Personal Health Record Security

In this study, PHRs were encrypted by RSA before being uploaded to the secure database. RSA is a public-key cryptosystem used for secure data transmission [12]. The encryption key is public and differs from the decryption key, which is private. The platform automatically creates the RSA public and private keys for users. When users upload their PHRs, the public key is used to encrypt the record. Thus, even if a malicious attacker were to overcome the firewall and all other security mechanisms, they would only be able to obtain the encrypted PHR and would have no means of decrypting it. The user private key is used to decrypt the PHR when exchanged.

Viewing Personal Health Record and Block Information for Personal Health Management

This study designed a PHR exchange architecture in which PHR contents are not read when users upload their PHRs; the platform only uploads encrypted PHRs to the secure database, thus ensuring the security of personal data.

Moreover, this study developed a user interface for personal health management that shows PHR contents when users want to access them. Using MHB as an example, when users use the application to read their PHRs, it means that the platform has the authority to read the PHRs. The PHRs are then decrypted by the user's RSA private key, and the platform reads PHR data, without storing them. This means that the platform cannot simply access PHRs without explicit user consent and action.

Blockchain Exchange Architecture

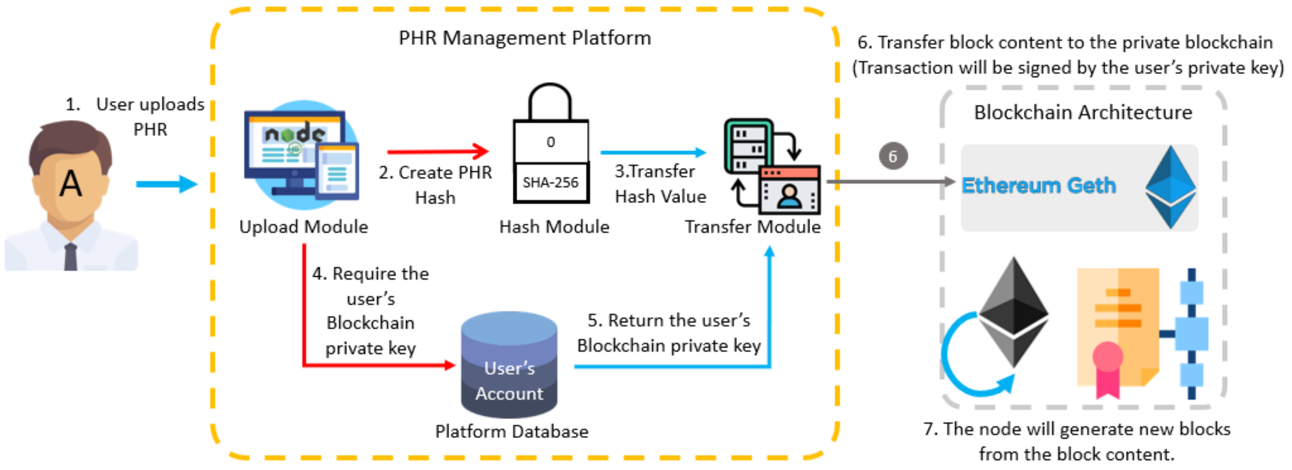
As the blocks in a blockchain cannot be tampered with or maliciously altered, this study stored PHR hash values in a blockchain to protect the PHR data and confirm the integrity of the PHR contents. Ethereum's private chain was used as the blockchain architecture, and the Geth (Go Ethereum) application, which is the Ethereum protocol, was used to transfer the transaction from the proposed platform to the blockchain exchange architecture, create a new block, and connect to the blockchain. The block creation process is shown in Figure 3.

To secure against private data being leaked during transmission on the network, the data are encrypted during the data transmission process. The health record uploaded to the secure database by the platform is also encrypted to ensure the privacy of the user. The block content includes the PHR hash and timestamp, where the PHR hash is used to check whether the PHR in the database has been tampered with. If a malicious attacker attempts to obtain the block content, they will only get a collection of random numbers. The encryption method combines hash encryption and asymmetric encryption. The block content is protected by a hash encryption function that uses SHA-256 to scramble data into a set of hexadecimal strings. Asymmetric encryption uses the elliptic curve digital signature algorithm to encrypt PHR transfer information, ensuring the integrity and nonrepudiation of transaction data, and then the PoA consensus mechanism is used for validation by a qualified verifier established by an audited authority to confirm the correctness and validity of the PHR and create the verified blocks of the blockchain.

Elliptic curve cryptography (ECC) is a public-key cryptography based on elliptic curve mathematics, also known as asymmetric cryptography. The elliptic curve digital signature algorithm is based on ECC for digital signatures. The working principle is similar to that of most digital signature algorithms. They are signed with a private key and verified with a public key, thus offering nonrepudiation. Compared with traditional digital signature algorithms (such as RSA), ECC is faster, offers stronger security, and requires shorter signatures.

In the proposed platform, each user has one password for a user account and a private key for blockchain and PHR decryption. To improve the platform efficiency, users can choose to store their personal blockchain private key in the platform's security database (or store it themselves). When data are uploaded to the platform, the system will retrieve the key from the database to complete the transaction process.

Figure 3. Block creation process. PHR: personal health record.



Proof of Authority for Block Creation

PoA is a technology that achieves consensus in a private chain. In the operation, an authorized node has the authority to generate the next block in a blockchain network. The blockchain information reaches the extreme value of the consensus of all nodes, which can guarantee that the latest blocks are accurately connected in series to the blockchain, and the blockchain information stored by the nodes is consistent, indivisible, and even resistant to malicious attacks. In this study, the private chain consensus mechanism is established, and the verifier is set on multiple simulated computers. The initial setup verifier node is set up on the simulated computers. In the feature, possible nodes represent cooperating institutions, medical institutions, research centers, and so on; the verifier uses this identity to obtain the right to verify.

Compared with other proof mechanisms, the key elements of the PoA network in this study include the following:

1. Improved efficiency: Block creation is accelerated and the waiting time for data exchange is reduced.
2. Verifier setup: A mutual supervision relationship with partner institutions is established to allow self-supervision and supervision of others, preventing the blockchain from being controlled by the node manager; the verifier can vote for a new verifier or remove an unqualified verifier at any time.
3. Highly scalable and highly compatible: It is also possible to complete intelligent collaborative construction and optimize it.

Hash Value for Block Corrected, Confirmed, and Connected

The cryptographic hash function is an important part of the blockchain. It is essentially a function that gives security capabilities to the created block, based on processed transactions, making them immutable. In Ethereum’s function, SHA-256 is used to create new blocks. The hash of a block is created based on the block content, previous hash value, and timestamp. The block content and architecture are shown in Figure 4.

Block content includes the following:

- Block number: Current block number
- Pre-Hash: The hash value of the previous block
- Hash: The hash value of this block
- Timestamp: Current time
- PHR hash: The hash value of PHR created by the platform
- PHR index: The index position of the health record in the secure database

Overall System Workflow

Personal Health Record Exchange Authority Mechanism

Users can manage the authority for PHR exchange once they have uploaded their PHRs. When users want to make their PHRs available to a doctor, the authority assignment procedure is as shown in Figure 5.

The workflow of the system comprises 3 components: upload, exchange, and view. To begin, a user uploads their PHR to the platform (Figure 6).

In the uploading process, the PHR is assigned a hash value by SHA-256. Then, the PHR is transferred to the secure database after encryption by RSA. Once the data are stored in the database, blockchain is used to ensure data security and integrity. SHA-256 and ECC are then used to create a block, and the Ethereum architecture is used as the blockchain architecture in this study. The PHR hash value and the PHR index in the database are transmitted to the Ethereum block by the user’s blockchain account (public key) and using the user’s private key signature. To create a block, block content must be verified and the block hash value must be calculated by the verifier node; it is then broadcast to each node.

The workflow of users sharing their PHRs with a doctor is shown in Figure 6. First, the platform sends the transaction to the blockchain architecture. The block architecture will then select the user’s block and read its content. The users’ PHRs will be obtained from the secure database based on the database index of the PHRs and decrypted using the users’ private key, and the hash value will be created again. The PHR will then be transferred to the doctor after being encrypted by the doctor’s RSA public key and decrypted by the user’s private key if the hash value is equal to the block content’s hash.

The workflow of viewing the PHR content is shown in Figure 7. When users want to view their PHRs or share their PHRs with a doctor, the platform will send the transaction to the blockchain architecture. The blockchain architecture will confirm that the PHR content has not been modified and that the user or doctor has the authority to view the PHR. The PHR will then be transferred to the user or doctor after being encrypted by their RSA public key. The user or doctor will then use their own private key to decrypt it. They will then be able to view the PHR content. MHB is used as an example in this study.

International Personal Health Record Exchange Implementation Process

The platform can be used at all places where the internet is available. This study used the data format designed in Taiwan MHB as an example to test the system in Asia. MHB contains all the necessary clinical health care data. In Taiwan, 99% of residents can access MHB. Therefore, we chose MHB as an example of PHRs for the AeHIN. The Philippines and Thailand were used as test cases for this study, and 2 of the physician representatives in this study were Dr Alvin in the Philippines and Dr Boonchai in Thailand.

A testing scenario was designed in which a patient from Taiwan travels to Bangkok and the Philippines and suddenly requires medical services. Both the patient and doctors in different countries were registered on this platform. Before the patient would see a doctor in a specific country, authorization to view the PHR would need to be given to the doctor by the patient. For this testing scenario, a patient's PHR with diagnoses of type 2 diabetes mellitus, epilepsy, brain stem stroke, and proteinuria NOS (not otherwise specified) and medication data was designed. The data of testing scenario is descripted in Table 1.

The scenarios consisted of the following scenes:

1. A patient from Taiwan travels to the Philippines.
2. The patient develops a headache and dizziness.
3. The patient goes to see a doctor who has been registered in our platform.
4. Authorization to view the PHR is given to the doctor.
5. The doctor retrieves the patient's PHR from the platform.
6. By viewing the previous PHRs of the patient, the doctor obtains the health profile of the patient and then completes a new diagnosis, treatment, or medication order according to the current status of the patient.
7. A new block is created and the new PHR is stored in the PHR database, if the doctor is willing to upload the new record.

Table 1. The data of testing scenario for international personal health record exchange.

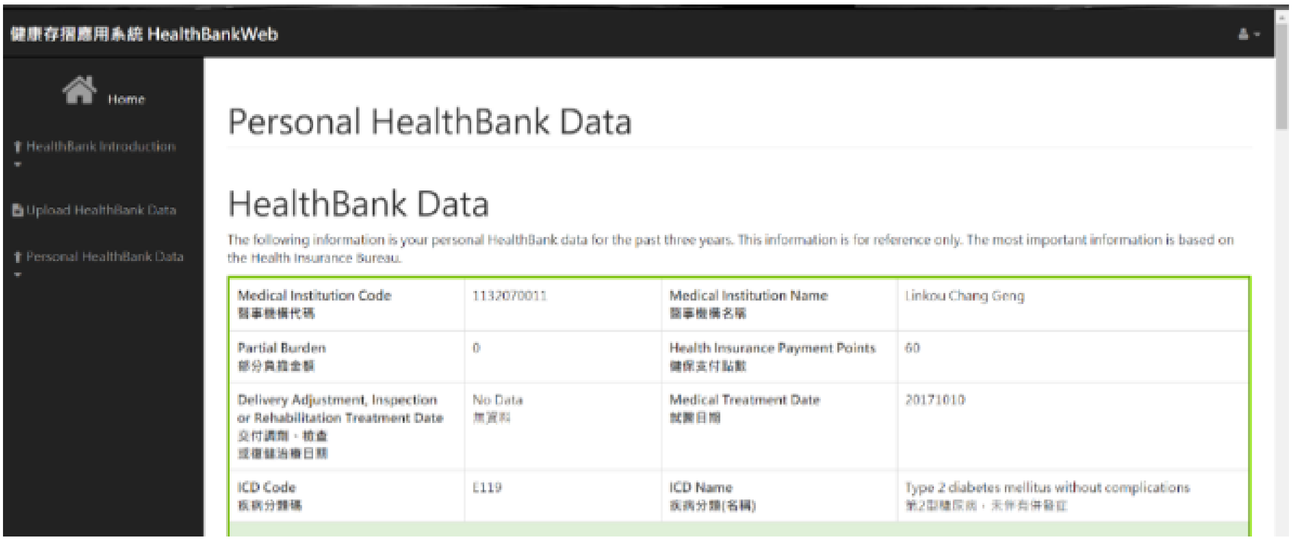
Num	Date	Diagnosis	Medical
1	October 10, 2017	Type 2 diabetes mellitus	Iunaidon Tablets *Yu Sheng*
2	July 16, 2017	Epilepsy	Neurtrol F.C. Tablets 300 mg.
3	May 25, 2017	Brain stem stroke	Cofarin Tab 1 mg
4	May 20, 2017	Brain stem stroke	Cofarin Tab 1 mg
5	January 20, 2017	Proteinuria not otherwise specified	Kaluril Tablets 5 mg

Results

Study Design

This study designed a blockchain-based PHR exchange architecture and management platform for the secure management transfer and sharing of PHR data between patients and medical health care providers. In the PHR management component, the user interface was established; its functions include viewing PHRs for personal health management, sharing PHRs with a doctor, and checking the blockchain content for security. The PHR viewer user interface is shown in Figure 8. MHB was used as an example in this study.

Figure 8. The user interface of a personal health record viewer.



Personal HealthBank Data

HealthBank Data

The following information is your personal HealthBank data for the past three years. This information is for reference only. The most important information is based on the Health Insurance Bureau.

Medical Institution Code	1132070011	Medical Institution Name	Linkou Chang Geng
Partial Burden	0	Health Insurance Payment Points	60
Delivery Adjustment, Inspection or Rehabilitation Treatment Date	No Data	Medical Treatment Date	20171010
ICD Code	E119	ICD Name	Type 2 diabetes mellitus without complications

The Personal Health Record Viewer User Interface of Platform

In Figure 8, the uploaded PHR is displayed. Records are sorted in a time sequence from the latest to the oldest. The display shows the record of each visit, and the patient's medication history. A doctor can view the latest related health record and recent medication status to give the patient the most appropriate diagnosis, while avoiding the problem of adverse reactions between repeated medications or adverse medications.

Blockchain Information in the Platform

The block content is shown in Figure 9 and includes the time at which the PHR was uploaded, the PHR owner, the PHR hash value, a timestamp, a block hash value, and a pre-hash value. Each block records the previous block location and concatenates to the previous block.

When users upload their personal MHB file, the system automatically converts the file to the FHIR format and transfers it to the security database. The data are then encrypted and uploaded to the blockchain. The users can view the uploaded data records and the contents of the block by uploading the module and obtain a health record for downloading in the FHIR format. A hospital can then upload that data to their system, as long as the system supports the FHIR format.

The blockchain architecture allows users to set their own PHR read permission using the PHR management platform to control who can view their records. The blockchain is used to confirm that the PHR content is correct. The authority control user interface is shown in Figure 10. The simple user interface design ensures that the platform and function are easy to navigate and operate. The design uses 2 columns to display a list of permissions, one of which is a list of trusted participants, and the other is a list of participants to whom the user wishes to grant permission to view their current PHR. When the user wants to grant a doctor permission to view their PHR, they select the doctor from the left-hand column and update the identity.

The blockchain architecture in this study is built by Ethereum, and the blocks are connected by the hash value of each block. The connection diagram is shown in Figure 11.

Testing Feedback from Physicians

This study used the MHB data as an example to demonstrate the functioning of the PHR exchange platform and the PHR exchange mechanism based on the blockchain architecture and encryption mechanism, which can ensure PHR storage security and its tamper-proof nature.

The system can more effectively manage self-health records and provide physicians with PHRs as a decision-making reference. The results of this study have been cross-nationally tested in Southeast Asian countries, exchanging PHRs via the AeHIN, and invited physicians from Southeast Asian countries as international participant doctors to allow users to exchange PHRs internationally for appropriate treatment.

The proposed platform was designed to easily share and exchange PHR information electronically. The contents of the PHRs were protected and kept unchanged by the technology of the blockchain architecture. The international standard format of Health Level 7 FHIR was designed in this platform to ensure the interoperability. Doctors could use the platform to upload and download PHR data from different places at any time, thereby allowing PHRs to be exchanged efficiently. Therefore, this platform could increase the accessibility, interoperability, timeliness, and usability of PHRs.

The platform is currently in its testing stage, and there is a low number of users on the network. The users' comments could be summarized as follows:

1. PHRs that are in a standardized format on this platform are a benefit for clinical service.
2. By using the platform, the exchange of PHRs is easy and efficient.
3. The protection offered by the blockchain technology can convince users that the system is secure.
4. Even if the role of the user is that of the platform manager, PHRs still cannot be read without the authorization given by the patient to view the PHR.
5. Personal health management functions can be designed in future work.

Discussion

Potential

Blockchain technology has great potential for electronic health records [13]. The core of the blockchain model ensures that any information involved has nonrepudiation to maintain the correctness of the historical process records [14]. Gary et al [15] Reviewed the current PHR definitions and multiple blockchain architectures for PHR management and found that blockchain technology is a key requirement for the management of consent to use private health data.

Many studies have proposed health applications based on the blockchain technology that can be used in the medical domain to achieve medical record sharing. In 2016, Ekblaw et al [16] created a decentralized medical record management platform that was built on the private network of Ethereum. The platform can only be accessed by authorized users, and blockchain was used to manage authentication, data sharing, and other security functions in the medical field. In the study, when any information was updated on the hospital side, it was uploaded to the blockchain; the platform was synchronized with the patient's database, and the patient would be reminded to update the block. However, patients were unable to upload data themselves, as the data were all still stored in the centralized hospital database. Omar et al [17] used Ethereum's smart contracts and a decentralized application to build a cloud-based PHR system. This system was used to store the PHR of each user and also to ensure the security and integrity of the uploaded data. Private accessible units (PAU) were responsible for all encryption, decryption, uploading of data, searching for data, and verification of data in which users can encrypt data with an encryption key and upload data to the blockchain through a smart contract, which then returns a block-id to the user uploading the data. The user would be responsible for remembering the block-id. To view the data, the user would provide the PAU with the block-id, and the system would automatically return the corresponding block content and decrypt it with the decryption key. This system, however, did not offer the capability of sharing personal medical records or system interoperability.

Peterson et al [18] presented a blockchain-based approach to sharing patient medical data that relies on a single centralized source of trust rather than network consensus to translate data and provides consensus on proof of structural and semantic interoperability. Zhang et al [9] presented a blockchain-based framework FHIR Chain that was designed to fit the technical requirements defined by the Office of the National Coordinator for Health Information Technology interoperability roadmap.

Precision medicine requires the accurate collection and management of all kinds of clinical data. To this end, this study constructed an innovative data storage mechanism, used blockchain technology to ensure the correctness and safety of the PHR data, and combined a security database storage structure with a data verification mechanism to complete data management. A Korean team implemented the blockchain PHR management platform; however, the data transaction time in their study was too long. To allow for the management of queries by a large number of patients, transaction and propagation times must improve [19]. Ahmed et al [20] proposed a blockchain-based emergency access control management system that can protect PHRs using a smart-contract design; however, the system manager can still retrieve real patient data, making privacy issues a concern. The platform designed in this study could offer patient-centered clinical record exchange and decision-making support and allow patients to view and share their own PHRs, as well as manage their health status and apply for medical data using other functions effectively. The platform and architecture could enable the meaningful use of PHRs and promote self-health management. The feasibility was demonstrated by an application test with international users in this study.

An important element of precision medicine is the exchange and management of PHRs and the subsequent provision of personalized medical treatment based on that data during the clinical diagnosis and treatment. This study therefore combined blockchain architecture and data verification methods to effectively solve the problems of data security, storage, and transmission and proposed a hybrid blockchain and data security approach that could enable effective international PHR exchanges. Using the AeHIN's cross-national network environment, PHRs were successfully exchanged, and an international network of medical and health care providers was established to improve the quality of health care and precision medicine internationally.

Principal Findings

The principal findings are as follows:

- A cross-country platform for PHRs was developed in this study. By using this platform, PHRs could be exchanged and shared between different organizations and individuals (doctors, patients, etc) in an efficient manner.
- A PHR platform was built using a blockchain architecture to ensure the security and privacy of health data. Few PHR systems based on blockchain technology have been developed for cross-country data exchange purposes.
- The platform has been tested by several users in different countries in the AeHIN and has shown that it is a suitable platform for PHR sharing and exchange.
- In our design, health data that can be used for precision medicine and can be stored and modeled in the architecture.

Limitations

Currently, our PHR platform is at the prototype stage. Users from limited groups are participating in testing of the platform. However, the hardware architecture will need to be expanded to ensure the good performance of the platform when a large number of users wish to access the system. Furthermore, as the contents of the PHRs will be exchanged and shared by different countries and regions, an international data standard, such as HL7 FHIR, will be required to ensure smooth implementation.

Future Directions

Important points regarding the comparison with prior work are as follows:

- Precision medicine is the future trend of health care and must be based on PHRs. Our PHR platform not only enables PHRs to be shared between countries but also creates space for future functions of precision medicine.
- Blockchain technology ensures data security and privacy and has been successfully used in financial data management systems.
- A cross-country medical care architecture must be developed in the present busy international activities.

Conclusions

On the basis of the blockchain technology, it is possible to remove all limitations to patients' ability to copy and transfer their own health records to other health service providers [21]. After data are uploaded in the blockchain, the block can guarantee that the records cannot be modified by anyone [22]. The PHRs are stored in a decentralized network; therefore, it is impossible to steal PHR data or hack the system illegally [21]. In addition to improved health record sharing and analysis, data sharing will be secured and privacy will be protected [23].

In addition, the blockchain technology is essential for future precision medicine applications. Through the blockchain architecture, the data required by precision medicine can be integrated from different sources. In addition to using blockchains as a ledger for patient care data, they can also be used to store various types of health care–related data, such as precision medical data and genomic data [24], health care plan data, patient-centered data [25], clinical trial data [26], medication supply chain data, and biomarker data [27-29]. In this study, we implemented a cross-country platform for PHRs. By using this platform, PHRs can be exchanged and shared between different organizations in an efficient manner. The platform has been tested by several users in different countries in the AeHIN and has been shown to be a suitable platform for PHR sharing and exchange. With our design, the health data that can be used for precision medicine can be stored and further modeled in the architecture. The security and privacy of PHRs can also be ensured by the features of blockchain technology, such as distributed node consensus algorithms, data transmission cryptography, and a decentralized network of smart contracts. However, an international standard, such as FHIR, will be required to ensure the PHR contents are internationally compatible.

Acknowledgments

This project has received funding from the Ministry of Science and Technology, Taiwan, under the project no. 108-3011-F-075-001 and Ministry of Education, Taiwan, under the project no. 107EH12-22.

Authors' Contributions

The work presented in this paper was carried out in collaboration among all authors. HL and CH conceptualized the study and study design and also designed the architecture of the system. HL, HK, and JU carried out literature review and system analysis. HK put a lot of effort in the implementation of the system. HL drafted the manuscript, and CH made significant revisions. JU, BK, and AM remotely tested the system. CH, JU, BK, AM, and LC supervised the methods of the implementation on a cross-country platform and suggested valuable improvements. All authors approved the final version of the manuscript.

Conflicts of Interest

Abstract

Background: Sexually transmitted infection (STI) rates are on the rise among adolescents and young adults in the United States. With the popularity of online dating, adolescents and young adults must increasingly rely on limited cues to make initial judgments about potential sexual partners, including judgments about STI risk.

Objective: This study aimed to assess whether in the context of online dating, an attractiveness heuristic would be used for STI risk assessment. We hypothesized that consistent with research on halo effects, decision makers would judge more attractive people to be less likely to have STIs.

Methods: In a survey experiment, we asked participants to determine which individual in each of 20 sets of paired photographs was enrolled in a personals website for people with publicly disclosed STIs.

Results: Despite financial incentives for accuracy and high levels of self-confidence in their judgments, participants performed no better than chance at identifying individuals with self-reported STIs. Contrary to our hypothesis, however, more attractive people were judged as being more likely to have an STI. This relationship appears to be mediated by inferences regarding the target individual's sexual behavior, with more attractive individuals considered to have more partners.

Conclusions: On showing adolescents and young adults photographs offering no diagnostic information about STIs, they appeared to use attractiveness as a cue for sexual risk, which was mediated by the belief that attractive individuals have more sexual opportunities. Health care providers may wish to address this heuristic process among their adolescent patients in discussions about sexual health.

KEYWORDS

risk perception; heuristics; sexually transmitted infections; online dating; dating apps; adolescents; sexual health; attractiveness; halo effect

Introduction

In the United States, sexually transmitted infections (STIs) are increasingly among the most commonly reported diseases, with the total cases of STIs reaching a historical high in 2017 [1,2]. Young adults and adolescents are at particular risk [2]. Public health officials have suggested that online dating and use of dating apps may play critical roles in this burgeoning problem. Over half of the users of popular dating apps are in the highest STI age bracket (under 25 years) [3]. Some young adults have a belief that they can "just tell" by looking whether a potential partner has an STI [4,5]. In a recent study, among a sample of young adults using dating apps, those who transitioned from a profile view to having an in-person date had higher self-reported rates of risky sexual behavior than those who did not transition to face-to-face interactions [6]. Here, we examine one aspect of the process that can lead to sexual contact and STI risk, which is the inference that young people make regarding potential partners' STI risk according to their personal appearance.

The interfaces of popular dating sites, such as Tinder, feature photographs of potential partners and encourage scrolling quickly through them and swiping "right" on appealing individuals for further examination [7]. Beneath the photographs are profiles that might be consulted for those who pass such initial screening. As it is socially awkward to ask about STI status [8] and dating apps rarely provide this information [9], young people must rely on intuition when making judgments about potential partners' STI risk. Attractiveness can be a valid cue for predicting disfiguring STIs (eg, advanced syphilis). On the other hand, for the far more frequent cases of asymptomatic STIs, attractiveness provides no directly relevant information. However, attractiveness could provide indirectly relevant information if it is correlated with risk factors, such as number of sexual partners, frequency of sex, access to health care, and use of condoms.

Existing research offers conflicting evidence regarding the roles of attractiveness judgment in inferences regarding STI risk. Some studies found that when asked explicitly, young people expect more attractive individuals to have greater STI risk, reasoning that they will have more opportunities for varied sexual activities and be more promiscuous [10,11]. A large body of studies, however, suggested the opposite. For example, one study found that male respondents provided lower estimates of STI risk for women described as "attractive" in thumbnail personality sketches [12]. Another found an inverse relationship between how "attractive" various qualities were perceived in a potential partner and how "risky" those qualities were judged to be [13]. These studies may involve a "halo effect," whereby one positive feature, such as physical attractiveness, encourages other positive perceptions [14,15]. Indeed, some evidence suggests that motivated rather than deductive reasoning may color subjects' judgments about sexual purity, when self-justifying their failures to use condoms with more attractive partners [16,17]. There is also strong evidence that people seen as more attractive are also viewed as more intelligent, academically and socially competent, politically knowledgeable, and cooperative [18-23]. This halo effect is present for visual judgments of both male and female individuals and remains in place once individuals have interacted with one another. If sexual risk is within the halo of attractiveness, young people may infer a lower STI risk from potential partners' physical attractiveness in online dating contexts.

In this study, we created such a context experimentally in order to examine whether attractiveness is a cue for risk when young people make judgments from photographic cues alone. We also examined their confidence and accuracy. We posited that people making quick judgments about potential dating partners in online dating profiles would apply an *attractiveness heuristic*. Namely, they would perceive attractive individuals as less likely to have an STI.

Previous studies of perceived STI risk have typically asked participants to make inferences from multiple (sometimes contradictory) cues [10,12] or have asked them to evaluate attractiveness and risk simultaneously, with explanation of their inferences [10-13,24]. Our study adds to this research by examining rapid judgments based on visual cues alone, with no prompt for reasoned inferences. Its results have implications for online dating contexts and, more generally, for the connections between fast and slow thinking [25].

We asked participants to judge the likelihood that individuals in photographs have STIs under conditions that should automatically evoke judgments of the targets' attractiveness (making snap judgments based on rapidly displayed pairs of photographs). The judgment is which of the two pictures has been drawn from a website for people with self-disclosed STIs. To develop this test set of photographs, we had a separate sample rate the target in each photograph in terms of attractiveness and several factors that might mediate the relationship with STI risk (number of sexual partners [as a proxy for STI exposure], intelligence, frequency of condom use, and decision-making competence [potentially protecting from exposure]).

Methods

Baseline Photograph Data Set

To characterize the photographs used in the experiment, we had a separate pretest sample of 125 heterosexual individuals (aged 18-25 years; 39% female), who were recruited from a university student pool, rate opposite-sex photographs for attractiveness and several risk-related characteristics. Raters were recruited for a web-based survey in which they would be "asked to make judgments about individuals," and they received university course credit for participating. They were eligible for the rating study if they self-identified as heterosexual, were at least 18 years of age, and self-reported not being in a romantic relationship. Photographs were drawn from profiles of residents across the United States. All photographs showed someone who identified as being between the ages of 18 and 25 years and heterosexual in their original online dating profile. Each individual was photographed looking directly at the camera. Among photographs of both male and female individuals, there were approximately 80% Caucasian people. Photographs were cropped square (1:1 aspect ratio) to show only the neck and face and to minimize surrounding visuals. Photographs were all in color and were selected by two independent research assistants as having a pleasant or neutral facial expression.

All photographs were publicly available, and use of the photographs complied with the terms of service of the websites at the time that the stimulus photographs were gathered. Although the photographs, by their nature, identified the individuals depicted, they were obtained from national sources; hence, there was a very low probability of including individuals known to the participants. The sources of the photographs were not revealed to the participants.

There were 96 photographs in total (48 photographs of male individuals and 48 of female individuals). Each photograph was rated by 10 raters. Each rater judged 12 unique, randomly selected, opposite-sex photographs. Photographs were rated on physical attractiveness (1 [very unattractive] to 7 [very attractive]), according to the approach in other studies on facial attractiveness [26,27]. Photographs were also rated on the following three risk-related characteristics drawn from prior studies [15], which could be protective against sexual risk: (1) *intelligence* (1 [not at all intelligent] to 7 [very intelligent]), (2) *competence* (1 [foolish] to 7 [sensible]), and (3) *condom use with a new partner* (1 [never] to 7 [always]). Additionally, photographs were rated on the following factor that could increase sexual risk: *likelihood of multiple sexual partners* (1 [not at all likely] to 7 [very likely]). Raters used the entire 7-point Likert scale. The average attractiveness score in ratings of photographs of male individuals ranged from 1.75 to 5.0 and in ratings of photographs of female individuals ranged from 1.35 to 5.50. Controlling for the website from which the photographs were drawn, photographs of male individuals were rated as slightly less attractive than those of female individuals (t_{77}=2.11, *P*=.04). There were no significant differences in the attractiveness ratings of photographs from each dating website (*P*=.11; the average attractiveness ratings for STI website photographs ranged from 1.61 to 5.00 and for non-STI website photographs ranged from 1.35 to 5.50).

Descriptive statistics for the pretest sample's ratings of the photographs that were ultimately retained to be used in the research study (10 pairs of male individuals and 10 pairs of female individuals; rated on a scale from 1 to 7) along with the correlations between them can be found in Multimedia Appendix 1. Individuals judged as more attractive were given higher ratings on the three protective factors (intelligence, frequency of condom use, and competent decision-making) and one risk factor (multiple sexual partners).

Study Participants

Our study included 87 participants (55 male and 32 female participants) recruited from a private university student participant pool using online postings and recruited on the street in a high foot-traffic neighborhood housing multiple universities (both public and private) with a sign posted outside a research laboratory. The posting stated that participants were being recruited for "a study to understand individual decision-making" and could participate if they met the inclusion criteria of being at least 18 years of age and not participating in rating the baseline photograph data set. Participants recruited from the university student participant pool were emailed a link to the study. Participants recruited on the street outside the laboratory completed the study on a computer inside a private cubicle.

Study Procedure

Participants were shown 20 pairs of photographs (10 pairs of male individuals and 10 pairs of female individuals) drawn from the prerated photograph set. One photograph in each pair was drawn from a personals website for people who have publicly disclosed an STI. The other photograph was drawn from a dating website without that disclosure. Participants were told about the two websites and the photograph sampling procedure. They were also asked to assume that people from the non-STI disclosure website had the same rate of STIs as the general population. For each photograph pair, participants were asked which photograph was from the STI website and about their confidence in the choice (from 50% [chance] to 100% [certainty]). For each pair, one photograph was randomly sampled from each site and assigned randomly to the right- or left-hand side.

Participants received US $5 in compensation for their time or university course credit. All participants received an additional US $0.25 for each correct response. This amount was selected to provide an incentive for accuracy without compromising the rapid judgment process. Such incentives have been found to increase attention without reducing errors attributable to heuristic use [28].

For those who completed the study online, the primary researcher evaluated responses for accuracy and emailed the participants about their payment, which was collected from another researcher. Although this researcher could infer the number of correct responses from the payment amount, there was no information about which stimuli a participant had seen. The data were fully deidentified upon payment and prior to the analysis.

After completing the task, participants answered questions about their relationship and sexual history, including binary response questions, such as *Are you currently in a romantic relationship?*, *Are you currently sexually active?*, and *Have you ever had a "one-night stand"?*, and numeric response questions, such as *How many sexual partners have you had in total?* and *How many times have you had sex in your lifetime?*, as well as a categorical sexual orientation question.

The study, including the acquisition and use of stimuli, was approved by the Institutional Review Board (IRB) of Carnegie Mellon University, which designated the study as posing minimal risk. The IRB did not require informed consent from the individuals in the stimuli as, at the time, all photographs were publicly available, with no requirement to create an account to view or download them for research purposes. To ensure the privacy of the individuals in the photographs, we have not made their images publicly available. Our code, survey, and stimuli rating data set are available publicly [29].

Results

Participant Characteristics

Of the 87 participants, 74 identified as heterosexual, 12 as homosexual or bisexual, and one did not respond. The participants ranged in age from 18 to 56 years, with a mean age of 22.8 (SD 7.8) years. Table 1 presents the participants' self-reported demographic characteristics.

Among the 87 participants, 79 (91%) responded to the question about prior sexual activity, with 50% (26/52) of male participants and 22% (6/27) of female participants reporting none.

Table 1. Participants' characteristics.

Variable	Value (N=87), n (%)
Gender	
Male	55 (67%)
Female	32 (33%)
Age[a]	
18-24	65 (75%)
25-34	10 (11%)
≥35	5 (6%)
Currently in a romantic relationship	
Yes	35 (40%)
No	45 (52%)
Currently sexually active	
Yes	42 (48%)
No	38 (44%)
Total lifetime instances of sex (eg, penile-vaginal, oral, and anal)	
0 instances	36 (41%)
1-10 instances	13 (15%)
>10 instances	31 (36%)
History of "one-night stands"	
Never	67 (77%)
At least once	13 (15%)

[a] Of the 87 participants, 7 (8%) did not provide complete demographic data.

Descriptive Statistics

Sample Size Considerations

Each of the 87 participants made 20 judgments about which individual in a pair of photographs was more likely to have an STI. Our effective sample size is somewhere between 87 observations (if each participant's responses are perfectly correlated) and 1740 observations (20 × 87). Assuming an effective sample size of 87, the statistical power is 0.15 to detect a small effect (r=0.1), 0.81 to detect a medium effect (r=0.3), and 0.99 to detect a large effect (r=0.5).

STI Identification

The mean percentage of correct STI identifications was 47% (9.85/20). Participants' mean confidence in their judgments was 67.2% (SD 16.0%). Thus, in aggregate, participants were overconfident, expecting more correct identifications than were observed.

Attractiveness Heuristic

To test for the use of an attractiveness heuristic in our primary experiment, we estimated a series of binary mixed logit models predicting the probability of participants predicting that an image was from the STI website as a function of the difference in the mean attractiveness ratings of the two images (for the pretest sample) and controlling for the "ground truth" of a self-disclosed STI. The following three models were created:

Models 1-3 in Table 2 are indexed by participant i and photograph pair j. The dependent variable y_{ij} was coded as 1 if participant i selected the photograph on the right from photograph pair j and as 0 otherwise. Each model used the logit function to relate p_{ij}, the modeled probability that participant i selects the right photograph in pair j as having an STI, to characteristics of the photograph and the participant. In model 1 (M_1), we included an intercept β_{0i} to allow for individual-specific tendencies to select the photograph on the right and β_{1i} times the difference in attractiveness between the right and left photographs for pair j to capture individual-specific tendencies to use attractiveness as a cue for STI risk. The coefficients β_{0i} and β_{1i} are assumed to be drawn from a multivariate normal distribution with mean 0 and an unrestricted variance-covariance matrix. Model 2 (M_2) adds an indicator variable for whether the photograph on the right involves an STI for photograph pair j, with a corresponding coefficient β_{2i} that captures individual i's ability to detect the presence of STI from the photographs. Model 3 (M_3) adds additional individual-level covariates. For all models, we used the

Nelder-Mead optimizer from the lme4 package in R for estimation.

As seen in Table 2, model 1 found that as the difference in attractiveness increases, participants are *more* likely to identify the more attractive individual as having been drawn from the STI website. This relationship held when, in model 2, the actual website was added to the equation, with that information not adding significant predictive power (consistent with participants predicting the actual website at chance level). Model 3 showed that the pattern held after adding four participant-level variables, none of which added predictive power (gender, age, gender match with the target individual, and the participant's reported number of lifetime sexual partners).

Across all participants, a greater difference in attractiveness between the two photographs being judged was associated with a higher probability of the participant predicting that the more attractive individual was from the STI website (*Z*=2.08, *P*=.04).

Table 2. Mixed logit models predicting whether the target was drawn from the sexually transmitted infection disclosure website, according to attractiveness ratings, the actual website, and personal characteristics.

Variable	Model 1 (1738 observations, 87 participants)			Model 2 (1738 observations, 87 participants)			Model 3 (1578 observations, 79 participants)

Role of Risk-Relevant Characteristics in STI Risk Judgments

We used binary mixed logit models to assess the role of other features of the photographs, using pretest sample ratings (Multimedia Appendix 1) added to models 4-6 (Table 3). As seen in Table 3, model 4 found that the difference in target-perceived intelligence added no predictive power. Model 5 found that the difference in the ratings of condom use added predictive power, without affecting the relationship with attractiveness. Model 6 found that the difference in the ratings of the targets having multiple partners added predictive power as well, with attractiveness no longer playing a role.

Table 3. Mixed logit models predicting whether the target was drawn from the sexually transmitted infection disclosure website, according to attractiveness ratings, the actual website, and photograph ratings.

Variable	Model 4 (1738 observations, 87 participants)			Model 5 (1738 observations, 87 participants)			Model 6 (1738 observations, 87 participants)

Discussion

Principal Findings

Young adults and adolescents engaging in online dating have to generate quick intuitive judgments when making choices about their interactions with potential sexual partners. Like other decision makers, when they lack statistical estimates, they may rely on heuristics to judge risk [30]. Online dating invites such heuristic judgments in decisions about engaging others as potential sexual partners. In this study, we examined the potential role of an attractiveness heuristic in sexual risk judgment by asking participants to predict which of two photographs came from a website for individuals with self-reported STIs. We assumed that participants would automatically evaluate the target's attractiveness and then apply the attractiveness heuristic to that judgment.

We did find that attractiveness predicts judgments about STI risk. However, the direction of the association was contrary to our prediction that STIs would seem less likely in more attractive individuals (ie, observing a "halo effect"). Instead, attractiveness appeared to be used as a cue for higher sexual risk. Analyses incorporating other variables led us to an alternative post hoc explanation, which is consistent with research findings that attractive people are perceived as more sexually promiscuous [10,11]. In our study, the relationship between judgments of attractiveness and STI risk appeared to be mediated by judgments of target individuals' numbers of partners; more attractive individuals are considered to have more partners and hence a greater STI risk. Thus, the archetype of an attractive individual may not be associated with "purity" as much as with "opportunity." It is also possible that the confidence judgments evoked more analytical and less heuristic thinking, producing more measured inferences about sexual "opportunity," even in a context designed to encourage snap judgments.

Whatever processes guided their judgments, participants were unable to predict which photographs were drawn from the website with STI disclosure, despite incentives for accuracy. Moreover, they showed overconfidence that is typical of difficult tasks [31]. Their predictions were related to the normatively valid cue of whether the target was rated (by the pretest sample) as someone likely to use condoms and, perhaps, with greater intelligence (Table 3). However, those perceptions appeared to reflect judgments of attractiveness, suggesting sound inferences based on unsound assumptions (Multimedia Appendix 1). As seen in model 6 (Table 3), inferences reflecting attractiveness appear to be subsumed by inferences regarding multiple sexual partners. Given how we created the stimulus set, attractiveness was not a valid cue for predicting a photograph's origin and yet it played a role in participants' judgments.

Limitations

Our study had several notable limitations. First, photograph pretesting was limited to judgments by male and female individuals identifying as heterosexual. Thus, it is possible that the attractiveness ratings for these photographs did not reflect the perceptions of the mixed heterosexual and bisexual participants in our experimental study sample. However, there is evidence that judgments of attractiveness of same and other-sex individuals differ by gender but not sexual orientation [32]. To the best of our knowledge, there is no analogous evidence regarding judgments of STI risk and our sample size did not allow subanalyses by sexual orientation. Understanding how such judgments relate to sexual orientation is a topic for future research, and it is particularly relevant given the popularity of dating apps among gay, bisexual, and other men who have sex with men, as well as their higher risk of contracting STIs [2].

Our convenience sample had a gender imbalance, perhaps reflecting greater interest among male participants (65%) in an experiment about "online dating." As such, our results are more generalizable to those who are interested in online dating. Within the constraints of our sample, STI predictions were unrelated to gender, gender match with photographs, age, or self-reported STIs (Table 2).

While our sample consisted primarily of college students recruited through a university student pool and other young people recruited in a public setting, we did have a sizable proportion (15/87, 17%) of participants aged ≥25 years. Our results did not differ by age group; however, the lack of age-based exclusion in our recruitment procedures should be noted when interpreting the findings in the pediatric context. Moreover, by advertising the topic, as well as recruiting some participants in person, we may have biased the recruited sample.

According to participants' self-reports, 41% (36/87) had no sexual encounters and 36% (31/87) had more than 10 encounters. The large representation of sexually inexperienced individuals is unlike much sex-related research [33-35] and higher than reports in national samples of this age group [36]. We cannot predict how this or other selection processes might have influenced our results. We attempted to focus participants on the images, rather than the individuals in them, by presenting targets who participants would never meet and by providing financial incentives for accuracy. This approach deprived participants of both valid and invalid cues available in everyday life, the most important of which may be the website on which the photograph appeared. Thus, our results suggest a form of heuristic thinking that young people may use, without indicating its power or prevalence.

Conclusions

Romantic interest in a target has been found to be driven primarily by sexual attractiveness [35]. For many people, the attractiveness of a potential partner's online image affects whether to proceed in engaging with them [37]. Using an experimental task that involved rapid judgments of photographs, we found that judgments of STI risk were related to both relevant risk factors and the irrelevant cue of attractiveness. The role of attractiveness appears to have been mediated by the rapid inference that attractive people have more sexual partners and hence greater STI risk. Although participants predicted STI risk at chance levels (47%), they had moderate confidence in their predictive ability (mean confidence 67%). Reliance on heuristic judgments of risk from visual cues alone, paired with a misplaced confidence in the ability to identify risk among others, could contribute to the higher rates of STIs among those who use online dating sites to initiate sexual encounters [38-40].

These findings may help inform conversations between health care providers and their young patients, providing content for STI counseling that many are eager to provide [41]. Such conversations offer one way to address the medical community's call for more proactive approaches to stem the rise in STI rates [42]. Those conversations may include discussions on the validity of the cues available in online dating apps. This research is a formative step toward understanding young people's inference processes when using apps that play central roles in many of their lives. Further research should examine heuristics that might better inform the snap judgments of sexual risk that accompany "swiping left or right."

Abstract

Background: Clinical free-text data (eg, outpatient letters or nursing notes) represent a vast, untapped source of rich information that, if more accessible for research, would clarify and supplement information coded in structured data fields. Data usually need to be deidentified or anonymized before they can be reused for research, but there is a lack of established guidelines to govern effective deidentification and use of free-text information and avoid damaging data utility as a by-product.

Objective: This study aimed to develop recommendations for the creation of data governance standards to integrate with existing frameworks for personal data use, to enable free-text data to be used safely for research for patient and public benefit.

Methods: We outlined data protection legislation and regulations relating to the United Kingdom for context and conducted a rapid literature review and UK-based case studies to explore data governance models used in working with free-text data. We also engaged with stakeholders, including text-mining researchers and the general public, to explore perceived barriers and solutions in working with clinical free-text.

Results: We proposed a set of recommendations, including the need for authoritative guidance on data governance for the reuse of free-text data, to ensure public transparency in data flows and uses, to treat deidentified free-text data as potentially identifiable with use limited to accredited data safe havens, and to commit to a culture of continuous improvement to understand the relationships between the efficacy of deidentification and reidentification risks, so this can be communicated to all stakeholders.

Conclusions: By drawing together the findings of a combination of activities, we present a position paper to contribute to the development of data governance standards for the reuse of clinical free-text data for secondary purposes. While working in accordance with existing data governance frameworks, there is a need for further work to take forward the recommendations we have proposed, with commitment and investment, to assure and expand the safe reuse of clinical free-text data for public benefit.

Introduction

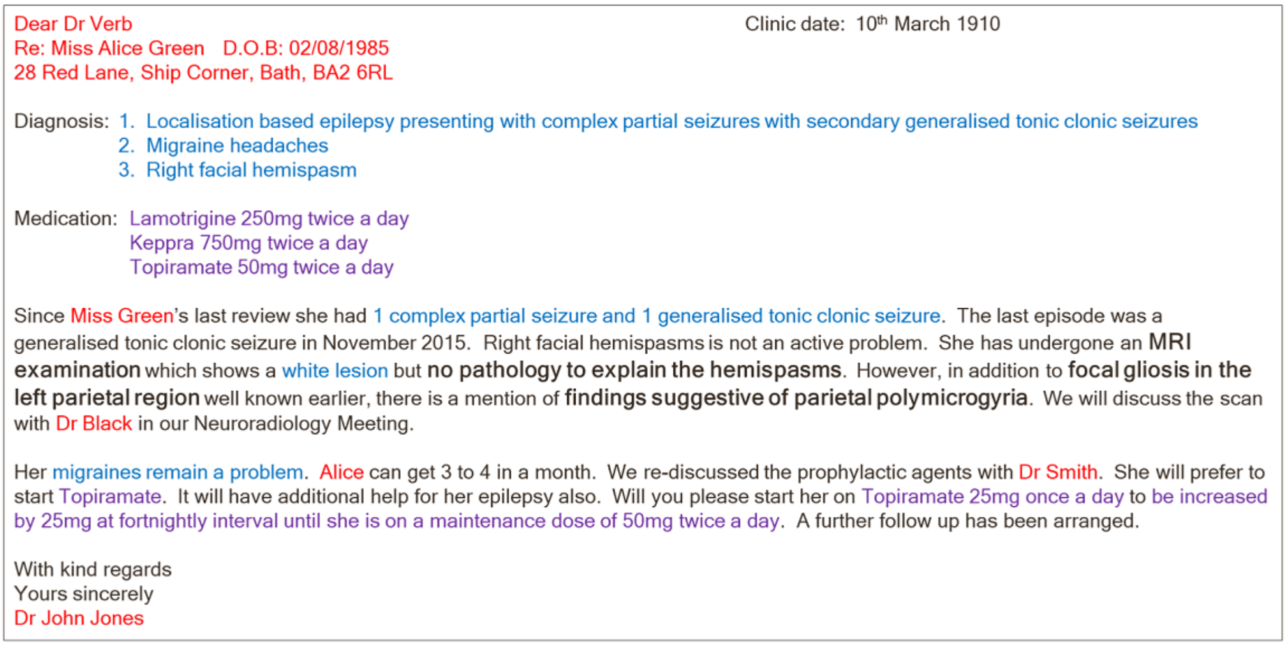
Background

Structured electronic health records (EHRs) have long been used in large-scale research to create new knowledge to inform clinical care, practice, and policy. There are many enterprises specializing in making EHR data available in accordance with jurisdictional legislation and governance [1-4]. We refer to structured data as information recorded in specified forms and fields within the EHRs. Generally, clinical data are highly personal and sensitive and, therefore, need to be deidentified or anonymized before they can be used for any secondary purposes outside the clinical environment. We refer to deidentified data as records from which the commonly recognized identifiers (eg, name, address, and date of birth) have been removed and anonymized data as information from which the data subject cannot be identified [5]. EHR data also contain free-text components, including notes made at consultations and referral letters, which, by definition, are unstructured. As such, they tend to be less available beyond the immediate setting and are typically not readily available for secondary uses such as research or service improvement. However, clinical free-text data represent a vast, untapped source of rich information to guide research and clinical care, including patient-specific context and details that clarify and supplement information coded in structured data fields. Furthermore, some clinical information in mental health, pathology, and imaging reports is not available in coding structures but only in free-text form. By their nature, free-text data are highly likely to contain sensitive information and patient identifiers, and this must be suitably processed to protect individual privacy before the information can be shared further. The key difficulty is that there are major challenges in finding effective methods to deidentify free-text on a scale that does not damage data utility as a by-product.

Methods from natural language processing (NLP) have been developed to automatically scan clinical free-text data to identify potential identifiers, such as patients’ names, significant dates, and their family members. There are generally 2 approaches to automated deidentification. In a method referred to as *blacklisting*, deidentification algorithms remove identifying information so that these variables are masked in the data extract. Alternative methods focus only on isolating the relevant clinical information from personal identifiers via extraction of specified variables such as medication dosage instructions or diagnoses, which are *whitelisted* and preserved in text. Whitelisting can be thought of as the converse of blacklisting in that it extracts clinically informative data rather than excluding disallowed pieces of information [6-8].

Each method has advantages and disadvantages and many permutations within them. For example, blacklisting can result in some personal identifiers remaining within deidentified text or important nonidentifiable data being removed from the text if the process is too stringent. Conversely, whitelisting can result in valuable data being left behind or false information being extracted inadvertently. Whitelisting also relies on a data extraction algorithm to choose the relevant clinical information, if no human is to see the identifiable data. A synthetic clinic letter is shown in Figure 1 to illustrate some of these challenges. As can be seen, a clinic letter can contain a variety of identifiable information about the patient and their care providers. Accuracy and the resulting privacy and utility in preparing free-text extracts for reuse depends on the sophistication of the methodologies in use. We provide some simple example problems for illustration purposes. Blacklisting could result in some personal identifiers remaining within purportedly deidentified text, for example, names that are also common words—Green and Verb. Conversely, whitelisting can leave valuable data behind, for example, *parietal polymicrogyria* without the word *suggestive* or *pathology to explain the hemispasms* without extracting the word *no*. There is much natural language processing and other methodological work underway to enable the creation of extracts that retain data utility and protect privacy. It is important to note that deidentification and extraction algorithms do not work *out of the box* but often have to be built and tested on specific data annotated by domain-specific experts to train and develop the algorithms. In general, algorithms can be trained to work to a standard comparable with that of a human annotator, but accuracy can decrease with increasing information complexity [6-8].

Figure 1. Synthetic clinic letter.



Dear Dr Verb
Re: Miss Alice Green D.O.B: 02/08/1985
28 Red Lane, Ship Corner, Bath, BA2 6RL

Clinic date: 10th March 1910

Diagnosis:
1. Localisation based epilepsy presenting with complex partial seizures with secondary generalised tonic clonic seizures
2. Migraine headaches
3. Right facial hemispasm

Medication: Lamotrigine 250mg twice a day
Keppra 750mg twice a day
Topiramate 50mg twice a day

Since Miss Green's last review she had 1 complex partial seizure and 1 generalised tonic clonic seizure. The last episode was a generalised tonic clonic seizure in November 2015. Right facial hemispasms is not an active problem. She has undergone an **MRI examination** which shows a white lesion but **no pathology to explain the hemispasms**. However, in addition to **focal gliosis in the left parietal region** well known earlier, there is a mention of **findings suggestive of parietal polymicrogyria**. We will discuss the scan with Dr Black in our Neuroradiology Meeting.

Her migraines remain a problem. Alice can get 3 to 4 in a month. We re-discussed the prophylactic agents with Dr Smith. She will prefer to start Topiramate. It will have additional help for her epilepsy also. Will you please start her on Topiramate 25mg once a day to be increased by 25mg at fortnightly interval until she is on a maintenance dose of 50mg twice a day. A further follow up has been arranged.

With kind regards
Yours sincerely
Dr John Jones

Being able to create free-text extracts that do not contain identifying information with a high degree of confidence is a fundamental issue but is not the only consideration for the governance of clinical free-text data. In addition, there are issues such as regulatory approvals including independent ethics committee review, working with or within the health service, accessing identifiable data for the deidentification and extraction process, engaging with clinicians to understand clinical concerns and point of care issues, patient involvement, questions around patient consent, retaining the ability for data linkage, and conditions and environments for data reuse.

Main Aim

In recognition of these challenges, the main aim of this study was to develop recommendations for the creation of data governance standards to integrate with existing frameworks for personal data use, to enable free-text data to be used safely for research for patient and public benefit. As such, it will form a position paper and inform further work. In this context, we define *safely* as where the identity of the individual is highly unlikely to be discovered. We refer to this study as TexGov. It focuses on data governance and health services within the United Kingdom, but the main findings are applicable more widely.

Methods

Study Design

TexGov was designed to cover a variety of activities to develop data governance standards for using clinical free-text data in research. It included an outline of the UK data protection landscape for context, a rapid literature review on governance aspects in previous UK research studies using clinical free-text data, UK case studies with systems providing access to free-text data for more in-depth information, engagement with researchers to explore barriers and solutions in working with free-text data, and engagement with the public for views on socially acceptable approaches. These activities are described in the following sections.

Data Protection Landscape

We reviewed the relevant legislation, regulations, and official guidance in place in the United Kingdom for context on governance aspects for the use of free-text data. This included the UK Data Protection Act (DPA) 2018 [9], the European Union General Data Protection Regulation (GDPR) 2016 [5], the Human Rights Act [10], the common law duty of confidentiality (CLDC [11]), the Caldicott Principles [11], and the Information Commissioner's Office guidance on data sharing and anonymization [12,13].

Free-Text Data Governance Practice

We gained information on data governance in working with clinical free-text data by carrying out a rapid literature review [14] and mini-case studies of systems making deidentified free-text data available for research in the United Kingdom. The methodology for the literature review is given below:

Search Strategy

Searches for studies indexed in PubMed and Web of Science (WoS) were conducted on January 15, 2019, using the following search terms: (1) "electronic health records" or "electronic medical records" or "electronic patient records" or "hospital records" or "personal health records" or "computerized patient records" or "computerized medical records" combined with (2) "text mining" or "natural language processing" or "free text" or "narrative." Given our sole interest in ethical and governance procedures in the United Kingdom, the search was then restricted to papers using UK databases containing free-text data by using the following terms: "UK" or "United Kingdom" or "Britain" or "England" or "Wales" or "Ireland" or "Scotland." The search was limited to human studies published in English. No restrictions were imposed on the year of publication.

Eligibility

To be eligible for this review, published research had to meet the following criteria: primary research using free-text records; UK-based health databases or data from UK hospitals; and information extracted from the text of (human, not veterinary) electronic medical records, medical letters or medical reports, and methods papers (eg, development or description of search and analytic tools), but only if the paper used patient data in the study.

Data Extraction

Characteristics of the included studies were extracted by one researcher and reviewed by another researcher and were as follows: (1) year published and lead author institution, (2) broad purpose of the study, (3) what and where data were accessed, (4) focus of free-text data, (5) whether the data were accessed in identifiable form, (6) whether the study used the health records in conjunction with other data, (7) main finding or conclusion, and (8) any ethics and governance detailed. We will focus on data governance aspects only, rather than the clinical value of using free-text data.

Case Studies

The case studies were conducted through face-to-face or telephone interviews in February 2019 and were structured to capture information about the main model for making data available, types of data included, data linkage capability, free-text deidentification or extraction method, and governance approvals. Notes were taken during the interviews and subsequently checked for accuracy with each interviewee.

Engagement With Clinical Text-Mining Researchers

We held a 1-day workshop (January 16, 2019) for clinical free-text mining researchers to explore their perceptions of barriers and solutions in working with free-text data for sharing outside the clinical setting. Participants were recruited via advertisements on the Healtex website. The workshop was attended by 44 people and included outlines of the TexGov study aims, the findings of a previous citizens' jury on using clinical free-text data for research [15], and data protection. These were followed by presentations from the NLP community on their approaches to working with clinical free-text data, during which the audience was asked to write down the topics to discuss in more detail. The identified topics were grouped into 4 themes and used in group discussions on challenges and solutions: (1) patient involvement at identifiable and deidentified data stages, (2) opt-in/opt-out consent models for the reuse of free-text data, (3) working with identifiable data for NLP algorithm development, and (4) deidentification methods and thresholds of reliability. Delegates were randomly allocated to one of the groups but were allowed to change to another if they felt strongly about a particular topic. Each of the discussions was facilitated and noted to capture views on the nature of the challenge, what can be done to address it, and how that can be achieved.

Engagement With the Public

We discussed the TexGov study with 2 public groups. The first event was advertised to the general public and patient interest groups by the Alan Turing Institute and held at their premises on March 28, 2019, attended by approximately 50 people. It included a presentation on the TexGov study and a role-play exercise to illustrate how clinical free-text data are collected at a hypothetical general practitioner (GP) consultation and to engage the audience in discussion. It also included a panel discussion so the audience could ask questions to the representatives from the National Data Guardian's office [16]; Understanding Patient Data, an independent patient data taskforce [17]; use MY Data, a movement of patients, carers, and relatives in support of using patient data [18]; and National Health Service (NHS) England [19]. Notes were taken during the panel discussion. This was followed by facilitated and noted group discussions on the topics of (1) Transparency and patient choice in the use of free-text data: what information do patients need and which are the best methods of dissemination? (2) Identifiability, deidentification, and anonymization: what is the best approach to making data available? and (3) Data access models and security in working with free-text data: how to balance restricting and facilitating access to data? These topics were prioritized from issues for discussion identified by registered delegates in advance of the workshop.

The second public engagement activity was conducted with the consumer panel based at Swansea University on May 1, 2019. This panel is made up of 18 members of the general public, and it advises on developments in the use of person-based data for research, such as via the Secure Anonymised Information Linkage (SAIL) Databank [20]. Following a description of the TexGov study and the preliminary findings, there was an open discussion so that members of the panel could provide their views on the work and the publicly acceptable way forward for the reuse of free-text data. Notes were taken on the views of the panel members.

Results

Data Protection Landscape

The Human Rights Act provides overarching legislation, with Article 8 setting out rights to enjoy a private life free of intrusion and interference, subject to restrictions in accordance with law in a democratic society [10]. Our review of UK statutory data protection law in the DPA [9] and the GDPR [5] showed that free-text data are not singled out by these instruments: the provisions apply to free-text data in the same way as any general person-identifiable data (PID) and special category health data. Similarly, free-text data given in confidence, such as in a physician-patient consultation, are subject to the same CLDC [11] principles and professional practice as for structured, coded data. The Caldicott Principles [11] set out fundamental good practices for the protection of information that could identify an individual but also highlight that data sharing can be as important as the duty to protect confidentiality. Within these principles and in the Information Commissioner's Office guidance on data sharing and anonymization, there is nothing specifically stated about free-text data (Table 1). The requirements are for data use to be subject to an appropriate lawful basis and for data to be processed to protect privacy before secondary uses, unless another justification (such as participant consent for research) is in place. This is a challenge for the reuse of clinical free-text data: the difficulty in being confident (and providing evidence) that deidentification is adequate when making claims of anonymity or minimizing the use of personal data, so that information derived from the unstructured format of free-text data can be safely taken forward for reuse.

Table 1. Summary of relevant data protection landscape.

Item	Key points
UK Human Rights Act	Sets out an individual’s rights to enjoy a private life free of intrusion and interference
European Union General Data Protection Regulation and the UK Data Protection Act	Provisions for processing general person-identifiable data and special category health data
Common Law Duty of Confidence	Governs the use of data given in confidence, such as in a physician-patient consultation
Caldicott Principles	Set out good practice for the protection of information that could identify an individual and the importance of data sharing
Information Commissioner’s Office	Provides guidance on data sharing and anonymization

Data Governance

The search identified 45 papers from PubMed and 340 papers from WoS, with 354 papers remaining after the removal of duplicates. After screening abstracts and full texts, 51 studies were defined as eligible for inclusion in the rapid review. Medical records were accessed via 3 main databases: (1) the Health Improvement Network (THIN) primary care database [21,22] (N=7) [23-29], (2) South London and Maudsley NHS Foundation Trust (SLaM) with clinical records accessed via the Clinical Records Interactive Search (CRIS) system [30-32] (N=16) [33-49], and (3) the Clinical Practice Research Datalink (CPRD) [50] (N=13) [51-62]. One study used the SAIL Databank [63]. There were 13 independent studies, which were not associated with a data management infrastructure [64-76].

The THIN and CPRD databases contain NHS patient primary care records, whereas the CRIS system includes clinical records for people who have used a range of NHS mental health services and substance misuse services in the United Kingdom. The study that used the SAIL Databank accessed the primary care dataset. The independent studies accessed a range of free-text records, including from accident and emergency department, outpatient department, intensive care, primary care, and prescribing datasets. All records in the studies that used THIN, CRIS, CPRD, and SAIL Databank were anonymized, and no personal information was, therefore, available to researchers. The independent studies were more variable depending on specific approvals and permissions, for example, identifiable data accessed by authorized hospital staff within an NHS organization [64,71] or data extracted following the ethical approval of the study [76].

All studies reporting the use of THIN noted ethical approvals, and 3 studies also cited the overarching THIN data resource approvals by the NHS South East Multicenter Research Ethics Committee. All but one [48] of the studies that used the CRIS data resource noted approval by the Oxfordshire research ethics committee and the service user-led oversight committee study approval, which must be granted before access to the anonymized data is permitted. Of the 13 studies using CPRD free-text data, 4 provided no ethical approval details [51-53,61]. All the remaining studies in this group detail some level of ethical approval, either study approval or the resource multicenter research ethics committee approval for all observational research using CPRD data. The study accessing free-text data in SAIL Databank does not cite the information governance review panel (IGRP) approval that must have been sought before access to SAIL data was granted [63]. Of the 13 independent studies, 7 detailed the local ethical approval process [67-69,72,73,75,76]. One stated that ethical approval was not necessary, as the purpose of the study was to measure service provision retrospectively without using identifiable patient information [74], and the remaining 7 studies did not mention ethical approvals [64-66,70,71].

None of the 7 studies that used THIN detailed the data access model, which could have been via a sublicense agreement enabling access for a defined period to conduct unlimited studies, subject to protocol approval, or release of data extracts consisting of subsets of raw data in accordance with researchers’ study protocols and specifications. CRIS is accessed within the NHS system by researchers at the Maudsley Biomedical Research Centre; as such, most lead authors (or at least one coauthor) of the 16 studies using SLaM clinical records were based at King’s College Hospital. Some, but not all, studies specify this access route. CPRD (formally known and referenced in studies as the General Practice Research Database) operated on a data release model under the strict CPRD and data control terms. Few of the retrieved studies specified this model. The study using free-text records in the SAIL Databank did not detail the access route, that is, following necessary governance approvals and safe researcher training, data can be accessed remotely within the safe haven with no external data release [77]. The 13 independent studies provided very little information on how data were accessed. A summary of key information from the rapid review is given in Table 2.

Table 2. Key information from the literature review.

Institute	Study	Free-text search	Linkage to additional datasets	Use of identifiable data	Ethical approval
THIN[a] (n=7)	[23-29]	[23] cause of death; [24] ischemic cerebrovascular events; [25] diabetic retinopathy and diabetic maculopathy diagnoses; [26] child maltreatment; [27] colorectal cancer recording; [28] endometriosis diagnosis; and [29] major malformations and comments assigned to referrals to specialists	Yes: [23,25,27,28]; no: [24,26,29]	Yes: [26]; all others: no	THIN data resource approved by NHS South East Multicenter Research Ethics Committee
CRIS[b] (n=17)	[33-49]	[33] smoking status; [34] extrapyramidal side effects and adverse drug events; [35] antipsychotic polypharmacy; [36] negative symptoms of schizophrenia; [37] mood instability; [38] cannabis use; [39] medication descriptions; [40] characteristics of people with Alzheimer disease; [41] delivery of cognitive behavioral therapy for psychosis; [42] notes and correspondence on diagnoses of mental disorders; [43] adverse drug events; [44] symptoms of severe mental illness; [45] risk factors for depression; [46] presence of negative symptoms and antipsychotic use; [47] suicide ideation and attempts; [48] information on hepatitis C and HIV; and [49] registered company addresses	Yes: [39,42,45]	No	CRIS approved for secondary analysis by the Oxfordshire Research Ethics Committee. A service user-led oversight committee considers all proposals before access to the anonymized data is permitted
CPRD[c] (n=13)	[51-62]	[51] heart defects; [52] congenital malformations; [53] pregnancy outcomes; [54] ovarian cancer diagnoses; [55] cause of death; [56] coronary angiogram results; [57] keywords for rheumatoid arthritis; [58] markers for rheumatoid arthritis; [59] disease-modifying antirheumatic drugs; [60] records of visible hematuria, jaundice, or abdominal pain; [61] drug usage values and administrations; and [62] terms indicating allergic bronchopulmonary aspergillosis cases	Yes: [51-53]; no: [54-62]	No	Multicenter research ethics committee approval was in place for all observational research using CPRD data
SAIL[d] (n=1)	[63]	[63] symptoms of ankylosing spondylitis	No	No	Ethical approval is not required for the use of anonymized data within SAIL. An independent information governance review panel assesses all proposed uses of SAIL data.

Institute	Study	Free-text search	Linkage to additional datasets	Use of identifiable data	Ethical approval
Independent studies (n=13)	[64-76]	[64] string "asth" for asthma; [65] range of clinical terms; [66] reason for admission; [67] test results for stages 3-5 chronic kidney disease; [68] search in reports of CT[e] scan of brain for stroke; [69] search in reports of CT scan of brain for stroke, subarachnoid hemorrhage, or ischemic stroke; [70] keywords on hearing aid decisions; [71] reasons for dose omissions; [72] reasons for deaths due to unsafe care; [73] breathlessness and wheeze symptoms; [74] focal liver lesions; [75] cardiology information; and [76] clinician discourses compared with patient narratives	Yes: [68,69,76]; no: [64-67], [70-75]	Yes: [64,71,73,76]; no: [67-69,72,74,75]; and not clearly stated: [65,66,70]	Variable depending on particular study

[a] THIN: The Health Improvement Network.

[b] CRIS: Clinical Records Interactive Search.

[c] CPRD: Clinical Practice Research Datalink.

[d] SAIL: Secure Anonymised Information Linkage.

[e] CT: computed tomography.

Table 2 summarizes the key information reported in the studies included in the rapid literature review. The first column shows the number of studies relating to each institute. The study numbers in subsequent columns are as per the reference list (and are not counts of studies). The extent to which individual studies reported approvals was variable, although (at least for those attached to THIN, CRIS, CPRD, or SAIL) they would have had to abide by the mechanisms in place before data access was granted because access is under institutional control. Rather than attempting to include all details by study, we showed the standard approvals in the final column with fuller information in the text.

The interviews provided further information on systems providing access to data derived from clinical free-text sources. The purpose was to learn about their methods and from their experiences. We do not describe the models in full detail, as that would be beyond the scope of this paper. The THIN database was created in 2003 by In Practice Systems (Vision). THIN is a primary care data repository with the capability to extract free-text as well as structured data from GP practices, but currently, only structured data are released to external researchers. THIN has collaborated with University College London (UCL) to promote academic use of the data. As part of this, a copy of the THIN database will sit in a UCL data safe haven, which can be accessed by UCL researchers. THIN is seeking ethical approval to enable the use of the free-text data for academic research within UK academic or NHS safe havens. Free-text data will be subjected to an automated deidentification process using a blacklisting method. The full data governance model at UCL is in the final stages of development at the time of writing. THIN is overseen by an advisory committee involving patient, clinician, and researcher representatives, and all studies are reviewed by a scientific review committee before data access can be granted [21,22].

CRIS is a medical record inquiry program that has been implemented in a number of mental health trusts. Our example relates to SLaM, and so, we refer to *CRIS at SLaM* because other NHS Trusts might not operate CRIS under exactly the same principles. Data are held in a repository inside the Trust firewall (ie, in the same domain as the original health record), which comprises a database of structured and free-text mental health records that are deidentified, but linkable at the individual level, before entering the repository. Unlike some blacklisting algorithms that rely on a lexicon to ascertain and remove names, the CRIS deidentification algorithm has access to individual health records and makes reference to this to blank out the name of the patient. CRIS at SLaM has ethical and s251 approval: the latter for occasions when PID need to be exported outside the firewall to enable linkage. It also has approval from the Trust Caldicott Guardian and the executive board. The person accessing the data in the safe haven must have a SLaM contract, a SLaM honorary contract, or a research passport (an accreditation issued by the Health Research Authority [78]). All projects must include at least one member of the study team who has an honorary or substantive SLaM contract and can act as a guarantor [30-32].

SAIL is a repository that holds multiple health and wider administrative datasets in a deidentified form about the population of Wales. SAIL Databank does not process PID but uses a trusted third party to receive the PID and carry out a matching and deidentification process, with the creation of a consistent identifier unique for each person represented to enable individual-level linkage across datasets. Further controls are enacted to provide access to data for research in anonymized form within a safe haven. The SAIL data comprise extracts of structured, coded data, with minimal free-text data at present. However, work is underway to incorporate free-text data so that they can be included in studies when needed. Unlike approaches that deidentify free-text data (blacklist) and incorporate the remainder, the algorithm used by SAIL extracts medical terms and descriptors (whitelist) at the NHS source for incorporation so that only nonidentifiable structured data leave the organization. SAIL Databank took this approach because of the risks of introducing insufficiently deidentified information into the databank. Working with free-text data at source is by means of an NHS honorary contract [8], and all proposals to use SAIL data must have received approval from an independent IGRP before access can be granted via the data safe haven [77].

CPRD operates on a data release model and used to collect and release deidentified (blacklisted) free-text data under strictly controlled protocols. However, this was discontinued in 2013 on advice from the Information Commissioner's Office, and the catalog of free-text data was destroyed. At present, CPRD has no plans to develop NLP or an automated text anonymization service. Instead, they liaise directly with GPs on behalf of researchers to validate codes to supplement coded data with additional information.

Engagement With Clinical Text-Mining Researchers

A summary of the information gained during the discussions on each theme is shown below in relation to the nature of the challenge, what could be done to address it, and how this could be achieved.

Patient Involvement at Identifiable and Deidentified Data Stage

This theme relates to the principles of engagement with the public for good research practice in general.

Nature of the Challenge

Delegates felt that there was a challenge in balancing what could be perceived as a lack of individual choice in nonconsented data cohorts with the risk of selection bias in consented cohorts, particularly if there is doubt about the level of knowledge among individuals, including conceptual differences between coded and free-text data.

What Can Be Done

Additional public engagement in free-text research was seen as needed. This should be linked with wider information about patient data uses to help people better understand the issues and gain their input. This could contribute to a checklist of recommendations for researchers using free-text data, so the public views on the use of free-text data are taken into account.

How It Can Be Achieved

Public panels and existing groups can help clarify reasonable expectations regarding the use of free-text data. It would be useful to have a repository of findings from research using free-text data showing its clinical benefits. This could also include information in lay format on advances in methodological research to improve processes of handling free-text data.

Opt-In/Opt-Out Consent Models for Reuse of Free-Text Data

This theme relates to managing individual choices in the use of free-text data for research.

Nature of the Challenge

Discussions focused on the need to convey a reasonable understanding of the motivations, risks, and benefits of researchers accessing free-text data and how data reuse is governed. In particular, the challenge of providing appropriate consent options was highlighted.

What Can Be Done

As consent might not be required, or even be possible, for processing large-scale free-text data across populations, delegates stressed the need for guidance and good practice on free-text data reuse in line with governance requirements and expectations.

How It Can Be Achieved

A wider examination of existing practice used by government departments along with clinical and regulatory codes of practice would provide further guidance on how to manage consent options. Possible solutions could be piloted and evaluated for practicality.

Working With Identifiable Data for Natural Language Processing Algorithm Development

This theme relates to the practicalities in accessing free-text data in identifiable form to prepare extracts for research.

Nature of the Challenge

Free-text data are needed in their original (raw) form for effective NLP algorithm development and maintenance, yet the data are identifiable, and some contain sensitive information. In addition, the free-text datasets accessed need to be of sufficient scale to avoid introducing bias when developing NLP methods.

What Can Be Done

There is a need to clarify whether enabling data access via a safe haven can provide a suitable solution, if patient data can be used without consent for the purpose of training algorithms, and the usefulness of publicly available datasets.

How It Can Be Achieved

Delegates suggested possible solutions by creating a *Text Bank* to support NLP development via data donation, the use of synthetic datasets, and sharing annotated free-text data with other developers.

Deidentification Methods and Reliability Thresholds

This theme relates to residual reidentification risk and data utility in the datasets used for research.

Nature of the Challenge

Delegates focused on the challenges in quantifying the residual risk of reidentification in free-text data extracts, particularly in the face of the high degree of data variability and the absence of a gold standard threshold for free-text deidentification.

What Can Be Done

Discussions highlighted the need for robust security with only trusted access and an audit trail, and that free-text data extracts should be treated as potentially identifiable. More research on the relationship between the accuracy of the deidentification algorithm, risk of reidentification, and data utility was identified as a need.

How It Can Be Achieved

Accessing free-text data extracts only within safe havens by small teams embedded within organizations, and with clear lines of accountability, was seen as a positive step. A range of risk models should be employed to avoid overscrubbing the data with consequent loss of data utility and to determine acceptable levels of deidentification.

Engagement With the Public: Panel Discussions at the Turing Institute Event

The panel discussion at the Turing Institute event with representatives from the National Data Guardian’s office, Understanding Patient Data, use MY Data, and NHS England raised some important points. The National Data Guardian representative highlighted that data protection legislation is not a barrier to data sharing, but there is a need for proper transparency and trustworthiness to build public confidence. In addition, there is a need for a joined-up approach in developing consistent standards, language, and message. The representative from understanding patient data stressed the huge potential in being able to use clinical free-text data beyond direct care but also highlighted the challenges in being able to enact this in an acceptable way, respecting privacy and ensuring accuracy in data extracted. They also spoke of the need for evidence of the potential benefits to patients of the use of their clinical free-text data. The representative from use MY Data emphasized the enormous potential of, as yet, largely underutilized free-text data for research purposes, seeing this as an *atrocious waste*. This was accompanied by an expression of the need for ongoing patient engagement and that use MY Data is an instruction, not a request, as the group wants greater use of patient data and is working hard to convey this message to decision makers. The NHS England representative spoke about the CLDC and the need for free-text data use not to impact the confidentiality of medical consultations. All the panelists emphasized the need to demonstrate to the public the benefits of using clinical free-text data and the importance of working in accordance with existing research and information governance frameworks, but that adaptations to these frameworks may be required for emerging data types and formats.

Engagement With the Public: Group Discussions at the Turing Institute Event

A summary of the points emerging from the group discussions with delegates at the Turing Institute event is provided in relation to knowledge gaps, involvement and engagement, and suggested solutions.

Transparency and Patient Choice in the Use of Clinical Free-Text Data: What Information Do Patients Need and Which Are the Best Methods of Dissemination?

Knowledge Gaps

The delegates acknowledged the efforts that go into public involvement and engagement but highlighted the seldom heard voices, such as hard to reach groups, marginalized groups, and young people.

Involvement and Engagement

They felt that because of risks of misunderstanding, information for the public should be layered, that is, it should be contextualized by founding it on health data and research before adding the particular features, risks, and benefits of free-text data.

Suggested Solutions

Information should be provided in plain language and in accessible formats, taking into account differing needs and abilities. Delegates recommended tapping into patient networks as authentic, credible ambassadors for discussions with the wider public and the value in working with communication experts. It was seen as important to explain that although there are challenges in effectively deidentifying free-text data, it is a format of data and not fundamentally different from other health data.

Identifiability, Deidentification, and Anonymization: What Is the Best Approach to Making Data Available?

Knowledge Gaps

The delegates felt unclear about how the GDPR (introduced in 2018) would apply within the context of the existing UK regulations and uncertainties around how best to make data available and minimize risks. There were uncertainties around how one might seek informed consent to participate in research in a way that participants would understand but also how wider public would be able to grasp concepts in the abstract.

Involvement and Engagement

The delegates expressed the need for clearer information on the relationship between having a lawful basis for data processing under the GDPR and the fact that this does not negate the need for consent to participate in research. With regard to identifiability, delegates felt that the research community should make a strong case for the use of free-text data in research, including that it was important not to lose that richness.

Suggested Solutions

Delegates felt that engagement and educational events should be carefully planned in terms of how they could empower people to make informed decisions when it came to reusing of free-text data. This would need to provide a compelling reason for research to look at minimally deidentified free-text data to preserve the richness, balanced against how the risks to participants could be managed.

Data Access Models and Security in Working With Free-Text Data: How to Balance Restricting and Facilitating Access to Data?

Knowledge Gaps

Delegates acknowledged a general lack of awareness of different data access models and the degrees to which data can be controlled, shared, or made openly accessible. They stressed the risks of not using the free-text data and the benefits that could be added to research.

Involvement and Engagement

Delegates felt that there should be more involvement and engagement with the public to explain due diligence processes and safeguards in managing free-text data. This should include interactive methods and demonstrations, not limited to passive information transfer.

Suggested Solutions

Delegates stressed that free-text data need to be used so that the United Kingdom does not lag behind other countries. The research community should be open to the public and explain that deidentification of free-text data may be imperfect. Patient groups should follow the example of use MY Data and lobbying data controllers for free-text data to be made more accessible to researchers.

Engagement With the Public: Consumer Panel

Having been presented with the findings of the previous engagement activities (described here), the consumer panel agreed and furthermore suggested that patient involvement should be included at all stages practical in the development of algorithms to avoid bias in relation to diversity; that involvement should be ongoing because of societal attitudinal changes over time and as new knowledge comes to light; and that a databank of clinical free-text data for algorithm development would be a good thing, provided that it is done transparently and properly managed.

Discussion

Principal Findings

To our knowledge, this is the first study to explore the data governance aspects for using clinical free-text data and to do this through a combination of outlining the legislative and regulatory backdrop, reviewing literature and systems using free-text data extracts in health research, and gaining the perspectives of free-text data researchers and members of the public. In terms of UK data protection legislation and guidance, there is nothing specific in relation to free-text data. In many ways, this was to be expected, as legislation tends to be high level needing interpretation and justification of an appropriate lawful basis on how data are to be used. In addition, free-text is a data format and not a different type or category (eg, health, political views, and ethnicity) of data, and so, it is covered by the data protection provisions for health data. In terms of official guidance, such as from the Information Commissioner's Office, the need to properly manage and process all personal data for reuse is addressed in codes of practice [12,13]. However, until recently, the vast majority of routine health data made available for secondary use was from coded records. As such, clinical free-text data are among the emerging research datasets, such as genomic and imaging data, and warrant further attention to develop official guidance to simultaneously safeguard individual privacy and maximize data utility for research in the public interest.

Our literature review revealed a variety of published studies that used data derived from free-text sources (eg, clinical notes and referral letters), sometimes in conjunction with coded health records and other datasets. The majority of these were conducted through established systems (eg, THIN and CRIS) specializing in making clinical free-text data available for approved research, in accordance with their operating and governance models. There were also some studies not associated with one of these systems. In many cases, the authors properly reported on how data were accessed and provided information on regulatory and governance approvals in place. However, there was also inconsistency and a lack of information in some studies, although this might reflect reporting rather than practice [79]. It is not always easy to ensure that authors provide governance details, but at least in studies from the established systems, this is a matter for publication policies that are part of their good governance practice. However, it should also be addressed by journal editors to ensure that there is a section providing transparency on methodology and data governance where free-text data (or person-based data) have been used.

There are a variety of automated methods to deidentify or extract data from free-text clinical documents for reuse in research or other purposes beyond direct clinical care. Our review showed that blacklisting methods are used by THIN and CRIS (and previously used by CPRD) and whitelisting methods are used by SAIL. THIN and SAIL operate in the higher education sector, whereas CRIS operates behind an NHS Trust firewall. All 3 institutes operate a data safe haven model, rather than external data release, and all have data governance models in place. From engagement with clinical text-mining researchers, it is clear that although the state-of-the-art systems achieve performance comparable with manual deidentification, there are still uncertainties about the efficacy of blacklisting methods and acceptable thresholds of reliability. Further work is needed to address this issue. However, whitelisting is not a panacea, as it also relies on algorithms that must be tested on identifiable data and can risk over- or underextracting data.

We have noted that using only small samples of identifiable free-text data sources can lead to bias. The creation of a free-text databank donated on a voluntary basis for developmental work would help to advance this field of work. At the same time, there is a need to minimize the need for human access to clinical free-text data through continual improvement in technological NLP methods for deidentification of clinical narratives. Further developments are also needed in other areas of text processing so that free-text data can be more efficiently converted to a structured format before reuse. Although this is advantageous in terms of risk minimization, it risks the loss of information richness that could be needed for qualitative research, exploring areas such as language, culture, and patient stories in the full free-text data, and reduces the future possible uses of the text data, with new extractions needed for subsequent research studies.

The clear need for patient involvement and engagement in the development of reusing free-text data was highlighted in the events with researchers and the public. This included a call for public-facing activities to be ongoing, inclusive, and transparent. Public delegates at the Turing Institute event and the consumer panel were generally positive about using free-text data for research, and this is in line with previous work with the Brighton Citizen's Jury (in 2018). This jury suggested that people's concerns could be mitigated with comprehensive patient-facing information about how, when, and under what conditions patients' free-text data might be used for research. Furthermore, patients should be involved as key stakeholders throughout all stages of the research process. The public also expects that researchers are committed to a culture of continuous improvement of methods for coding, anonymizing, processing, and safeguarding clinical free-text data [15].

Participant consent was a theme discussed at the clinical text-mining researcher workshop and again at the Turing Institute event, as it was at the Brighton Citizens' Jury. There was a recognition that it would not generally be practicable to seek opt-in consent to incorporate deidentified free-text extracts into data safe havens for reuse in research. The possibilities of opt-out consent were also explored and were considered favorable if they could be enacted in accordance with existing patient data guidelines. In England, there is a national opt-out where patients can choose not to have their data used for purposes beyond their direct care. However, in practice, this only applies to situations where the reuse of the data relies on s251 approval to set aside the CLDC [80]. As such, it is not a comprehensive opt-out mechanism and is not equipped to allow someone to specify a particular data format. Working in Wales, SAIL Databank operates its own opt-out mechanism by allowing individuals to inform their GP that they do not wish their data to be provided to the databank; again, this is an all-or-nothing option. More granular optouts would present difficult challenges in defining data content for inclusion and exclusion. Nevertheless, the mechanisms in place do provide individuals with choices they can exercise in relation to their patient records.

The panel discussion at the Turing Institute event stressed the importance of operating within existing frameworks for all data, not singling out clinical free-text data as fundamentally different. Although challenges remain for meaningful opt-out consent, mitigation can be provided via clear privacy notices, lawful bases for data processing, and transparent information on safeguards and their limitations. However, although the group discussions highlighted the great importance of being able to make good use of clinical free-text data, we are still left with the situation that the deidentification (blacklisting) of free-text data is imperfect, and extracting only certain elements (whitelisting) produces only a study-specific data extract. Although established data systems making free-text extracts available in one form or another have data governance controls in place, there are cases where further measures are needed at the project level. Two examples are studies that are not associated with established systems such that the data might be subject to external release (ie, to be held outside a data management infrastructure) and studies that need to use free-text data for qualitative analysis, where having the data translated into coded form would not be adequate.

Recommendations

In addition to good practice in handling person-based data in general, we propose the following set of recommendations and suggestions for further work to operate in accordance with, and augment, existing research and information governance frameworks:

- There is a need for clear regulatory guidance on data governance for the reuse of clinical free-text data, taking into account factors including whether the data are deidentified through blacklisting or extracted via whitelisting; the native data are housed at their original source or safe havens or exported to external users, and the extracts are in a coded or raw free-text form.
- Patients and the public should be better informed about free-text data flows and uses, including the availability of opt-out arrangements for the reuse of patient data for research in accordance with jurisdictional policies. This requires commitment from researchers and the public.
- The use of free-text data and results of studies should be publicized to all stakeholders, but particularly patients, so that the public can see that free-text data can bring additional benefits. This could take the form of regularly updated case studies in a central location, including information about the data used and the findings of the study.
- Further improvements are needed in deidentification and extraction algorithms with a better understanding of the relationships between the accuracy of deidentification and thresholds of reidentification risk. This could be facilitated by a national challenge with public demonstrations on how free-text data are deidentified.
- Owing to the current uncertainties, blacklisted clinical free-text data should be treated as potentially identifiable and access for research restricted to accredited data safe havens, unless a thorough review is conducted before release.
- Organizations providing access to clinical free-text extracts should stipulate in their publication policies a data governance statement to be placed in publications, and journals should require a suitable statement for all studies using data derived from free text.
- The specifics around the creation of a databank of donated clinical free-text data to support the construction of deidentification and extraction of algorithms should be explored; this would necessarily include further public engagement and government and NHS commitment.

Limitations

We acknowledge that the TexGov study was subject to limitations. It was a small study of a few months in duration and, as such, could not be comprehensive in scope. It was limited to the United Kingdom, and the governance of data use may differ in other jurisdictions. However, we believe that the principles will be largely applicable beyond the United Kingdom. We were unable to engage specifically with data providers or clinicians who created the data to gauge their viewpoints. This could be a focus of future work.

Conclusions

It is well known that clinical free-text data represent a rich resource for reuse in research, but that there are particular challenges in working with unstructured data to safeguard privacy and maximize data utility. We have shown that lessons can be learned from established systems providing access to data derived from clinical free text and that the views of text-mining researchers and members of the public provide valuable insights. We present the new knowledge gained in this unique study in the form of a position paper to work toward the development of data governance standards for the reuse of free-text data. While recognizing that free-text data are not fundamentally different from other patient data and the need to work within existing data governance frameworks, we propose that there is a need to develop the TexGov recommendations, with commitment and investment, to expand and assure the safe use of free-text data for public benefit.

Acknowledgments

TexGov was funded by the Engineering and Physical Sciences Research Council via Healtex, the UK health care text analytics research network (grant number EP/N027280/1).

Abstract

Background: Health services researchers spend a substantial amount of time performing integration, cleansing, interpretation, and aggregation of raw data from multiple public or private data sources. Often, each researcher (or someone in their team) duplicates this effort for their own project, facing the same challenges and experiencing the same pitfalls discovered by those before them.

Objective: This paper described a design process for creating a data warehouse that includes the most frequently used databases in health services research.

Methods: The design is based on a conceptual iterative process model framework that utilizes the sociotechnical systems theory approach and includes the capacity for subsequent updates of the existing data sources and the addition of new ones. We introduce the theory and the framework and then explain how they are used to inform the methodology of this study.

Results: The application of the iterative process model to the design research process of problem identification and solution design for the Healthcare Research and Analytics Data Infrastructure Solution (HRADIS) is described. Each phase of the iterative model produced end products to inform the implementation of HRADIS. The analysis phase produced the problem statement and requirements documents. The projection phase produced a list of tasks and goals for the *ideal* system. Finally, the synthesis phase provided the process for a plan to implement HRADIS. HRADIS structures and integrates data dictionaries provided by the data sources, allowing the creation of dimensions and measures for a multidimensional business intelligence system. We discuss how HRADIS is complemented with a set of data mining, analytics, and visualization tools to enable researchers to more efficiently apply multiple methods to a given research project. HRADIS also includes a built-in security and account management framework for data governance purposes to ensure customized authorization depending on user roles and parts of the data the roles are authorized to access.

Conclusions: To address existing inefficiencies during the obtaining, extracting, preprocessing, cleansing, and filtering stages of data processing in health services research, we envision HRADIS as a full-service data warehouse integrating frequently used data sources, processes, and methods along with a variety of data analytics and visualization tools. This paper presents the application of the iterative process model to build such a solution. It also includes a discussion on several prominent issues, lessons learned, reflections and recommendations, and future considerations, as this model was applied.

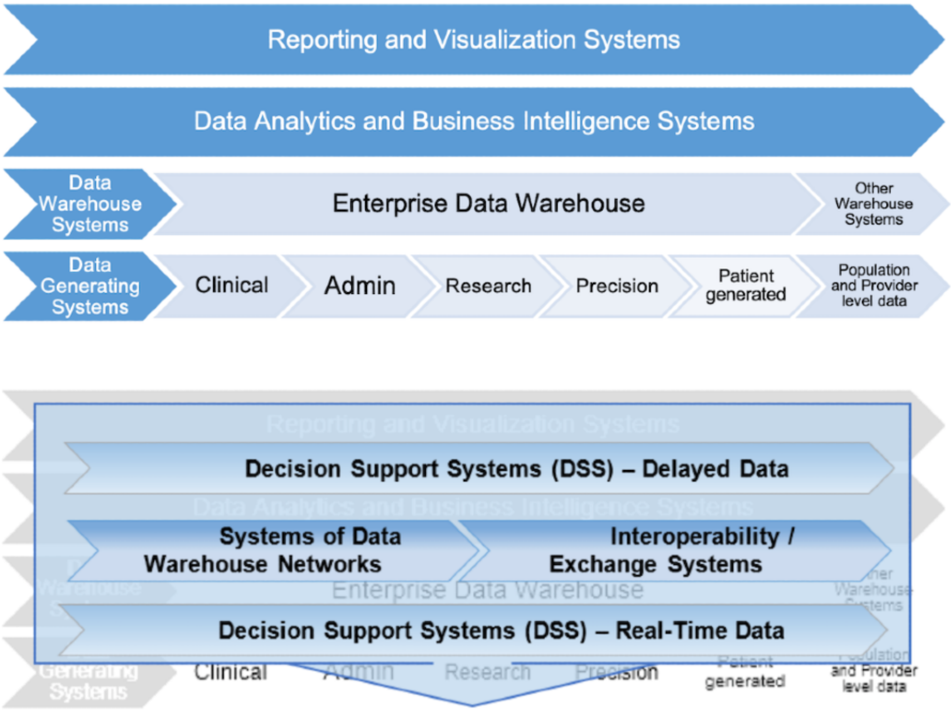
Introduction

There are a variety of data sources most frequently used for health services research, a multidisciplinary research field that investigates the implications of factors such as social determinants, organizational structures and processes, technologies, financing and reimbursement, individual choices and behaviors on the access and quality of health care delivery, and overall health and well-being of individuals [1]. Most of the data sources for health services research are provided by the Centers for Medicare and Medicaid Services (CMS); however, there are also data sources provided by other government agencies and nonprofit or for-profit data providers. Health services researchers, especially those using secondary data, can expand their research analytics by using merged datasets for health services research. In the absence of a single data warehouse from which to retrieve and analyze data from previously disparate datasets, health services researchers are forced to perform separate and often redundant data-related tasks on each individual dataset. Anecdotal reports suggest that researchers spend as much as 60% of their time on data preparation. At best, we can describe the current data-related processes as inefficient, costly, time-consuming, and cumbersome [2]. Moreover, the current uncoordinated and isolated efforts on these disparate datasets can be wasteful as they may generate research findings that are not reproducible or sometimes misleading because of the unaddressed inherent problems within these datasets. Furthermore, without the needed information technology (IT) infrastructure, analytics, and data visualization tools, the potential of the ever-growing health-related big data accumulated in these disparate datasets would still be untapped [3]. Therefore, there is a need for a cyberinfrastructure that integrates these disparate databases in a secure and consistent manner and provides the necessary analytics and visualization tools.

Background: Systems Around Health Data

In its life cycle, health-related data mainly move through four types of systems, as indicated in the top part of Figure 1 (adapted from the study by Ozaydin et al [4]). Patient-level data are usually generated in one of the operational systems that fall into categories of clinical, administrative, research, and precision medicine systems and systems that manage medical devices that patients use. The clinical systems include everything that is part of the electronic health record (EHR) and systems dealing with laboratories, imaging, physician notes, medications, histories, procedures, and diagnoses, regardless of whether or not they are part of the EHR. Administrative systems include admittance-discharge-transfer; billing, scheduling, and claims systems; as well as systems that are not specific to health care, such as systems that manage human resources and payroll. The research-related health data are generated by the systems for clinical research, clinical trials, and various registries. Furthermore, there are systems generating precision medicine data, such as genomics, phonemics, and microbiome, and systems where patient-generated data are generated, such as mobile health and telehealth systems, internet-of-things, and other data-generating medical devices, social media, and patient portals. After being created in one of the data-generating systems, the patient-level data are usually aggregated at an institutional enterprise data warehouse system. These data warehouses usually serve as the infrastructure on which institutional data analytics and business intelligence (BI) systems—based on which reporting and visualization systems, such as dashboards—run [4]. There are also other data warehouse systems outside of individual institutions, such as systems used for public health purposes [5,6].

Figure 1. Systems that deal with health-related data: First layer (top), second layer (bottom).



As indicated in the bottom part of Figure 1, there are also second-layer systems that operate between the systems shown in the top part of Figure 1. The second-layer systems include decision support systems, systems that provide interoperability between the first-layer systems (ie, interface engines), health information exchanges, and networks of institutional data warehouses. These second-layer systems are closer to data-generating systems if they are required to use real-time data. In the absence of the use of real-time data, these systems rely on delayed data provided by the data warehouse systems. As decision support systems mature, there are increasing expectations to provide their results back to the data-generating systems as close to real time as possible. To date, several data warehouse networks, such as the networks of informatics for integrating biology and the bedside (i2b2) systems called the shared health research information network, have been developed as data warehouse networks to integrate clinical and administrative data extracted from various systems of health care entities.

Need for the Healthcare Research and Analytics Data Infrastructure Solution

The systems described so far are mostly geared toward integrating patient-level electronic health, billing, and other administrative data to be used for clinical and translational research [2], without much focus on the organizational-level data. The first-layer systems also include systems that generate population- and provider-level data and data warehouse systems for them as indicated on the right-hand side of Figure 1. The population-level warehouse systems focus on epidemiological systems, systems managing national and regional indexes and surveys, and systems managing the Centers for Disease Control and Prevention databases. The provider-level warehouse systems focus on systems that manage data for health services administration, such as quality measures, satisfaction scores, inspections, financial performance, and services offered.

In addition to data warehouse networks for patient-level data, there have also been attempts to create integrated data repositories to include certain portions of the selected data sources for health services research for various purposes (ie, Research Data Assistance Center [ResDAC] [7] and Wharton research data services [WRDS] [8]). However, we could not find evidence of any mature platform that integrates all of the targeted data sources mentioned in Textbox 1 or of any effort to create such a platform in the literature. A majority of health services data continue to aggregate and evolve as isolated silos within various governmental or nongovernmental entities [2], with research efforts to interpret the data also operating in silos. In an era where the generation of data surpasses the efforts to extract meaning out of it, these uncoordinated silos of research efforts delay the necessary improvements in much-needed research efficiency. Therefore, enhancing health services research efficiency necessitates a platform that has the potential to integrate the disparate silos of datasets and research efforts.

Textbox 1. Data sources included in the first phase of the Healthcare Research and Analytics Data Infrastructure Solution.

- Centers for Medicare and Medicaid Services (CMS) Medicare cost reports
- CMS impact and final rule files
- Datasets from CMS Hospital Compare, including Hospital Consumer Assessment of Healthcare Providers and Systems
- Area health resources files
- American Hospital Association (AHA) annual survey
- AHA health information technology supplement
- Dartmouth Atlas
- Bureau of Labor Statistics

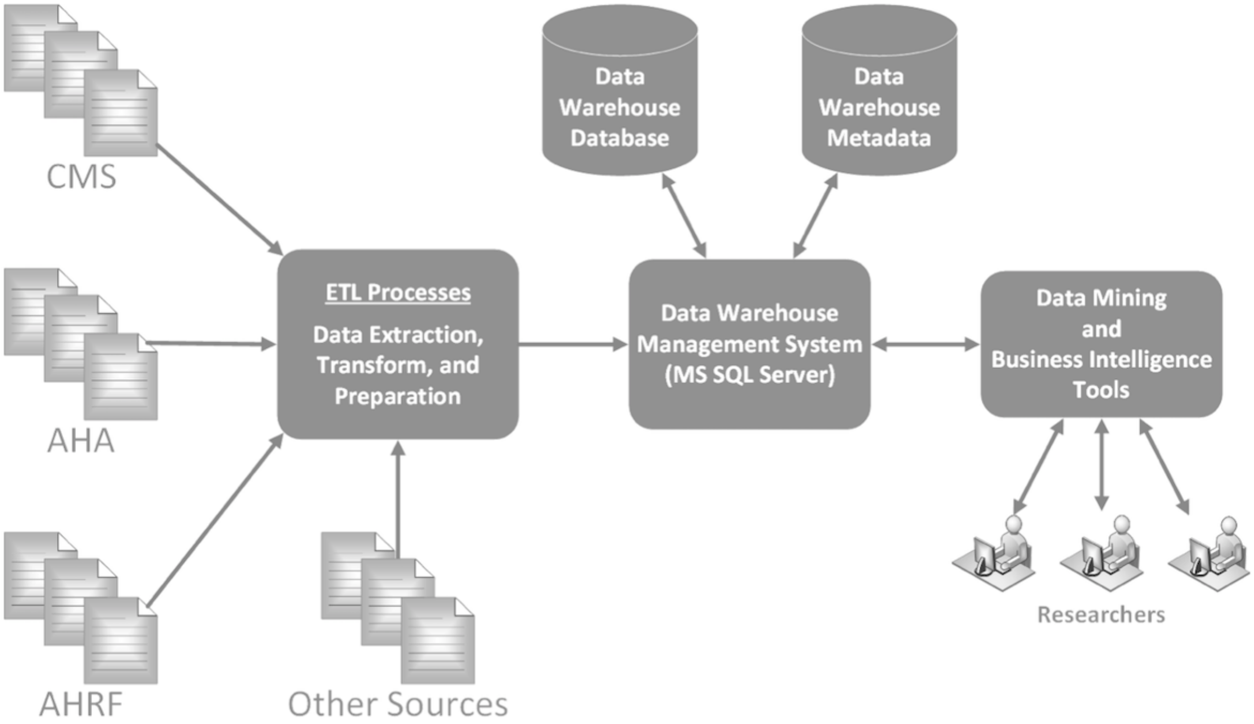
Methods

This section introduces data sources and architecture for the Healthcare Research and Analytics Data Infrastructure Solution (HRADIS) platform and the theoretical orientation and explains how the theoretical background is used to inform the methodology for this study.

Healthcare Research and Analytics Data Infrastructure Solution Data Sources and Architecture

To address the aforementioned need, this project aimed to generate a cyberinfrastructure by initially creating a data warehouse using the Microsoft SQL Server platform to integrate these frequently used health services data sources in a reliable, secure, and consistent manner and then to build a BI system that includes tools for data mining, analytics, and visualization, as depicted in Figure 2 (adapted from Kroenke and Auer [9]). The elements of HRADIS include data; metadata; procedures and applications of the data and metadata; other data tools; and users, groups, and data access policies. As shown in Figure 2, there are several different areas of data interaction. First, the data interact with the ETL (extract, transform, load) processes where data are prepared for storage in the data warehouse. Next, the data warehouse management system stores the data and metadata and handles data interaction between various other system tools and the stored data. Finally, the health services researchers interact with a graphical user interface to access the data through data mining and BI tools. The first phase of HRADIS hosts data from the data sources listed in Textbox 1.

Figure 2. The healthcare research and analytics data infrastructure solution architecture. CMS: Centers for Medicare and Medicaid Services; AHA: American Hospital Association; AHRF: area health resources files.



Some of the data sources listed in Textbox 1 have been made available through several research data centers such as ResDAC at the University of Minnesota, WRDS at the University of Pennsylvania, and the National Bureau of Economic Research (NBER) [10]. However, these research data centers do not include most of the data sources listed in Textbox 1. They primarily provide training and technical assistance on specific data sources such as CMS Medicare and Medicaid data in the case of ResDAC, focus on nonhealth care areas such as finance and business in the case of WRDS or improve the accessibility of existing data sources such as CMS Medicare cost reports (MCR) in the case of NBER. There are also commercial data centers, which provide reports on quality, finance, and inpatient and outpatient outcomes, for individual hospitals such as the American hospital directory [11] or hospital profiles such as Hospital-data [12]. However, these commercial data centers are not as comprehensive as, and some lack research focus when compared with HRADIS.

HRADIS is designed to be sustainable and scalable so that the inclusion of new data sources and updates of existing ones is efficient. This allows health services researchers to apply their models to updated data or data from new sources without having to merge new data to their research datasets.

A challenge exists in interpreting complex data dictionaries, layouts, and other metadata elements that accompany raw data to be able to identify and reliably extract parameters of interest for a given research project. To address this issue, HRADIS integrates metadata and ETL processes that utilize it to identify and extract parameters of interest based on how the parameters are defined by the metadata, rather than keeping metadata in a separate file repository or in an accompanying document warehouse [13]. To accomplish this, the source data are put through an initial phase of ETL tasks to populate database tables created based on the relational HRADIS data model in the entity relationship diagram format. Furthermore, HRADIS includes a second phase of ETL tasks to populate dimensions and measures that are created for the most frequently used parameters for more efficient performance of data mining, analytics, and visualization tasks based on the multidimensional HRADIS data model in a star schema diagram format. In other words, HRADIS benefits the advantages of both relational and dimensional models and their diagrammatical representations, as described in studies by Corral et al [14] and Schuff et al [15].

Currently, we have loaded MCR, AHA, Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS), Dartmouth Atlas, Bureau of Labor Statistics (BLS), and parts of Hospital Compare datasets with HRADIS and have begun data extraction from multiple data sources for pilot projects. Although most of the data incorporated into the system come from publicly accessible sources, some of the data are restricted. As we populate HRADIS with data, we are also implementing the security and data governance components of the system. Security and data governance are important for users to access only the parts of the data for which they are authorized.

Sociotechnical Systems Theory

Although cyberinfrastructures can be designed and developed in a system-centric vacuum, the associated functionality must consider the role of the user and how the user will interact with the data housed in the cyberinfrastructure. A sociotechnical systems approach that takes into account the interaction between the human and the technology [16,17] is therefore appropriate because it promotes theoretical development while enabling system designers and developers to incorporate social awareness, organizational behavior, or other underrepresented domains, such as culture, which may be a critical component in system use. Many engineered system innovations fail in terms of adoption or use due to their lack of attention on human-technology interactions that are necessary and unavoidable [18,19]. An innovative cyberinfrastructure that introduces various changes to the existing practices would potentially fail if its psychosocial implications are not recognized. Moreover, in the current era, both the continuous coevolution of society and technology [20,21], especially the emergence of virtual organizations [22] that utilize telecommunication [23] or electronic-learning tools [24-26], and a surge in the amount of digital data (ie, big data) [27] create challenges for system developers in designing user-friendly, yet adaptive and sophisticated cyberinfrastructures. HRADIS considers the importance of intuitive user interfaces that are cognizant of the psychosocial and educational backgrounds of its users. It is worth noting that achieving the adaptability and sophistication with the simplicity that user-friendliness requires may necessitate more investment in the information systems design and development processes.

Iterative Process Model as a Conceptual Framework

Multiple databases are available, but remain disparate, making it difficult, if not impossible, for the health services researcher to conduct and collaborate on innovative and rigorous research that has currency and relevance. The literature provides evidence of the importance of the design theory in focusing on the design process in artifact development [28,29]. As such, we used a design science process framework to guide the design of an artifact that aims to improve data delivery to health services researchers such that practitioners more readily benefit from the insights and findings.

Design science is an essential component in information systems research that holds promise to improve research capabilities. Through artifact creation, health services researchers have immediate access to multiple and expanding datasets, offering opportunities for comparisons previously thought cumbersome and time-consuming. This artifact can be a construct, method, model, or instantiation [30]. This paper focused on the *method* used to design and develop a data warehouse for health services researchers.

Offermann et al [31] synthesized the design research process into 3 categories: (1) problem identification, (2) solution design, and (3) evaluation. This paper reports the information systems design *problem identification and solution design* categories only.

The literature offers multiple approaches for problem identification [32,33]. Historically, interviews were conducted with relevant end users so that designers could understand the issues as the users saw them. In addition, previous studies in the literature illuminate the problems that researchers look to solve. However, more recently, one needs to only read the headlines for problem identification: a lot of data, in many different places, accumulating very quickly. Some call this *big data*, but regardless of what label it is given, health services researchers are clamoring for efficient ways to cleanse, combine, analyze, and visualize the disparate datasets for ease of analysis, collaboration, action, and publication. Doing so holds promise to analyze and visualize combinations of data to reveal information that, when put into practice, can give their organization a competitive advantage.

Although there is much literature on design engineering information systems to accept data, there is very little literature on considerations to design solutions specific to disparate health datasets, or more simply stated, a *how to* approach [5,6].

Solution design is part of an evolutionary process that helps to operationalize solutions and general system analysis and design principles. The model proposed by Jonas [34], as shown in Table 1, is appropriate for use as a conceptual model in the design and development of a data warehouse for health services researchers because it allows for consideration of the entire process and encourages creative solution design. In Figure 3, 4 domains of design inquiry (ANALYSIS, PROJECTION, SYNTHESIS, and COMMUNICATION) are indicated as *phases* of the iterative macro process of design and are denoted with all capital letters. The 4 *steps* of the iterative microprocess of design (Research, Analysis, Synthesis, and Realization), on the other hand, are *denoted with first capital and the other lower-case letters*. Each previous microprocess *step* informs the next microprocess *step*, as indicated by the arrows. Similarly, the output from each macro process *phase* of design, which considers each step of the iterative microprocess of design, then informs the next macroprocess *phase*. The dotted lines on the arrows between the microprocess steps and the macroprocess phases denote that this is an iterative process. As COMMUNICATION is the driver for all macrophases and microsteps, this continual and iterative process is denoted by a dotted circular process arrow.

The 12 shaded sections in Figure 3 contain what occurs for each respective step. For example, in the ANALYSIS/Synthesis step, there needs to be an understanding of the current situation relative to the whole. The model is not prescriptive in exactly *how* this understanding occurs and thus allows for various types of individualized design processes. Within the first 2 phases of the iterative macroprocess (ANALYSIS and PROJECTION), the model allows for moving from Research (gathering data about the problems) to Analysis (understanding those problems) to Synthesis (expressing the problems from the perspective of looking at the system as a whole and assigning the problems into categories) and then Realization (presenting these problems as a problem/requirements statement). The difference between these first 2 phases is that during ANALYSIS, the model allows us to focus on the current problems and requirements, whereas during PROJECTION, the model allows for focusing on future problems and the requirements of an ideal system. In both cases, the end product is the presentation of the problems in their respective categories. In SYNTHESIS, all the knowledge learned from the previous 2 phases informs the Research, Analysis, Synthesis (or design), and Realization (or development and implementation) of the core functionalities of the entire system, that is, the first version of the system. We address how we interpret COMMUNICATION in the *Methodology* section.

Figure 3. The iterative process model.

		Steps of the iterative **micro-process** of design			
		Research	Analysis	Synthesis	Realization
Phases of the iterative **macro-process** of design	ANALYSIS – "the true" (how it is today)	Gathering data on the current situation	Understanding the current situation	The current situation relative to the whole situation	Usable presentation of the current situation
	PROJECTION – "the ideal" (how it could be)	Gathering data on future changes	Understanding future needs	Scenarios incorporating possible future situations	Usable presentation of goals and future evolutions
	SYNTHESIS – "the real" (how it is tomorrow)	Gathering data for immediate use	Understanding the requirements	Design solutions	Usable solutions for immediate use
	COMMUNICATION – "the driver"	Understanding the process for moving it forward			

Methodology

Consistent with the iterative process model, the first phase, ANALYSIS, is to understand the current situation with the data and then to realize a usable presentation of the current situation. This is accomplished through the following:

- Research: gathering disparate data, databases, their metadata, and the problems health services researchers currently face dealing with these data sources.
- Analysis: understanding the data, its structure, and metadata in each database and the domains of problems health services researchers face.
- Synthesis: merging these domains of problems and our understanding of the data and metadata from the perspective of the data warehouse project as a whole.
- Realization: creating an initial problem statement and requirements documentation for the project.

Table 1 presents a summary of this process relative to the ANALYSIS phase of the data warehouse project.

Once this first phase, ANALYSIS of how the data, metadata, disparate databases and their structures and evolution up to this point, and the problems around utilizing them for health services research, is appreciated, it is time to consider phase 2, PROJECTION, or what the ideal state of HRADIS would be. This second macrophase in the iterative design process is concerned with the future needs of the project. First, in the Research step, we gather data about the additional problems and requirements that may surface as a result of Analysis, Synthesis, and Realization of the ANALYSIS phase as well as data about future additions and changes of the source databases and their structures. Next, in the Analysis step, we work to understand the future needs of the ideal system based on the information gathered during the Research step. Third, in the Synthesis step, we further synthesize the future needs into possible future scenarios. Finally, in the Realization step, we present the project goal based on the anticipated needs of the data sources and system users. Table 2 presents a summary of this process relative to the PROJECTION phase of the HRADIS project.

The SYNTHESIS phase of the iterative (macro) process design considers how HRADIS will be in a usable state. First, the Research step takes into account the realizations of the previous ANALYSIS and PROJECTION phases to inform the gathering of data on the requirements for the first version of the HRADIS project that addresses its core functions with an understanding of what its future functions will be. Second, the Analysis step involves understanding the requirements of the core functions by creating process and data models for these core functions. Third, the Synthesis step involves the creation of design solutions, and finally, the Realization step involves the development and implementation of these core functionalities. Table 3 presents a summary of this process relative to the SYNTHESIS phase of the HRADIS project.

Table 1. The iterative process model—phase 1 (ANALYSIS).

Macroprocess	Research	Analysis	Synthesis	Realization
ANALYSIS—the true (how it is today)	Gathering data, databases, metadata, and problems researchers face using these data sources	Understanding of the data, data schemas, metadata of each data source, and domains of problems researchers face	Merging the problem domains and data/metadata analysis for the perspective of data warehouse project as a whole	Creating an initial problem statement and requirements document

Table 2. The iterative process model—phase 2 (PROJECTION).

Macroprocess	Research	Analysis	Synthesis	Realization
PROJECTION—the ideal (how it could be)	Gathering additional problems and requirements, including potential data sources to be added and additions and changes to the data and structure of existing data sources	Understanding future data needs and additional requirements of the ideal system	Identifying scenarios that describe user/system interaction of the ideal system from the perspective of the data warehouse project as a whole	Creating use case and project goals documents to include considerations for the future data sources and updates of the existing data sources as well as the requirements of the ideal system

Table 3. The iterative process model—phase 3 (SYNTHESIS).

Macroprocess	Research	Analysis	Synthesis	Realization
SYNTHESIS—the real (how it is tomorrow)	Gathering data on the requirements of the initial version of the data warehouse project that includes its core functions	Understanding of requirements of the core functionalities using process and data modeling tools	Creating design solutions based on process and data models	Development of the design solutions and implementation of the first version of the data warehouse project

The COMMUNICATION phase allows for understanding the process to move the project forward and encompasses the other 3 macroprocess phases of iterative design. The main premise of the COMMUNICATION phase is to keep the entire project team(s) on the same page as the iterative process evolves, and the design continuously changes. Considering a sociotechnical approach, COMMUNICATION also includes how the systems and its users and stakeholders interact.

As its name indicates, the model is both horizontally and vertically iterative (hence the arrows to illustrate the iterative movement); therefore, it allows for continuously updating each shaded box in Figure 3 as we increase our understanding of the requirements and the design of the project.

Results

This section describes the application of the iterative process model to the design research process of problem identification and solution design for HRADIS.

Iterative Process Model—Phase 1: ANALYSIS

As part of the Research step, we downloaded raw data files and data layout and/or data dictionary (metadata) files for all available data releases from the following data sources that are most frequently used by health services researchers: CMS MCR, impact/final rule files, HCAHPS, the area health resources files, AHA annual survey and IT supplement, Dartmouth Atlas, and BLS. Consistent with the iterative process model, the goal was to capture data and metadata from all of the data sources in a single database as is, without changing the source data structure. In general, data and metadata file structures for a given data source were mostly consistent among its releases. Within the release of a particular data source, there were one or multiple data files along with a metadata file. For each data file that was included in the latest release of a particular dataset, we created a table in the data warehouse, naming the table the same as the data file name with a prefix that corresponds to its data source. In cases where previous releases included a data file that was not in the latest release, we also added tables for the additional data files to the data warehouse in the same manner. For example, for the CMS MCR data source, the latest release included 3 data files, namely, ALPHA, NMRC (numeric), and RPT (report). Some of the earlier releases had another data file named ROLLUP. For each of these 4 data files, we created the following tables with an MCR prefix to indicate their data source and a HOSP prefix to distinguish them from other health organization types, for which we may include MCR data in the future: MCR_HOSP_ALPHA, MCR_HOSP_NMRC, MCR_HOSP_RPT, and MCR_HOSP_ROLLUP. Similarly, we created a table named MCR_HOSP_DATAELEMENTS for the metadata files.

Before importing data from data files into the data warehouse, we created an additional column for each table to store the release information. Then, we imported the data values from the data files into their corresponding tables, merging multiple release files into a single corresponding table. When possible, we repeated the same process for the metadata files. The aforementioned processes resulted in a database with data and metadata from all data sources, whose different releases merged into their corresponding tables with their release information preserved. Although data from different sources are not related together as an integrated database yet, having such a database allows for a better understanding of the source data structure and changes to the data structure and metadata over time and also enables data integration from different sources at the query level and the ability to save that query logic. Finally, these manual import processes inform the automation of the import tasks of future releases.

Analysis of the data, metadata, and the problems and issues the health services researchers identified helped inform the Synthesis step. In this step, we considered categories of the problems, each corresponding to a module of the system as a whole (design-focused synthesis and problem categorization). As a result, in the Realization step of the ANALYSIS phase, we generated a list of problems that HRADIS should address, as displayed in Textbox 2.

As part of the Realization step, we also developed the requirements document based on the above problem statement, as displayed in Textbox 3.

Textbox 2. Problem statement at the Realization step of the ANALYSIS phase.

General problems

- Duplication of effort for each project
- Problems related to dealing with a large amount of data
- Management of licenses, data use agreements, and data access levels of users with different roles (administrative, faculty, student, etc)

Integration problems

- Disparate storage of data
- Problems related to dealing with data updates
    - Updates of static data (previous release data does not change; new release data gets added to the previous releases)
    - Updates of dynamic data (new releases add new data; also, update some of the previous release data)
- Integration of data elements from different data sources
    - Lack of standards in how data elements from different sources are integrated
    - Integration of data and metadata

Lack of standards in research data processing to deal with

- Changes of data structure from one data release to another
- Matching data elements from different releases
- Missing data values
- Inconsistent data values
- Variability and lack of documentation of assumptions about the data and the clean-up processes
- Definition and use of measures and indexes

Textbox 3. Requirements document at the Realization step of the ANALYSIS phase.

The system should be able to:

- Store data and metadata from multiple data sources in a single storage (all data should be in one place)
- Store relationships among data elements within and across data sources
- Store rules and procedures for content-specific data processes
    - Imputation of missing values (sometimes even multiple methods for a single data element)
    - Creation of new data elements based on existing ones (calculations, indexes, conversions, etc)
    - Identification of measures and dimensions
- Integrate data sources through the stored relationships, rules, and procedures
- Extract data based on predetermined criteria (data marts)

Iterative Process Model—Phase 2: PROJECTION

Given that the PROJECTION phase deals with *the ideal* during its Research step, collaboration with fellow health services researchers is important to pinpoint potential future problems and requirements and better understand the generic workflow of a hypothetical secondary data analysis research project.

The analysis of the information gathered from the Research step provided insights into the goals and user scenarios for HRADIS. The synthesis of these insights that considers the system as a whole led to the Realization step of the PROJECTION phase, in which we identified a list of tasks and goals for the ideal data warehouse, as displayed in Textbox 4.

Textbox 4. List of tasks and goals for the ideal system at the Realization step of the PROJECTION phase.

- Development of generalized solutions for
  - anticipated data structure changes to the existing data sources
  - addition of new data sources
- User interfaces for the system administrator user role
- In addition to provider-level data, the inclusion of patient-level data
- Addition of data sources about entities health services researchers are interested in other than hospitals (ie, nursing home data)
- Metadata search interface that allows keyword search based on a taxonomy similar to Table 4.
- A user-friendly query builder interface
- An infrastructure that allows
  - multiphase larger projects (harmonious efforts)
  - building new projects based on existing ones
- Inclusion of data analytics toolset
- Inclusion of data visualization toolset
- User interfaces for researchers to utilize analytics and visualization toolsets
- A knowledge base that encompasses metadata, measures and indices, analytics and visualization tools, and references related to all these knowledge base items from the literature

In addition, in the Realization step, we acknowledge the sociotechnical system theory that suggests the development of a technology by always considering the needs of end users. Relative to this project, bringing together various data sources would generate thousands of variables and measures. Moreover, sifting through thousands of variables can be very discouraging unless this process is simplified by considering the needs of the health services researchers. Therefore, to enable seamless development of research projects, an interface that allows intuitive browsing and filtering of metadata through taxonomies is a vital feature of HRADIS. Similar to biologic taxonomy, data taxonomies also separate data elements based on certain common characteristics and simplify browsing [35]. For this purpose, we have developed a data taxonomy (Table 4) by combining our own experience, information on dimensions of health care quality from the CMS Hospital Compare website [36], and hierarchical categories frequently used by health services researchers [37-42]. This taxonomy is incorporated into metadata tables and is dynamic in nature, meaning that one data element can be classified into several categories. In other words, the envisioned user interface will provide some flexibility for health services researchers in categorizing the data elements. This process embodies the use-inspired research model and facilitates further taxonomy growth and development as use and application increase.

Another product of the Realization step of the PROJECTION phase is high-level use cases for the health services researcher and system administrator user roles. Use case analysis is used in systems analysis and design to document the interaction of each user role with the system being considered to be created [43]. Use case analysis is usually performed after requirements definition and user role determination. The use cases are then used for creating the process and data models. For the health services researcher user role, use cases include browsing data elements (metadata) without creating a project, browsing completed projects and selecting one to create a new project by editing it, retrieving data for a given project, and creating a new project. Similarly, for the system administrator user role, use cases include creating system rules, editing system rules, managing user credentials, managing user groups, and managing user and group permissions.

As an example, Figure 4 shows the casual format use case for the researcher user role, which does not include the input/output data elements and their sources/destinations.

The iterative process model allows for considering *the ideal* in early stage design processes. Therefore, decision support tools facilitating the following future state use cases for the health services researcher user role are considered: (1) browsing appropriate data analytics methods, (2) selecting appropriate data analytics methods, (3) browsing data visualization methods, and (4) selecting data visualization methods.

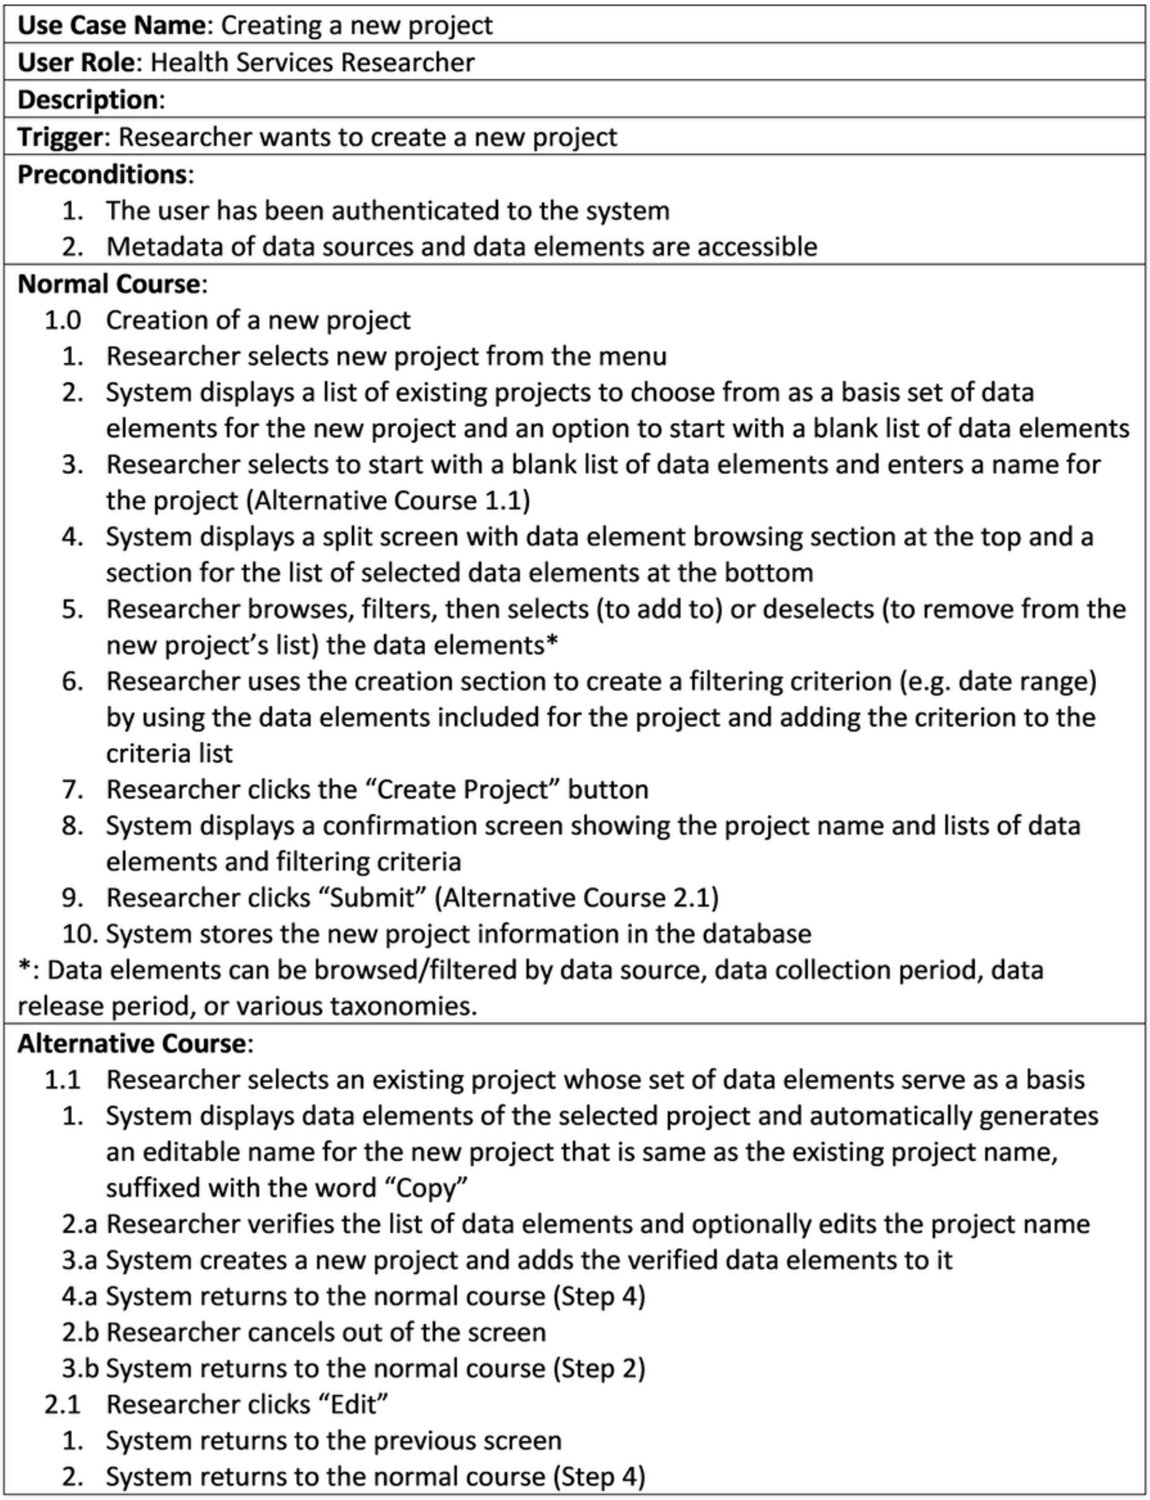
Table 4. Data taxonomy for health services research.

First-level classification	Second-level classification	Examples
Organizational/structural characteristics	• N/A[a]	• Size (number of beds) • Location • System membership
Staffing	• Nurse • Physician • Other	• Registered nurse FTEs[b] per inpatient day • Physician FTEs per inpatient day • Radiology technician staffing
Quality	• Structural measures • Patient experience • Timely and effective care • Outcome measures	• Safe surgery checklist • Communication with doctors • Heart attack—aspirin at arrival • 30-day readmission/mortality
Financial performance	• Profitability • Liquidity • Capital structure • Activity • Utilization	• Operating margin • Current ratio • Equity financing • Total asset turnover • Occupancy rate
Environmental/market characteristics	• N/A	• Market (ie, county, health referral region, or health service area) competition • Managed care penetration • Per capita income (county)

[a] N/A: not applicable.

[b] FTE: full-time equivalent.

Figure 4. A casual format use case example.



Use Case Name: Creating a new project

User Role: Health Services Researcher

Description:

Trigger: Researcher wants to create a new project

Preconditions:

1. The user has been authenticated to the system
2. Metadata of data sources and data elements are accessible

Normal Course:

1.0 Creation of a new project

1. Researcher selects new project from the menu
2. System displays a list of existing projects to choose from as a basis set of data elements for the new project and an option to start with a blank list of data elements
3. Researcher selects to start with a blank list of data elements and enters a name for the project (Alternative Course 1.1)
4. System displays a split screen with data element browsing section at the top and a section for the list of selected data elements at the bottom
5. Researcher browses, filters, then selects (to add to) or deselects (to remove from the new project's list) the data elements*
6. Researcher uses the creation section to create a filtering criterion (e.g. date range) by using the data elements included for the project and adding the criterion to the criteria list
7. Researcher clicks the "Create Project" button
8. System displays a confirmation screen showing the project name and lists of data elements and filtering criteria
9. Researcher clicks "Submit" (Alternative Course 2.1)
10. System stores the new project information in the database

*: Data elements can be browsed/filtered by data source, data collection period, data release period, or various taxonomies.

Alternative Course:

1.1 Researcher selects an existing project whose set of data elements serve as a basis

1. System displays data elements of the selected project and automatically generates an editable name for the new project that is same as the existing project name, suffixed with the word "Copy"

2.a Researcher verifies the list of data elements and optionally edits the project name

3.a System creates a new project and adds the verified data elements to it

4.a System returns to the normal course (Step 4)

2.b Researcher cancels out of the screen

3.b System returns to the normal course (Step 2)

2.1 Researcher clicks "Edit"

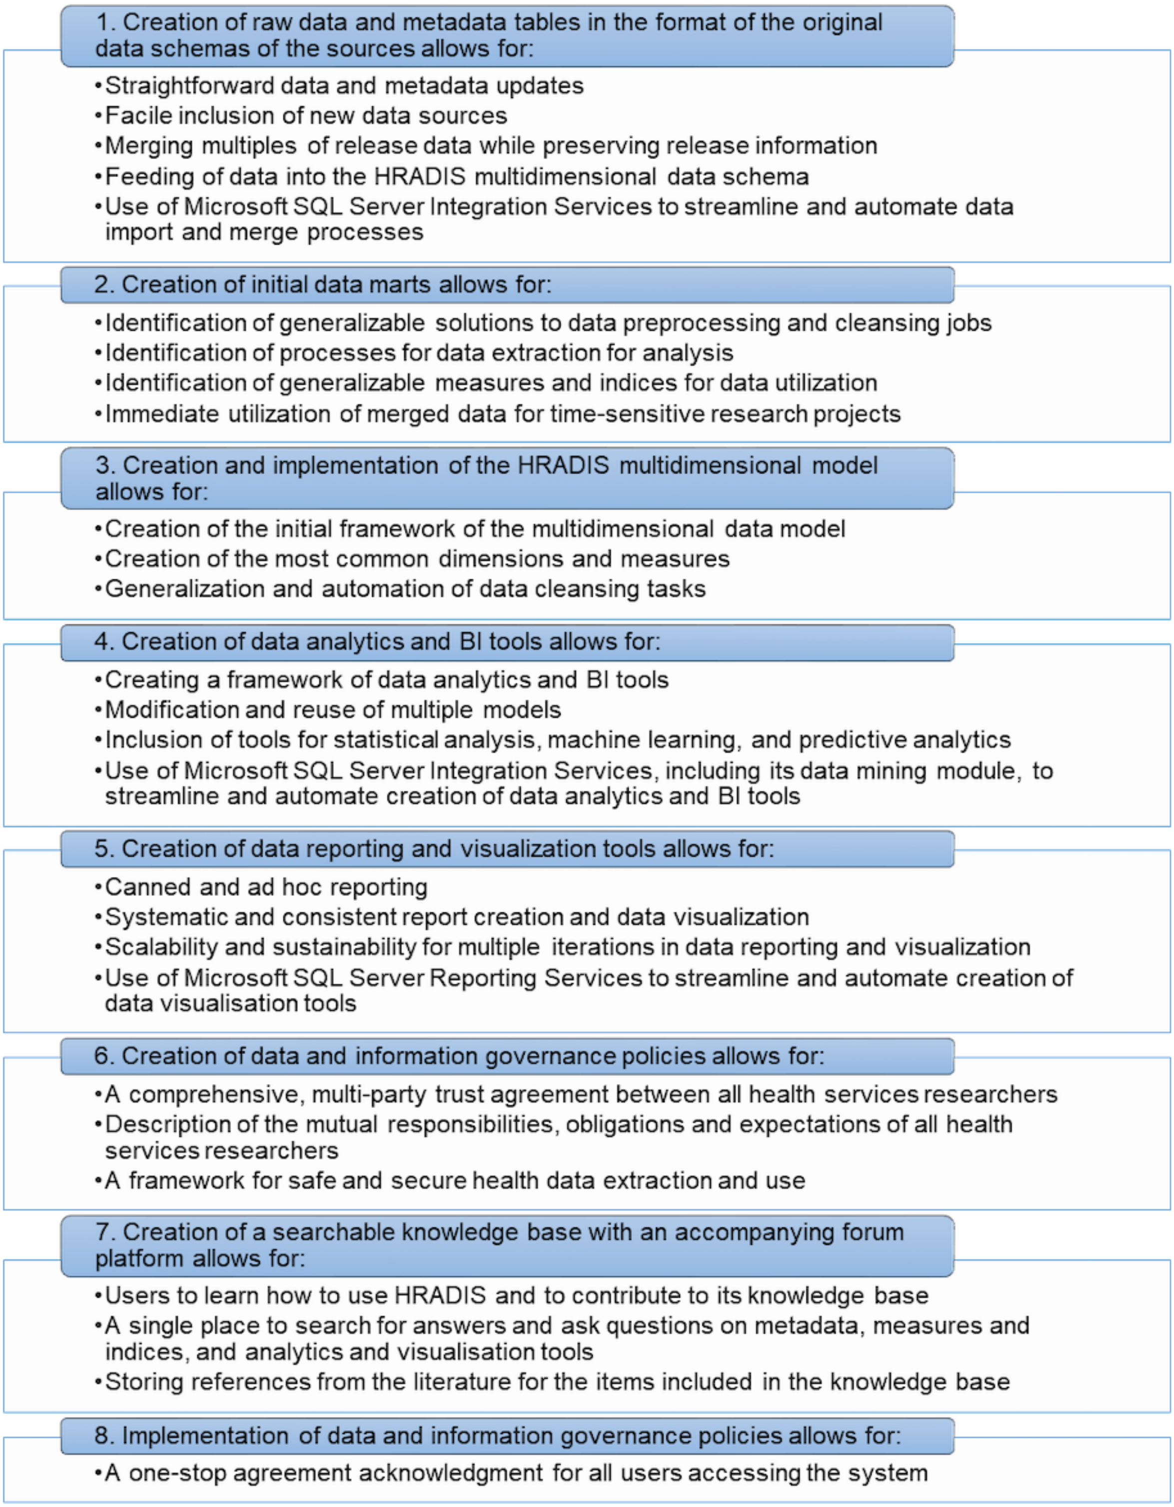
1. System returns to the previous screen
2. System returns to the normal course (Step 4)

Iterative Process Model—Phase 3: SYNTHESIS

Considering that the SYNTHESIS phase focuses on *the real*, its Research step gathers the information from the results of the Realization steps (end products) of the ANALYSIS and PROJECTION phases to develop practical solutions for immediate use. Analysis of the initial problem statement and requirements, use cases, future requirements, and goals of the system revealed that any practical solution has to balance time spent on priority data requests for immediate research projects and time investment required for the development of the data warehouse infrastructure.

For the Realization step, we laid out the process for a plan to implement the first version of HRADIS with its core functionalities. We then expanded this process to include high-level steps to implement some of the future functionalities, such as data analytics and visualization modules. Figure 5 explains the steps of this process, which can also be described as system modules, the reasoning behind why each module is considered, and the tasks involved in each. The iterative process model enables partial-phase completion to develop a system for immediate use, while building out other functionality in an iterative environment. As such, only various parts of the Analysis, Synthesis, and Realization steps of the SYNTHESIS phase were completed. To date, we have implemented the first 3 modules of Figure 5.

Figure 5. The process for a plan to implement healthcare research and analytics data infrastructure solution; BI: business intelligence. HRADIS: healthcare research and analytics data infrastructure solution.



1. Creation of raw data and metadata tables in the format of the original data schemas of the sources allows for:
- Straightforward data and metadata updates
- Facile inclusion of new data sources
- Merging multiples of release data while preserving release information
- Feeding of data into the HRADIS multidimensional data schema
- Use of Microsoft SQL Server Integration Services to streamline and automate data import and merge processes

2. Creation of initial data marts allows for:
- Identification of generalizable solutions to data preprocessing and cleansing jobs
- Identification of processes for data extraction for analysis
- Identification of generalizable measures and indices for data utilization
- Immediate utilization of merged data for time-sensitive research projects

3. Creation and implementation of the HRADIS multidimensional model allows for:
- Creation of the initial framework of the multidimensional data model
- Creation of the most common dimensions and measures
- Generalization and automation of data cleansing tasks

4. Creation of data analytics and BI tools allows for:
- Creating a framework of data analytics and BI tools
- Modification and reuse of multiple models
- Inclusion of tools for statistical analysis, machine learning, and predictive analytics
- Use of Microsoft SQL Server Integration Services, including its data mining module, to streamline and automate creation of data analytics and BI tools

5. Creation of data reporting and visualization tools allows for:
- Canned and ad hoc reporting
- Systematic and consistent report creation and data visualization
- Scalability and sustainability for multiple iterations in data reporting and visualization
- Use of Microsoft SQL Server Reporting Services to streamline and automate creation of data visualisation tools

6. Creation of data and information governance policies allows for:
- A comprehensive, multi-party trust agreement between all health services researchers
- Description of the mutual responsibilities, obligations and expectations of all health services researchers
- A framework for safe and secure health data extraction and use

7. Creation of a searchable knowledge base with an accompanying forum platform allows for:
- Users to learn how to use HRADIS and to contribute to its knowledge base
- A single place to search for answers and ask questions on metadata, measures and indices, and analytics and visualisation tools
- Storing references from the literature for the items included in the knowledge base

8. Implementation of data and information governance policies allows for:
- A one-stop agreement acknowledgment for all users accessing the system

At this stage, as it was essential to obtain a better understanding of the data and the structures in the source systems, we have not yet created a multidimensional data model for HRADIS (a multidimensional model results in faster analysis and output of large and complex datasets). Instead, we kept the data schemas of the source systems in their original state, and table creation only considered the raw data and metadata tables (the first item in Figure 5). These tables will later feed data into the tables based on a new multidimensional HRADIS data schema, whose data model will be designed as part of the Synthesis step (the third item in Figure 5) and will be implemented as part of the Realization step. As part of the process, we merged data from all releases of AHA, Dartmouth Atlas, MCR, Hospital Compare, and HCAHPS data sources into their respective tables in the database. By doing so, we have encountered examples of data preprocessing and cleansing tasks from which to learn and apply in future iterations. As these examples included tasks that are typical for health services research projects, identifying generalized solutions for these assists with isolating the ETL processes, the dimensions and measures for the HRADIS multidimensional model, and the data analytics and visualization tools needed to be created as part of the next steps in the development.

Discussion

Principal Findings

This study provides theoretical underpinnings of the processes and methodologies in developing a data warehouse system as an infrastructure to support health services research. This paper addresses existing inefficiencies, disparate and unnecessary duplication of efforts, and the lack of harmony among health services researchers during the obtaining, extracting, preprocessing, cleansing, and filtering stages of data processing. For this purpose, we envision HRADIS as a full-service data warehouse integrating frequently used health services research data sources, processes, and methods along with a variety of data analytics and visualization tools. A conceptual iterative process model framework combined with sociotechnical systems theory provided guidance on the design process. We presented the application of 4 phases (ie, ANALYSIS, PROJECTION, SYNTHESIS, and COMMUNICATION) of the iterative process model. In the following paragraphs, the discussions on several prominent issues with supporting examples, lessons learned, reflections and recommendations, and future considerations are provided.

In terms of the application of the iterative process model (Figure 3) into the development of HRADIS, the guidance provided to synthesize the ANALYSIS and PROJECTION phases was quite significant. Traditionally, some system development strategies suggest the development and implementation of the core functionalities of a system as the first version, then additional features are added in the later phases or versions. However, the iterative process model provides a solid framework for consideration of the entire system as the pieces are being developed. With the model, the PROJECTION phase guides us to analyze the future requirements of the ideal state of the system before designing the core functionalities of the system for its first version. This allows designers to be informed by the envisioned end product of the PROJECTION phase, hence resulting in the design considerations in the SYNTHESIS phase for the *solutions for the immediate use* to include the goals of the ideal system, some of which will be designed and implemented in the future.

When a small-scale development team comprises only a few members, formal COMMUNICATION may not be as critical. In such an environment, the team is in constant communication naturally and is able to utilize agile development methods, where the features that are immediately needed are analyzed, designed, and implemented. The implemented features satisfy the immediate requirements and may later go through slight modifications to be generalized and fit into the larger project. This is also how the HRADIS project was initially implemented, by creating ad hoc data extracts, transform and load procedures, and queries for immediate research projects. Working with larger teams, on the other hand, requires more formal COMMUNICATION to create a shared understanding of the immediate processes as well as awareness of the larger *to be* project. As mentioned earlier, how the system communicates with the users and stakeholders in the general sense, and COMMUNICATION in this specific context, is critical, for example, interactions between the system and its users when there is a request for a new data source to be included in the warehouse as well as when a data extract is requested from the system.

Conclusions

During the development of HRADIS, several issues were found that are worth further discussion. We believe that for those who consider attempting a similar project, the following lessons learned, reflections, and recommendations would be instrumental.

First, seamless progress requires a balance between immediate/urgent needs and the need to generalize the solutions being considered. To achieve this balance, we developed practical solutions by recognizing the trade-off between the quality and cost during the SYNTHESIS phase. The time investment into a highly generalized, reusable, better-quality solution to a specific problem that would yield time savings in the long term comes with its opportunity cost of not spending that particular time into multiple, less effective but working, ad hoc solutions that may yield results in the short term. For example, as we considered various geographical categorizations of hospitals based on county, health service area (HSA), and health referral region (HRR) codes in the AHA data for a study, we recognized missing values in the data and considered several ways to calculate the missing codes. We were faced with making a decision between creating a generalized solution that would encompass all possible ways to calculate the missing values or create an ad hoc solution specific to the pilot project we were working on at the time. The generalized solution would take a longer time investment to create, with the potential to be used for many studies, compared with the specific solution. In this particular case, we chose to implement the generalized solution as the long-term benefits of reuse outweighed the opportunity cost of delaying the use of HRADIS for particular pilot projects. However, these types of decisions must be considered on a case-by-case basis, as the decision would strongly depend on the potential reuse of the generalized solution and the urgency of the particular study. When making decisions on such trade-offs, one should also consider the potential benefit of the ad hoc solution in developing a generalized solution given that the ad hoc solutions sometimes provide the required knowledge base and intimacy between the designer and the data.

Second, the issue of static versus dynamic data import that was mentioned in Textbox 2 is an important consideration. When developing general solutions for data import, we realized that there was a need for two different approaches for data import processes. This need was due to inherent differences in the data sources. The former approach is static as the data source itself is static, meaning that once data are published, the content of the data does not change over time. The latter approach is dynamic as the data source itself is dynamic, meaning that the data are updated at regular intervals, and the content changes even for the archived versions (ie, years) of the data. A good example of a dynamic data source is CMS MCR; reports for earlier years can be reopened after settlement, and even the archived data are updated quarterly [44]. In our case, importing data from static data sources did not require much effort, as it was sufficient to create simple SQL scripts for import tasks. Importing data from dynamic sources requires writing SQL stored procedures that automatize and simplify the quarterly data import processes. This process addressed our ultimate goal to improve research efficiency and reduce the amount of time spent on redundant tasks.

Third, as mentioned in Textbox 3, when designing such a data warehouse, the team may consider potential ways to improve data by utilizing different data sources. In our case, sometimes, the same variable or measure existed in different datasets or was sourced from another dataset. To enhance the completeness of the data and address any missing value issues, we examined both datasets by comparing and ultimately imputing the missing values. For example, when developing certain measures, such as the Herfindahl-Hirshman index, we needed to use certain geographical market area designations such as HSA, county, or HRRs. However, due to missing information in the existing dataset for certain years, we realized that there is a need to examine the original data source (Dartmouth Atlas). Further examination revealed that the missing information could be imputed by developing an algorithm that utilizes both the information from the original data source and the existing dataset.

The fourth lesson learned pertains to the importance of the iterative design process. The conceptual iterative process model framework adapted from Jonas [34] was very useful during the development of HRADIS. Although the iterative back and forth movements may be initially perceived as inefficient and time-consuming, they were crucial in developing generalized design solutions that are beneficial in the long term. Although it may be tempting to develop a system in response to urgent data needs, we found it essential to adhere to the iterative process model. Doing so created a development expectation with our colleagues.

In the future, we plan to improve HRADIS by drawing on by the successful growth strategy and story of research electronic data capture (REDCap). Doing so considers that both HRADIS and REDCap are products of academic research and have ambitious goals, but they start small because of limited resources [45]. We plan to collaborate with researchers who have potential contributions by asking them to work with us in generalizing their contributions to fit the HRADIS framework. In this way, the contributor would have access to all the HRADIS offerings, and the existing user base would have access to the new contribution (within the data governance limitations).

Abstract

Background: In the era of information explosion, the use of the internet to assist with clinical practice and diagnosis has become a cutting-edge area of research. The application of medical informatics allows patients to be aware of their clinical conditions, which may contribute toward the prevention of several chronic diseases and disorders.

Objective: In this study, we applied machine learning techniques to construct a medical database system from electronic medical records (EMRs) of subjects who have undergone health examination. This system aims to provide online self-health evaluation to clinicians and patients worldwide, enabling personalized health and preventive health.

Methods: We built a medical database system based on the literature, and data preprocessing and cleaning were performed for the database. We utilized both supervised and unsupervised machine learning technology to analyze the EMR data to establish prediction models. The models with EMR databases were then applied to the internet platform.

Results: The validation data were used to validate the online diagnosis prediction system. The accuracy of the prediction model for metabolic syndrome reached 91%, and the area under the receiver operating characteristic (ROC) curve was 0.904 in this system. For chronic kidney disease, the prediction accuracy of the model reached 94.7%, and the area under the ROC curve (AUC) was 0.982. In addition, the system also provided disease diagnosis visualization via clustering, allowing users to check their outcome compared with those in the medical database, enabling increased awareness for a healthier lifestyle.

Conclusions: Our web-based health care machine learning system allowed users to access online diagnosis predictions and provided a health examination report. Users could understand and review their health status accordingly. In the future, we aim to connect hospitals worldwide with our platform, so that health care practitioners can make diagnoses or provide patient education to remote patients. This platform can increase the value of preventive medicine and telemedicine.

KEYWORDS

machine learning; online healthcare assessment; medical informatics; preventive medicine

Introduction

In the ever-changing technological era, the internet can provide rapid and convenient medical services in the form of health care, preventive medicine, and telemedicine. Medical informatics is a multidisciplinary field that comprises medicine and computer science. As computer technology continues to advance, medical informatics can be used to develop various applications such as electronic medical records (EMRs), medical image processing, clinical diagnosis decision systems, hospital information management systems, telemedicine, and internet and health information systems [1-4].

To construct a health care information system, several factors must be considered: the hospital information system, including both clinical management and diagnosis services; the storage and processing of patient information, such as EMRs and electronic health records; decision support systems, such as expert diagnosis systems; and the artificial intelligence (AI) algorithms that need to be applied to those factors (eg, data mining in EMRs and decision-making in clinical diagnosis) [5-8].

The mass application of EMRs and the digitalization of medical equipment and instruments have led to the continuous expansion of information capacity in hospital databases. Therefore, informatics research should focus on basic electronic medical database construction, data collection and analysis, medical decision support, and automatic knowledge acquisition. Furthermore, the use of machine learning (ML) technology in AI to extract the most important information has led to cutting-edge research in medicine [9-13]. The goal of AI is to construct an intelligent machine that imitates the natural intelligence of humans. Computers, robots, and software that are made with such technology will have human-like thinking processes, but with the ability to utilize superhuman speed and power effectively. Knowledge engineering is an essential part of AI research, especially ML, because AI operations require a significant amount of real-world data.

ML is defined as a “machine that is capable of self-learning without any guidance.” Therefore, the main purpose of ML is to make computers self-learning and auto-correcting when analyzing data. The core technology of ML must identify specific patterns and information hidden within very large data sets using statistical analysis and prediction automatically [14-17].

Disease and disability are influenced by several factors: environmental factors, genetic predisposition, pathogens, and lifestyle choices. Some conditions are a dynamic process that can affect an individual before they are aware of any problem [18-20]. The core of preventive medicine is to prevent chronic diseases among people who are at risk of certain diseases. In some cases, it can also be used to reverse their condition, returning them to a good health status. In the past, due to information asymmetry, doctors and hospitals led the medical environment, and patients did not have access to any appropriate methods or information to implement real-time self-management. Patients who failed to obtain an early diagnosis would have to pay higher health care costs. Therefore, the spirit of prevention medicine is that “an ounce of prevention is worth a pound of cure” [21-23].

Metabolic syndrome (MetS) is a cluster of conditions comprising high blood sugar, high blood pressure, abnormal blood lipid levels, abdominal obesity, and other metabolic risk factors. It is a warning sign of potential future chronic disease. People with MetS have an increased risk of subsequent development of type II diabetes, hypertension, hyperlipidemia, heart disease, and stroke compared with healthy people [24-28].

Chronic kidney disease (CKD) is defined as kidney function that is impaired for longer than 3 months, leading to irreversible damage. The National Kidney Foundation Kidney Disease Outcome Quality Initiative guideline classifies CKD into 5 stages according to the estimated glomerular filtration rate (eGFR) and using the recommended Modification of Diet in Renal Disease (MDRD) equation [29]. There are many causes of CKD, such as congenital anomalies of the kidney, urinary tract obstruction, urinary tract infection, and glomerulopathy. In addition, hypertension, diabetes, and gout are common chronic diseases that cause CKD if undertreated [30,31].

Telemedicine uses information and telecommunication technology to deliver medical information and physicians’ diagnoses to patients without the limitations of time and space. It combines information and communication technologies with medical expertise to provide various services: remote consultation and conferencing for doctors; comprehensive medical care for residents in remote and outlying islands; and teaching and training opportunities for medical staff. The internet can be used to assist with the popularization of telemedicine to achieve a two-way communication channel between patients and medical practitioners [32,33]. Therefore, this study aims to construct an online ML-driven medical database system from EMRs of subjects who have undergone health examination, and provide online self-health evaluation for MetS and CKD.

Methods

Setting

The study was conducted at the Health Management Center (HMC) of Taipei Medical University Hospital (TMUH). Electronic medical records (EMRs) were obtained and reviewed from the HMC, which receives approximately 60 to 70 visits per month.

Ethics

The study was approved by the Institutional Review Board (IRB) of TMUH prior to data collection (TMUH TMU-JIRB number N202003088), in accordance with the original and amended Declaration of Helsinki. The IRB waived the need for informed consent because of the retrospective nature of this study.

EMR Database and System

The databases and the selected predicting variables (Table 1) were derived from previous publication on MetS and CKD [34-36]. Figure 1 shows an overview of the system and the main functions. Briefly, using a series of complicated procedures, the two databases (MetS and CKD) were connected to an internet platform to construct one integrated system. This web-based system was embedded with ML models to provide various medical evaluations and analyses. The online system was constructed on a server as a web-based environment. The frontend implementation included the programming language JavaScript (Oracle Corp), the framework VueJS (Vue), and the styling Syntactically Awesome Style Sheets (Sass). The backend implementation used Java and R as the programming languages, and all ML calculations and evaluations were conducted using the statistical program R (version 3.6.1, R Foundation for Statistical Computing). The back web framework was Spring Boot (Pivotal Software), connecting the MySQL (Oracle Corp) database as the storage system.

Study Populations

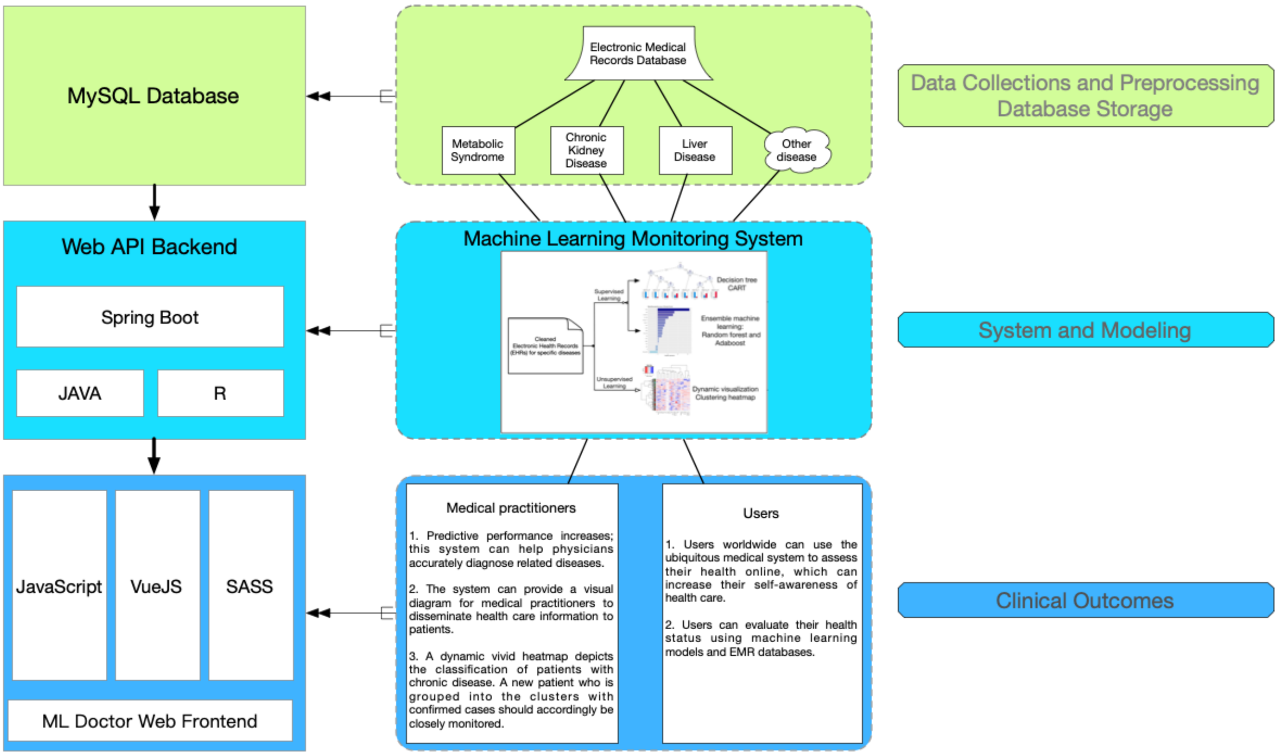
Figure 2 [37-39] shows an overview of the main study population and the validation populations. Briefly, the starting study population included 48,628 EMRs of Taiwanese adults aged over 18 years who underwent a self-paid health examination at TMUH from July 2015 to December 2019. All the study participants completed a self-questionnaire on demographics, existing medical conditions, and the use of medications.

Table 1. The list of predicting variables in the electronic health care records.

Disease and predicting variable	Unit
Metabolic syndrome	
Sex	Male/Female
Age	years
Body mass index	kg/m^2
Waist circumference	cm
Glutamic-oxaloacetic transaminase	IU/L
Glutamate pyruvate transaminase	IU/L
γ-Glutamyl transpeptidase	U/L
Total bilirubin	mg/dL
Alkaline phosphatase	IU/L
Blood urea nitrogen	mg/dL
Creatinine	mg/dL
Uric acid	mg/dL
Albumin	g/dL
Cholesterol	mg/dL
High-density lipoprotein	mg/dL
Low-density lipoprotein	mg/dL
Hemoglobin A_{1c}	%
Glucose AC	mg/dL
Triglycerides	mg/dL
Systolic blood pressure	mm Hg
Diastolic blood pressure	mm Hg
Elastic modulus (E) score	kPa
Controlled attenuation parameter (CAP) score	dB/m
Chronic kidney disease	
Sex	Male/Female
Age	years
Body mass index	kg/m^2
Waist circumference	cm
Glutamic-oxaloacetic transaminase	IU/L
Glutamate pyruvate transaminase	IU/L
γ-Glutamyl transpeptidase	U/L
Total bilirubin	mg/dL
Alkaline phosphatase	IU/L
Blood urea nitrogen	mg/dL
Creatinine	mg/dL
Uric acid	mg/dL
Albumin	g/dL
Cholesterol	mg/dL
High-density lipoprotein	mg/dL
Low-density lipoprotein	mg/dL

Disease and predicting variable	Unit
Hemoglobin A_{1c}	%
Hypertension	Yes/No

Figure 1. The structure of web-based machine learning medical system. API: application programming interface; EMR: electronic medical record; ML: machine learning.



Medical practitioners

1. Predictive performance increases; this system can help physicians accurately diagnose related diseases.

2. The system can provide a visual diagram for medical practitioners to disseminate health care information to patients.

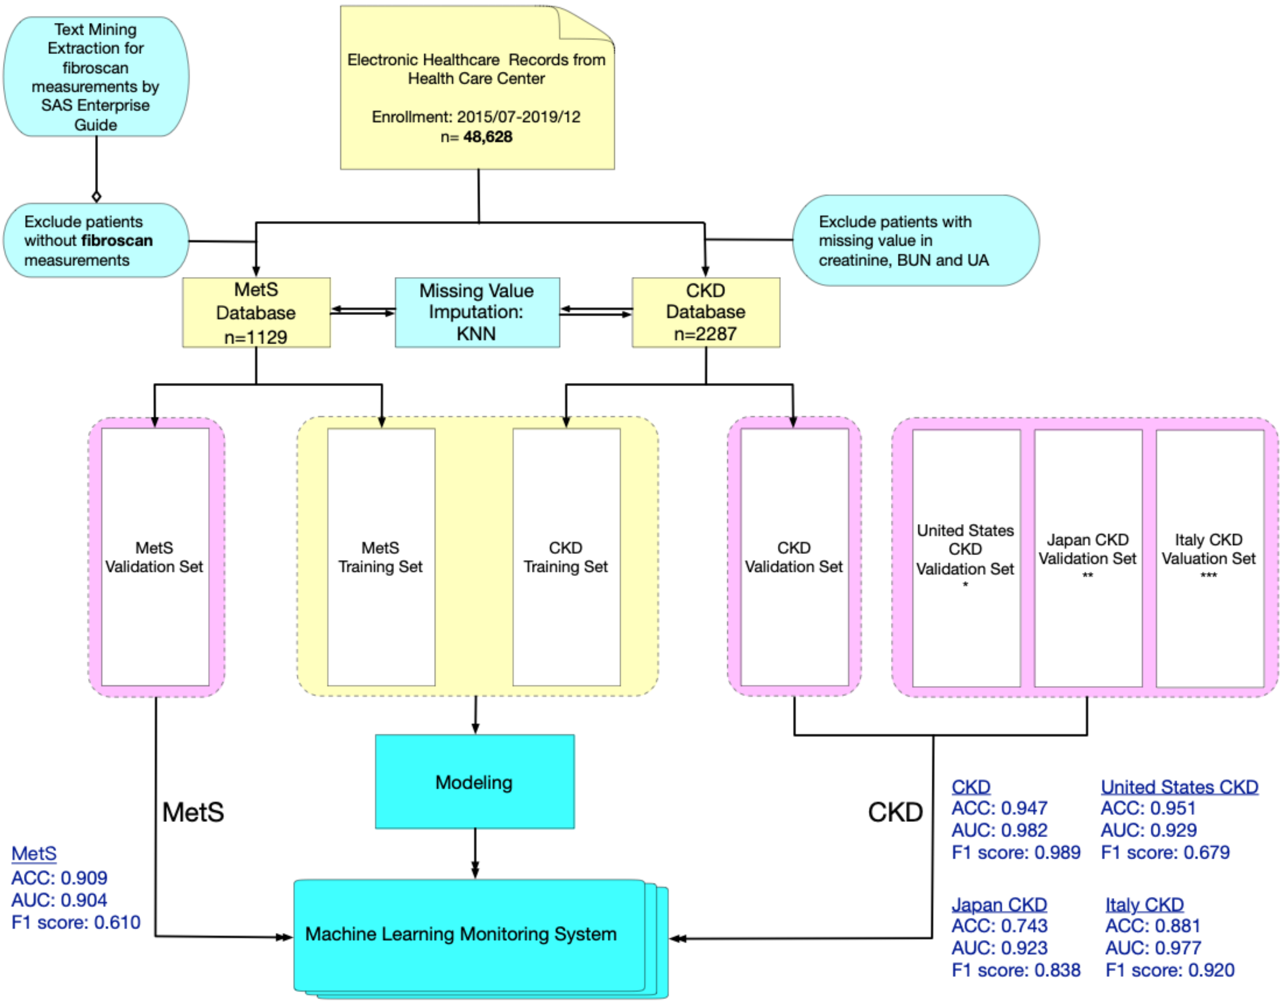
3. A dynamic vivid heatmap depicts the classification of patients with chronic disease. A new patient who is grouped into the clusters with confirmed cases should accordingly be closely monitored.

Users

1. Users worldwide can use the ubiquitous medical system to assess their health online, which can increase their self-awareness of health care.

2. Users can evaluate their health status using machine learning models and EMR databases.

Figure 2. Flowchart of data collection and preprocessing for MetS and CKD data sets including training and validation sets. SAS Enterprise Guide is a software that combines the analytic ability of SAS software with a user-friendly interface. It provides several functions of Structured Query Language (SQL), which includes a text mining technique. ACC: accuracy; AUC: area under the curve; BUN: blood urea nitrogen; CKD: chronic kidney disease; KNN: k-nearest neighbors algorithm; MetS: metabolic syndrome; UA: uric acid. * Centers for Disease Control and Prevention (CDC) and National Center for Health Statistics (NCHS) [37], ** Iimori et al [39], *** De Nicola et al [38].



Subsequently, the starting population data underwent data cleaning and preprocessing to form two distinct databases (MetS and CKD) for ML. For the MetS database, there were a total of 1129 participants after the exclusion of participants without FibroScan (Echosens) measurements. For the CKD database, there were a total of 2287 participants after the exclusion of participants without values for creatinine, blood urea nitrogen, and uric acid.

Due to the inconsistent definition of MetS across the world, the ML performance of the MetS database and the CKD database were validated using different study populations. The ML performance of the CKD database was validated using Taiwanese, Italian, US, and Japanese data sets, but the ML performance of the CKD database was only validated using a Taiwanese data set [37-39]. Since different variables may be unavailable in different validation data sets, unavailable variables were simply excluded in ML performance analysis for a balanced comparison.

ML Techniques

The ML techniques used in this system included supervised learning models, such as classification and regression tree (CART) and random forest [35,36]. Supervised learning was applied to classify the patients in the training set and predict patients with a specific chronic disease or syndrome in the validation set before the prediction model was available on this system [40,41]. In addition, unsupervised learning (hierarchical clustering using the Ward method and Euclidean distance) was embedded in a heat map, providing classified visualization between new input records and the database. An interactive heat map that could be rearranged or zoomed in and out was applied to this system [42-47].

All outcomes were presented on the web platform after the ML system evaluated the users' EMRs. Although the ML system was developed on a web-based interface, it could be embedded in the Internet of Medical Things (IoMT) environment, for example, as apps or real-time monitoring systems between several medical centers and hospitals [48-50].

Questionnaire Selection

To measure the usability of websites, we invited potential users of the ML system (physicians, medical staff, and potential users) to fill out a system usability scale (SUS) evaluation questionnaire. SUS was chosen as the usability test tool because previous studies found it to be reliable and quick to answer, and the final score is provided with interpretation based on a well-established reference standard [51,52]. In general, the higher the SUS score, the better the usability of the website. Details about the questionnaire design (the 10 questions), score summary, and results of reliability and validity tests are given in Multimedia Appendix 1.

Results

The web-based health care ML system provides online diagnosis of three diseases (Figure 3), and it is available on the internet [53]. The website provides an assessment of MetS and CKD; the system for noncancer liver disease is still under beta testing. Report pages are provided for online diagnosis of each disease. Therefore, users from all over the world can choose the evaluation provided depending on their requirements. Users input the predicting variables (Table 1) into the website to evaluate their health (Figure 4), and the evaluation results will appear in <5 seconds when there is a single request. Missing predicting variables are allowed, and the missing values will be imputed based on the mean values from the database. However, the users are warned that missing predicting variables may result in poorer prediction accuracy. The details of stress tests with different numbers of requests (100 to 800) can be found in Multimedia Appendix 2. Briefly, a stress test with 800 requests reports a throughput of 4.7 requests per second. To evaluate the usability of the system, we invited 30 volunteers to complete the SUS evaluation questionnaire. The volunteers included 6 physicians, 12 medical staff, and 12 potential users (Multimedia Appendix 1). It was found that the average SUS score is 74, which indicates a good usability rating [54]. In addition, results were found to be reliable and valid by Kaiser-Meyer-Olkin and Bartlett tests. The entire analysis process follows a strict privacy policy, so that none of the patients' private information is ever recorded.

Figure 3. Home page of the machine learning health care system.

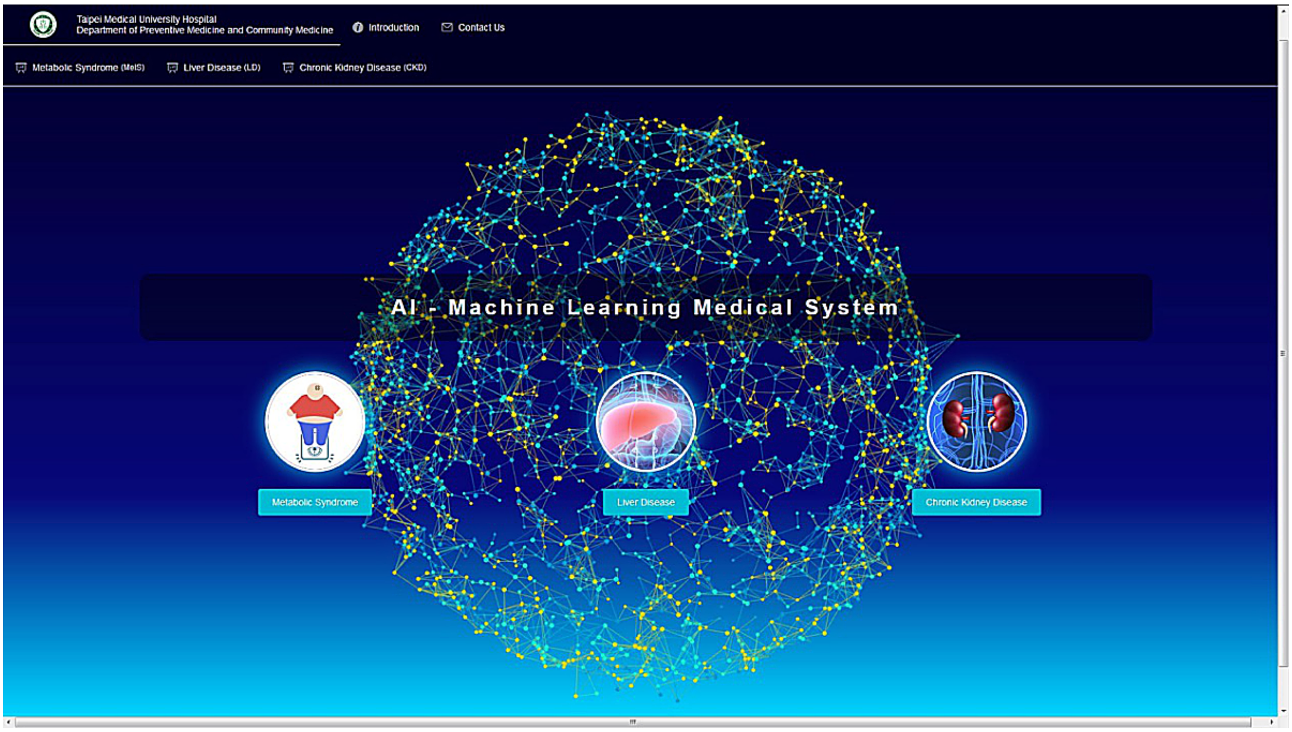


Figure 4. Interface of the input page for disease assessment.

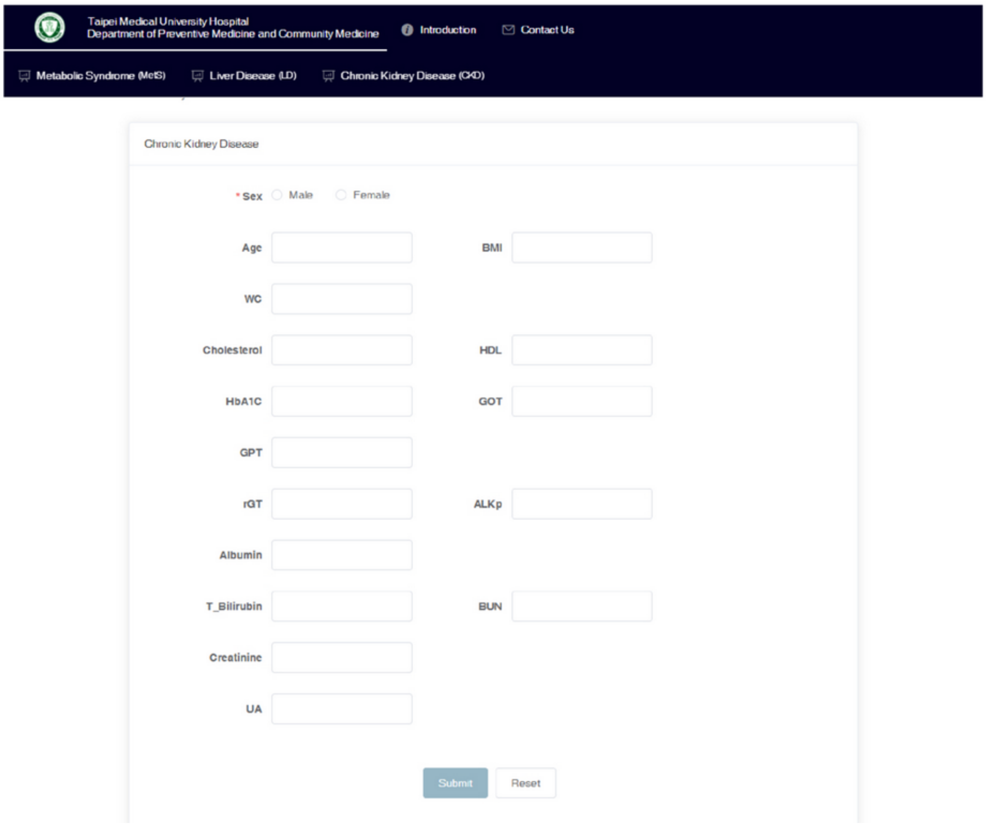
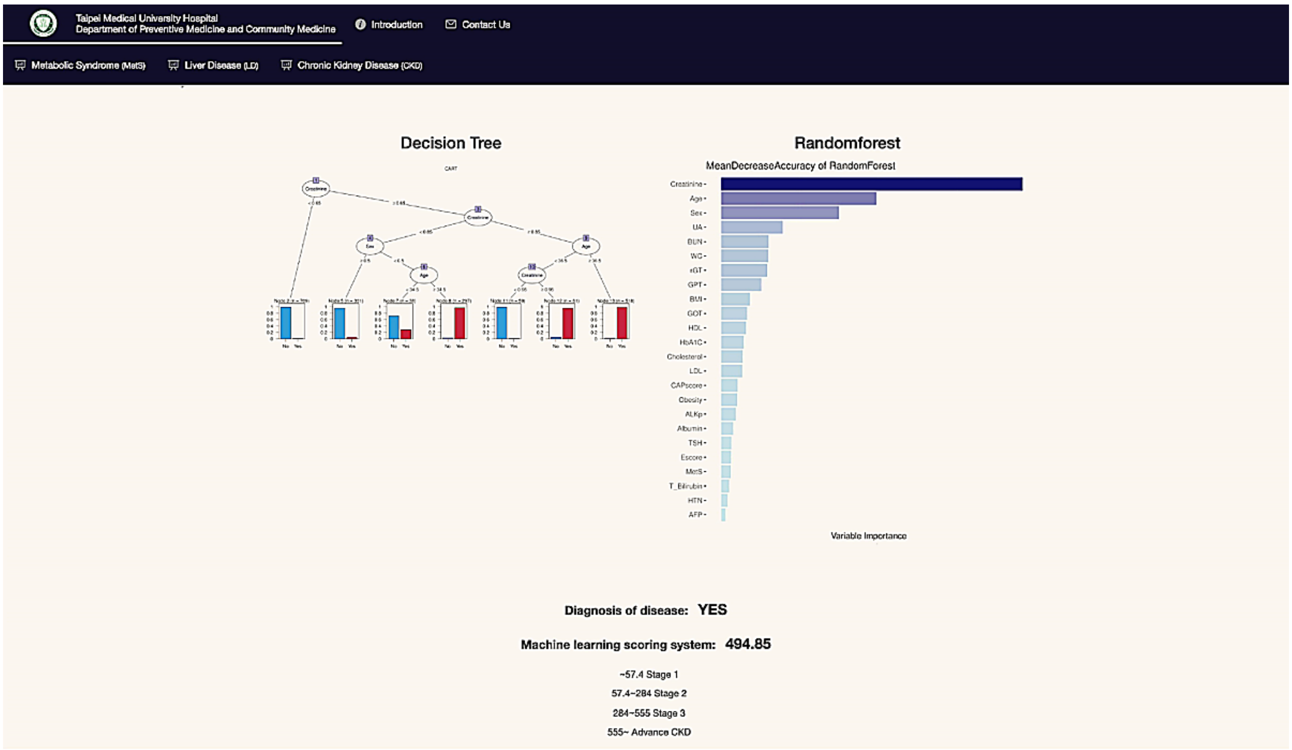


The clinical outcomes established by our database are reported on the website when users have finished entering their medical record data on the website (Figure 5). The CART model and ensemble learning model (random forest) are shown in the output interface. A scoring prediction model obtained using the supervised learning model is also provided online. For unsupervised learning, a color visualization of the clustering heat map depicts a vivid medical pattern of the patient's EMR data, and a record of each user is also constructed using hierarchical clustering with yellow highlights labeling in the heat map (Figure 6). The user will then be classified as more similar to either a healthy subject (green column on the lower left) or an unhealthy subject (orange column on the upper left). A blue bar depicts abnormal values, while a red bar depicts normal values. In addition, on the web system, users can choose to view it as landscape or portrait. The zoom-in and zoom-out functions and the height of the cluster are also dynamic, with users being able to change the settings online to inspect the medical outcomes in detail.

Figure 5. Outcome page for supervised learning models and the scoring system for disease diagnosis.

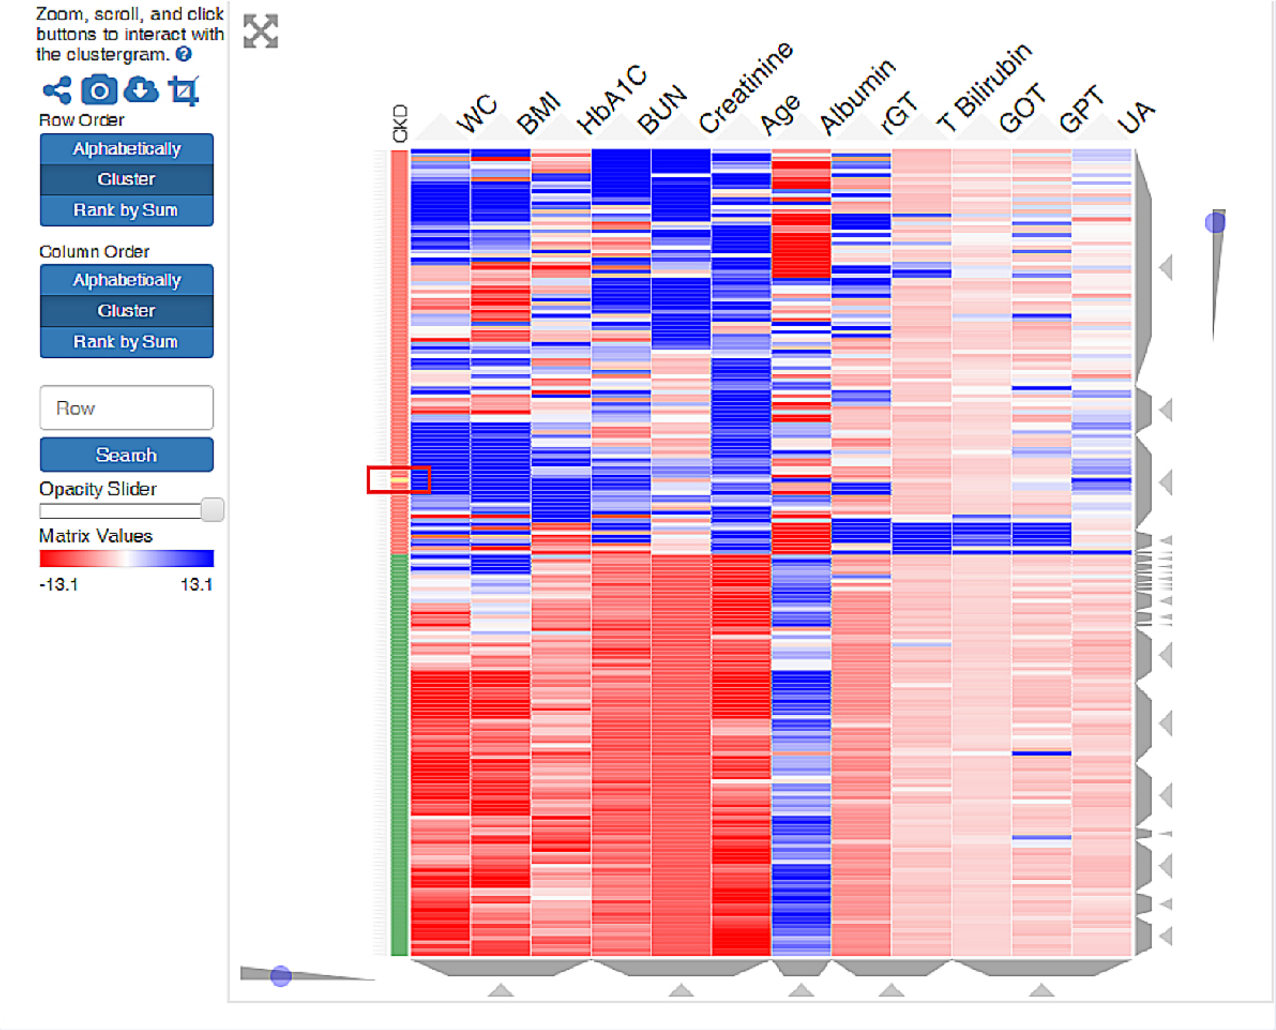


Diagnosis of disease: YES

Machine learning scoring system: 494.85

~57.4 Stage 1
57.4~284 Stage 2
284~555 Stage 3
555~ Advance CKD

Figure 6. Dynamic interactive heat map obtained using unsupervised clustering. Green: healthy patients; orange: CKD patients; blue: normal values; red: abnormal values. The new patients (yellow bar in red rectangle) are compared and clustered into the system's patient database.



Zoom, scroll, and click buttons to interact with the clustergram.

Characteristics of participants in the training and validation data set for MetS can be found in Table 2 and the characteristics of participants of the training set and the validation sets for CKD can be found in Table 3. In general, there are minimal differences in patient characteristics between the training data set and the validation data set for the Taiwanese population of MetS and CKD. However, when comparing the characteristics of the Taiwanese population with other populations (US, Italy, and Japan) for CKD ML performance validation, it was found that there are substantial differences in age and presence of hypertension (Table 3).

Table 2. Characteristics of participants in the training and validation data set for metabolic syndrome.

Characteristics	Training data set (n=904)	Validation data set (n=225)
Sex		
Female, n (%)	411 (45.5)	108 (48.0)
Male, n (%)	493 (54.5)	117 (52.0)
Age, years, median (IQR)	44 (37-50.25)	43 (38-50)
Body mass index, kg/m^2, median (IQR)	23.6 (21.3-25.9)	22.9 (21.2-26)
Waist circumference, cm, median (IQR)	81.75 (74.5-88)	80.5 (74-87)
Albumin, g/dL, median (IQR)	4.6 (4.4-4.8)	4.6 (4.4-4.8)
Alkaline phosphatase, IU/L, median (IQR)	58 (49-69)	58 (48-69)
Glutamic-oxaloacetic transaminase, IU/L, median (IQR)	20 (17-24.25)	20 (17-25)
Glutamate pyruvate transaminase, IU/L, median (IQR)	20 (14-31)	19 (14-28)
Total bilirubin, mg/dL, median (IQR)	0.6 (0.5-0.9)	0.6 (0.4-0.8)
γ-Glutamyl transpeptidase, U/L, median (IQR)	18 (12-27)	17 (11.55-25)
Controlled attenuation parameter (CAP) score, dB/m, median (IQR)	247 (211-284)	241 (216-282)
Elastic modulus (E) score, kPa, median (IQR)	4.2 (3.4-4.9)	4 (3.3-4.8)
Blood urea nitrogen, mg/dL, median (IQR)	12 (10-15)	12 (10-14)
Creatinine, mg/dL, median (IQR)	0.8 (0.6-0.9)	0.8 (0.6-0.9)
Estimated glomerular filtration rate (eGFR) using the Modification of Diet in Renal Disease (MDRD) equation, median (IQR)	90.23 (80.49-104.77)	91.28 (82.72-107.26)
Uric acid, mg/dL, median (IQR)	5.5 (4.5-6.6)	5.4 (4.3-6.6)
Systolic blood pressure, mm Hg, median (IQR)	114 (105-125)	114 (105-126)
Diastolic blood pressure, mm Hg, median (IQR)	73 (67-80)	72 (66-81)
Cholesterol, mg/dL, median (IQR)	189 (165-209)	185 (168-209)

[a] Not available.

Table 4 shows the validation performances of supervised learning models in predicting MetS and CKD. In general, it was found that the random forest ML model has higher accuracy than the CART model. Using the random forest ML model, MetS can be predicted with an accuracy of 0.909, and CKD can be predicted up to an accuracy of 0.947. Due to the inconsistent definition of MetS globally, the ML performance of the MetS database has only been validated using the Taiwan data set. However, the ML performances of the CKD database have been validated using data sets from Taiwan, Italy, the United States, and Japan. In general, the CKD database shows good external applicability, and has high AUC for all 4 validation data sets (Taiwan: AUC=0.982; USA: AUC=0.929; Italy: AUC=0.977; Japan: AUC=0.923). However, the validation accuracy and F1 value of CKD prediction differs more substantially, as the unavailable data were excluded from the analysis. When compared to the Taiwanese CKD data set, the respective unavailable data are approximately 6% for the US data set, 50%

for the Italy data set, and 67% for the Japan data set. Therefore, it is observed that the Japanese validation data set has the lowest accuracy (0.743) in predicting CKD, as it also has the highest proportion of unavailable data.

Table 4. The performance of supervised learning models on predicting metabolic syndrome and chronic kidney disease.

Model and disease	Accuracy	Area under the curve (AUC)	F1 score
Classification and regression tree (CART)			
Metabolic syndrome (Taiwan)	0.874	0.887	0.448
Chronic kidney disease (Taiwan)	0.945	0.928	0.965
Random forest			
Metabolic syndrome (Taiwan)	0.909	0.904	0.610
Chronic kidney disease (Taiwan)	0.947	0.982	0.989
Chronic kidney disease (United States)	0.951	0.929	0.679
Chronic kidney disease (Italy)	0.881	0.977	0.920
Chronic kidney disease (Japan)	0.743	0.923	0.838

Discussion

Overview

This ML medical system for three common diseases in family medicine (MetS, CKD, and liver diseases) was constructed from EMR subjects who underwent self-paid health examination. Several ML prediction models are applied to the databases, and the outcomes are summarized and presented visually on the website for users and medical staff. The accuracy of predicting MetS reached 90.9%, and AUC was 0.904 in this system. For chronic kidney disease, the prediction accuracy reached 94.7%, and the AUC was 0.982. In general, users who were invited to test this system rated it with good usability and could easily assess their health online through this web-based ML monitoring system.

CART

Decision trees are an important type of ML algorithm for predictive modeling. They are commonly used in data mining with the objective of creating a model that predicts the dependent variable (the target) based on numerous independent variables [34,37].

A decision tree is a nonparametric ML modeling technique used for regression and classification problems. In classification problems, the target variable is categorical, and the tree is used to identify which group or class a target variable would likely fall into. In regression problems, the target variable is continuous, and the tree is used to predict its value. To find solutions, a decision tree makes a sequential, hierarchical decision about the outcome's variable according to the predictor [55-57].

Hence, CART can provide a visual tree-based diagram for medical practitioners to disseminate health care information to patients. It also helps users to understand the significance of different risk factors for specific diseases. For example, the cut-off controlled attenuation parameter (CAP) score was used to separate patients with MetS and those with other health observations. The CAP score was brought to the attention of users, thereby increasing their awareness of self-health [34].

Random Forest

Random forest, also called random decision forests, is a popular ensemble learning method in ML. Ensemble methods use multiple learning algorithms to improve ML results by combining several decision tree models. This approach allows better predictive performance compared with a single model. Random forest is a parallel ensemble method in which the base learners are generated in parallel. The basic motivation of parallel methods is to exploit independence between the base learners because the error can be reduced dramatically by averaging [58,59]. As random forest provides a bagging technique for feature estimates, it also offers efficient estimates of the test error without incurring the cost of repeated model training associated with cross-validation. Moreover, random forest ranks risk factors in prediction models, which clinicians can use as a reference for diagnosis, and remote users can use to review their risk assessment of related diseases [34,60-62]. For instance, clinicians can refer to significant factors of certain diseases to determine whether those factors exceed the thresholds or not, allowing patients to be more vigilant about their risk of developing such diseases. In addition, sequential ensemble methods such as AdaBoost and XGBoost will be implemented and uploaded to our system in the future.

Clustering

Hierarchical clustering is a widely used unsupervised learning technique that groups data with similar characteristics. Both agglomerative and divisive approaches use dendrograms for the results. A heat map is a color graphical representation of data, which uses a matrix with color gradients to present the similarity of data.

Many studies on genetic bioinformatics and bacterial ecology have used heat maps for the analysis of large and complicated data sets, and some medical studies have used heat maps with clustering to present the relationship between various biomarkers according to their characteristics [34,63-65]. Furthermore, our system provides an interactive clustering heat map for health care. From the perspective of big data, users can evaluate their health status by using ML models and EMR databases. In addition to online health evaluation, in the future, this system could be implemented into different IoMT to assist medical practitioners in achieving real-time health evaluations and monitoring remote patients or patients in specific wards. For the heat map, the EMR data of users were grouped into clusters of patients with diseases in the database; they would then be classified as clinically high-risk objects requiring close attention in the clinical setting [34]. Therefore, whether it is applied in preventive medicine for health management, in a monitoring system for critical care, or in the telemedicine environment, our system can provide real-time monitoring and help predict patient conditions.

Limitations and Future Work

To the best of our knowledge, this is the first web-based machine learning system based on self-paid health examination subjects that can provide an online self-health evaluation for several common diseases (MetS, CKD, and liver diseases). The version 1.0 web-based system still has several limitations that may be improved in the next update. First, the 1.0 system is not yet ready for embedding into a hospital for real-time assessment. We are currently working on an improved system to accept unstructured data input and multimodal data, which are especially essential for the prediction of eye diseases such as macular degeneration. Second, the 1.0 system did not have a user login or account security function. Retrievable prediction and security will be improved as the system is matured for hospital embedment. Third, the 1.0 system does not have whole dynamic analyses such as an interactive decision tree; whole dynamic analyses will be incorporated in subsequent versions to improve communication between the medical staff and patients.

In the future, more clustering algorithms will be implemented in subsequent versions to make the prediction results more robust and reliable. Although the 1.0 system can currently only evaluate three chronic diseases (MetS, CKD, and liver diseases) frequently encountered in family medicine, more chronic disease prediction models, such as those for coronary artery disease, will be added in the near future.

Conclusion

We constructed an ML health monitoring system to offer an online health assessment service to medical units, telemedicine patients, and all health-conscious users worldwide. Our aim is that this system will be implemented in medical centers as a real-time patient monitoring system and provide regular health evaluations for telemedicine patients. Online users can now access our platform and use ML technology to estimate their health status, increasing self-health awareness.

Abstract

Background: As an innovative approach to providing web-based health care services from physical hospitals to patients at a distance, e-hospitals (ie, extended care hospitals through the internet) have been extensively developed in China. This closed health care delivery chain was developed by combining e-hospitals with physical hospitals; treatment begins with web-based consultation and registration, and then, patients are diagnosed and treated in a physical hospital. This approach is promising in its ability to improve accessibility, efficiency, and quality of health care. However, there is limited research on end users' acceptance of e-hospitals and the effectiveness of strategies aimed to prompt the adoption of e-hospitals in China.

Objective: This study aimed to provide insights regarding the adoption of e-hospitals by investigating patients' willingness to use e-hospitals and analyzing the barriers and facilitators to the adoption of this technology.

Methods: We used a pretested self-administered questionnaire and performed a cross-sectional analysis in 1032 patients across three hierarchical hospitals in West China from June to August 2019. Patients' sociodemographic characteristics, medical history, current disease status, proficiency with electronic devices, previous experience with web-based health services, willingness to use e-hospitals, and perceived facilitators and barriers were surveyed. Multiple significance tests were employed to examine disparities across four age groups, as well as those between patients who were willing to use e-hospitals and those who were not. Multivariate logistic regression was also performed to identify the potential predictors of willingness to use e-hospitals.

Results: Overall, it was found that 65.6% (677/1032) of participants were willing to use e-hospitals. The significant predictors of willingness to use e-hospitals were employment status (P=.02), living with children (P<.001), education level (P=.046), information technology skills (P<.001), and prior experience with web-based health care services (P<.001), whereas age, income, medical insurance, and familiarity with e-hospitals were not predictors. Additionally, the prominent facilitators of e-hospitals were convenience (641/677, 94.7%) and accessibility to skilled medical experts (489/677, 72.2%). The most frequently perceived barrier varied among age groups; seniors most often reported their inability to operate technological devices as a barrier (144/166, 86.7%), whereas young participants most often reported that they avoided e-hospital services because they were accustomed to face-to-face consultation (39/52, 75%).

Conclusions: We identified the variables, facilitators, and barriers that play essential roles in the adoption of e-hospitals. Based on our findings, we suggest that efforts to increase the adoption of e-hospitals should focus on making target populations accustomed to web-based health care services while maximizing ease of use and providing assistance for technological inquiries.

innovation adoption; e-hospital; internet hospital; eHealth; barriers; facilitators

Introduction

The vast majority of high-quality medical resources (eg, well-trained medical workers and advanced medical equipment) are focused in tertiary hospitals in the urban cities of China. This has led to a lack of patients in secondary hospitals and primary health care centers (PHCs), as well as overcrowding in tertiary hospitals. Consequently, patients in tertiary hospitals have long registration and queue times, long waiting times, long dispensary and payment queue times, and short physician visit times, coined as the “three long and one short” condition [1].

In order to reduce the unbalanced distribution of medical resources, China has developed a hierarchical medical treatment system, in which medical institutions of various levels receive and treat patients according to the severity and urgency of their diseases [2,3]. Specifically, tertiary hospitals treat patients with complex and urgent conditions, whereas secondary hospitals treat patients with common diseases. Providers in PHCs have the responsibility of chronic disease management, and they refer patients to specialists or hospitals when necessary [4]. However, despite a great amount of financial investment [5], many PHCs still have poor clinical performance and deficient medical knowledge, as they lack well-trained and qualified physicians [6,7]. Specifically, previous research has found that more than half of the health practitioners in China do not have a bachelor’s degree, and the education level is particularly low for providers in rural areas [8]. Therefore, crowds of patients continue to travel to overfilled top-level hospitals in pursuit of quality care at the cost of escalating health care expenditure and time [9].

Major developments in information and communication technology (ICT) and increased prevalence of electronic devices have enabled innovations in health delivery in developed countries, such as the United States, the United Kingdom, and Canada, particularly for low-resource and underserved communities [10-13]. The World Health Organization defines electronic health (eHealth) as “the use of ICT to support the delivery of health services and the management of health systems” [14]. Studies on eHealth interventions have found positive effects for various diseases, including symptom reduction, improved health care accessibility, and higher patient and clinician satisfaction [15-18].

Similar benefits have resulted from eHealth efforts in China as well [19]. As a priority eHealth project, e-hospitals were proposed by the National Health Commission of China as an innovative approach to health care service delivery in 2015 [20], and they were expected to alleviate the dilemmas regarding accessibility, cost, and quality [21]. There are two major kinds of e-hospitals. There are e-hospitals that are administrated by physical tertiary hospitals, where patients are able to reach physicians in these tertiary hospitals via the internet and are referred to PHCs or secondary hospitals in the region. Other e-hospitals are established by investment companies and have registered physicians from all over the country [22].

E-hospitals, also known as “extended care hospitals,” take the form of a smartphone app or website, and they represent a new approach to outpatient service delivery through the internet [23]. E-hospitals have strengthened the communication pathway between health specialists and patients by overcoming time and distance barriers. Through this technology, health care professionals are able to provide high-quality continuous services to their patients, improve disease management, have more frequent follow-ups, answer patient concerns, and receive appointment requests.

To access these health care services, individuals need to register their information, such as name, age, and gender, at their e-hospital of choice. Once registered, users are able to describe their condition via written text, voice message, or video, and upload relevant documents and laboratory images. This information is conveyed to specialized physicians in tertiary hospitals through a chat platform where the patient and physician can have a remote conversation. Depending on the condition, the physician may issue an e-prescription for users to purchase medicines at the linked web-based pharmacy or make an appointment at a nearby PHC or secondary hospital and provide instructions for treatment remotely. Lastly, e-hospitals can provide posttreatment care and monitoring for patients after they are discharged from a physical hospital [24]. E-hospitals make it possible for patients, regardless of their location, to communicate with skilled medical experts, which thereby improves the efficiency and accessibility of quality medical services while saving indirect health costs [23].

Over the past 4 years, 294 e-hospitals have been established in China to help distribute the health services of tertiary hospitals to patients in distant underserved areas [25]. However, this new medical technology has had a lower adoption rate than expected, as it did not appear to rid tertiary hospitals of the inefficiencies described by the “three long and one short” condition [26]. Furthermore, a large number of these e-hospital programs ended in the early stages due to lack of users [27,28].

The implementation cycle plays a critical role in the effective use of this new technology [29]. A primary issue regarding the implementation cycle of e-hospitals is the inadequate understanding of how to best facilitate individuals’ and organizations’ adoption of the technology [30]. Organizations may fail to successfully implement e-hospitals as a result of a lack of readiness [31,32], which is defined as the preparedness of health care users to adopt eHealth for the provision and management of health services [33]. A number of factors may impact user readiness, which thereby affects the success of eHealth programs and whether the desired health outcomes are achieved [34,35]. At the organizational level, factors, such as coordination with concerned stakeholders and proper training, can impact readiness for eHealth implementation [36,37].

Critical readiness-determining factors for health care providers include the intensity of their current workload and the perceived quality of the new technology [38]. Unsurprisingly, patient readiness is also essential to the success of the implementation cycle of eHealth interventions. Relevant research on this topic has been conducted in Western countries, and actions that overcome financial and technical barriers to facilitate successful adoption should be undertaken [39-42]. Even though these patient attitudes toward eHealth projects can to some extent be contextualized to other countries [43], the lack of studies directly assessing the Chinese population leads to ambiguous policy suggestions for health care administrators and managers of e-hospitals in China.

Taking all these factors into account, this study aimed to (1) examine how familiar patients in Western China are with e-hospitals and how willing they are to adopt the technology; (2) investigate the potential factors that influence patient adoption of e-hospitals; and (3) explore various patient perceptions of the advantages and disadvantages of using e-hospitals. We intended for our results to provide evidence-based insights for policy regarding the integration of e-hospitals into China's health care system and ultimately deepen the adoption of e-hospitals in China.

Methods

Setting and Ethical Consent

This cross-sectional study was conducted in three hospitals in Chengdu, the capital of Sichuan province, located in West China, with a population of roughly 83.4 million people [44]. For context, there are more PHCs in Sichuan than any other province in China [45]. In an attempt to mitigate selection bias, the study included patients from all hospital tiers as follows: a tertiary hospital (West China Hospital of Sichuan University), a secondary hospital (First People's Hospital of Longquan District), and PHCs (Community Health Centers of Chenghua District). Institutional review board approval was obtained from the Research Ethics Committee of the West China Hospital, Sichuan University.

Study Design and Population

All adult patients (aged 18 years or above) presenting at the aforementioned hospitals from June to September 2019 were asked to complete an anonymous self-administered questionnaire in the physicians' offices of corresponding departments. No restriction for patients' diseases or health care status was an approach to remediate selection bias in our study. Respondents were provided with information about the objectives and scope of the survey and were asked, without incentives, to provide consent to participate in the study. Those who agreed to participate were administered the questionnaire by a research investigator, and careful attention was paid that the participants were not in physicians' offices to avoid potential discomfort. Since acute illnesses are explicitly excluded from e-hospital treatment, patients who went through an emergency procedure were not eligible to participate.

Instrumentation

Our survey (Multimedia Appendix 1) involved multiple-choice questions divided into the following five categories: (1) sociodemographic and disease characteristics; (2) current usage of electronic devices; (3) previous experience with web-based health care services; (4) willingness to use e-hospitals; and (5) perceived facilitators or barriers regarding e-hospital use. More specifically, depending on the response to part 4, in part 5, participants were asked either what encourages their e-hospital usage or what deters it.

We developed the questionnaire based on a literature review of relevant studies [46,47]. To ensure its validity, we pilot tested the questionnaire using two complementary approaches. First, the questionnaire was evaluated by five experts in the fields of hospital administration, medical informatics, and health care policy, and suggestions were used to increase clarity. Second, we pilot tested the questionnaire with 20 patients and used their feedback to make adjustments to the questionnaire.

Measures

Our survey consisted of multiple-choice questions regarding sociodemographic, medical, and eHealth usage–related variables. The variables analyzed were age, gender, level of education, employment status (working vs retired), household location (Chengdu vs outside Chengdu), monthly income, and type of medical insurance. Age ranges were selected based on the categorization by the National Bureau of Statistics of China. To clarify, urban employee health insurance is mainly funded by a person's employer, whereas rural and urban resident health insurances are mainly funded by government subsidies [48]. The response options for monthly income were stratified into four groups (<2000; 2000-5999; 6000-10,000; and >10,000 CNY) [49]. Furthermore, data about whether participants had chronic diseases were recorded to represent the long-term health demand for chronic disease management. Whether a participant had an operation was also recorded to indicate the eventual need for postoperative rehabilitation care.

Furthermore, information technology (IT) skills and living with children (yes vs no) were surveyed to measure participants' technical skills and the potential for technical support from younger generations, respectively. Overall IT proficiency was measured by evaluating responses regarding "number of owned electronic devices," "capability to connect to Wi-Fi," and "capability to install apps." Each category was given a score of 0 to 5, and then, the scores were summed in order to generate an overall IT score. For binary questions, a score of 0 was given to a "no" response and 5 was given to a "yes" response.

Additionally, participants were asked if they had previous experience with web-based health services (yes vs no). Respondents with previous experience were then asked to indicate the extent of their satisfaction on a 5-point Likert scale (5, extremely satisfied; 4, satisfied; 3, neutral; 2, dissatisfied; and 1, extremely dissatisfied). For evaluation of familiarity with e-hospitals, another 5-point Likert scale was used (5, extremely familiar; 4, quite familiar; 3, know a little bit; 2, only heard the term; and 1, never heard the term).

Data Collection and Entry

Four trained research staff distributed the paper-based questionnaires to participants. They followed a verbal script and were instructed to address any potential doubts related to the topics covered by the questionnaire. To confirm that the questionnaire was completely filled out, researchers reviewed the responses immediately after the participant completed the questionnaire.

Two authors (PL and YL) experienced in data entry independently entered all case record data into EpiData (version 3.1, EpiData Software). The two Excel spreadsheets were then compared and discrepancies were resolved by checking the original questionnaires, eventually reaching a consensus between the two authors.

Data Analysis

For statistical analysis, categorical variables were expressed as frequencies and percentages, and continuous variables were expressed as mean values with standard deviations. Descriptive analyses, including the chi-square test, Kruskal-Wallis test, Fisher test, *t* test, and variance analysis, were performed according to the data characteristics. Specifically, multiple significance tests were employed to examine whether there existed differences across age groups. Similarly, statistical significance tests were conducted to examine the association between all other variables and the willingness to use e-hospitals.

Furthermore, a multivariate logistic regression analysis with a range of variables was performed to identify potential indicators of patients' willingness to use e-hospitals. All variables in the descriptive analysis of the willingness to use e-hospitals were included in the multivariate logistic regression model. Variables with a two-tailed *P value* <.05 were considered statistically significant. Additionally, a chi-square test was employed to analyze age-related variations in perceived facilitators and barriers.

All statistical analyses were performed using SPSS (version 25, IBM Corp).

Results

Participants

A total of 1108 patients completed the survey after 43 patients refused to respond. Seventy-six patients were excluded due to incomplete responses. Overall, this study had a high response rate of 89.7% (1032 patients).

Sociodemographic and Medical History

The descriptive analysis in Table 1 shows that socioeconomic attributes varied across age groups. Among the participants, 44.4% (458/1032) were male. Among those aged 18 to 34 years, the number of female participants (166/260, 63.8%) was nearly double that of male participants (94/260, 36.2%), although there appeared to be slightly more male participants (139/276, 50.4%) than female participants (137/276, 49.6%) among those aged 65 years or older. In addition, younger participants were more educated than older participants (*P*<.001). Specifically, 64.2% (167/260) of participants aged 18 to 34 years had attended college or above, whereas this was only true for 14.1% to 37.0% of participants in the other three age groups.

The proportion of retired individuals was significantly higher among those aged 65 or older (270/276, 97.8%) than among the other age groups (50-64 years: 164/258, 63.6%; 35-49 years: 21/238, 8.8%; 18-34 years: 4/260, 1.5%). In addition, participants' monthly income appeared to decline with age (*P*<.001).

Moreover, 55.7% (575/1032) of participants reported living outside of Chengdu. Participants aged 35 years or older appeared to be more likely than younger participants to seek health care services in Chengdu despite not living there (18-34 years: 109/260, 41.9%; 35-49 years: 150/238, 63.0%; 50-64 years: 160/258, 62.0%; 65 years or older: 156/276, 56.5%; *P*<.001). Additionally, nearly half of the older participants did not live with children (50-54 years: 142/256, 55.0%; 65 years or older: 128/276, 46.4%; *P*<.001).

Table 1 also shows that medical history varied across age groups. Older participants appeared to be more likely to have chronic diseases; over 64.9% (179/276) of those aged 65 years or older reported having chronic diseases, whereas this was reported by only 8.5% (22/260) of those aged 18 to 34 years (*P*<.001). Nearly half of the participants (500/1032, 48.4%) underwent an inpatient surgery, and of these, the majority were aged 35 to 64 years. Finally, younger participants more frequently had employee and urban resident insurance than rural and other types of insurance, whereas older participants more frequently had rural resident insurance (*P*<.001).

Current Usage of Electronic Devices and Web-Based Health Care Services

Results in Table 2 show that younger participants were generally more active in web-based activities. Overall, the mean number of electronic devices owned by those aged 18 to 34 years was 2.4 (SD 1.24) and those aged 65 years or older was 0.54 (SD 0.75) (*P*<.001). Meanwhile, 81.9% (226/276) of those aged 65 years or older reported that they were unable to connect their electronic devices to Wi-Fi and 92.4% (255/276) of these participants also indicated that they did not know how to install a new app.

In addition, there was a statistically significant association between previous usage of web-based medical services and age (*P*<.001). Specifically, 90.8% (236/262) of participants aged 18 to 34 years reported that they had at least once received health services over the internet, whereas this was reported by only 15.9% (44/276) of participants aged 65 years or older. Meanwhile, 83.1% (463/557) of current users indicated that they were satisfied with their web-based medical experiences. Lastly, the proportion of individuals who had never heard of e-hospitals was significantly lower among those aged 18 to 34 years (59/260, 22.7%) than among those aged 65 years or older (241/276, 87.3%).

Table 1. Sociodemographic and medical history of the study participants.

Characteristic	Total value	Age stratification in years				*P* value
		18-34	35-49	50-64	≥65	
Sample size, n	1032	260	238	258	276	
Gender, n (%)						.002[a]
Male	458 (44.4)	94 (36.2)	98 (41.2)	127 (49.2)	139 (50.4)

Willingness to Use E-Hospitals

It was found that 65.6% (677/1032) of participants were willing to use e-hospitals to manage their disease (Table 3). The results suggested that willingness to use e-hospitals was associated with age (*P*=.04), education level (*P*<.001), employment status (*P*<.001), monthly income (*P*<.001), living with children (*P*<.001), medical insurance type (*P*<.001), chronic diseases (*P*<.001), skillful IT operation (*P*<.001), previous experience of web-based health care services (*P*<.001), and familiarity with e-hospitals (*P*<.001) (Table 3).

Table 4 presents the results of the multivariate logistic regression analysis of the willingness to use e-hospitals (all variables from Table 3 were included). The results showed that age did not make a difference after controlling for covariates in the model. Similarly, variations in monthly income, medical insurance type, chronic diseases (yes vs no), and familiarity with e-hospitals could be explained by other covariates.

In contrast, employment status, education level, living with children, IT skills, and previous experience with web-based health care were closely associated with the willingness to use e-hospitals (Table 4). Specifically, employed participants were 1.88 times more likely to be willing to use e-hospitals compared to retired participants (95% CI 1.11-3.18) after adjusting for all other covariates in the model. Furthermore, participants with higher education were more likely to be willing to use e-hospitals (junior high school: OR 1.95, 95% CI 1.21-3.15; senior high school: OR 1.84, 95% CI 1.00-3.37; college or above: OR 2.16, 95% CI 1.09-4.28). In addition, participants living with children had a higher likelihood of being willing to use e-hospitals compared to those living without children (OR 1.88, 95% CI 1.34-2.64). Furthermore, participants with higher IT skills had a higher probability of being willing to use e-hospitals (OR 1.11, 95% CI 1.05-1.17). Lastly, participants with previous experience of using web-based medical services were 2.69 times more likely to be willing to use e-hospitals (OR 2.77, 95% CI 1.80-4.26).

Perceived Facilitators for Users and Barriers for Nonusers

The vast majority of participants considered convenience (641/677, 94.7%) to be a major facilitator for e-hospital adoption. The next most popularly agreed upon facilitator was improved access to skilled experts (489/677, 72.2%), followed by improved health outcomes (184/677, 27.2%), privacy protection (180/677, 26.6%), and active participation in disease self-management (144/677, 21.3%). Furthermore, differences in terms of perceived facilitators and barriers appeared to exist across age groups (Figure 1). It was notable that younger participants (aged 18-34 years) showed greater interest in improved health outcomes (79/208, 37.98%; *P*<.001), privacy protection (103/208, 49.5%; *P*<.001), and disease self-management (74/208, 35.8%; *P*<.001) as compared with the other three age groups. In addition, participants aged 50 to 64 years appeared to show greater interest in convenience

(165/167, 98.8%; *P*=.04). There was no relevant difference in interest regarding improved accessibility to skilled experts across the age groups (*P*=.32).

The barriers reported were inability to operate electronic devices (238/355, 67.0%), familiarity with face-to-face health care (108/355, 30.4%), doubts regarding the authenticity and reliability of e-hospitals (86/355, 24.2%), useless perceptions about e-hospitals (37/355, 10.4%), and concerns with insurance reimbursement (27/355, 7.6%). The older groups (aged over 65 years) showed greater concerns with regard to the operation of electronic devices (144/166, 86.7%; *P*<.001) as compared with the other groups (Figure 2). Those aged 35 to 49 years showed more concerns about the authenticity and reliability of e-hospitals (16/46, 34.8%; *P*=.046). Furthermore, young participants (aged 18-34 years) most often reported that they were reluctant to use e-hospitals because they were accustomed to face-to-face treatment (39/52, 75.0%; *P*<.001) and were concerned about insurance reimbursement (13/52, 25.0%; *P*<.001). Lastly, there was no age-related difference when considering “unhelpful for my specific disease” (*P*=.39).

Figure 1. Perceived facilitators for users (%).

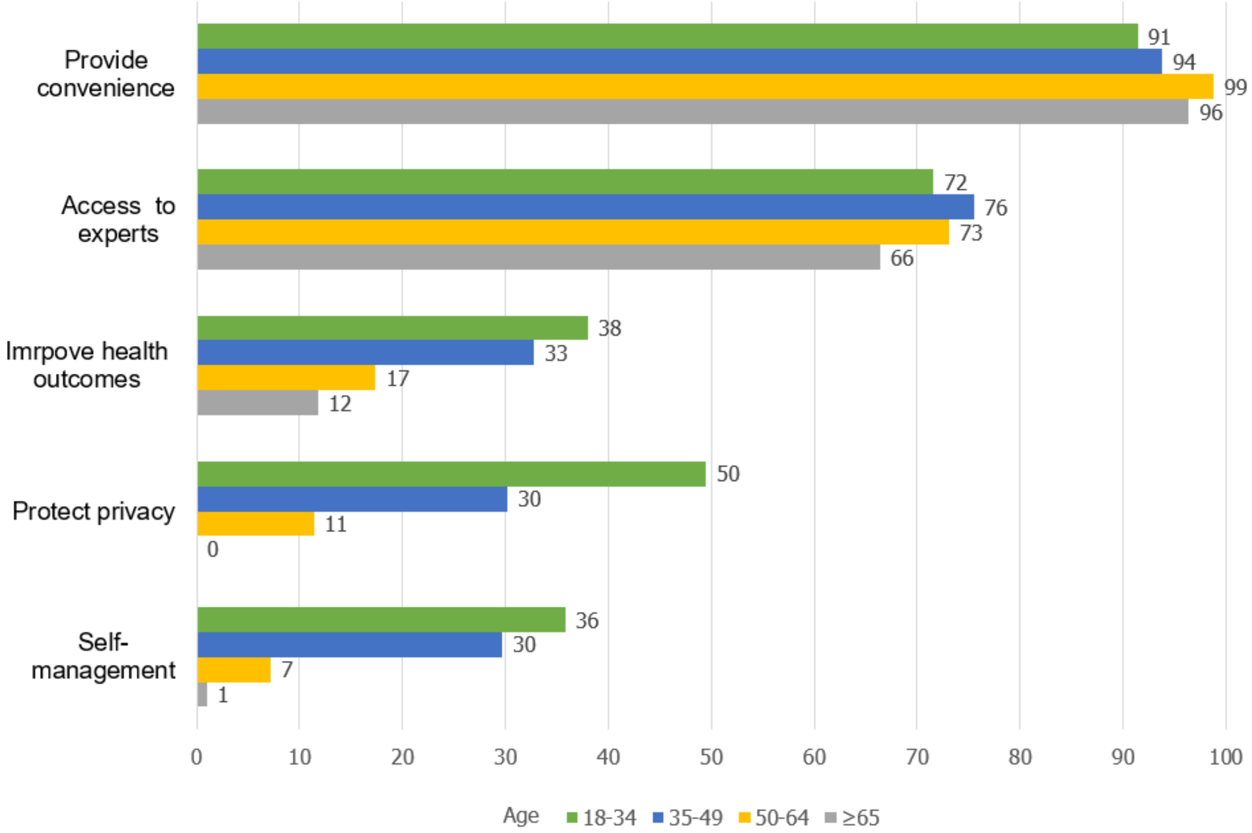

Figure 2. Perceived barriers for non-users (%).

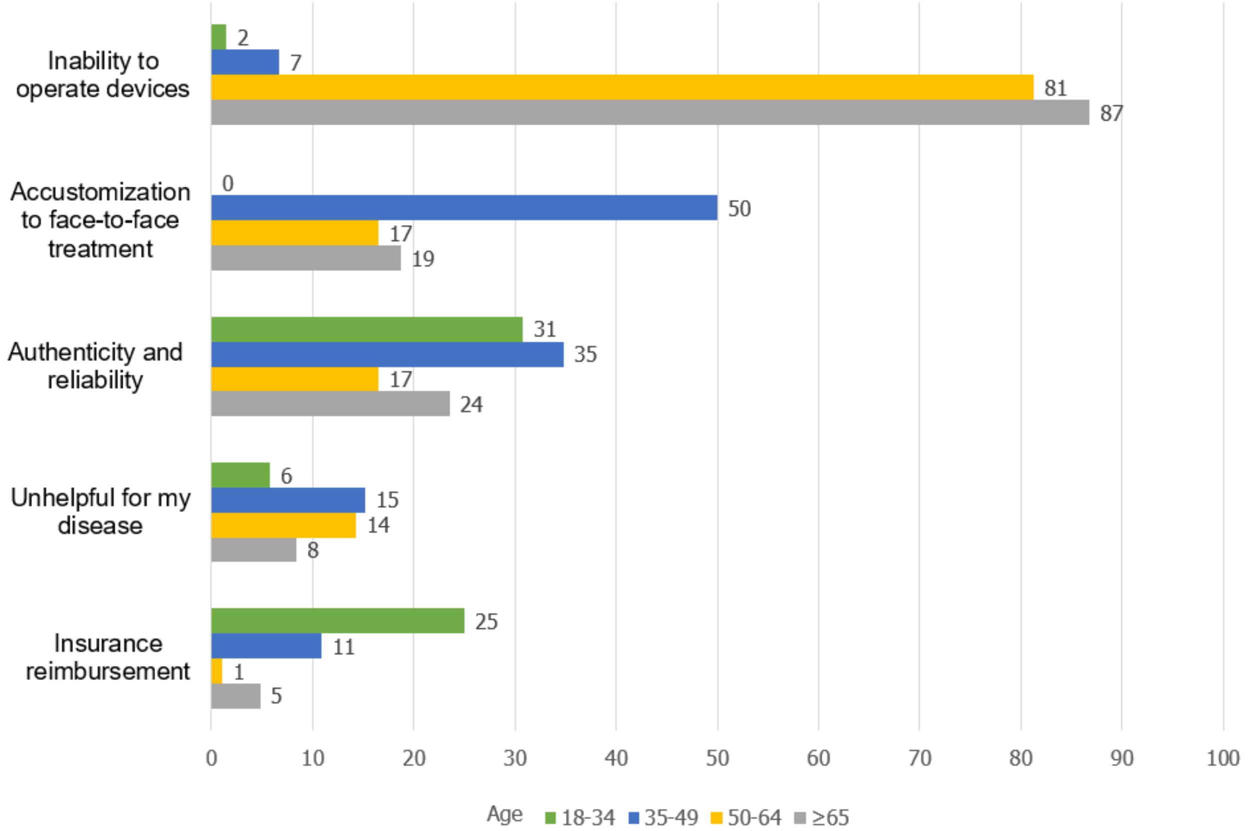

Discussion

Study Importance

Research has shown that eHealth programs hold promise for improving health care accessibility and quality [50]; however, this success is contingent on patient acceptance. Therefore, the factors impacting the extent to which people are willing to engage with new eHealth interventions need to be understood in order to facilitate the adoption of these technologies [51,52]. This is the first survey to assess patients' attitudes, facilitators, and barriers toward e-hospital adoption and to provide related insights for decision makers about the essential factors necessary for successful adoption of e-hospitals in China's health care system.

Principal Findings: Part 1

Our results demonstrated that few patients in China know about e-hospitals and even fewer have experience using them. The proportion identified as familiar with e-hospitals (22.2%) in this study is consistent with what has been previously found for this region (18.6%) [53]. Both the prior study and our study indicate that urgent actions should be carried out to ensure broader awareness and familiarity with e-hospitals.

The health care needs and expectations of the older population have reached an unprecedented high in China as a result of reduced mobility and increasing morbidity [54]. In light of this, e-hospitals were theorized as a solution for increasing the efficiency of health care among elderly patients. Although previous research has shown that younger individuals are more likely to use web-based health tools [55,56], our results indicate that this age disparity regarding e-hospital readiness is based on technological proficiency. This may be explained by the pervasiveness of electronic devices in the modern age, which has caused young people to be more technologically proficient as compared with other generations. Nonetheless, this indicates that individuals ordinarily willing to use mobile health, such as elderly patients, may be deterred due to concerns regarding their ability to use technological devices [57,58]. Therefore, even though there is a growing number of e-hospital apps available to support elderly patients in China, their effectivity will likely be minimal unless such apps are designed to be user friendly and accessible for elderly populations.

In addition, our findings revealed that elderly people living with younger generations have higher usage of e-hospitals. This may be related to the fact that seniors living with children are able to get additional instructions and help from relatives. This finding is important, since in recent years, the one-child policy has contributed to reduced family size and an increase in the number of elderly "empty nesters" who are childless or whose children have already left home [59]. As a result, empty nesters' adoption will be a critical issue given that they are less likely to have access to technical support [60]. Therefore, it would be beneficial to provide solutions, such as offering e-hospital technical services at hospitals and over the internet, to facilitate e-hospital adoption for those who have minimal technological skills [61].

We found that educational disparity is an important determinant of the adoption of e-hospitals, which echoes the findings of previous research [62]. This finding once again underlines the importance of user-friendly interfaces and suggests that app developers should take the needs of people with any education level into account to further minimize the "digital gap" between users and nonusers [63].

Our results also indicated that working participants were more willing to use e-hospitals. This is unsurprising due to the time constraints work imposes on individuals and the convenience of e-hospitals. This is also in accordance with the results of previous studies that found employed individuals to be more interested in eHealth [62]. This indicates that modifying the opening hours of e-hospitals to better accommodate employed patients may play an important role in facilitating adoption.

Furthermore, we found that patients who had previous experiences with web-based medical services expressed positive interest toward e-hospital services. Our findings are in line with the results of previously published surveys, which found correlations between positive attitudes toward web-based health services and interest in eHealth in other contexts [64,65]. However, we found that patients requiring long-term disease management and postoperative rehabilitation did not have much higher willingness to use e-hospitals. This reluctance is congruent with the results of a previous survey that reported low interest toward telemedicine among patients with chronic lung disease [66]. One possibility is that patients with long-standing diseases or poor health conditions are less likely to trust a new less-mature health care delivery model, since they are more aware of the importance of regular thorough self-examination and follow-up. Regardless, these results were not expected, and they contradict one of the aims of e-hospitals, which is to heighten the efficiency and accessibility of chronic disease management and postoperative rehabilitative services. Given that there existed a positive correlation between previous experience with web-based health services and willingness to use e-hospitals, we suggest offering patients who have chronic illnesses or have undergone surgery a cost-free opportunity to get acquainted with e-hospital apps in order to encourage their usage and improve the success of this aim [67].

Principal Findings: Part 2

Research has shown that receptive patients are most encouraged by the convenience brought about by telemedicine [68], which is consistent with our findings and the current priority of e-hospitals.

However, there was less confidence regarding the "improve health outcomes" facilitator, given that a number of patients reported resistance to e-hospitals due to unassured authenticity and reliability of e-hospitals. Creating an effective e-hospital and integrating it into the system of physical hospitals is a complex endeavor that requires a multipronged strategy that addresses technical and operational issues constrained by local factors. For instance, maintaining the quality of nonprofit medical services is particularly challenging for e-hospitals constructed by for-profit companies. Therefore, establishing a government supervision mechanism [69] and increasing communication among stakeholders may play a key role in assuring the quality of adoption [70]. In addition, evaluation efforts should incorporate robust measures to document the outcomes of e-hospitals and establish a pathway for quick resolution of reported issues.

Given that privacy protection was one of the prominent facilitators for the use of e-hospitals among young individuals, cybersecurity must be prioritized in e-hospitals in order to prevent reluctance to adoption among patients [71,72]. This is substantiated by research [73] reporting that patients were worried about privacy protection when physicians used mobile devices and were particularly concerned with the possibility of individual health data and personal information being exposed. Therefore, we recommend that e-hospitals invest in cybersecurity capability development [74].

Moreover, insurance reimbursement is a key barrier, yet it has not been addressed by any of the 158 e-hospitals in China. In a study conducted in New York, it was reported that nearly half of users stopped using health care apps because of extra costs [46]. To avoid a similar situation, China's National Healthcare Security Administration should accelerate the pace of integrating e-hospitals into the public medical insurance reimbursement scheme [75].

Strengths, Limitations, and Future Research

This study has several strengths. First, the sample was relatively large and widely representative, which provided the opportunity for accurate examination of potential variations. Second, participants in the study were very sociodemographically and medically diverse, which allowed for in-depth analysis of variations in attitudes toward e-hospitals among a broad range of patients.

Despite the strengths, this study has several limitations. First, our sampling method was not randomized, and we used convenience sampling, such that participants were patients who happened to visit the hospitals of interest during the period of the survey. Consequently, our results are at risk of having statistical bias. Second, we did not collect text explanations in the survey, which thereby limited the possibility to investigate other facilitators and barriers to the adoption of e-hospitals. Third, as this was a pilot study, our results may not be generalizable to other regions with different sociodemographic characteristics, since we only included patients within one specific context of West China. However, it provided a preliminary analysis, and more research is needed to understand the complexity of the adoption of e-hospitals in China and elsewhere. Additional research will need to be conducted to better understand attitudes toward e-hospitals in other regions. Another limitation is the noninclusion of patients who underwent emergency procedures, and thus, our results do not take into account the possible intricacies of this cohort. Furthermore, this study does not provide insights into the attitudes of those who chose to not participate or complete the questionnaire; therefore, the specific needs and barriers of these users are unknown. We also did not record the demographics of nonresponders. Moreover, we measured connectivity to the internet using Wi-Fi, which is a common approach in the region; however, other forms of connectivity (eg, direct internet access through SIM cards) should be studied. It is hence plausible that there were limitations with the instrument and the collected data.

The integration of e-hospitals into China’s health care system requires an adequate understanding of not only patient attitudes toward acceptance but also the effects of such interventions. Although we identified several themes that can guide the research and technological development of e-hospitals, this study did not elucidate the potential risks of the application of this new technology. To maximize acceptability and usability, future research should focus on user testing with specific e-hospital prototypes. Such user testing should consider including a wider sample of the population, as well as measure the health care outcomes of e-hospital use. In addition, cost-effectiveness analysis is encouraged. Lastly, since the involvement of multiple stakeholders is essential to achieve effective adoption, implementation, and maintenance for systems in practice [76,77], further studies should consider the perspectives of various stakeholders, such as physicians and nurses.

Acknowledgments

This work was supported by the National Natural Science Foundation of China (grant: 71874115) and the Science & Technology Department of Sichuan Province, China (grant: 2018KZ0046 and 2017FZ0104). The funder had no role in the design of the study; collection, analysis, and interpretation of data; or writing of the manuscript. We sincerely thank the three medical institutions and all participating individuals for helping conduct the survey. Additionally, we would like to thank all those who shared their perspectives throughout this study. We would like to acknowledge Dr Li Ma, Dr Yan Jiang, and Dr Zi Liu for their clinical assistance with this research. We would also like to sincerely acknowledge Mr Guanhua Qing for his assistance in improving this article.

Authors' Contributions

PL conceived and designed the study and questionnaire, carried out the survey and statistical analysis, and drafted the manuscript. YL was involved in the design of the questionnaire and was in charge of data collection and entry. XY performed the statistical analysis and interpretation of the data. JW helped with the design of the questionnaire. EM and MSJ consulted with the analysis and interpretation of the results, contributed to further development of the analysis and content, and revised the manuscript for important intellectual content. WL was the principal designer of the study and was responsible for all results of the study, as well as review and approval of the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Survey questionnaire for patients’ perceptions of barriers and facilitators to the adoption of e-hospitals.

Abstract

Background: Although the most effective methods of contraception are available in Bolivia, unmet need for contraception among women aged 15 to 19 years is estimated to be 38% (2008), and the adolescent fertility rate is 71 per 1000 women (2016). Mobile phones are a popular mode to deliver health behavior support. We developed a contraceptive behavioral intervention for young Bolivian women delivered by mobile phone and guided by behavioral science. The intervention consists of short instant messages sent through an app over 4 months.

Objective: This trial aimed to evaluate the effect of the intervention on young Bolivian women’s use of and attitudes toward the effective contraceptive methods available in Bolivia.

Methods: This was a parallel group, individually randomized superiority trial with a 1:1 allocation ratio. Women were eligible if they were aged 16 to 24 years, owned a personal Android mobile phone, lived in La Paz or El Alto, reported an unmet need for contraception, and could read Spanish. The target sample size was 1310 participants. Participants allocated to the intervention had access to an app with standard family planning information and intervention messages. Participants allocated to the control group had access to the same app and control messages. Coprimary outcomes were use of effective contraception and acceptability of at least one method of effective contraception at 4 months. Secondary outcomes were use of effective contraception during the study, acceptability of the individual methods, service uptake, unintended pregnancy, and abortion. Process outcomes included knowledge, perceived norms, personal agency, and intention. Outcomes were analyzed using logistic and linear regression. We also asked participants about physical violence.

Results: A total of 640 participants were enrolled, and 67.0% (429) of them contributed follow-up data for the coprimary outcome, the use of effective contraception. There was no evidence that use differed between the groups (33% control vs 37% intervention; adjusted odds ratio [OR] 1.19, 95% CI 0.80 to 1.77; *P*=.40). There was a borderline significant effect regarding acceptability (63% control vs 72% intervention; adjusted OR 1.49, 95% CI 0.98 to 2.28; *P*=.06). There were no statistically significant differences in any of the secondary or process outcomes. The intervention dose received was low. In the control group, 2.8% (6/207) reported experiencing physical violence compared with 1.9% (4/202) in the intervention group (Fisher exact test *P*=.75).

Conclusions: This trial was unable to provide definitive conclusions regarding the effect of the intervention on use and acceptability of effective contraception because of under recruitment. Although we cannot strongly recommend implementation, the results suggest that it would be safe and may increase the acceptability of effective contraception if the intervention messages were offered alongside the download of the app.

Trial Registration: ClinicalTrials.gov NCT02905526; https://clinicaltrials.gov/ct2/show/NCT02905526

KEYWORDS

Bolivia; contraception; mobile phone; cellphone; reproductive health; young adults

Introduction

Unintended pregnancy is associated with numerous poorer health outcomes for both women and their children [1-5]. Satisfying the unmet need for contraception is essential in helping women avoid unintended pregnancies, which requires an understanding of the barriers to use in specific settings [6]. A woman who has an unmet need for contraception is of reproductive age (15-49 years); is legally married, cohabiting, in a consensual union, or unmarried and sexually active; is not using any method of contraception; and is fecund and does not want to have a child (or another child) in the next 2 years or at all [6]. Modern contraceptive methods include oral contraceptives, injectables, intrauterine devices (IUDs), implants, the patch, the ring, male and female sterilization, male and female condoms and other barrier methods, modern fertility awareness methods, and emergency contraception [7]. *Effective* contraceptive methods are methods with less than 10% typical use failure rate at 12 months, that is, all modern methods besides condoms, other barrier methods, and modern fertility awareness methods [8,9].

In Bolivia, the latest Demographic and Health Survey (2008) reported that 85% of sexually active women aged between 15 and 19 years wanted to avoid a pregnancy, yet only 49% of these women reported using any contraceptive method [10]. Male condoms and the injection were the most common modern methods reported by this group (19.6% and 6.2%, respectively), with 2% reporting that they use withdrawal and 13% using periodic abstinence. A more recent survey (2016) reported that the adolescent fertility rate was 71 per 1000 women [11]. The 2016 survey found that among unmarried, sexually active women aged 15 to 19 years, an estimated 34% were not using any method of contraception [11], which was down from 52% in the 2008 survey [10]. Although unmet need may have changed since, the most recent data from 2008 suggest that unmet need among women aged 15 to 19 years was estimated to be 38% [10,12]. The (nonpermanent) effective methods available in Bolivia are oral contraceptive pills, IUDs, injectables, implants, and the patch. These methods are available for a fee (between US $1.50 and US $3.00) at the Centro de Investigación, Educación y Servicios (CIES), our partner organization, which operates 18 clinics in 7 of the 9 departments in the country. The public health care system provides only condoms to young people; however, young people usually buy condoms from private pharmacies.

The option of delivering health interventions by a mobile phone has gained popularity, particularly over the last decade [13-24]. Using mobile phones to deliver support to young people regarding sexual and reproductive health at the time of their choosing may be particularly useful, given the sensitivity of the topic. Randomized controlled trials have provided evidence that interventions delivered by a mobile phone can improve contraceptive use [25-27] and knowledge [25,28-30]. Other trials, however, have not found a beneficial effect [31-35]. The mixed evidence could be because of variability in the quality of the intervention development (eg, the target group may not have been adequately consulted), the content of the intervention (eg, the intervention content was not grounded in theory or behavioral science), and trial methodology.

The London School of Hygiene & Tropical Medicine (LSHTM) and CIES developed a contraceptive behavioral intervention for young Bolivian women delivered by mobile phone [36]. We developed the intervention guided by an established approach grounded in behavioral science [37]. The intervention is informed by the Integrated Behavioral Model (IBM) [38] and consists of short instant messages sent through CIES's *Tú decides* app over 4 months. In this report, we present the results of the evaluation of the intervention by randomized controlled trial. The aim of the trial was to establish if the intervention increases young Bolivian women's use and acceptability of the effective contraceptive methods.

Methods

Study Design and Participants

The methods reported in this section were first published in the trial protocol [39] and the statistical analysis plan [40].This was a parallel group, individually randomized superiority trial with a 1:1 allocation ratio that evaluated the effect of the intervention delivered by CIES's app. Women were eligible to take part if they were aged 16 to 24 years, owned a personal Android mobile phone, lived in La Paz or El Alto, reported an unmet need for contraception (ie, are sexually active, not using effective contraception, and want to avoid a pregnancy), and could read Spanish. Participants must have been willing to download the app and receive messages about contraception on their mobile phone. The trial was promoted through CIES's service delivery points in La Paz and El Alto, the CIES website, flyers distributed through CIES's youth network, and social media sites. Participants provided informed consent through the secure web-based trial database and randomization system.

Ethics Approval and Consent to Participate

The trial was granted ethical approval by LSHTM Interventions Research Ethics Committee on May 16, 2016, and by La Comisión de Ética de la Investigación del Comité Nacional de Bioética on September 20, 2016.

Intervention and Control

The intervention was developed with young Bolivian people in 2015 to 2016, guided by a systematic protocol for the development of behavior change interventions [36]. The development process involved the following steps: (1) needs assessment (activities included establishing a project planning group, a literature search, focus group discussions, and interviews with the target group and interviews with local service providers), (2) specifying behavioral change to result from the intervention, (3) designing the intervention components by selecting behavior change methods, and (4) producing and refining the intervention content. The needs assessment revealed that young people in El Alto and La Paz were eager to receive information about contraception on their phone, lacked comprehensive knowledge about contraception, and expressed a range of negative beliefs about effective methods. The intervention messages were tested with young people and refined after each consultation in an iterative process until the context was acceptable to them.

The intervention provided accurate information about contraception, targeted the beliefs identified in the development phase that influence contraceptive use (eg, specific misconceptions about the side effects and health risks of contraception), and aimed to support young women in believing that they can influence their reproductive health. The messages contained 10 behavior change methods [41], adapted for delivery by mobile phone: belief selection, facilitation, anticipated regret, guided practice, verbal persuasion, tailoring, cultural similarity, arguments, shifting perspective, and goal setting. Participants allocated to the intervention group received 0 to 3 messages per day (a total of 183 messages) for 120 days. Please see the protocol [39] and the intervention development publication [36] for a more detailed description of the intervention.

The Tú decides app itself contained standard family planning information and no behavior change methods. Participants allocated to the intervention arm had access to the app and the intervention instant messages. Participants allocated to the control arm had access to the Tú decides app and 7 control instant messages about the importance of their participation and reminding them to contact the project coordinator if they change their number (which intervention participants also received). All participants who received usual care were free to seek any other support, whether existing or new.

Allocation and Intervention Delivery

After providing informed consent, participants completed the baseline questionnaire through the database and randomization system. The allocation sequence was generated by the remote computer-based randomization software. Randomization occurred immediately after baseline data were submitted. All participants downloaded the app immediately after they submitted their baseline data. The messages commenced within 24 hours after participants downloaded the app.

Protecting Against Bias

Owing to the nature of the intervention, participants would have been aware of the allocation soon after they started receiving the messages. Local research staff collecting outcome data were masked to allocation unless the participant revealed it to them. Researchers who analyzed the data were masked to treatment allocation.

Outcomes

Coprimary Outcomes

The coprimary outcomes at 4 months post randomization were (1) self-reported current use of effective contraception and (2) the proportion of participants reporting that at least one method of effective contraception was acceptable. The primary outcome measure was constructed based on guidelines for measuring IBM constructs [38,42,43] and tested for face validity with the target group. The acceptability of each method was measured by the following stems: “Using the [method] ...causes infertility, ...causes unwanted side effects, ...is easy, ...is a good way to prevent pregnancy” and “I would recommend the [method] to a friend.” The IUD and implant include an additional stem: “The [method] insertion would not be a problem for me.” The response options for each stem were “strongly disagree,” “disagree,” “not sure,” “agree,” “strongly agree,” and “I do not know what the [method] is.” A method was acceptable if participants reported “agree” or “strongly agree” for all scales except for “...causes infertility” and “...causes unwanted side effects” stems, for which “disagree” or “strongly disagree” indicated acceptability [39].

Secondary Outcomes

The following secondary outcomes were self-reported: use of effective contraception at any time during the study, acceptability of each effective contraception method, attendance at a sexual health service during the study, unintended pregnancy during the study (the proportion reporting that they became pregnant and they did not want to become pregnant), and abortion during the study.

Process Outcomes

The following process outcomes were self-reported: knowledge of effective contraception, perceived norms, and personal agency in relation to using and communicating with partners about contraception, intention to use effective contraception, and intervention dose received.

Data Collection

Data were collected at baseline and at 4 months post randomization using questionnaires. At baseline, we collected personal and demographic data and the coprimary outcome acceptability. At follow-up, we collected all outcomes and the following: if participants report using an effective method, where they obtained it; current pregnancy intention; whether they knew someone else who had also participated in the study and, if so, if they read each other’s messages; and to assess potential adverse outcomes, we asked participants if they have experienced physical violence since being in the study and if anything good or bad happened as a result of receiving the messages. An instant message that included a link to the database to complete the follow-up questionnaire was sent to all participants through the app 4 months after downloading the app. If participants did not complete the follow-up questionnaire themselves, local research staff unaware of participants’ allocation contacted them by telephone to collect their data.

Sample Size

The trial was powered to detect a 10% absolute difference in the use of effective contraception between the intervention and control groups at 4 months. The 10% difference was based on a trial evaluating a postabortion mobile phone intervention, which found that 18% more women in the intervention arm than those in the control arm were using effective contraception at 4 months (64% vs 46%) [27]. We assumed that our trial would observe a smaller increase in contraceptive uptake, as it does not specifically involve women who had just had an abortion, who had already accessed services, and who may also have a greater intention to use contraception compared with the women in our trial. Therefore, we powered our trial to detect a smaller absolute difference of 10% uptake in effective contraception at 4 months.

The best estimate at the time of designing the trial was that the proportion of women aged 16 to 24 years in a partnership living in La Paz or El Alto using effective contraception was around 44% [44]. In total, 1048 participants provided 90% power to detect a 10% absolute difference, at the 5% significance level, assuming 44% use in the control group versus 54% in the intervention group (corresponding to an odds ratio [OR] of 1.49). Allowing for 20% loss to follow-up, the sample size was 1310.

Statistical Analysis

The trial protocol was accepted for publication on November 3, 2017 [39], and the detailed statistical analysis plan was publicly released on November 7, 2017 [40]. Analyses were according to the randomized arm, and only participants with complete outcome data were included in the principal analysis. All statistical tests were two sided and were considered significant at the 5% level. The analysis was conducted using Stata 15 (StataCorp). Unmasking occurred on February 6, 2018, after the analyses outlined within the analysis plan were complete on masked data.

Loss to Follow-Up and Missing Data

We used a chi-square test to investigate the evidence for whether losses to follow-up differed by trial arm. We used logistic regression to compare the baseline characteristics of participants who completed follow-up with those who did not. We investigated whether predictors of loss to follow-up differed by trial arm by testing for an interaction.

Principal Analysis

Analysis of the Coprimary Outcomes

We compared the proportion that reported using a method of effective contraception or finding at least one method acceptable between the groups using logistic regression. We report the crude and adjusted OR along with the 95% CI and P value. The primary analysis was adjusted for the following prespecified baseline covariates: age (16-19 and 20-24 years), number of children (0 and ≥1), education level (university and other), and acceptability of effective contraception at baseline (at least one method acceptable and no methods acceptable) [39,40].

Analysis of the Secondary Outcomes

The analysis of the secondary outcomes was similar to the analysis of the primary outcome, although for the acceptability of the individual methods, the acceptability of that method at baseline replaced the acceptability of at least one method at baseline as a covariate.

Analysis of the Process Outcomes

The process outcomes comprised ordinal scales. Each scale was analyzed individually using ordered logistic regression to estimate proportional ORs. For knowledge, each correct answer received one point. The points were summed, and an overall score was produced for analysis. We used linear regression to test for a difference in the mean scores between the trial arms. To assess the *dose* of the intervention that the intervention participants received, we analyzed the number of messages that participants reported to have read (all, most, some, and none) and whether they stopped the messages.

Additional Analyses

Sensitivity Analyses

We conducted 2 sensitivity analyses allowing for the missing data. In the first analysis (an *extreme case* analysis), we considered that all participants lost to follow-up did not use an effective method of contraception or did not find at least one method acceptable. In the second analysis, we adjusted for the main baseline predictors of missingness. Both sensitivity analyses were adjusted for the baseline covariates, as mentioned above.

Subgroup Analysis

We conducted an exploratory subgroup analysis for each coprimary outcome to determine if the intervention effect varied by baseline characteristics. The prespecified subgroups were age (split at the median), marital status (married/not married), number of children (0/≥1), geographical location (El Alto/La Paz), occupation (in education/other), and education level (university/other). Within the subgroups, we assessed the heterogeneity of treatment effect with a test for interaction [45-49]. We estimated ORs with 95% CIs for each subgroup.

Contamination

To assess the potential for contamination, we report the proportion of control group participants who reported that they read another participant’s messages and the proportion of intervention participants who reported that their messages were read by another participant.

Report of Physical Violence

We report the proportion of participants in each group who reported experiencing physical violence during the study.

Results

Recruitment, Randomization, and Exclusions

Between March 1, 2017, and July 29, 2017, there were 645 randomizations by the system. Follow-up ended on February 8, 2018. During the trial follow-up, we discovered that 3 participants enrolled and were randomized twice. For the 1 participant who was allocated to the same arm on both randomizations, we kept this participant in the analysis using the baseline data from their first record. For the 2 participants who were allocated to different arms, we excluded them from the analysis. This resulted in 640 participants included in the trial.

Of the 640 participants, 321 were allocated to the intervention arm and 319 participants were allocated to the control arm (Figure 1).

Baseline Characteristics

The baseline characteristics of trial participants are reported in Table 1. Mean age was 20 years. In addition, 90.4% (579/640) of the participants did not have children, and only 8% (26/640) of the participants found at least one method of effective contraception acceptable. Acceptability was very low for the individual methods (1%-3%). Characteristics were similar between the 2 groups.

Loss to Follow-Up

Overall, 67.0% (429/640) participants completed the trial follow-up for the coprimary outcome use (control, n=215 and intervention, n=214; Figure 1), and 63.4% (406/640) participants completed the follow-up for the coprimary outcome acceptability (control, n=203 and intervention, n=203). Retention did not differ between the arms (215/319, 67.4% in the control arm and 214/321, 66.7% in the intervention arm; *P*=.84). Among the participants who completed the use coprimary outcome, the strongest predictor of retention was being aged 20 to 24 years (OR 1.33, 95% CI 0.96 to 1.86; *P*=.09). There was some evidence that the effect of this predictor differed by arm (interaction test *P*=.09). Detailed characteristics of participants who completed follow-up and those who did not are reported in Multimedia Appendix 1.

Primary Outcomes

In the intervention arm, 37.4% (80/214) of participants reported the use of effective contraception compared with 33.5% (72/215) of participants in the control arm (Table 2). There was no evidence of a difference in use between the groups (crude OR 1.19, 95% CI 0.80 to 1.76; *P*=.40 and adjusted OR 1.19, 95% CI 0.80 to 1.77; *P*=.40).

Secondary Outcomes

There were no significant differences in any of the secondary outcomes between the groups (Table 3).

In the intervention arm, 71.9% (146/203) of the participants reported that at least one method of contraception was acceptable compared with 62.6% (127/203) of participants in the control arm (Table 2). There was borderline evidence of a difference in acceptability between the groups (crude OR 1.53, 95% CI 1.01 to 2.33; *P*=.05 and adjusted OR 1.49, 95% CI 0.98 to 2.28; *P*=.06).

Process Outcomes

There were no significant differences in any of the process outcomes between the groups (Table 4).

Table 2. Coprimary outcomes.

Outcomes	Control		Intervention		Adjusted odds ratio (95% CI)	*P* value
	N	n (%)	N	n (%)		
Use of effective contraception[a]	215	72 (33.5)	214	80 (37.4)	1.19 (0.80 to 1.77)	.40
At least one effective method is acceptable[a]	203	127 (62.6)	203	146 (71.9)	1.49 (0.98 to 2.28)	.06

[a] Adjusted for age, number of children, education level, and acceptability at baseline.

[c] IUD: intrauterine device.

[d] N/A: not applicable.

Potential for Contamination

A total of 1.0% (2/209) of control participants said that they read the messages of someone else in the study. Moreover, 3.9% (8/205) of intervention participants said that someone else in the study read their messages.

Report of Physical Violence

A total of 2.9% (6/207) of participants in the control group and 2.0% (4/202) in the intervention group reported that they experienced physical violence since being in the study (Fisher exact test *P*=.75).

Intervention Dose

A total of 25.7% (53/206) of intervention participants reported that they read all or most of the intervention messages, with 28.6% (59/206) stating that they read none of the messages. In addition, 11.2% (23/205) of the participants reported that they stopped the intervention messages. Reasons intervention participants provided for not reading the messages or uninstalling the app were concerns about confidentiality, the app took up too much space on their phone, there were too many messages, and some messages were repetitive. In addition, 18.9% (39/206) of the intervention participants who answered the open-ended question “Did anything good or bad happened as a result of receiving the messages?” said that they did not receive any messages.

Participants’ Report of Anything Good or Bad That Happened During the Study

Almost half of the intervention participants that answered this question (97/206) reported something positive about the messages. The most common comment was that they learned new information. One participant said that they got pregnant and another said that they had *a scare due to carelessness.*

Sensitivity Analyses

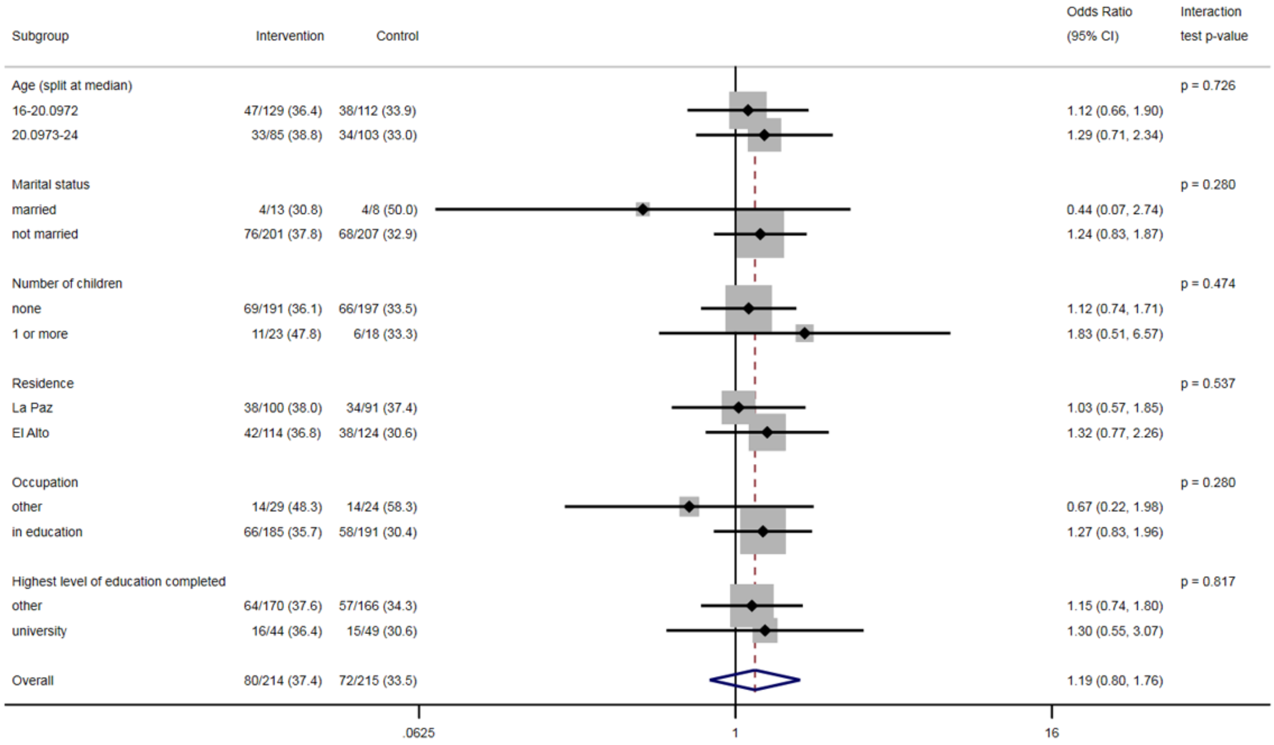
When we considered that participants who were lost to follow-up did not use an effective method or find an effective method acceptable, the effects observed in the principal analysis were reduced (use: OR 1.14, 95% CI 0.79-1.64; *P*=.48 and acceptability: OR 1.26, 95% CI 0.92-1.74; *P*=.15).

The strongest predictor of retention was being aged 20 to 24 years. Age was a baseline covariate, so the model in the second sensitivity analysis (adjusting for the main baseline predictors of missingness) is the same as the primary analysis model.

Subgroup Analysis

There was no evidence that the effect of the intervention differed within the different levels of the subgroups (Figures 2 and 3).

Figure 2. Intervention effect on the use of effective contraception by subgroups.



Subgroup	Intervention	Control	Odds Ratio (95% CI)	Interaction test p-value

Discussion

Principal Findings

The observed difference in contraceptive use between the groups (absolute difference=3.89%) was smaller than expected. Although the use was higher in the intervention group, the difference was not statistically significant. There was a borderline significant effect regarding the acceptability coprimary outcome, which favored the intervention group. No statistically significant differences between the groups in any of the secondary or process outcomes were observed. The intervention dose received was low, based on participants' report.

Strengths and Limitations

The main limitations of this trial were that we did not recruit to target and achieved less than 80% follow-up completion.

Although effect estimates or both primary outcomes favored sending the intervention messages with the Tú decides app, the differences between the groups were smaller than what we expected. The recruitment and follow-up challenges meant that the trial was underpowered and therefore unable to produce unequivocal estimates regarding the effect of sending the intervention messages in addition to the app (with 429 participants, the trial had 54% power to detect a 10% absolute difference in use of effective contraception between the groups). Another limitation is in relation to the self-reported outcome measures. As they are self-reported, they are more likely to be biased than if the outcomes were objective, such as clinic-verified use of contraception.

Despite the limitations, this study had several strengths. Our trial database and randomization system generated and concealed the allocated and achieved well-balanced groups. There was no evidence that the intervention was associated with an increase in self-reported violence, a potential adverse outcome related to others viewing the messages, unwanted by the participant. We considered this a potential adverse outcome, given the stigma associated with sex before marriage in Bolivia [36]. However, we cannot determine the effect of the app on partner violence because both groups had access to it. Despite this, it is reassuring that the self-reported prevalence in this trial was low (2%).

Comparisons With Existing Research

Trials evaluating contraceptive behavioral interventions delivered by mobile phone have had mixed results [25-35], with some showing an improvement in contraceptive use [25-27] and knowledge [25,28-30]. The results of this trial are not inconsistent with our trials of similar interventions among young people in Tajikistan [50] and Palestine [51]. In the Palestine trial, participants who received the intervention were more than twice as likely to find at least one method of contraception acceptable (OR 2.34, 95% CI 1.48-3.68; $P<.001$). There were also improvements in knowledge, acceptability of individual methods, perceived norms about friends using contraception, and intention to use contraception compared with the control group. In the Tajikistan trial, there was contamination between the intervention and control groups, and no differences were found between the groups. As with this Bolivian trial, the Tajik and Palestinian trials also did not suggest that the intervention was associated with an increase in violence.

Implications of the Findings

The uncertainty regarding the efficacy of the intervention means that we cannot strongly recommend implementation in Bolivia. The low dose of the intervention is likely to have reduced the effect estimates. Only 25.7% (53/206) of the participants reported that they read all or most of the intervention messages, with 28.6% (59/206) reporting that they read none of the messages. This could have contributed to the smaller than anticipated observed differences. As we did not collect data on why these people did not read most of the messages, we do not know the reasons for this. A total of 47% (97/206) of intervention participants who answered the question “Did anything good or bad happen during the study?” (97/321, 30.2% of all intervention participants and 97/214, 45.3% of those who completed follow-up) reported something positive about the messages. Although participants in the development work were positive about the message content, sending the messages to the target group as they are intended to be sent (eg, over the entire 4 months) and then interviewing participants about their experience may have identified barriers to successful intervention receipt. We have done this in previous studies, but our timeline and resources did not allow for this in this trial.

Another possibility for the smaller than anticipated differences could be that the intervention is only moderately more effective than offering standard family planning information on a mobile app. It may be that offering good-quality family planning information on mobile app pages in this context is sufficient enough to improve the use of and attitudes toward contraception. However, the results suggest that the intervention messages could increase the acceptability of effective contraception if they were offered alongside the download of the Tú decides app and would not cause harm if done so.

It is difficult to determine exactly why we were unable to recruit to target. Some factors that likely contributed to the under-recruitment are (1) the trial promotion was not targeted to eligible people as much as it could have been, (2) young women were reticent to admit to being sexually active, (3) they did not want to have the app on their phone (although the development work indicated that this would not be a problem for them), and (4) they were not interested in taking part in a trial. Although the target sample size was much lower in the Tajik and Palestine trials (n=570 for each), this Bolivian trial actually recruited more participants and had a narrower inclusion criterion (women aged 16-24 years with an unmet need for contraception). Potential ways to improve recruitment in future trials of contraceptive behavioral interventions delivered by a mobile phone could be to promote the trial in settings where recruiters have a very good chance of accessing eligible people. In addition, only assessing potential participants on their own may improve the chance that they would admit to being sexually active.

In deciding how to analyze the scales, we thought it would be better to avoid false positives. For participants to score *acceptable* for a method, they must have chosen *agree* or *strongly agree* to the positively worded stems and *disagree* or *strongly disagree* to the negatively worded stems. To illustrate how stringent this definition of *acceptability* is, a participant could respond *strongly agree* to the statement that the method has unwanted side effects but could still use the method because the benefit of using it (avoiding a pregnancy) outweighs the risk [51]. This does not have implications on the effect of the intervention relative to the control. Nevertheless, the very low baseline acceptability of all methods highlights the need for interventions such as the one evaluated in this trial—interventions that provide accurate, nonjudgmental information about contraception and that address negative beliefs and misconceptions.

Conclusions

This trial was unable to determine unequivocally if the intervention was effective at increasing the use and acceptability of effective contraception among young women with an unmet need in Bolivia. The intervention messages when delivered in addition to an app providing standard family planning information may moderately improve acceptability. Future research could first identify why around one-third of participants did not read the intervention messages and then evaluate the effect of the intervention on the use of contraception in different contexts.

Acknowledgments

The authors would like to thank the young people in Bolivia who participated in the intervention development phase and the trial, promoted the study, and assisted with collection of the follow-up data. The authors are extremely grateful for their hard work and volunteering their time. The authors would also like to thank the International Planned Parenthood Federation for funding the trial and Alison McKinley, the Senior Research and Evaluation Officer for the Innovation Program, for her support throughout the project. The trial was supported by the International Planned Parenthood Federation Innovation Programme.

Authors' Contributions

OM designed and managed the trial, conducted the analysis, and wrote the manuscript. CA coordinated and conducted the trial recruitment and follow-up. MT facilitated trial implementation. JG facilitated trial implementation and took overall local responsibility for the project. SH contributed to planning discussions regarding the trial. IA developed the trial database and randomization system. BL provided advice regarding the statistical analysis and reviewed the Stata analysis code. PE oversaw the statistical analysis. MP managed the trial follow-up when OM was on maternity leave and reviewed the primary outcome Stata analysis code. CF provided guidance regarding the trial design and took overall academic responsibility for the project. All authors revised the work, approved the version to be published, and agreed to be accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: The integrity of data in a clinical trial is essential, but the current data management process is too complex and highly labor-intensive. As a result, clinical trials are prone to consuming a lot of budget and time, and there is a risk for human-induced error and data falsification. Blockchain technology has the potential to address some of these challenges.

Objective: The aim of the study was to validate a system that enables the security of medical data in a clinical trial using blockchain technology.

Methods: We have developed a blockchain-based data management system for clinical trials and tested the system through a clinical trial for breast cancer. The project was conducted to demonstrate clinical data management using blockchain technology under the regulatory sandbox enabled by the Japanese Cabinet Office.

Results: We verified and validated the data in the clinical trial using the validation protocol and tested its resilience to data tampering. The robustness of the system was also proven by survival with zero downtime for clinical data registration during a Amazon Web Services disruption event in the Tokyo region on August 23, 2019.

Conclusions: We show that our system can improve clinical trial data management, enhance trust in the clinical research process, and ease regulator burden. The system will contribute to the sustainability of health care services through the optimization of cost for clinical trials.

Introduction

Clinical trials involve a large flow of medical information, and it is necessary to secure the transparency and traceability of clinical data. The International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use–Good Clinical Practice (ICH-GCP) provides guidance for monitoring the conduct of a clinical trial to verify that reported clinical data are complete, accurate, and accounted for by source records. The long-standing practice in the pharmaceutical and medical device industries has been frequent site visits and 100% source data verification (SDV) on site to ensure that data captured in source records are transferred correctly to the case report forms. It has been estimated that clinical trial monitoring by SDV can consume one-quarter of the sponsor's entire budget for a clinical trial [1]. As the complexity and size of clinical trials grow, it has become increasingly expensive to apply the 100% SDV approach [2,3]. For regulators of trials, such as the US Food and Drug Administration (FDA), European Medicines Agency (EMA) in the European Union, and Pharmaceuticals and Medical Devices Agency (PMDA) in Japan, data auditing is challenging since there is no easy and secure way to access or view complex data. As such, process improvement is an active area of research [4]. With the involvement of more parties and more exchanges, the risk for human-induced error, whether unintentional or malicious, will increase. Previous studies have shown that 17% of authors of clinical trials reported they were personally aware of intentional fabrication in research [5,6]. In the case of misconduct in a clinical trial by an employee of Novartis Pharma, clinical data were manipulated to attribute qualities to the hypertension drug valsartan that it did not possess, such as preventing stroke [7]. The fabricated clinical data were used in an advertising campaign for the drug, and patients were prescribed the drug based on incorrect information. Following misconduct in clinical trials, the Japanese government established and enforced the Clinical Trials Act in 2018 [8]. It obligates clinical researchers to monitor and assure quality, observe practice criteria, and manage conflicts of interest.

Blockchain is emerging as a groundbreaking technology for secure data control in different areas. Bitcoin was the first application of blockchain as a digital currency in extensive use [9]. Recently, researchers have started to focus on using blockchain methodology for building a cryptographic proof of medical systems [10]. They have applied blockchain technology in various health care systems, with potential applications in supply chain management of health care products [11-13], insurance claims processing [14], management of electronic health records and electronic medical records [15-18], maintenance of protocols in clinical trials [19-21], and data management in clinical trials [22-25]. Although there can be many applications of blockchain technology, it is necessary that blockchain be an appropriate technical solution to a particular problem. If there are no incentives for data tampering and all writers can be trusted, blockchain technology is not necessary. On the other hand, if there are incentives for data tampering and it costs a lot to use a trusted third party, such as the Clinical Research Organization, using blockchain makes sense [26]. Due to the frequent occurrences of misconduct in clinical trials and the large consumptions of clinical trial budgets and time by current SDV practices, blockchain is an appropriate technical application in the data management of clinical trials to solve these problems.

We propose a solution to challenges in the current clinical trial system by using blockchain technology coupled with technologies such as client hashchain, encryption protocol, and health check function in servers for hazard management. The system was used in a clinical trial at the National Cancer Center of Japan that investigated the effect of home-based high-intensity interval training for breast cancer survivors. The project was conducted to demonstrate clinical data management using blockchain technology under the regulatory sandbox of the Japanese Cabinet Office [27,28]. This sandbox allows organizations to apply for demonstration and evaluation of new technology, such as blockchain and Internet of Things, without being subject to existing regulations. It simultaneously opens up the possibility for future deregulation measures. During the trial, we experienced the disruption of Amazon Web Services (AWS) cloud servers in the Tokyo region on August 23, 2019 [29]. We report the effect of the blockchain network and health checkup function, which resulted in system survival with zero downtime and secure clinical data registration during the hazardous server shutdown event.

Methods

Breast Cancer Clinical Trial

A clinical trial that investigates the effect of intervention by home-based high-intensity interval training for breast cancer patients was conducted. The study was a parallel-group, single-blind randomized controlled trial. Patients were randomly assigned to the active group with the habit-B program (high-intensity interval training, exercise counseling and guidance, home-based exercise support using information and communication technology, and a wearable device) or treatment as usual with a wearable device.

The eligibility criteria for participants were (1) female, aged between 20 and 59 years at diagnosis; (2) diagnosed with stages I to IIa breast cancer and currently 2 to 13 months postsurgical treatment; (3) not requiring cancer chemotherapy aside from hormone therapy; (4) ability to read, write, and understand Japanese; (5) ability to complete an electronic Patient Reported Outcome Questionnaire via smartphone; (6) consent to trial participation obtained in writing from the patient themselves; and (7) currently engaging in not more than moderate intensity exercise for 30 minutes on two separate days per week (total of 60 minutes).

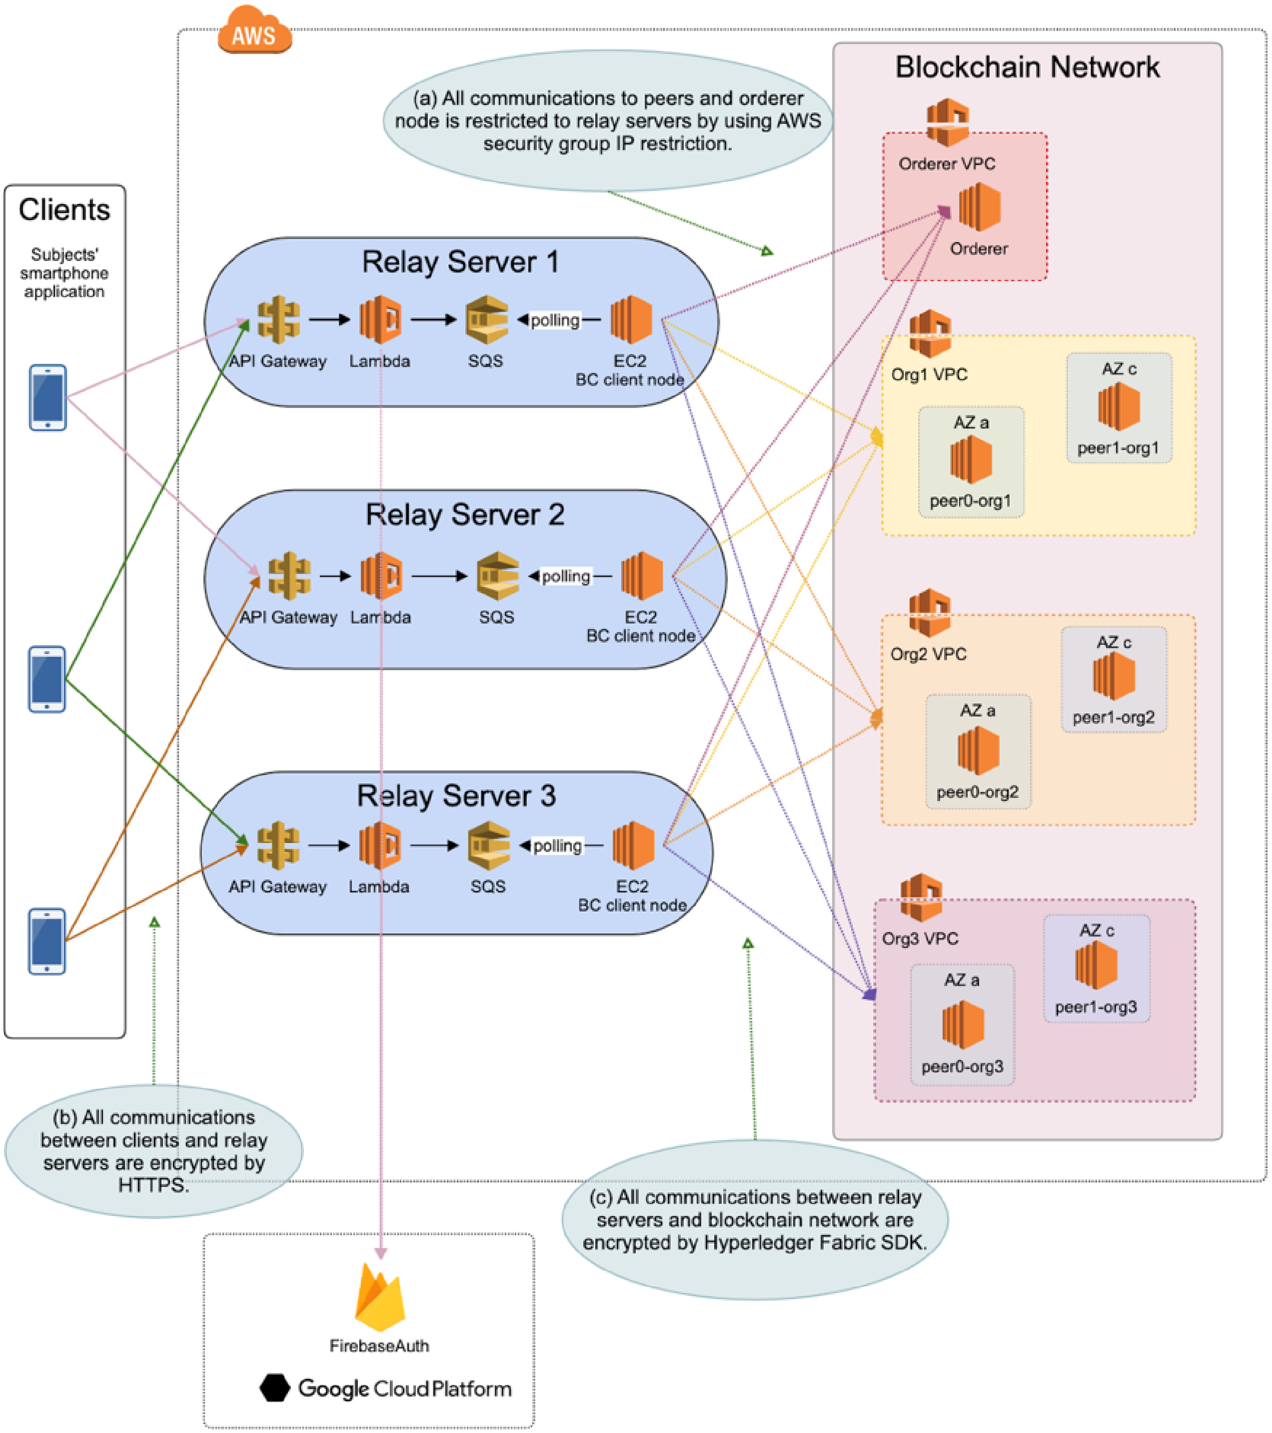
The researcher provided computer-generated random allocation. Using the generated account, the contents of the app that participants used during the clinical trial were assigned automatically to either the habit-B program or the control. When a participant first visits the hospital, she is randomly assigned to an intervention, either with the habit-B program or treatment as usual with a wearable device, after signing informed consent. An independent data center provides computer-generated random allocation as a log-in account for the app. Based on the allocation sequences, the contents of the app participants use during the trial are assigned automatically to either the habit-B program or the control.

The study received ethical approval from the institutional review board of the National Cancer Center Japan and was registered at University Hospital Medical Information Network–Clinical Trial Registry [UMIN000036400]. Participants provided written informed consent to take part in the study. The study began in May 2019 and is ongoing [30].

Architecture of the Data Management System

The data management system that collects the clinical trial data consists of client smartphones, relay servers, and a blockchain network (Figure 1). The relay servers and blockchain network are built on AWS in the Tokyo region. We use Hyperledger Fabric v1.0 (Linux Foundation), an open-source blockchain platform that has been widely used, to operate the blockchain network. Hyperledger Fabric enables throughput of more than 3500 transactions per second in popular deployment configurations [31].

Figure 1. Data management system including client smartphones, relay servers, and blockchain network. The collected data from patient smartphones were sent to the blockchain network via relay servers. We used three relay servers, and the app randomly selected two relay servers to send the data after the authentication of the client device. We have configured the blockchain network to span multiple availability zones in Amazon Web Services.



Data collected from patient smartphones are sent to the blockchain network via relay servers. We use three relay servers, and the app randomly selects two relay servers to send the data after the authentication of the client device. The client app contains an authentication key, and the relay servers verify the key so that the relay server only accepts access from the app for the clinical trial. The relay servers also verify the account for the app using Firebase authentication. These communications between clients and relay servers are encrypted using https. By deploying the relay server and setting the blockchain software development kits to append-only mode, the relay servers send the received data to the blockchain network. The data sent from the relay servers to the blockchain network are encrypted using the authentication protocol by the Hyperledger Fabric. By configuring the internet protocol address restriction to the listed relay proxy, the blockchain network, which contains the clinical trial data, is protected against malicious attack from the external network. The blockchain network is made up of three organizations, each of which contains two validating peers. Each identification and password for relay servers, blockchain network organizations, and nodes of the blockchain network is managed by two independent departments in SUSMED Inc and the National Cancer Center of Japan [22].

We have configured the blockchain network to span multiple availability zones (AZs) in AWS. Each AZ is made up of one or more data centers equipped with independent power, cooling, and networking to ensure fault tolerance. We have also implemented a periodic health check function using the Amazon EC2 Auto Scaling Service. The function continues to maintain a fixed number of instances even if an instance becomes unhealthy. If an instance becomes unhealthy, the group terminates the unhealthy instance and launches another instance to replace it.

In order to increase system durability and prevent data loss, we have configured two kinds of queues in our system. The mobile app puts clinical data into the queue before sending, dequeues and sends the message, and then removes the data from the queue. If relay servers are unavailable, the sending process fails and the data remain available in the queue until the relay servers process it. The other queue is in a relay server system, and the queue is configured using AWS Simple Queue Service (SQS). When a relay server system receives the clinical data, the data are enqueued. In the relay server system, an EC2 instance is responsible for dequeuing and sending the message to the blockchain network. The data are removed from the queue after being successfully processed by the blockchain network. Otherwise, the data remain available in the queue until the sending process succeeds or the SQS retention period expires. In this system, we set the SQS retention period to 7 days. In doing so, we have seven days’ time to recover the blockchain network if there is a breakdown.

Data Collection Using Smartphone

The Global Physical Activity Questionnaire is an internationally standardized questionnaire for surveying physical activity level [32-34]. Fear of cancer recurrence is assessed by the overall fear index score on the Concerns About Recurrence scale [35,36]. Depression is assessed using the Patient Health Questionnaire–9 [37]. Fatigue is assessed by the Cancer Fatigue Scale. Sleep is assessed by the Athens Insomnia Scale [38]. Quality of life is assessed using the EuroQol 5-Dimensions questionnaire [39,40]. All data listed above are stored in JavaScript Object Notation format in the database.

Data Registration to the Blockchain Network

When a participant first logs in to the system, the app generates a secret hash key and preserves it in the client device until the end of the study. The client device calculates a hash value based on the data generated by the patient and the secret hash key as well as the previous hash value using the SHA-256 hash algorithm [22,41]. Thus, the hash value in the client device comprises the chain structure. The hash value is also registered in the blockchain network along with the clinical data in order to guarantee tamper resistance of the value, although the secret hash key was preserved in the client device until the end of the study. The collected data and client hash value are sent to the blockchain network via relay servers. We use three relay servers, and the app randomly selects two relay servers to send the data after the authentication of the client device. Client nodes of the blockchain network are settled in the relay servers and the data are sent from the relay server to the blockchain network. The transactions are validated and accepted by the blockchain network in the following processes:

- Proposal: transaction is sent from client app to the endorsers in each organization
- Endorse: each endorser verifies that (1) the transaction proposal is well formed, (2) it has not already been submitted, (3) the signature is valid, and (4) the client is properly authorized to perform the proposed operation, which is described in the chaincode. If the transaction is validated, the chaincode is executed and the result with the signature is returned to the client
- Submit: client verifies that the number of signatures from the organizations satisfies the endorsement policy. If it is satisfied, the transaction is sent to the ordering service, which orders the series of transactions in chronological order and creates the block of transactions
- Broadcast: the block is delivered to all nodes
- Commit: if each block is well formed and validated to fulfill the endorsement policy, the block is appended to the chain in each node [22]

Data Validation and Verification

When participants complete the data input for the clinical trial, it is necessary to verify all data records sent to the blockchain network to satisfy the following conditions:

- Blockchain network has received all required data types for each participant
- All data records for each participant are correct as a client hashchain
- Blockchain network has received clinical records from two relay servers for each record, and the records are the same

The first condition means that the blockchain network has received all records that are expected to be sent from clients. There are three types of records in the clinical trial. To begin with, a client sends a record that indicates that a secret hash key has been generated. When clinical data are created, the data are sent to the blockchain network via two relay servers. Finally, when the participants complete the clinical trial, the client sends the secret hash key to the blockchain network.

The second condition verifies that all data records registered to the blockchain network are correctly linked as a client hashchain. We sort all data records by their generated time and make a hash value from the clinical data, the secret hash key preserved in the client device until the end of the study, and the previous hash value. Then, we compare the results with the hash value that has been registered to the blockchain network. Due to the sensitivity of a hash function output in relation to its input, changing the data will result in a completely different hash string. Therefore, we can confirm these hash values are generated by the client device that preserves the secret hash key. By verifying this condition, we can detect if a malicious attacker has falsified the clinical data using hash values and clinical data that were stolen.

The purpose of the last condition is to confirm that the relay servers have not been hacked. Clients send their clinical data to two relay servers that are randomly selected from the three relay servers. If malicious users hack a relay server and they send some data from the relay server, the blockchain network will store the data. In order to detect the fraud access and verify the data, we need to confirm that all clinical data is received from two relay servers simultaneously and the data records are identical.

Data Availability

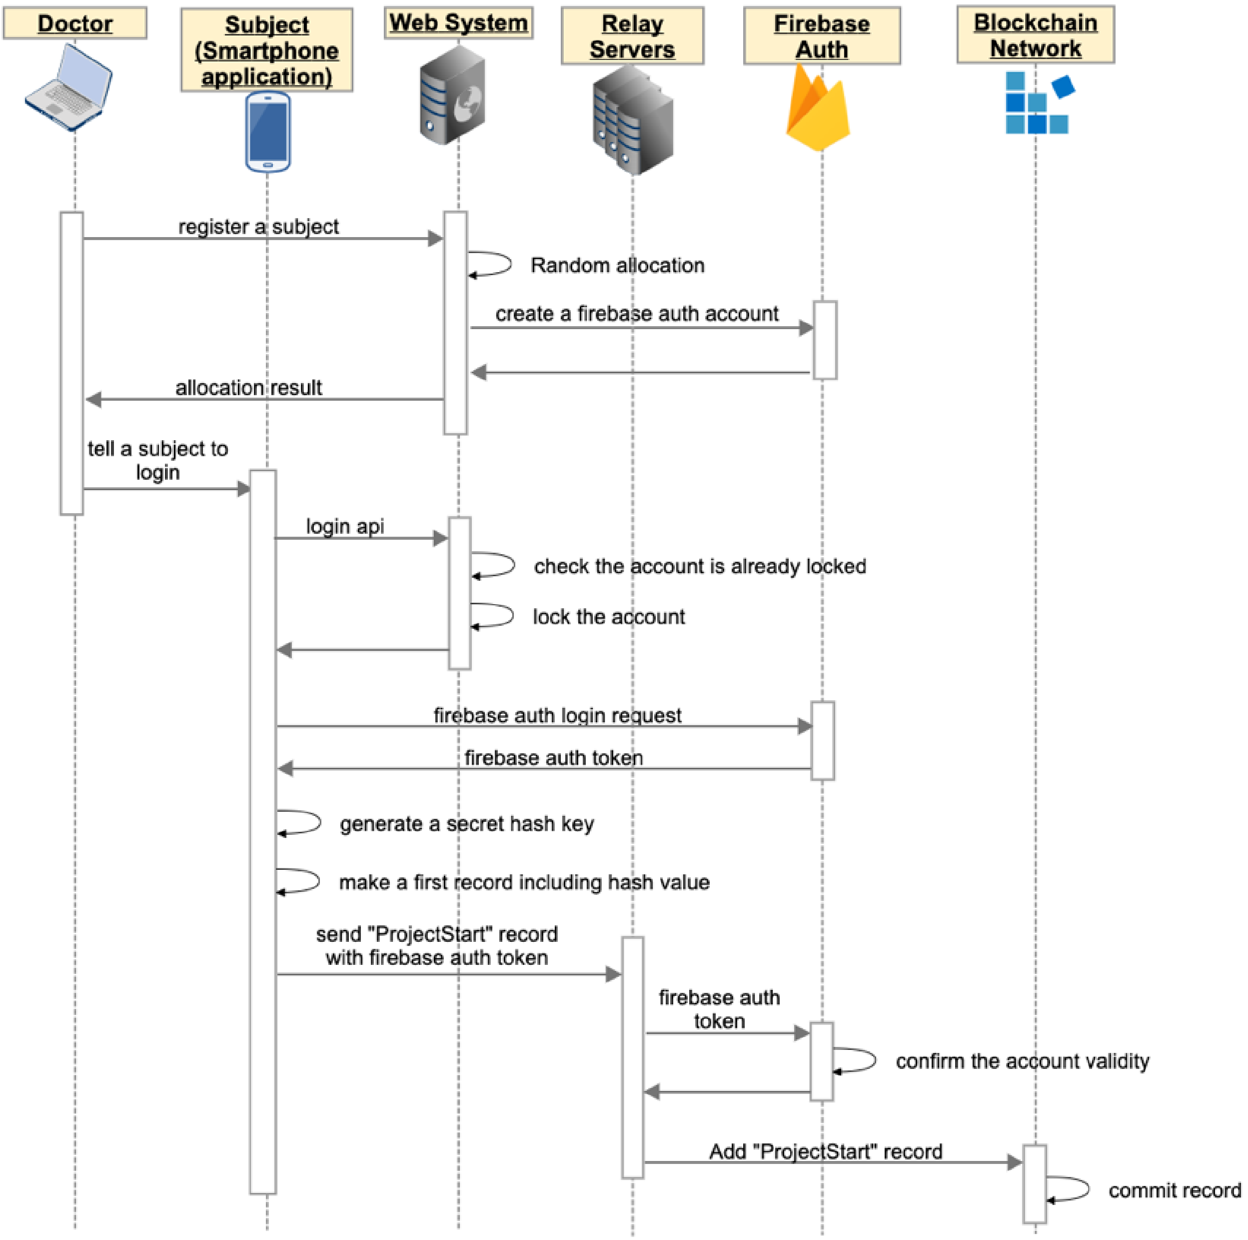
The data that support the findings of this study are available from the corresponding author upon reasonable request.

Results

Registration and Assignment

The participant downloads the app to their own smartphone through the internet and logs in to the system using the account provided by the researcher. When the participant first logs in to the system, the app generates a secret hash key and preserves it in the client's device until the end of the study. The account is locked when the participant first logs in to the system in order to prevent impersonation by stolen account or brute force attack (Figure 2).

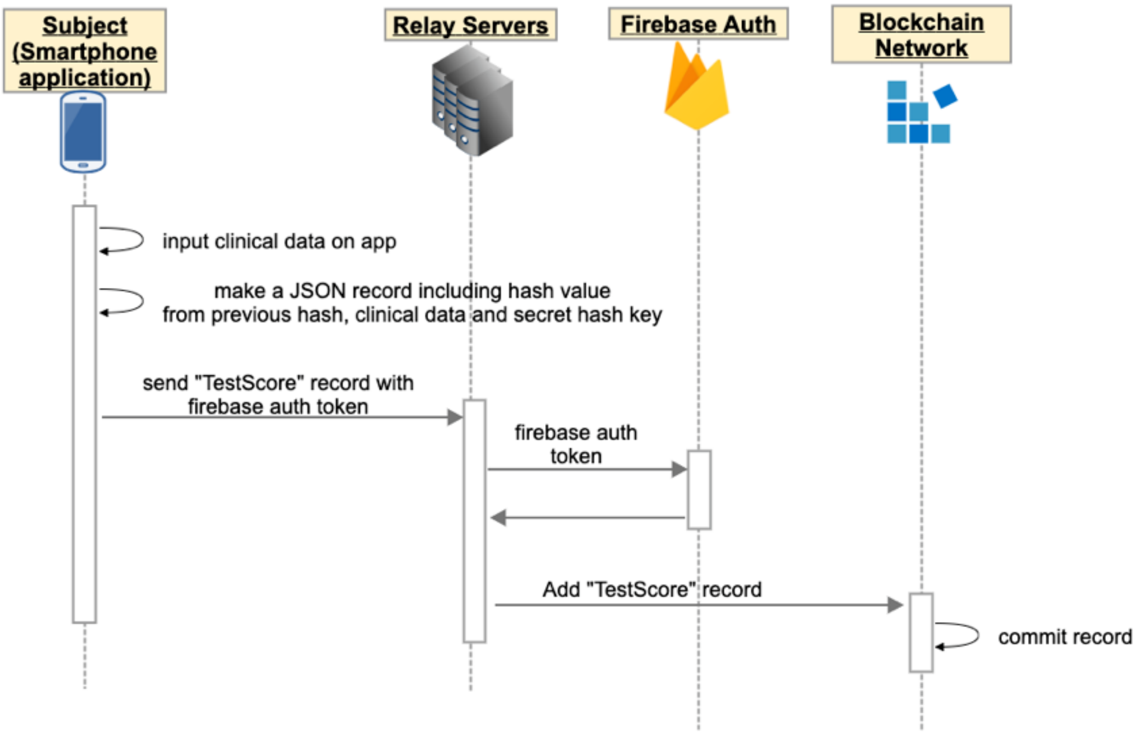
Figure 2. When a participant first visits the hospital, a medical doctor decides if they fit the eligibility criteria. After obtaining informed consent, the doctor registers the patient to the clinical trial using a web-based allocation system. The system automatically creates an account for the participant, and the doctor gives the account to the participant. The participant downloads the app to their smartphone, and they can log in to the app using the account created by the doctor. When the participant first logs in to the app, the account is locked to prevent impersonation, and the secret hash key is then generated. The secret hash key will be preserved in the client app until the participant completes the trial. Using the secret hash key in the client device, the app calculates a hash value. The app sends the first record to the blockchain network via relay servers, and the data is registered in the tamper-resistant blockchain system.



Data Collection

During the trial, the participant inputs the data using the app, and the data are registered to the blockchain network via relay servers (Figure 3). The secret hash key is preserved only in the client’s device during the clinical trial. The client app calculates a hash value based on the medical data, the secret hash key, and the previous hash value using the SHA-256 hash algorithm. The client hash value is also sent to the blockchain network along with the clinical data.

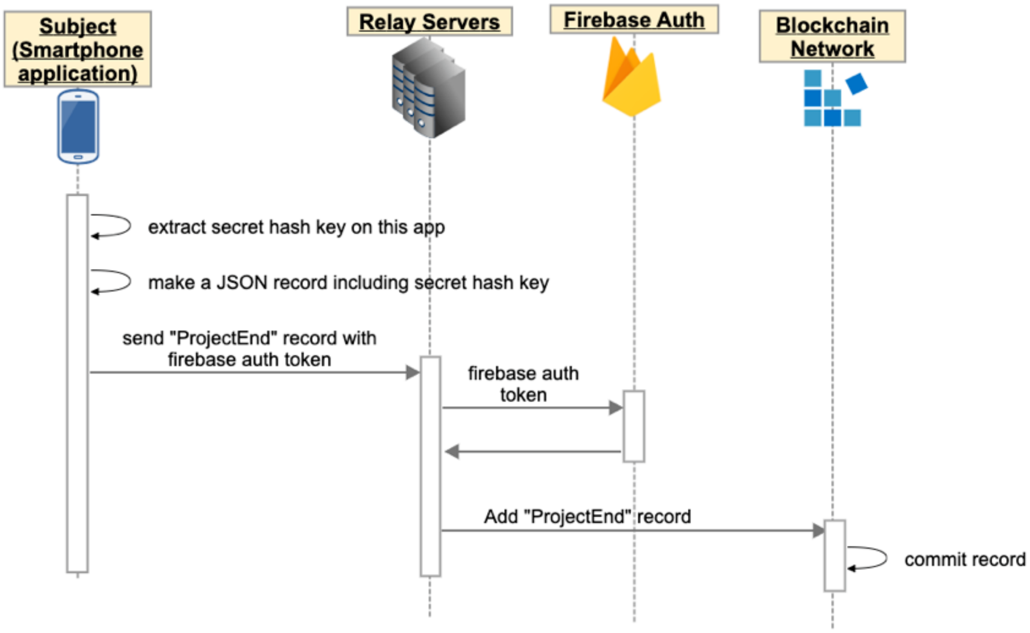
Figure 3. During the clinical trial, participant inputs clinical data using the mobile app. The app calculates the hash value based on the clinical data, the secret hash key preserved in the smartphone until the end of the study, and the previous hash value. The app sends the clinical data and a hash value to the blockchain network via relay servers.



Completion of the Clinical Trial

When the participant completes the clinical trial, the app sends the secret hash key to the blockchain network, and all data of the participant is registered to the blockchain network (Figure 4).

Figure 4. At the end of the clinical trial, the app extracts the secret hash key from the smartphone and sends it to the blockchain network via relay servers.



Data Validation and Verification

We verify and validate the patient's data collected in the clinical trial using a predetermined protocol. For regulators such as FDA, EMA and PMDA, the full transaction history since the beginning of the study is readily available with precise log data, and the auditing process can be done quickly and with the reliance that all clinical data are guaranteed or version controlled [23].

Blockchain technology ensures a secure and tamper-proof transaction history so that the blockchain network provides an integrity-protected data storage and process transparency [24]. However, there can be vulnerability before registration to the database in the blockchain network. The data can be tampered with and impersonation could occur, resulting in impairment of reliability of the data. To prevent impersonation of the client, we have configured the mechanism so that the account is locked when the participant first logs in to the system. The client app contains the authentication key, and the relay server checks the key so that the relay server only accepts access from the app for the clinical trial. By configuring the internet protocol address restriction to the listed relay server, the blockchain network, which contains the medical data, is protected against external attack. This configuration makes our system highly secure. Even if an attacker breaks the above security system under impersonation or unauthorized access to the relay server, we can validate and distinguish the correct data using the client hashchain function. In order to complement the tamper resistance of the blockchain network and ensure reliability of the entire system, we verified and validated the data integrity using client hashchains and multiple relay servers. User data along with the client hashchain are registered to the blockchain network. The app sends the user data and client hashchain to the blockchain network during the clinical trial. At the end of the trial, the app sends the secret hash key preserved in the client device to the blockchain network. Using the secret hash key, we verify the integrity of the data by calculating the hashchain retrospectively (Figure 5). User data and the client hashchain are sent from multiple relay servers to the blockchain network. A client app sends its clinical data to two relay servers, which are randomly selected from the three relay servers. In order to detect fraudulent access and verify the data sent from the relay servers, the data are compared with each other to confirm that the records are the same (Figure 6).

Figure 5. Data verification and validation using client hashchain. The first hash value is made from the first data and secret hash key. Subsequent hash values are made from clinical data, the previous hash key, and secret hash key.

Every record starts with Relay Server ID like "Admin@org1.eprobc.susmed.io". We can confirm that every record is sent from at least 2 relay servers and the data records are the same.

To evaluate the validation, we have simulated and tested client impersonation and data falsification by fraudulent access to the relay server. The integrity of the data can be maintained even if attacker tries to manipulate the data by impersonating the client device (Figure 7) or fraudulently accessing the relay servers (Figure 8). The result suggests that our proposed function of client hashchain and multiple relay servers can be a complement to the tamper resistance of the blockchain network to ensure the reliability of the entire system.

Figure 7. Simulation of data falsification by client impersonation. If an attacker successfully logs into the app using a stolen account or brute force attack, the attacker can create clinical data from another client device. The data from the impersonated client will be denied since only the true participant's app preserves the secret hash key that is required to calculate the hashchain.

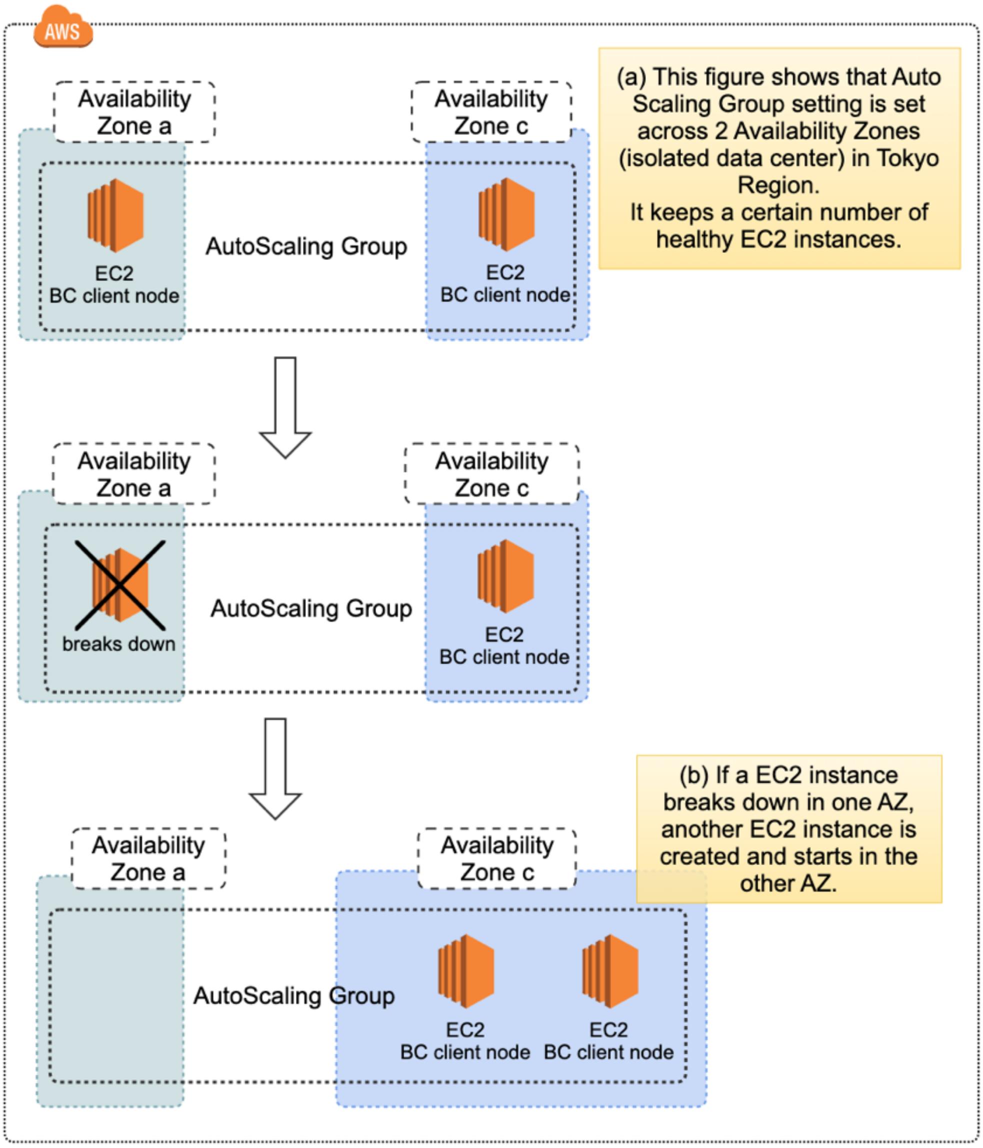
Data Integrity During Amazon Web Services Disruption Event

During the trial, we encountered a disruption event of the AWS cloud server in the Tokyo region on August 23, 2019 [29]. This resulted in impaired EC2 instances for some resources in the affected area of the AZ. One of the blockchain network nodes shut down due to disruption of the data center. Since the blockchain network was composed of three organizations that contain two validating peers and we had configured the blockchain network to span multiple AZs in AWS, the redundancy maintained stable operation of the system during the event. Furthermore, our configuration of a periodic health check function using Amazon EC2 Auto Scaling Service automatically restored the affected node in a healthy data center (Figure 9). We have confirmed there were no error records during the disruption event.

Figure 9. System resilience during Amazon Web Services disruption event in the Tokyo region. To secure the redundancy of the system, we have configured the blockchain network to span multiple availability zones (AZs) in Amazon Web Services. Each AZ is made up of one or more data centers equipped with independent power, cooling, and networking to ensure fault tolerance. We have also implemented a periodic health check function using the Amazon EC2 Auto Scaling Service. When one of the nodes in the blockchain network broke down due to the severe disruption of the data center on August 23, 2019, our system maintained stable operation and lost no data by the redundancy of the blockchain network. Furthermore, the health check system using the Amazon EC2 Auto Scaling Group enabled the automatic recovery of the blockchain node in a healthy AZ after the data center disruption event.



(a) This figure shows that Auto Scaling Group setting is set across 2 Availability Zones (isolated data center) in Tokyo Region.
It keeps a certain number of healthy EC2 instances.

(b) If a EC2 instance breaks down in one AZ, another EC2 instance is created and starts in the other AZ.

Even if further instances in the blockchain network or relay server components break down, we are able to prevent data loss. There are queues in the client smartphone app and relay servers, and the queues retain the clinical data until data are successfully sent. While the queues contain the data, we can recover the affected system.

Discussion

Principal Findings

In this study, we showed that a data management system using blockchain technology can reliably protect medical data and provide an immutable and fully traceable audit trail in a clinical trial. Due to the sensitivity of a hash function's output in relation to its input, any change in clinical data will result in a completely different hash string. This string will be an input of the next block's hash function, and the resulting string will be completely different from what it was prior to the data modification. As such, data integrity in a blockchain-based data management system can be checked by simply comparing the hash values of a blockchain. Verifying integrity can be done quickly, as the regulator needs only check for hash string equivalence. Our system can thus offer an improvement in clinical trial data management, enhancing trust in the clinical research process and easing regulator burden [23]. Although we used Hyperledger Fabric for the blockchain platform, other open-source platforms such as Ethereum can also be applied [42,43]. Furthermore, our system can also be used in clinical trials that collect data via other devices like PC or Internet of Things.

ICH-GCP provides guidance for monitoring conduct of a clinical trial to verify that reported clinical data are complete, accurate, and accounted for by source records. Representatives from the pharmaceutical and medical device industries must visit hospitals frequently and verify data by SDV to confirm that collected medical data are transferred correctly to the case report forms. It has been reported that almost half of the total budget for a phase 3 clinical trial is GCP-related and half of the GCP-related cost is related to SDV [1,3]. The total cost for current SDV in a typical phase 3 trial is estimated at US $90 million, which will be added to the price of the drug [3]. As the size and complexity of clinical trials grow, the cost of monitoring by the traditional method has become increasingly expensive. EMA and FDA have published updated guidelines for the monitoring and oversight of clinical trials. Both agencies encourage study sponsors to implement remote and risk-based monitoring [44,45]. Although remote monitoring may be an attractive alternative to traditional SDV, some studies have shown that remote monitoring can be more time-consuming than traditional monitoring and may be insufficient as a complete alternative for SDV [46]. Another option, risk-based monitoring, also needs risk assessment before its implementation and will not eliminate the need for data verification by the human eye. Conversely, our blockchain-based system enables secure data management without labor-intensive monitoring operations in medical practice. It can drastically reduce the cost of human resources and the risk of human-induced error. Information technology systems for the management of clinical trials need to keep audit trails permanent, tamper-proof, and verifiable, as stipulated by FDA 21 CFR part 11. Blockchain for clinical research involves a promising set of technologies that may advance data integrity and efficiencies in clinical research.

This study was conducted to demonstrate clinical data management using blockchain technology under certification of the regulatory sandbox of the Japanese Cabinet Office. The Japanese government aims to actively explore innovative and disruptive technologies through this regulatory sandbox system under the Cabinet Secretariat to address challenges such as extreme aging of the population [28]. Japanese society is facing challenges like increased national public health expenditures, higher demand for health care services lacking appropriate cost controls, and shortage of health care workers. Some of these challenges are becoming more acute, with recent data indicating that expenditures in health care insurance are growing in Japan [47]. The data collected through the demonstrations in the regulatory sandbox will be used in deliberation for regulatory reform, which will facilitate the creation of innovative business activities with new technologies and new business models.

Severe disruption of cloud server services occurred in the AWS Tokyo region on August 23, 2019, during the clinical trial. Thousands of companies, ranging from internet retailers and smartphone payment platforms to game providers, were affected and their services were suspended. During the event, customers of these services could not access their own information and lost data that should have been generated during the event. Our system maintained stable operation and lost no data from the participants of the clinical trial during the disruption event due to the redundancy of the blockchain network. The configuration of the blockchain network to span multiple data centers in AWS, along with the health check system using Amazon EC2 Auto Scaling, enabled automatic recovery of the blockchain network after severe disruption of the data center. These features in our system, which provide zero downtime for the availability of patient data, are suitable to meet the requirements of clinical trials.

Limitations

Further studies are needed to verify the scalability of the system for conducting various kinds of clinical trials. Although the transaction throughput in the Hyperledger Fabric platform that we used is much higher than public blockchain, further studies like multiple clinical trials in a single system may be fruitful. Data collection via multiple devices should also be tested toward the dissemination of virtual clinical trials.

Conclusion

In our study, we ran a clinical trial for breast cancer using a blockchain-based clinical data management system. The data were validated by protocol, and traceability was secured. Even with the severe disruption event of cloud server services, our system preserved the integrity of the clinical trial data. The study was conducted as a regulatory sandbox project by the Cabinet Office of Japan and will open the possibility for future deregulation measures enabling efficient clinical development.

Acknowledgments

This work was supported in part by the New Energy and Industrial Technology Development Organization (NEDO) and the Cabinet Office of Japan. We thank Kuniharu Tanabe and Satoshi Ota for the critical reading of the manuscript.

Authors' Contributions

TU designed the research; TH, TM, KO, KT, YM, and YO performed the research; TH and DI analyzed the data; and TH, TM, TK, DI, and TU wrote the paper.

Conflicts of Interest

TH, TM, KO, KT, TK, DI, and TU are members of SUSMED Inc. YM has received speaker fees from Suntory, Pfizer, Mochida, Eli Lilly, Morinaga Milk, and NTT Data and is conducting collaborative research with Morinaga Milk and SUSMED Inc.

Abstract

Digital health innovations have been rapidly implemented and scaled to provide solutions to health delivery challenges posed by the coronavirus disease (COVID-19) pandemic. This has provided people with ongoing access to vital health services while minimizing their potential exposure to infection and allowing them to maintain social distancing. However, these solutions may have unintended consequences for health equity. Poverty, lack of access to digital health, poor engagement with digital health for some communities, and barriers to digital health literacy are some factors that can contribute to poor health outcomes. We present the Digital Health Equity Framework, which can be used to consider health equity factors. Along with person-centered care, digital health equity should be incorporated into health provider training and should be championed at the individual, institutional, and social levels. Important future directions will be to develop measurement-based approaches to digital health equity and to use these findings to further validate and refine this model.

(J Med Internet Res 2020;22(6):e19361) doi:10.2196/19361

virtual health; digital determinants of health; digital health equity; digital health; equity; COVID-19; public health; eHealth; social

Introduction

The public health crisis posed by coronavirus disease (COVID-19) has ignited rapid implementation of digital health care. In this commentary, we urge the implementation of health equity–informed digital health solutions. We introduce the Digital Health Equity Framework (DHEF) to identify the digital determinants of health and their links to digital health equity. In the current response to the COVID-19 pandemic, digital health has been rightly heralded as an innovative health solution that can ensure ongoing access to clinical care and allow public health measures that stem rapid viral transmission and spread [1,2]. However, unexamined inequities in access to and implementation of digital health as well as the quality of care afforded by digital health can recapitulate and deepen the inequities that have long existed within our health care system.

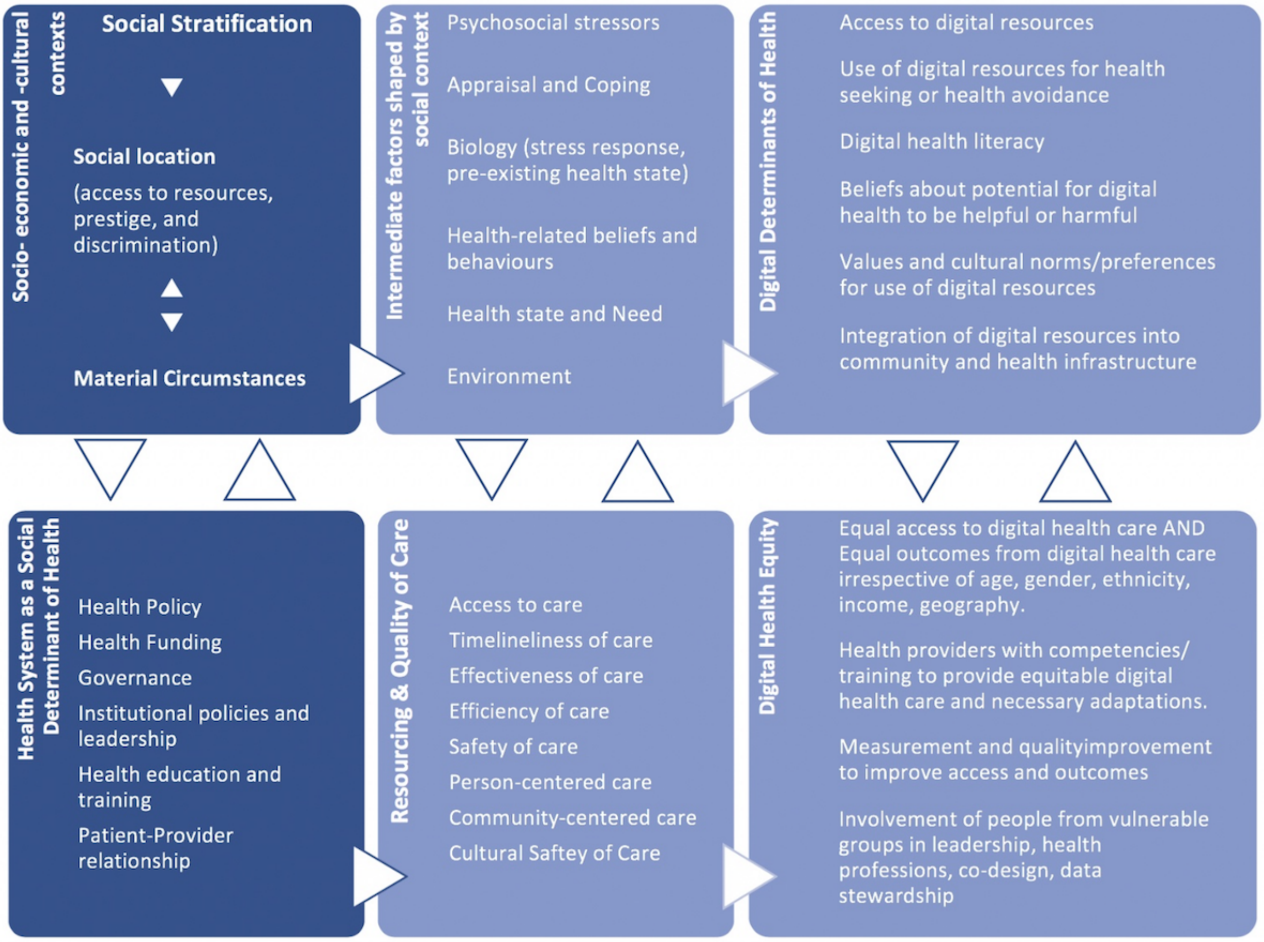
Digital health is broadly defined as "the field of knowledge and practice associated with the development and use of digital technologies to improve health" [3] across the full range of health technologies introduced into care, including telehealth, mobile health apps and wearable technologies, and online health services and tools. During the COVID-19 public health crisis, two modes of digital health have been commonly used: virtual health care, or televideo-enabled interactions between health providers and patients, and health information that is accessed online or via mobile apps.

Some media commentators [4] have stated that COVID-19 is the "great leveler" because it knows no boundaries and can infect rich and poor, young and old. However, this uncritical perspective misses the systemic factors that impact outcomes of illness and create health inequities between communities and across the life courses of individuals. Mounting evidence suggests that the COVID-19 pandemic has far greater associated morbidity and mortality in racialized groups that struggle with poverty and poor access to health care; the pandemic has also been suggested to compound preexisting inequities [5]. Similarly, there has been a lack of attention to health equity in the development of digital health solutions [6]; therefore, when these solutions are applied within the pandemic response, they may have unintended consequences of furthering health inequity. For example, access to technology can be limited by poverty, under-resourcing of health systems and neighborhoods, homelessness, and other factors that decrease engagement with technology and with digital health literacy skills. Health providers may also lack training and competencies in consideration of digital health equity as well as the cultural humility to understand how their patients and communities may experience or interact with technology. Digital health technologies interact with social, cultural, and economic realities and with social determinants of health to indirectly contribute to health equity.

The Digital Health Equity Framework (DHEF)

Here, we propose the DHEF (Figure 1), which applies many health equity factors outlined by Dover and Belon [7] in 2019, integrated with digital determinants of health and digital health equity. In their recent approach, Dover and Belon survey the many frameworks proposed for considering social determinants of health and address some of the limitations of the health equity field by moving from a superficial description of factors to a more comprehensive, ecological approach that considers the multitude of social, cultural, and economic factors that impact health and well-being as well as the interactions among these factors. Most significantly, they link these social determinants to health equity and begin to delineate a structure through which health equity can be measured within organizations and at a health system level.

Figure 1. Digital Health Equity Framework.



In Dover and Belon's model, which informs the foundation of the DHEF, the process of social stratification within economic and cultural social contexts refers to the hierarchical allocation and unequal distribution of power, prestige, and resources; this stratification assigns individuals to a social location, which is defined by intersectional factors such as race, age, income, geography, rurality, gender, ability, and occupation as well as other social factors. A person's social location governs exposure to health-related risks and vulnerabilities, including discrimination. A person's social location and material circumstances can be mutually reinforcing, and they also intersect with intermediate factors that shape health and health behaviors, including psychosocial stressors; styles of appraisal and coping; biology, including current and health status and preexisting conditions; health-related beliefs and behaviors; current health needs; and their environment [7].

Similarly, in the DHEF (Figure 1), *digital determinants of health* interact with other *intermediate health factors*, such as psychosocial stressors, preexisting health conditions, health-related beliefs and behaviors, and the environment, along with the person's current health state and needs. For example, access to digital health resources and digital health literacy interact with the degree and kind of psychosocial stress a person is currently experiencing; job loss or poverty, level of education, and previous exposure to digital media can all impact access. Styles of coping and appraisal of risk, along with health-related beliefs, can shape beliefs and behaviors regarding digital health; for example, some patients may have a tendency to avoid health care or to minimize risk, leading to issues such as corollary avoidance of digital health care, privacy-related concerns, or failure to appraise the quality of digital health information. Just as a person's environment shapes their health care access and quality, it also shapes their digital health access and quality; people living in overcrowded homes may lack privacy or, as with underhoused and homeless populations, may not have access to digital health solutions at all. All these intermediate factors are set into play, are reinforced, and in turn reinforce the *socioeconomic and sociocultural context* and the *social stratification* process. Intersections of race, gender, and geography are among the variables that determine one's power in society and define one's social location, which is closely linked to and interacts with one's material circumstances.

The DHEF expands on the *health system as a social determinant of health*. Moving the dial on health equity, including digital health equity, requires looking beyond individual factors to the health system. We need to ensure that at every level, from health care providers to institutions, insurers, health regulators, and government, we are able to detect, understand, and work to improve the *resourcing and quality of digital health care* for all social groups to reduce digital health disparities. Quality of care, which ensures that care is person-centered, safe, timely, effective, and efficient, is also care that is equitable [8]. This includes the quality of digital health care. For example, if digital health care is not experienced as culturally safe by a population of users, or if the environments (living spaces, communities, institutions, and infrastructure) and material circumstances of groups of people are not considered when developing institutional digital health strategies or in the provisioning of funding and remuneration models for providers working with vulnerable populations, the quality of digital care will suffer, and digital health equity will be impacted. The DHEF model highlights the importance of approaching digital health technologies from an ecological perspective, considering the ways that the use of technology by an individual extend out into (and are shaped by) their social, cultural, and economic position in the world. The case shown in Textbox 1 illustrates this interplay using COVID-19 as an example.

Textbox 1. Example of digital health equity related to COVID-19.

> Mr Seow is a 48-year-old man living with his older adult father and three children in an apartment in a socioeconomically disadvantaged urban neighborhood. His economic insecurity forces him to continue in his job as a food delivery worker; this exposes both Mr Seow and his father to higher risk of COVID-19 infection. Overcrowding in their apartment adds to that risk. Mr Seow has poorly controlled diabetes, a preexisting health condition that creates a risk of worse health outcomes with COVID-19 infection and is a consequence of the same social inequities. He also suffers from depression.
>
> Mr Seow's health risks related to COVID-19 may be further compounded by his own style of appraising risk and his own health behaviours. He tends to minimize risk, he smokes, and he has limited awareness of public health advice. His community has aging infrastructure, and the health resources in his neighborhood include an overcrowded hospital with inadequate access to lifesaving equipment such as ventilators.
>
> The effects of these social, cultural, and economic factors compound across Mr Seow's life course and include intergenerational cumulative effects of social location and material circumstances. Mr Seow's father, an older adult, is an immigrant who spent time in a detention center many years ago; he equates hospital with imprisonment, also avoids health care, and has many unmet health needs.
>
> The promise of digital health in relation to Mr Seow's situation is evident. Virtual visits (ie, telehealth) will allow him to continue to access health care for his diabetes and depression while enabling him to avoid exposure to the overcrowded hospital in his community. This has potential to mitigate some of his health risks and support health equity. However, digital determinants of health and likely outcomes of digital health equity should also be examined. Mr Seow's outcome of receiving virtual health may vary greatly compared with that of a man of the same age living in more economically advantaged circumstances. These inequities must be recognized to be addressed. For example, does Mr Seow have access to technology that supports virtual care? Can he meet with a health provider in a private space within his crowded living situation? Does he have a minimum degree of digital health literacy, with the ability to access and appraise reliable information? Do his own personal beliefs and values about technology support his use of digital health? Are digital health resources available in his community, and do they integrate with other points of access to health care in his community (ie, is this option covered by his insurer, or is it integrated with his primary care provider)?
>
> At the provider level, are Mr Seow's health care providers, such as doctors and nurses, trained to think about health equity? Do they possess the cultural humility to recognize some of these potential gaps and disadvantages of virtual care for Mr Seow and to make necessary adaptations? Are they trained to monitor outcomes of virtual health in their setting and to consider sociocultural variables in these outcomes?
>
> Addressing health equity extends far beyond the individual and the patient-provider dyad to systemic and social contexts. To ensure digital health equity, primary care, hospitals, and governments must have digital health strategies that identify and addresses potential gaps in digital health care based on these digital determinants of health. To know whether they are successful in achieving digital health equity, they need to conduct ongoing measurements of equity and of digital health outcomes. Health equity considerations must also be part of quality of care considerations, along with person-centered care that considers patient choice and autonomy.

There are examples, albeit few, of digital health research that incorporates considerations of social determinants and health equity, particularly in developing contexts [6]; however, this approach needs to become mainstream in all implementations of digital health. Only one week ago, the World Health Organization (WHO) released its 4-year draft global strategy on digital health [3], which aims to support international efforts "to develop the infrastructure for information and communication technologies for health…[and] to promote equitable, affordable and universal access to their benefits" along with promoting the development of national digital health strategies. In line with the 2030 Agenda for Sustainable Development, the WHO seizes on the "great potential to accelerate human progress, to bridge the digital divide and to develop knowledge societies." Within the WHO strategy, one of the strategic objectives is to advocate for people-centered health systems that are enabled by digital health. For example, they seek to advance "digital health literacy, gender equality and women's empowerment and inclusive approaches to adoption and management of digital health technologies." The report mentions a number of approaches that relate to health equity throughout; however, these are as yet unformulated within the WHO's implementation plan.

To consider digital health equity within our health and social contexts, we need to establish systematic ways to ensure that potential health inequities are identified and addressed in digital health policies, strategies, and programs so that existing health inequities are not reinscribed onto our virtual health landscapes. Implementation science, which specifies factors relevant to increased uptake of an innovation, is emerging as a critical factor to guide the spread and scaling of digital health; however, implementation models often fail to incorporate health equity factors or to address social determinants of health. To ensure health equity within digital health, we need to be purposeful in implementing digital health in an equitable way and in measuring health outcomes through an equity lens. If we do not collect health equity data, we cannot monitor health equity outcomes. In turn, understanding the population health needs of vulnerable groups can identify barriers to implementation that create innovation gaps, such as the gap between population health interest in digital health care and the capacity of US hospitals to deliver digital health care in response to COVID-19 [9]. Integrating a health equity approach such as the DHEF with a health implementation approach is an urgent need, particularly at this time of rapid advances in digital health innovation. This should include determining appropriate health equity metrics and measures for digital health.

Perhaps most importantly, to avoid duplicating the social stratification that exists in society at large, we need to ensure the meaningful involvement of people from marginalized and vulnerable groups in positions of digital health leadership, as health providers, and in codesign at all stages of innovation and implementation, including as stewards of their own health outcome data. In times of crisis, such as the current COVID-19 pandemic, utilitarian principles of innovation are often viewed as a way to maximize overall social benefits, while egalitarian principles that address inequalities are set aside [10].

Conclusion

There is no question that virtual health care can provide sustained access to essential health care; however, this commentary aims to draw attention to the unintended health equity impacts of the pivot to digital health care from the early days of the response to the current pandemic. One of the major limitations of this commentary is that we do not have available data to quantify these concerns. We believe that measurement-based approaches to health equity are a high priority for digital health research. There is emerging work in this area [11], and we hope that the framework we propose can further stimulate investigation into the multiple ways in which digital determinants of health may impact digital health equity. In turn, these data will lead to refinement of the proposed framework. During the COVID-19 pandemic and in its aftermath, we need to urge ongoing attention to health equity, including digital health equity, and to develop processes and measures to prevent our own blind spots and inattention in this regard. The celebrated curve of innovation cannot reinforce the social gradient of health, whereby people in less advantaged socioeconomic positions have less access to digital health care, poorer quality of digital health care, or worse health outcomes.

Abstract

Background: In case of a population-wide infectious disease outbreak, such as the novel coronavirus disease (COVID-19), people's online activities could significantly affect public concerns and health behaviors due to difficulty in accessing credible information from reliable sources, which in turn causes people to seek necessary information on the web. Therefore, measuring and analyzing online health communication and public sentiment is essential for establishing effective and efficient disease control policies, especially in the early stage of an outbreak.

Objective: This study aimed to investigate the trends of online health communication, analyze the focus of people's anxiety in the early stages of COVID-19, and evaluate the appropriateness of online information.

Methods: We collected 13,148 questions and 29,040 answers related to COVID-19 from Naver, the most popular Korean web portal (January 20, 2020, to March 2, 2020). Three main methods were used in this study: (1) the structural topic model was used to examine the topics in the online questions; (2) word network analysis was conducted to analyze the focus of people's anxiety and worry in the questions; and (3) two medical doctors assessed the appropriateness of the answers to the questions, which were primarily related to people's anxiety.

Results: A total of 50 topics and 6 cohesive topic communities were identified from the questions. Among them, topic community 4 (suspecting COVID-19 infection after developing a particular symptom) accounted for the largest portion of the questions. As the number of confirmed patients increased, the proportion of topics belonging to topic community 4 also increased. Additionally, the prolonged situation led to a slight increase in the proportion of topics related to job issues. People's anxieties and worries were closely related with physical symptoms and self-protection methods. Although relatively appropriate to suspect physical symptoms, a high proportion of answers related to self-protection methods were assessed as misinformation or advertisements.

Conclusions: Search activity for online information regarding the COVID-19 outbreak has been active. Many of the online questions were related to people's anxieties and worries. A considerable portion of corresponding answers had false information or were advertisements. The study results could contribute reference information to various countries that need to monitor public anxiety and provide appropriate information in the early stage of an infectious disease outbreak, including COVID-19. Our research also contributes to developing methods for measuring public opinion and sentiment in an epidemic situation based on natural language data on the internet.

coronavirus; anxiety; pandemic; online; health information exchange; topic modeling

Introduction

The recent appearance of the novel coronavirus disease (COVID-19) has been devastating worldwide. In South Korea, hundreds of new cases have been diagnosed daily since late February 2020. The cumulative number of confirmed cases at the time of writing (April 1, 2020) exceeded 9000. Internationally, over 800,000 cases have been confirmed in more than 200 countries, areas, and territories [1], despite the World Health Organization's request for global efforts to slow down the spread of the virus the previous month [2]. Most countries have strongly recommended basic preventive methods such as quarantine and isolation of suspected cases, a macrolevel campaign on improving personal hygiene (eg, more frequent hand washing), or using masks in public sites. Additionally, some countries including Korea are now implementing more severe measures such as a social distancing that require the general population to refrain from congregating in public places.

In the event of a population-wide infectious disease outbreak such as COVID-19 people's online activities could significantly affect public concerns and health behaviors. Many studies have indicated people's active use of online information in various crisis situations, including a public health crisis [3,4]. Information and emotional exchanges between people on the internet form public opinions and concerns, which in turn affects people's cognition and behavior. Although these opinions and information on the internet are sometimes useful, they are not always appropriate. There could be dissemination of misinformation, which may lead to inappropriate medical advice or unnecessary anxiety [5-7].

Analyzing data on the internet that records how people voluntarily exchange opinions and information about COVID-19, such as relevant posts from social media services, provides a valuable opportunity to understand and monitor the public concerns over COVID-19 and the dissemination of related information on the internet. Considering the need to manage rumors and monitor public opinions and behaviors in the context of a mass infectious disease, and the importance of internet opinions in the event of a population-wide outbreak, the analysis of the online data has great implications for the formation of efficient and effective health policies and appropriate provision of information. These spontaneously written language materials contain a wealth of information about various topics on COVID-19 that cannot be thoroughly predicted by health policy makers and public health researchers, and thus cannot be measured by a traditional predetermined questionnaire. Hence, analyzing web-based data can supplement traditional surveys and contribute to making health policies for the general population [7-9].

Web data analysis is particularly valuable in the early stage of an infectious disease outbreak. In the early stage of a new disease outbreak, health authorities may lack proper guidelines for the disease, and people may not find trustworthy information from other sources. Because of this situation, people might be more affected by uncertain information on the internet. Thus, monitoring web data in the early stage of an infectious disease outbreak is important to prevent inappropriate dissemination of misinformation or unnecessary anxiety that could occur in the early stage of an outbreak.

This study primarily evaluated the public concerns over COVID-19 in the outbreak's early stage using data from the online social questions and answers (Q&A) forum in Korea's largest search engine, Naver.com [10,11], and analyzed the characteristics of item responses. The Naver Q&A forum (the service named "Jisik-In," meaning "an intellectual" in Korean) resembles Quora.com, as it allows users to post questions and answers on any topic. We used 13,148 questions and threaded answers posted on Naver's Q&A forum in the early stage of the COVID-19 outbreak to analyze the characteristics of the public's online concerns and the appropriateness of information circulated there.

In summary, our research questions include the following:

1. What is the focus of the questions on COVID-19 in the Naver Q&A forum?
2. How do the subjects observed in numerous questions change by time and main events?
3. What are the main objects concerning anxiety and worry on COVID-19?
4. How appropriate or significant is the information provided in the answers to the questions communicating anxiety and worry?

Methods

Data Collection

This study used the question and answer data available on Naver's Q&A forum. The forum is open to the public and allows individuals to post both questions and answers, anonymously or otherwise.

There were two main reasons for selecting Naver's Q&A forum among numerous online services available for public opinion exchange. First, Naver is a service provider with a dominant market position in Korea. It receives about 30 million visitors daily and is estimated to be used by about 76% of Korean Internet users as the main search portal website based on a recent survey [10,12]. Moreover, Naver is the only search engine of massive users with a Q&A forum that allows users to freely access the information exchange. Although similar information exchanges could happen in other internet communities and social network services, in general, only their members could approach and see them, so their influence is limited. Therefore, Naver's Q&A forum data better illustrates the Korean public's concern generated through online postings. Second, Unlike data from other social media, language data from a Q&A forum includes a detailed context of the author's interests and feelings. The question and answer form allows the user to post detailed information because its aim is to help others understand the full situation. A Twitter post, for example, often simply reveals an author's feelings or anxieties; however, a question from Naver's Q&A forum explains the issue's background. Our data, thus, may allow more informative analysis on general public concerns over COVID-19 than other sources of web-based data.

COVID-19–related questions posted between January 20, 2020, and March 2, 2020, and their respective answers were collected from Naver's Q&A forum and used for analysis. January 20, 2020, was chosen as the starting point for data collection since it corresponds with the diagnosis of the first patient with COVID-19 in Korea, and questions before this date are scarce. Duration of the previously mentioned data was then confirmed by considering the frequency and characteristics of the data during preprocessing. The procedure for identifying the COVID-19–related posts comprised several steps.

First, one question and its attached answers were considered as one document. We collected all the documents (questions and answers) containing the word "코로나" (in English, "corona") from December 30, 2019, to March 2, 2020. This, however, also extracts questions and answers using the word "코로나" that refers to objects other than COVID-19.

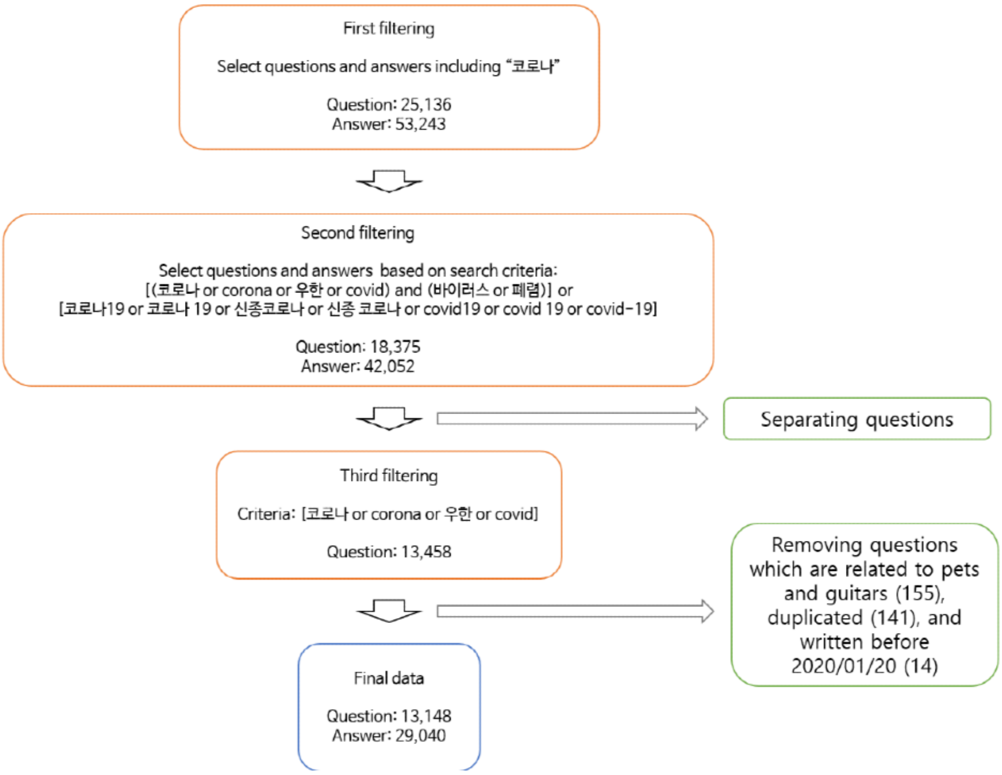
Second, the data were reselected from the results of the first step using additional search criteria to select COVID-19–related questions and answers more accurately. The search criteria were as follows: ([코로나 or corona or 우한 or COVID] and [바이러스 or 폐렴]) or (코로나19 or 코로나 19 or 신종코로나 or 신종코로나 or COVID19 or COVID 19 or COVID-19). English and Korean words were mixed in the search criteria because Koreans use both languages commonly. The English translations of the Korean words used here are as follows: 코로나=corona, 우한=Wuhan, 바이러스=virus, 폐렴=pneumonia, 신종코로나=novel corona. Therefore, we included biological words such as virus or pneumonia, or a relatively formal name referring to this disease, such as COVID19 or corona19, in the search criteria. These criteria were used to identify questions and answers that were related to COVID-19 and contained at least a fraction of biological perspective, as we assumed that the biological words and formal name reflect the perspective at least a little. Since COVID-19 is a controversial issue in domestic politics, we searched for posts that contained at least some biological perspective and excluded posts written purely from a political viewpoint.

Third, we isolated the questions from the selected data and again selected the questions satisfying the following search criteria: (코로나 or corona or 우한 or COVID). Questions including irrelevant words (eg, pets, guitars) were removed. Since dogs or cats could be infected with a different type of coronavirus than COVID-19, there were questions about it. We excluded the questions related to pets. Questions related to "corona," the guitar-producing company in Korea, were also excluded. The advanced criteria were applied only to the questions because some users supplied answers without considering the questions' contents. In other words, although rare, there were cases in which answers related to COVID-19 were attached to questions unrelated to COVID-19. This ensured that both questions and answers were related to COVID-19.

Fourth, the duplicate questions were deleted. Q&A forum users sometimes reposted the same question or posted a similar question with a slight change in the wording, which were unhelpful. The criteria used to find duplicate questions were whether the first 50 or the last 50 characters of the question, including blank spaces, were duplicated.

Fifth, the few questions (n=14) posted before January 20, 2020, were deleted, as the data in this period cannot represent public concern properly. As a result, 13,148 questions and 29,040 answers, which were assumed to be related to COVID-19, were collected. Figure 1 presents a schematic summary of this process.

Figure 1. Data filtering process. COVID-19: coronavirus disease.



Data Analysis

Several text-mining techniques, including structural topic modeling and word network analysis, were used to analyze public concerns from 13,148 questions. Language data analyses have often used human interpretation capability [13]. The theme in language materials results from synthesizing various information, more than what is simply and explicitly expressed. Therefore, it is convenient to capture themes by mobilizing human ability to interpret texts. However, there is a clear limitation on the amount of data that can be processed by a few researchers. This explains why several previous studies analyzing medical-related media or internet posts used a small amount of sample data [14-16]. These studies were also susceptible to the unfavorable effects of human researchers' subjectivity. Using text mining techniques to extract useful information from large volumes of data using computers, this study objectively estimated public concerns from large volumes of language data.

Although text mining allows us to examine a huge amount of data, these techniques usually cannot capture delicate nuances. For example, using basic text mining techniques, determining whether the answer is correct information or a rumor is somewhat difficult. This poses a challenge to the researcher because rumors, especially convincing rumors, use similar words and connection of words with valid information. To compensate for this, we also used a method that allows medical doctors (family medicine specialists) to categorize answers to questions on a particular topic and then analyze the characteristics of those answers.

In summary, three main methods were used for analysis: the structural topic model (STM), network analysis, and professional qualitative classification. Each method is described in the following sections.

Structural Topic Model

The STM, a type of topic modeling method, was selected to extract the overall themes or focus of 13,148 questions and examine how the theme or focus changed over time.

Like most topic modeling methods developed after the latent Dirichlet allocation (LDA), the STM can extract multiple topics and the topics' probability distribution in each document from a large number of documents. The extracted topics and their distribution are information that summarizes the given documents [17,18].

The topic estimation process is based on several assumptions. Topic modeling methods assume that a document is a simple set of words and a topic is a probability distribution of words (eg, cat: 0.015, dog: 0.01, pet: 0.009, etc). Each document contains multiple topics with specific probability distributions (eg, the first document: topic 1=0.4, topic 2=0.2, and topic 3=0.4). It is then assumed that individual documents were randomly generated from the topics and their distribution per document, and were not directly written by humans; thus, the most probable topics and their distributions are estimated considering the given data [17-19].

Naturally, the probability distribution of words itself does not have intuitive meaning; however, we can interpret the meaning of the topic from the probability distribution of words. When a topic is expressed qualitatively, it mainly appears as an unequal use of words. For example, suppose a topic of "cancer screening test" exists in the language materials. Certain words like "screen" or "mammography" would be used more frequently in this material than other words. Therefore, if we can deduce the word probability distributions, which are likely to produce the given documents, we can also deduce the topics' meanings by noting the high probability words in the corresponding probability distributions.

Distributions of topics in each document are also important information for interpreting the topics because they can be used to identify how each topic is realized into language material. We can also identify documents that have the highest proportion on each individual topic. For example, we can identify the top ten documents with the highest proportion of topic 2 among all documents. After reading the ten documents, we can understand the detailed context and intuitive meaning of topic 2 more accurately.

In short, the topic modeling method estimates topics and their probability distributions per document that explain the given documents appropriately. Although the probability distribution itself does not provide intuitive meaning, researchers could interpret the topics' meaning.

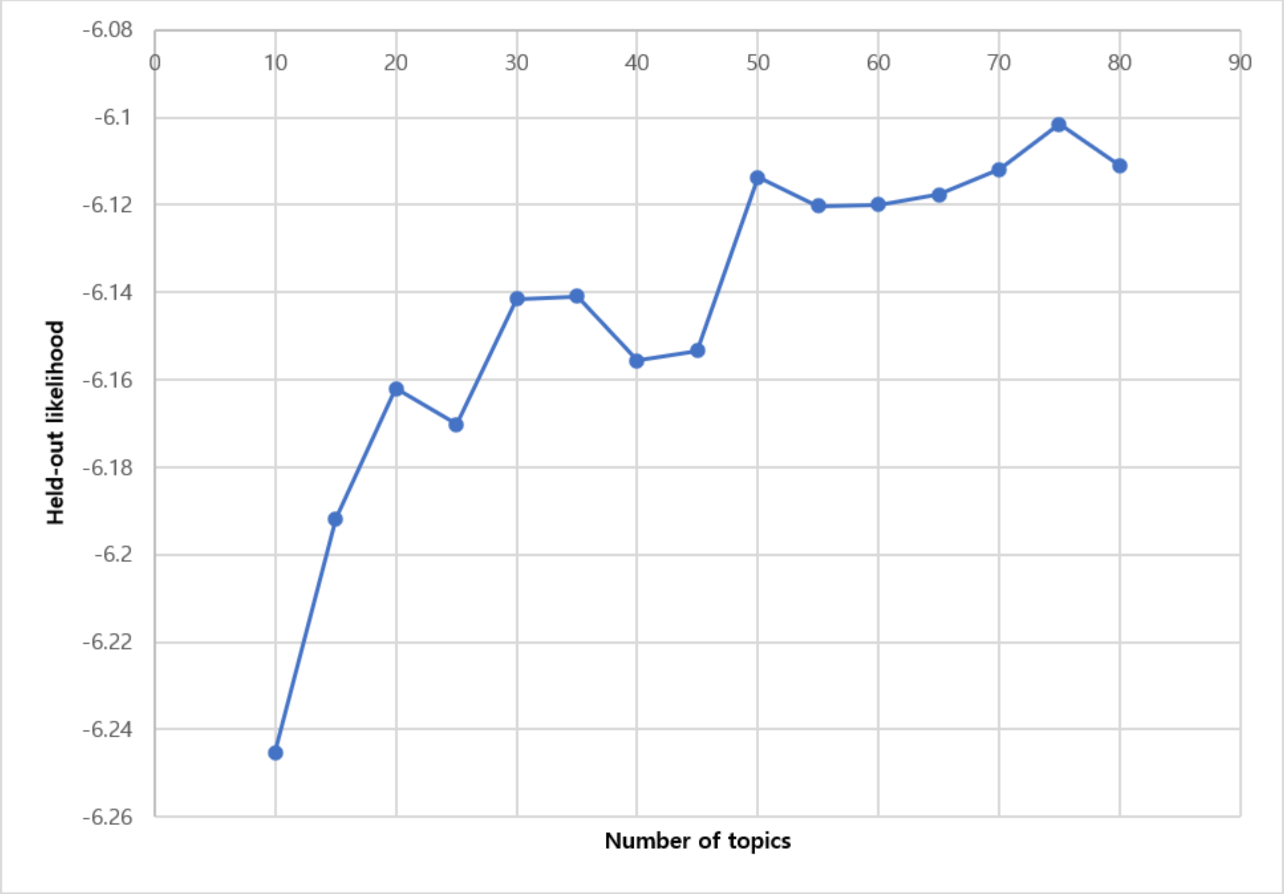
Besides this general function of topic modeling, the STM estimates how much of the document's meta information affects the topics' proportion or content [20,21]. Meta information refers to other information that exists in the document outside the document's content (eg, when a document was written or the type of author). The STM estimates how the meta information affects the proportion and content of the extracted topics. Given that this study primarily aimed to analyze how the topics of questions changed over time, these attributes of the STM were deemed appropriate to achieve our research objectives. This study estimated how the time of posting the question affected the proportion of question topics.

The application of the STM to the questions is described as follows. Of the 13,148 questions, 12 questions were additionally eliminated in the preprocessing for the STM. We only used the words that appeared in at least 2 questions and questions that contained at least 2 words, as a word that only appears in a single document or a question that contains only 1 word carries little information for topic modeling. We estimated 50 topics from the remaining 13,136 questions. The number of topics was set at 50 because there was no significant improvement in topic modeling performance after 50 as measured by the held-out likelihood [22] when changing the number of topics from 10 to 80 in increments of 5 (Figure 2). The posting time of the questions, which was measured by the unit of 1 day, was used as a covariate in our model for estimating topics' proportion change by time.

All the topics were interpreted and labeled by considering three kinds of information: the words given high probability in each topic, the words with a high frequency and exclusivity (FREX) score in each topic, and the documents with a high proportion of each topic. The importance of the high probability words and the documents estimated to have a high proportion of each topic in interpreting topics has been explained previously. The words with a high FREX score supplement the high probability words by considering exclusivity and frequency together [21]. That is, a high FREX score word of a topic is important, especially in the topic. All the authors collectively interpreted and labeled 50 topics, considering the top 15 probability words, the top 15 FREX score words, and the top 10 questions with a high proportion of each topic.

We also used the STM to sample representative questions containing subjects related to anxiety and worry. To analyze the appropriateness of the answers to the questions related to the public's anxiety and worry, most representative questions needed to be reselected from the entire batch of questions. Since it is impossible for a small group of human researchers to review 13,148 questions directly, the STM results were used to select questions that contained anxiety- and worry-related topics. We extracted questions that contained a high proportion of topics discussing physical symptoms and self-protection methods against COVID-19 because they were revealed as the main targets of anxiety and worry.

Figure 2. Held-out likelihood.



Network Analysis

Topic modeling is useful for identifying broad topics in a large volume of documents; however, a researcher cannot control the model to see results on specific subjects. Therefore, analyzing the relationship between particular words of interest is important in achieving our research goals.

One of our research objectives was to identify the objects and contexts of anxiety and worry expressed by people. To identify the source of anxiety and worry, we extracted the top 20 words that appeared most frequently in the questions including the words “불안” or “걱정,” which are Korean words for “anxiety” and “worry,” respectively. We considered both words appearing in the same question as a linkage or an association between the words.

Additionally, we created a word network using the top 50 words linked to the two Korean words referring to anxiety and worry to analyze the context of people’s anxiety and worry comprehensively. Observing individual words associated with anxiety and worry cannot accurately analyze the full context of anxiety and worry. A network of words linked to anxiety and worry allowed us to further analyze the context of anxiety and worry. Therefore, the top 50 words associated with the two Korean words referring to anxiety and worry were gathered, and the network was created. Connection criterion is a coappearance of words in the same question. This network is extremely dense because the network is made of words that are used in a similar context. Only the most prominent links were required to be selected to extract particularly prominent meanings. For this, only the links with the highest weight, (ie, 500 of the most frequent connections) were extracted to create a subnetwork. This subnetwork was assumed to contain the most prominent contexts related to people’s anxiety and worry.

The network community detection algorithm was applied to this subnetwork to extract distinguished themes from the network. This algorithm identifies relatively more cohesive communities of nodes within a network [23-25]. When applied to our word network, it worked to find a set of words that appeared more frequently with each other in the entire network. For example, the algorithm could judge that a “China,” “Wuhan,” “pneumonia,” “infection,” and “travel” word cluster appeared frequently in the entire word network. This was interpreted as a distinct theme that we found through network analysis. In other words, the network community detection algorithm identified the most prominent and distinct contexts that appeared when people expressed anxiety or worry. We identified cohesive communities of words, which contained at least 5 words because this amount was required to interpret the word community into a meaningful theme.

Walktrap was selected from the various network community detection algorithms because of its excellent performance while overcoming the “resolution problem” [25,26]. A resolution problem refers to a situation in which algorithms do not capture a community of a small number of nodes properly, a frequently faced problem in applying network community detection algorithms. Put simply, the Walktrap algorithm calculates the distance between nodes in the network using a random walk from each node and finds communities based on that distance. The analyst sets the step of the random walk for distance calculation, which we set to 2. The network analysis was implemented through the igraph package of R (R Foundation for Statistical Computing).

The Walktrap algorithm was also used to identify cohesive communities of topics related to each other. The STM estimates the correlation between topics [20,27]. A positive correlation between two topics means that the two topics are likely to appear together in the same document. We assumed this positive correlation to be a link between topics and formed a network of all topics. Next, using the network community detection algorithm, we analyzed whether there were relatively more cohesive communities of topics in the entire network of topics. In other words, we tried to identify sets of topics that were often expressed together. Consequently, we identified 6 topic communities that were judged to be cohesive. We labeled each topic community to express broader themes embracing topics belonging to the topic community, considering each topic's interpretation made through the STM.

That is, after estimating 50 topics from 13,136 questions, these topics were summarized into 6 topic communities using the Walktrap algorithm and then interpreted. This additional step was employed due to the fact that, although 50 topics is a great summary, it is still a lot of information for a person to grasp intuitively.

Professionals' Qualitative Coding

Using the results of the aforementioned methods, we assessed the appropriateness of the answers to questions dealing with the main targets of anxiety and worry, and found that the main themes were physical symptoms and self-protection methods. We selected sample questions and answers that addressed these two subjects. Two medical doctors, who are family medicine specialists and the authors of this paper, classified the answers into 5 independent categories: appropriate answers, unrelated answers, wrong answers, advertisement, and other. If there was a disagreement on an answer's category, they discussed until they reached an agreement and recorded the agreed result.

The sample questions were selected by considering the proportion of topics in each question that resulted from using the STM. The themes of physical symptom and self-protection correlated with the fourth and fifth topic communities, respectively. Choosing high proportion questions from each community of topics could form good sample questions that appropriately represent each theme. Therefore, the proportion of the topic communities 4 and 5 was calculated for each question based on the topic proportion information per question. It was created by adding up the proportion of topics belonging to each topic community. The top 100 questions were selected for both topic communities 4 and 5, and the answers to each question were identified. The number of answers was 250 and 306, respectively.

Morphological Analysis and Part of Speech Tagging

For the previously mentioned methods, especially STM and network analysis, to function properly, morphemes need to be extracted from our language data. That is, we need information about what kinds of words appeared from where and at what frequency. The program used to determine this is called a morphological analyzer. From the many types of morphological analyzers applicable to Korean, Komoran was used because it is resilient to the spacing problem in Korean and is sufficiently qualified, as it won awards from the National Institute of Korean Language in 2016.

We would like to mention in advance a caveat regarding the words extracted from the data by Komoran; Korean and English do not respond 1:1. For example, there are several Korean words that can be translated as fever ("열" and "발열"). When translating such words into English, we numbered them (eg, fever_1, fever_2).

Results

Frequency of Documents and Words

Our data included a total of 13,148 questions. Figure 3 presents the number of questions sorted by date.

Of the words that appeared in the questions, Table 1 presents the top 30 frequency words. Those occupying the top 5 positions include "cough," "symptom," "throat," "mask," and "confirmed diagnosis."

Figure 3. Number of questions by date.

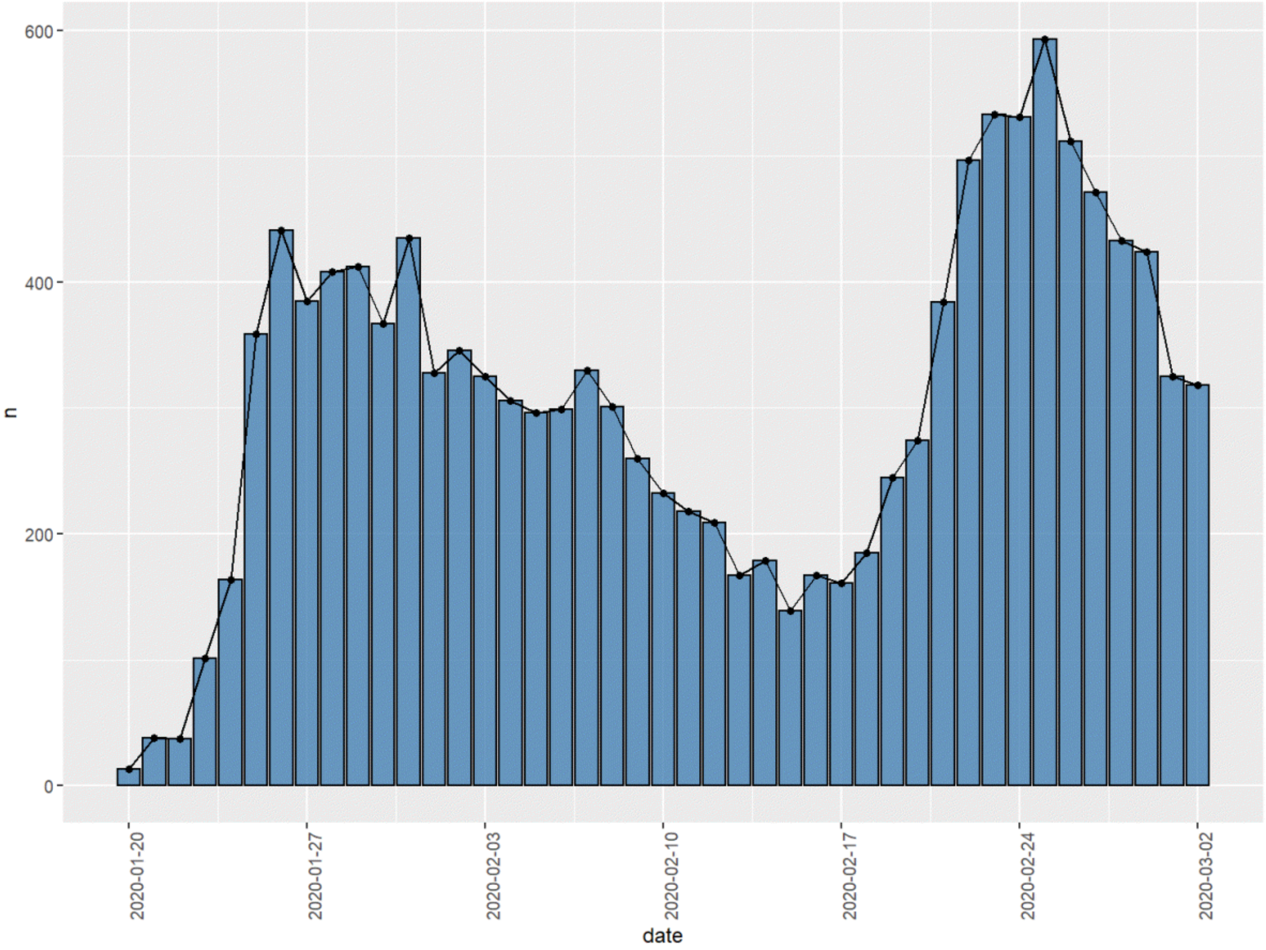


Table 1. Top 30 frequency words in all questions (nouns, excluding words containing “corona”).

Structural Topic Model

About 50 topics were estimated from 13,136 questions using the STM and were interpreted by the authors. Table 2 presents the results of the interpretation. The first column from the left is the topic number, the second column is the topic’s interpretation, and the third column is the topic community number that each topic belongs to. Topic numbers and topic community numbers are nominal numbers for distinction.

Most topics had an apparent subject or consistent contents that allowed a precise interpretation. Some topics, however, were extracted because of expressions that appeared repeatedly in various questions, regardless of the content of the question. This is because topic modeling captures the coappearance patterns of multiple words observed in documents without considering the meanings of words. For example, if many questions on different subjects contain similar expressions, like “please answer my question or you could be cursed,” the topic model would capture that pattern and estimate the topic based on the pattern. In our model, several topics were extracted because of unique Korean language usages. In this case, we unified the interpretation of the topic as “Questions involving particular Korean language expressions without a common subject.” Additionally, we presented the most prominent Korean expression in these topics in Korean in parentheses and translated its meaning into English.

The third column in Table 2 resulted from applying Walktrap to the topics’ correlation network for grouping topics into several cohesive communities. A total of 50 topics were categorized into 6 topic communities, each given a number (the rightmost column). The topics in Table 2 were sorted according to the topic community numbers to help readers easily identify topics belonging to each topic community. Figure 4 presents a visualization of the entire topics network and communities of topics identified through Walktrap. A node is a topic, the number below a node is the topic number, a link is a positive correlation between topics, and the color of the node indicates the topic grouping. Therefore, topics of the same color belong to the same community. Table 3 presents the result of the authors' interpretations of topic communities.

The STM calculates the proportions of topics on a per-document basis. This allowed us to calculate the proportion of each topic in the entire document, which could also be used to calculate the proportion of the topic communities in the entire document. We aggregated proportions of topics belonging to the same community. Additionally, the STM calculated the proportion variation of all topics over time because the time variable was set as a covariate in our STM. The estimates of topics' proportion changes over time could also be aggregated to produce the proportion change of the topic communities over time. Figures 5 and 6 present the results.

Topic community 4 (questions suspecting possible COVID-19 infection after developing a particular symptom) occupied the largest proportion of all the questions. It increased sharply in late February when the number of infections had begun to increase earnestly in Korea. In Figure 6, the yellow line (topic community 4) and the dashed line (the number of confirmed patients) are almost parallel after the second increase for topic community 4, the yellow line mimicking the increase in the number of confirmed patients. Moreover, it is noticeable that the portion of topic community 2 (concerns over working conditions caused by COVID-19) increased slightly as the COVID-19 situation became prolonged.

Table 2. Interpretations of topics.

Topic number	Interpretation	Topic community number
14	Questions on interpretation of English text related to COVID-19[a]	1
21	Questions on daily life that have little relevance to COVID-19	1
34	Questions on using public transport	1
37	Questions suspecting possible COVID-19 infection from past activity or experience	1
39	Questions on screening centers or hospital visits	1
44	Questions suspecting or worrying about possible COVID-19 infection by going outside or coming in contact with people	1
45	Questions suspecting or worrying about possible COVID-19 infection in their family	1
49	Questions involving particular Korean language expressions (“~때”: a noun indicating the particular point in time[b]; “~문제”: problem regarding ~) without a common subject	1
28	Questions regarding the impact of COVID-19 on their working conditions or days off work	2
30	Questions regarding part-time workers coping with the difficulties from COVID-19	2
1	Questions on the current status of the COVID-19 outbreak in Korea	3
2	Questions on the current status of the COVID-19 outbreak outside of Korea	3
3	Other questions regarding COVID-19	3
5	Questions on the expectation of further spread of the COVID-19 outbreak	3
6	Questions on the specific information of confirmed patients in a regional area, including patients’ “route map”	3
10	Questions regarding the end of the COVID-19 epidemic.	3
12	Questions involving particular Korean language expressions (“~가궁금하다”: I wonder~; “~를알려달라”: please explain about~) without a common subject	3
13	Questions expressing the author’s fear and difficulty related to COVID-19	3
15	Questions about treatment of COVID-19 in hospitals	3
18	Questions on specific circumstances that lead to COVID-19 infection	3
23	Questions involving particular Korean language expressions (“부탁드립니다”: could I ask~ please) without a common subject	3
24	Questions on the impact of the COVID-19 outbreak on the stock market	3
25	Questions relating to religion and donation	3
26	Questions about government policies on COVID-19, including an entry ban	3
29	Questions related to the Sincheonji Church and religious events	3
32	Questions involving particular Korean language expressions (“가능할까요”: is it possible to~) without a common subject	3
33	Questions involving particular Korean language expressions (“완전”: an adverb expressing the importance, such as completely or totally; “~겁니다”: an auxiliary verb indicating the current status[c]) without a common subject	3
35	Questions on a COVID-19 vaccine and treatment	3
40	Questions about Wuhan pneumonia in China	3
46	Questions on school opening and delay of school opening; questions on postponing the beginning of the school semesters and reopening date	3
47	Questions involving particular Korean language expressions (“~한데”: I feel like~ then; “~되는데”: it comes to~) without a common subject	3
50	Questions involving particular Korean language expressions (“요즘”: these days or at the moment) without a common subject	3
4	Questions suspecting possible COVID-19 infection after developing a sore throat	4
9	Questions suspecting possible COVID-19 infection after developing chest discomfort	4

Topic number	Interpretation	Topic community number
16	Questions suspecting possible COVID-19 infection after developing a febrile sense and respiratory abnormality	4
19	Questions suspecting possible COVID-19 infection after developing a fever	4
22	Questions on the risk of catching COVID-19 from an exposure to cold weather or in day-to-day living	4
27	Questions suspecting possible COVID-19 infection after developing respiratory discomfort	4
31	Questions suspecting possible COVID-19 infection after developing a headache and cough	4
38	Questions suspecting possible COVID-19 infection after developing diarrhea and eating particular food	4
43	Questions suspecting possible COVID-19 infection after travelling	4
8	Questions about personal protection such as wearing a mask	5
11	Questions on the novel coronavirus contamination mechanism	5
17	Questions about how to use a mask	5
41	Questions on nonscientific knowledge related to COVID-19	5
42	Questions about hand sanitizer and parcels	5
48	Questions about disinfectants and air purifiers	5
7	Questions about the safety of traveling or visiting public places	6
20	Questions about safety related to travel	6
36	Questions on travel and flight cancellation procedures and fees	6

[a] COVID-19: coronavirus disease.

[b] Similar to *when* in a sentence (ie, *when* I was young).

[c] Similar to *have* in a sentence (ie, I *have* a headache).

Figure 4. Topics network and topic communities.

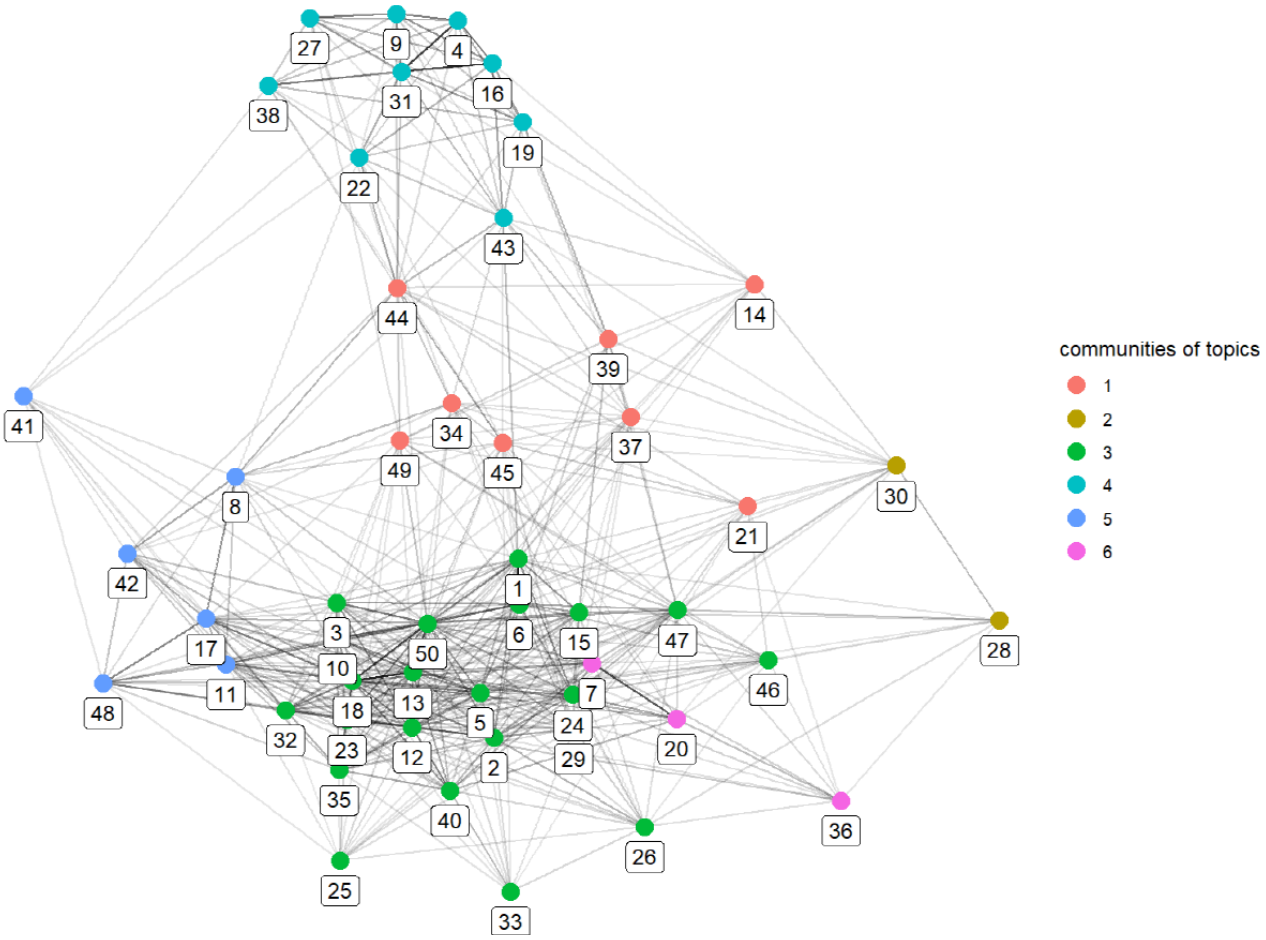

Table 3. Interpretations of topic communities.

Topic community	Interpretation
1	General concern about COVID-19[a] infection
2	Concerns over working conditions caused by COVID-19
3	Questions about the current status of COVID-19 in Korea and government policies
4	Questions suspecting possible COVID-19 infection after developing a particular symptom
5	Questions related to self-prevention measures such as wearing a mask
6	Questions about travel and going out

[a] COVID-19: coronavirus disease.

Figure 5. Proportion of topic communities in all questions. COVID-19: coronavirus disease.

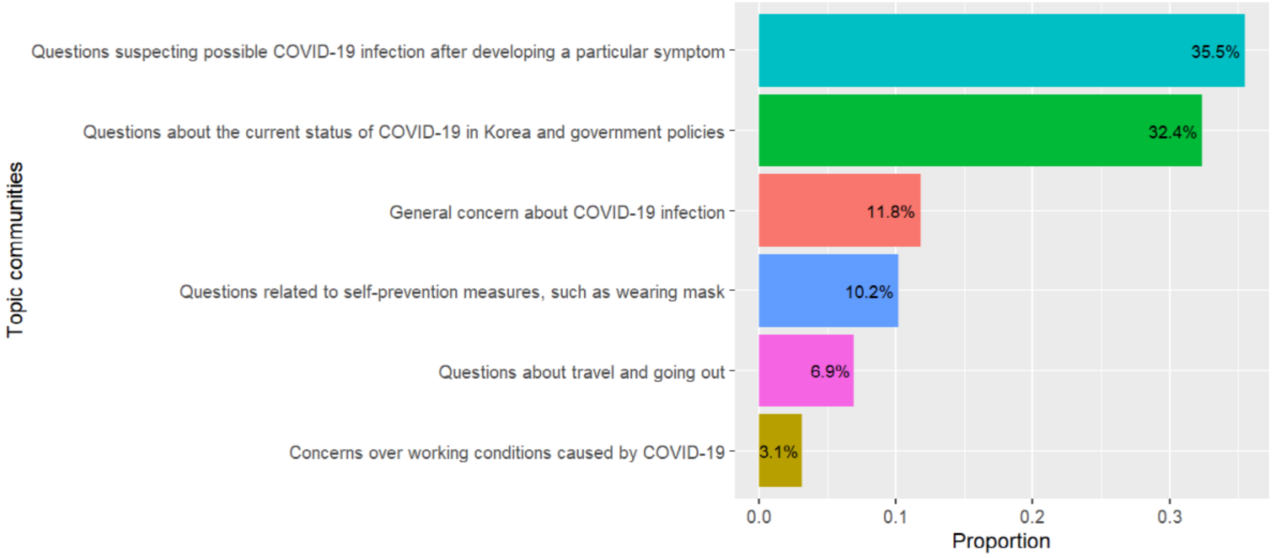

Figure 6. Proportion of topic communities by date.

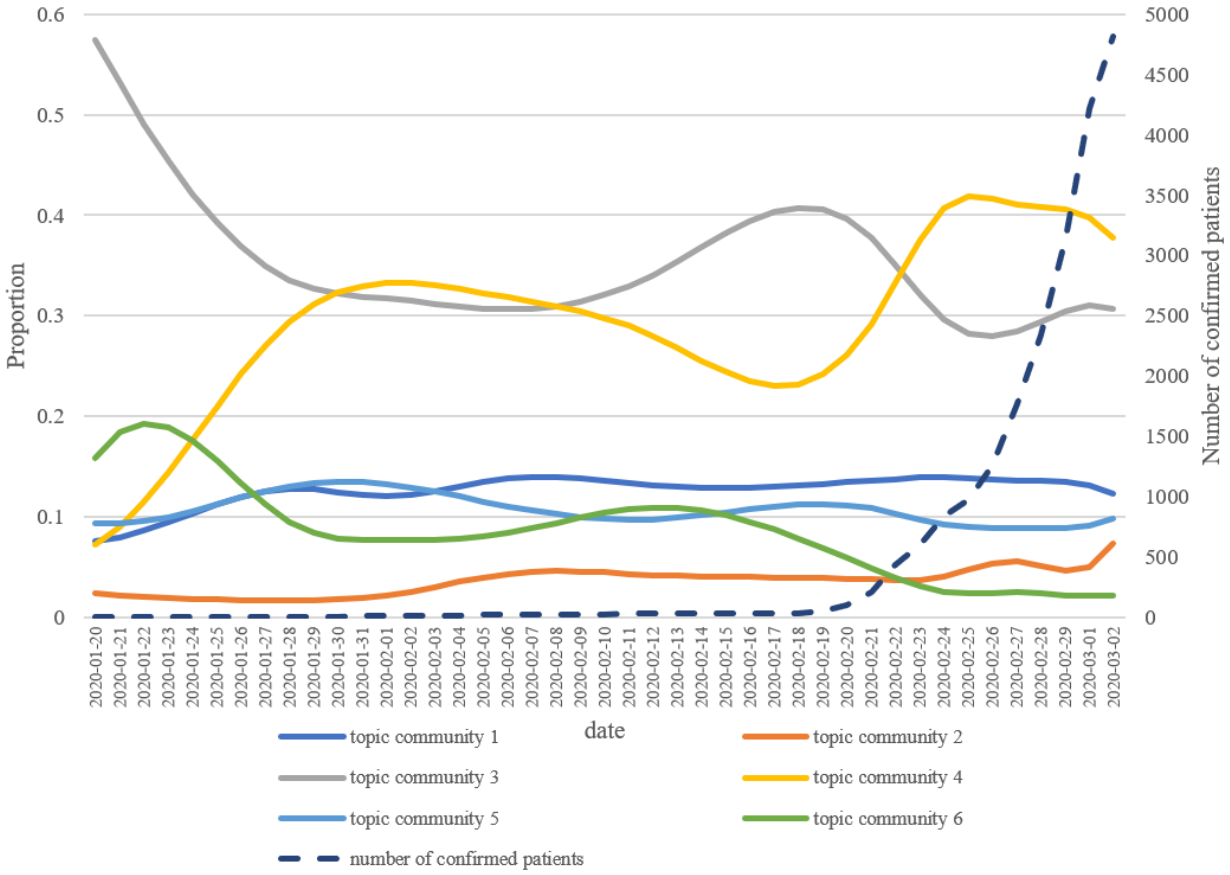

Network Analysis

We extracted 20 words that were most frequently connected with words referring to anxiety and worry (in Korean, "불안" and "걱정," respectively) from the questions posted from January 20 to March 1, 2020. Table 4 presents the results. In Table 4, the top 5 words include "cough," "symptom," "throat," "mask," and "cold." This allowed us to infer that people's anxiety was centered on physical symptoms and key self-protection methods, such as wearing masks.

We also checked whether the list of words associated with anxiety and worry would vary with time. The period (January 20-March 1, 2020) was divided into 6 weeks, and the top words associated with anxiety and worry was extracted from the data of the 6 subperiods (Figure 7). During the week of January 20-26, when the first confirmed COVID-19 cases were reported, the primary subject of anxiety was “China and traveling.” This was natural, considering that COVID-19 was limited to the Chinese Mainland at that time. However, as the number of confirmed COVID-19 cases increased in Korea, words related to physical symptoms appeared as the top words. The period after February 17 was when the number of confirmed cases increased sharply in South Korea by 2 or 3 digits. Henceforth, Koreans needed to be careful about contact with confirmed patients, and the word “confirmed diagnosis” emerged as the main word associated with anxiety. The word “mask” was consistently included in the top 10 words in all periods. In other words, the anxiety and worry about self-protection have been prevalent consistently throughout the entire period.

We formed a word network using the top 50 words linked to anxiety and worry and extracted its subnetwork based on the most prominent 500 links. By applying the Walktrap algorithm to the subnetwork, we could extract three cohesive word communities or three distinct themes. Figure 8 presents a visualization of the three sets of words comprising at least 5 words. One is related to physical symptoms, another is related to self-protection, and the last is related to China. In other words, people’s anxiety was expressed in three main themes. This result was consistent with our reasoning based on the types of words linked to anxiety and worry.

Table 4. Top 20 frequency words appearing with anxiety and worry in all questions (nouns, excluding words containing “corona”).

Word	Frequency, n
Cough	895
Symptom	750
Throat	602
Mask	507
Cold	418
Degree	409
House	404
Confirmed diagnosis	400
Recent	399
Human	386
Hospital	386
Sputum	383
Fever_1	348
Wuhan	322
China	310
Pneumonia	308
Work	274
Rhinorrhea	271
Headache	245
Thought	238

Figure 7. Top 20 frequency words appearing with anxiety and worry in all questions by week (nouns, excluding words containing "corona").

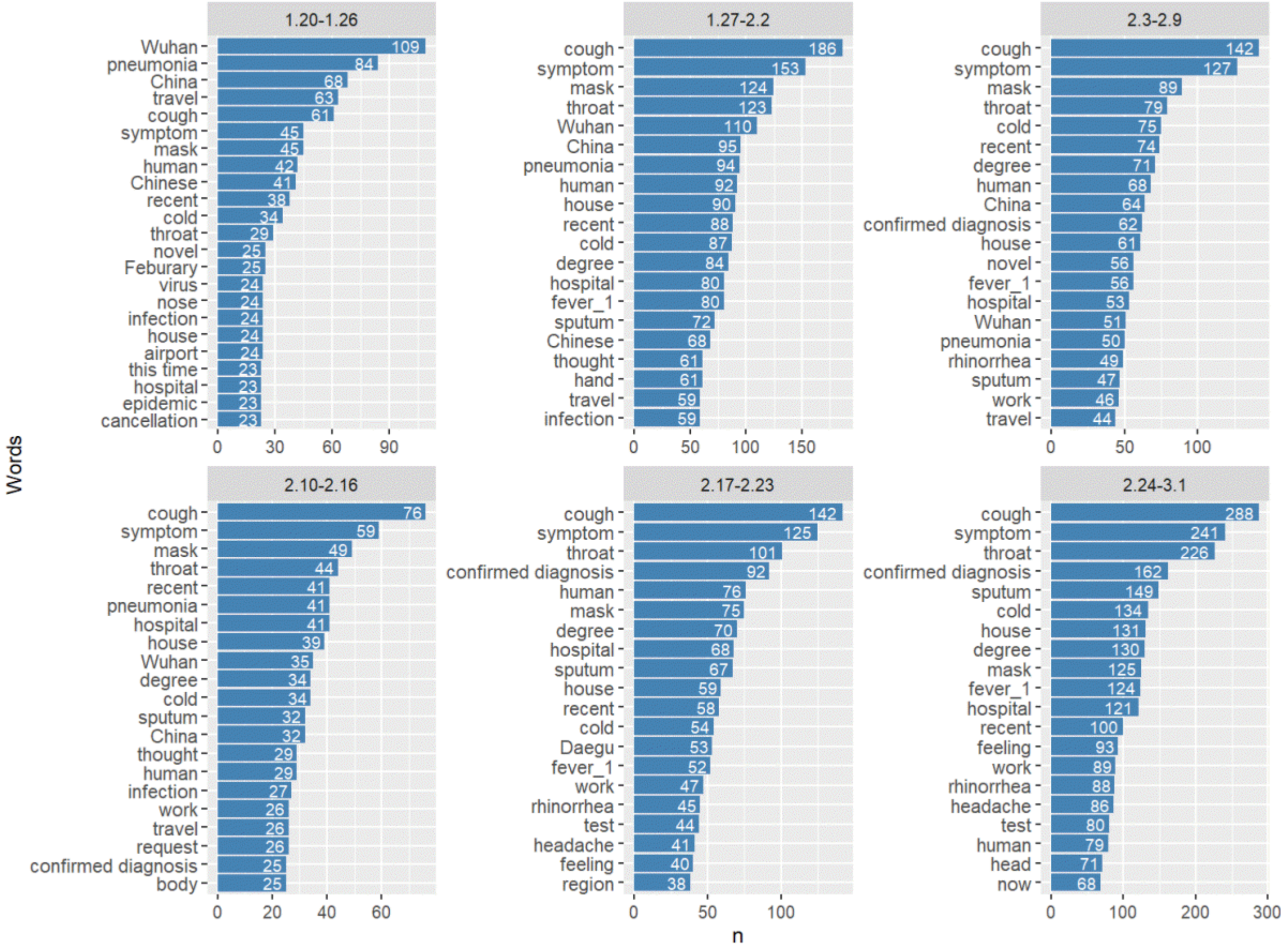

Figure 8. Word network of top 50 words linked to anxiety and worry.

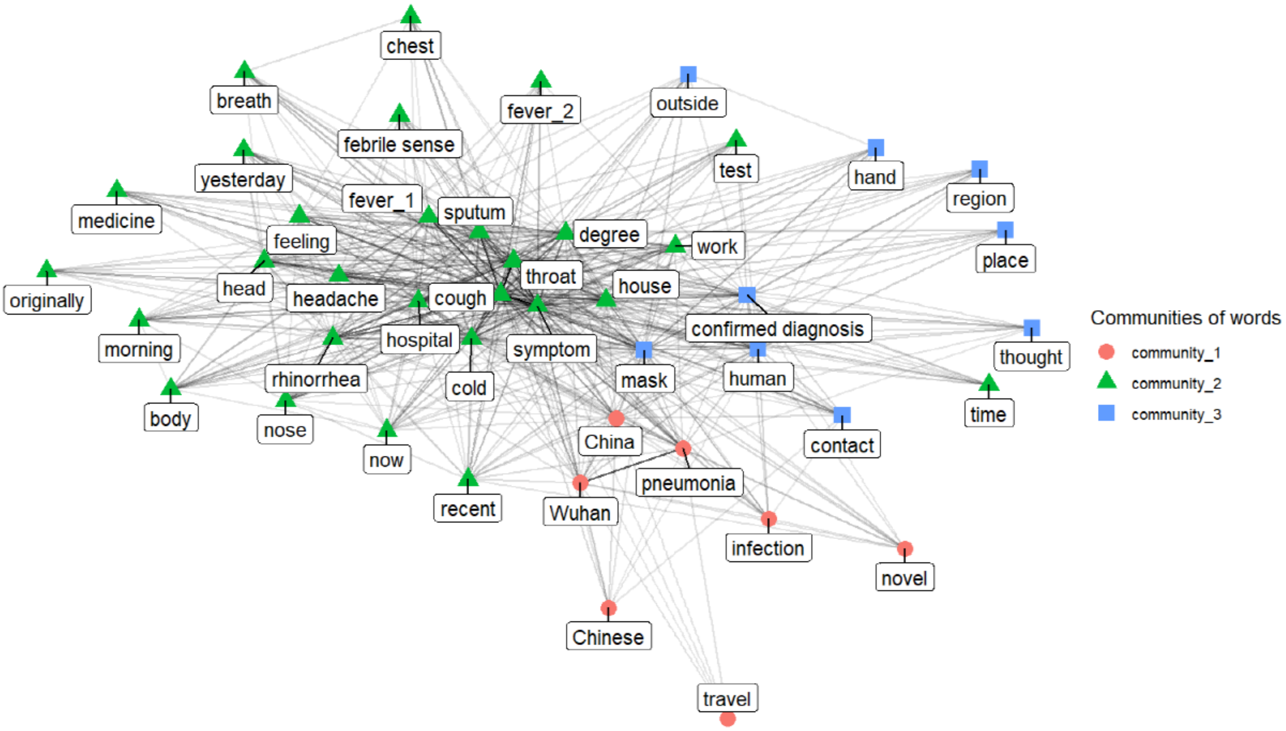
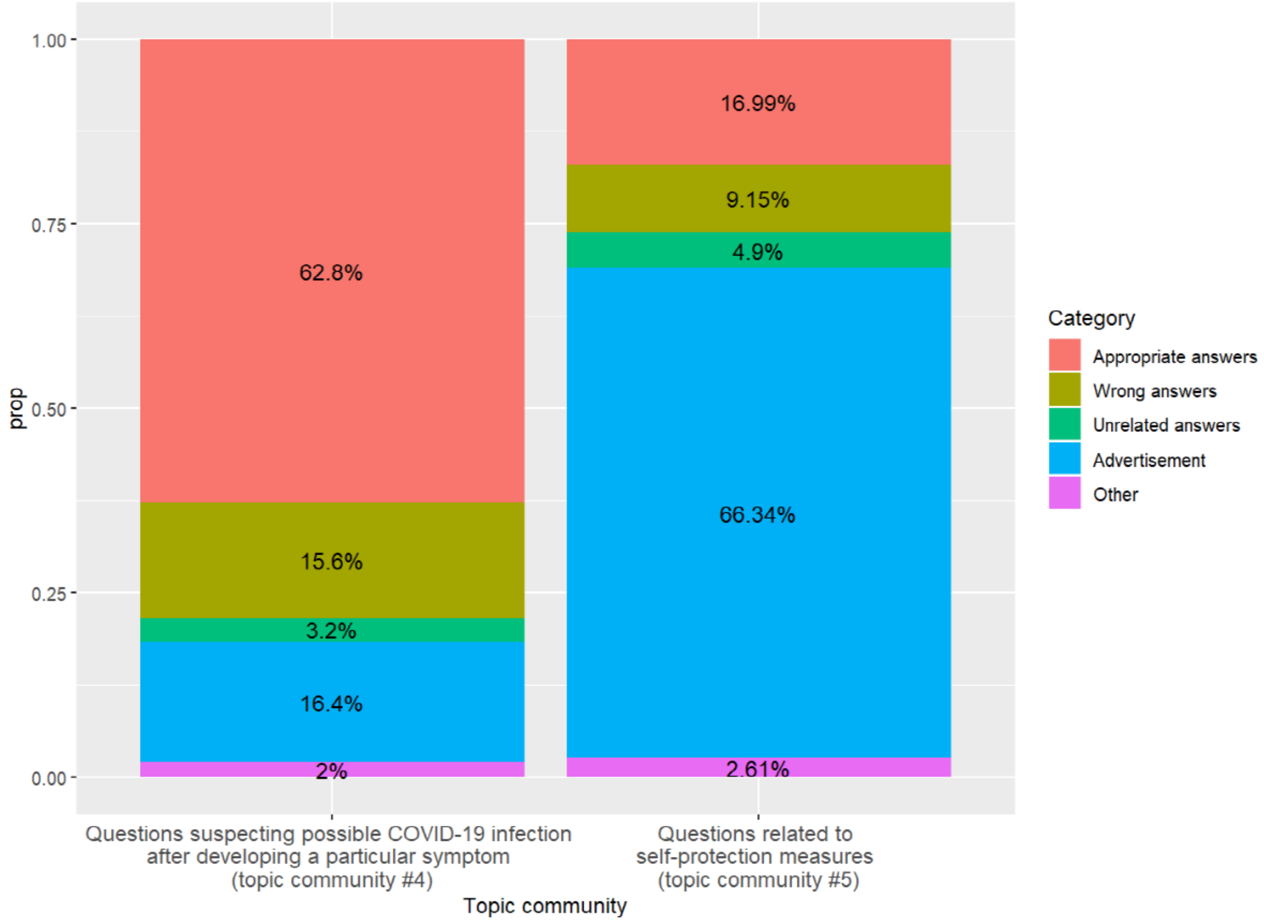


Professionals' Qualitative Coding

Figure 9 shows the results of two medical doctors' categorization of the answers to sample questions dealing with the main targets of anxiety and worry into five categories.

The answers to questions about physical symptoms were often appropriate and relatively less distorted. On the other hand, there were many advertising answers to questions related to self-protection measures.

Figure 9. Proportion of answer categories (based on sample data). COVID-19: coronavirus disease; prop: proportion.



Discussion

In the event of a novel infectious disease outbreak, the general population cannot easily assess the accuracy of the information regarding the disease, and there is increased reliance on online information. Obtaining appropriate and accurate information is extremely difficult, especially in the early stage of an outbreak, due to the uncertainty about the disease. There may be a delay before the governance body, such as health authorities, announces official statements regarding the disease, including symptoms, treatment, or preventive measures. However, it is unlikely that the public would refrain from seeking information and patiently wait until the accurate information becomes publicly available. In this scenario, it is more probable that the members of the populace would seek to acquire the much-needed information from other sources such as the internet.

Consistent with previous studies, our data showed that people sought information regarding COVID-19 on the web. The analysis of 13,136 questions revealed that the largest proportion of topics was regarding anxiety and worries about possible COVID-19 infection after developing a particular symptom. The proportion of topics regarding concerns over working conditions also slightly increased as the COVID-19 outbreak became prolonged. Physical symptoms such as cough, throat pain, and sputum as well as self-protective measures such as wearing a mask were some top key words that simultaneously appeared with the words *anxiety* and *worry* in the word network analysis. This implies that the people were mainly concerned about whether developing a particular physical symptom was relevant to COVID-19 and ways to protect them from COVID-19.

We also analyzed the appropriateness of the answers that replied to the questions. About 63% of the total answers to questions on suspecting possible COVID-19 infection after developing particular symptoms were evaluated as appropriate, while 15.6% of the answers were incorrect, implying a potential dissemination of misinformation. For questions regarding self-protective measures, such as questions asking how to wear masks properly, as much as 66.3% of the answers were advertisements. Thus, it can be assumed that the general population may have difficulty in obtaining appropriate information on self-protective measures.

This study contributes to the establishment of early health communication about public concerns and anxiety observed at the early stage of COVID-19. The initial stage of the epidemic is when neither the health authorities' policies nor people's understanding of the epidemic has stabilized. Under these circumstances, people's online exchange of information and emotion can have a great influence. Governments should implement proper measures to establish online health communication in the early stage of an outbreak to provide appropriate and accurate information. Considering that web data-based studies related to COVID-19 are rare at present, our research's policy and academic value is more pronounced. Although there are studies that use web data to analyze various characteristics of public psychology for other infectious diseases, there are few studies related to COVID-19. Given that numerous countries have been affected recently and are in the initial stage of the COVID-19 outbreak, our study on South Korea, which experienced COVID-19 relatively early, could be a reference point for policy making in other countries.

This study also contributes to devising methods of measuring public psychology using language data in the circumstance of an infectious disease outbreak. Understanding public psychology and culture is essential when dealing with infectious diseases [28] because public psychology greatly impacts the management of infectious diseases [29]. Public anger toward the infected, for example, is common in infectious disease outbreaks, which can induce the infected to hide from quarantine efforts such as screening tests. This is because the infected people will try to avoid the intense social anger directed at them. To prevent this, it is necessary to promptly measure public sentiment in detail and organize appropriate responses such as creating social support for the infected. However, as previously indicated, traditional surveys are relatively difficult to implement quickly and are not free from limitations (eg, effect of researchers' frame on answers, relative difficulty of collecting real time data) [30]. Recently, analysis of language data using computers and statistical models has been introduced, and several scholars have suggested its usefulness [13,31,32]. Our paper provides examples of its use concerning an infectious disease outbreak. Beyond the Q&A forum, various language materials are available on the internet, which can be used to actively supplement existing methods of investigation and create diverse methods to approximate public anxiety. In short, this study shows the potential for "online data-based health policy decision making."

Additionally, this study is differentiated from other studies in how we used text mining techniques. Previously, papers using health-related text data often used frequency as the main information, such as the number of Twitter mentions [33], or applied LDA [34,35], which is the most commonly used topic modeling technique [36]. By using the STM, this study more systematically analyzed how the proportions of COVID-19–related topics varied over time while maintaining the advantages of topic modeling methods. Moreover, this study does not merely apply existing text mining techniques to health-related data but also contributes methodologically on how to use topic modeling methods. Various topic modeling methods have been used as the LDA in many studies [36], most of which draw conclusions from the estimated topics. However, solely focusing on topics has one downside: if the amount of data is substantial, the number of topics will also increase, making it difficult to identify overall patterns that appear in the entire data set. Too many topics, for example 300 topics, represent vast information, which would likely pose a formidable barrier to human researchers. Our research has introduced a way to find sets of topics connected to each other by forming a network of topics and finding cohesive topic communities in them through a network community detection algorithm. In our results, 6 topic communities were found and each community contained content-related topics. It is surprising that the topics belonging to each topic community are meaningfully interrelated, as the topic communities are derived from the community detection algorithm and a correlation matrix deduced by the STM results, not through human researchers' categorization based on the topics' contents. In other words, this study proposes a data-driven method of making topic clusters, which could be used for detecting broader themes from numerous topics that were estimated from a vast number of documents.

Various advanced analyses are possible using the data and results of this study. One of the notable results in our study is that the proportion of topic community 4 (questions suspecting possible COVID-19 infection after developing a particular symptom) seems to be linked to the actual number of confirmed patients. Considering that the symptoms observed in topic community 4 (eg, cough, throat pain, and sputum) were reported as common symptoms of COVID-19 in other clinical reports, this linkage might not be a coincidence. This suggests that information extracted from web data may help identify and even predict the actual trend of infectious diseases. Future research could use sophisticated time series analyses to scrutinize this possibility. Additionally, it is noteworthy that a certain kind of question could have a high proportion of answers written from commercial motivations (Figure 9). This implies that there are many attempts to commercially exploit the infectious disease crisis, and the social effects related to these attempts could be explored using this study's results. Finally, if adequate data of a longer period is available, analyzing how the importance of online information and communication changes over time would be a valuable research project. These further studies will enhance the efficient use of online data for public health.

This study has limitations concerning the range of data. Although Naver is the most popular portal website in Korea, people are not just using this one service. For further comprehensive analysis of information and emotion exchange in online spaces, various sources of web data, including various social network services, need to be incorporated. Furthermore, since the internet user population does not appropriately represent the entire population, it is necessary to consider using the data produced through traditional methods such as surveys and the internet natural language data together.

Nevertheless, this study showed how health information exchanged based on the disease transmission related to people's anxiety and commercial interest in new infectious disease outbreak via a novel approach using online data analysis and topic modeling.

Abstract

The outbreak of the coronavirus disease (COVID-19), caused by severe acute respiratory syndrome coronavirus 2, spread worldwide after its emergence in China. Whether rich or poor, all nations are struggling to cope with this new global health crisis. The speed of the threat's emergence and the quick response required from public health authorities and the public itself makes evident the need for a major reform in pandemic surveillance and notification systems. The development and implementation of a graded, individual-level pandemic notification system could be an effective tool to combat future threats of epidemics. This paper describes a prototype model of such a notification system and its potential advantages and challenges for implementation. Similar to other emergency alerts, this system would include a number of threat levels (level 1-5) with a higher level indicating increasing severity and intensity of safety measures (eg, level 1: general hygiene, level 2: enhanced hygiene, level 3: physical distancing, level 4: shelter in place, and level 5: lockdown). The notifications would be transmitted to cellular devices via text message (for lower threat levels) or push notification (for higher threat levels). The notification system would allow the public to be informed about the threat level in real time and act accordingly in an organized manner. New Zealand and the United Kingdom have recently launched similar alert systems designed to coordinate the ongoing COVID-19 pandemic response more efficiently. Implementing such a system, however, faces multiple challenges. Extensive preparation and coordination among all levels of government and relevant sectors are required. Additionally, such systems may be effective primarily in countries where there exists at least moderate trust in government. Advance and ongoing public education about the nature of the system and its steps would be an essential part of the system, such that all members of the public understand the meaning of each step in advance, similar to what has been established in systems for other emergency responses. This educational component is of utmost importance to minimize adverse public reaction and unintended consequences. The use of mass media and local communities could be considered where mobile phone penetration is low. The implementation of such a notification system would be more challenging in developing countries for several reasons, including inadequate technology, limited use of data plans, high population density, poverty, mistrust in government, and tendency to ignore or failure to understand the warning messages. Despite the challenges, an individual-level pandemic notification system could provide added benefits by giving an additional route for notification that would be complementary to existing platforms.

Introduction

Despite a dramatic improvement in health care affordances and extensive public health measures around the world, the emergence and re-emergence of infectious pathogens and associated diseases have become a common phenomenon. The first 2 decades of the 21st century have already witnessed several major disease outbreaks such as severe acute respiratory syndrome (SARS) in 2003, with the most severe outbreak being the coronavirus disease (COVID-19) pandemic [1,2].

In December 2019, the outbreak of COVID-19, caused by a novel coronavirus named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was first reported in Wuhan, China [3,4]. Full-genome sequencing and phylogenic analysis revealed that SARS-CoV-2 is distinct from both severe acute respiratory syndrome–related coronavirus (SARS-CoV) and Middle East respiratory syndrome–related coronavirus (MERS-CoV) but closely linked [5]. Within a brief period, the disease has spread to virtually all regions of the world with a total of 6,112,902 confirmed cases and 369,593 deaths as of May 31, 2020 [6]. The World Health Organization (WHO) announced COVID-19 a “Public Health Emergency of International Concern” on January 30, 2020, and subsequently declared a pandemic on March 11, 2020 [7].

COVID-19 is primarily a respiratory illness and the majority of patients present with flu-like symptoms such as fever, cough, fatigue, shortness of breath, headache, and muscle pain; although, a significant minority experience different symptoms, some of which are highly distinctive (eg, ageusia, anosmia) [1,3,8,9]. Although most patients usually develop mild illnesses (81%), it can cause severe pneumonia, respiratory failure, and even death, particularly in individuals with an existing high-risk condition such as chronic obstructive pulmonary disease or diabetes [1,3,8,9]. It has been reported that about 14% of the patients develop a severe disease that requires hospitalization and oxygen support, and 5% require intensive care support [4,10]. Although the case fatality rate is expected to be around 0.5-1% [11,12], it is significantly higher among older adults and those with a high-risk condition [1,4,8]. Accordingly, countries with a higher older demographic are experiencing more critically ill patients and mortality in absolute terms [13,14].

In comparison to SARS and Middle East respiratory syndrome (MERS), which showed a mortality rate of 10% and 34%, respectively [15,16], COVID-19 appears to be less deadly. However, a sharp initial increase in the number of cases indicates that SARS-CoV-2 could be more contagious than the previously emerged coronaviruses [17]. The basic reproduction number (R_0) of SARS-CoV-2, which indicates the average number of new cases generated from an infected person, is comparable to SARS [18]. Nevertheless, as a large number of patients develop a mild or asymptomatic form of the illness and may not seek medical advice, it greatly increases the risk of community transmission and larger outbreaks [19,20].

Overall, the emergence and re-emergence of highly infectious pathogens pose a substantial threat to human health. Air travel and tourism now allow for epidemics to quickly become pandemics [21]. In fact, the current pandemic was predicted and foreseen previously on multiple occasions [22]. The lessons from the ongoing global health crisis indicate that a substantial improvement is needed in our pandemic response, and this is possible by making use of mobile technology. The impact of future outbreaks can be mitigated through an improvement in pandemic notification systems by harnessing such technology.

Existing Global Platforms for Infectious Disease Surveillance

The Program for Monitoring Emerging Diseases (ProMED; also known as ProMED-mail) is an internet-based, publicly available, and free of charge digital surveillance system dedicated for rapid collection and circulation of information on emerging infectious diseases and toxins that affect humans, animals, and plants [23,24]. This novel platform was founded in 1994 by the Federation of American Scientists and later became a part of the International Society for Infectious Diseases in 1999. ProMED has grown substantially since its establishment, and the number of subscribers increased to approximately 80,000, which represents every country in the world [23,24]. The ProMED system collects information from a variety of sources (eg, media reports, official reports, local observers); a multidisciplinary team of experts from different countries synthesizes the information, which is then disseminated to the subscribers directly by email and posted online on the ProMED website. The ProMED system continuously monitors emerging disease status and delivers updates as required in near real time. This platform was the first to report major disease outbreaks including SARS, MERS, Ebola, and Zika [23,24]. ProMED is now being used by a wide range of professionals and organizations including government officials, private organizations, researchers, physicians, and journalists.

Another global platform to address emerging public health issues is the Global Public Health Intelligence Network (GPHIN), developed by the Government of Canada in collaboration with the WHO [25]. Unlike ProMED, GPHIN is a fee-based service with subscription offers limited to only selected organizations involved in public health issues. GPHIN gathers information from global media sources (ie, Factiva and

Al Bawaba) on a variety of public health topics [26,27], which is then filtered by an automated process for appropriateness and made accessible to the WHO, relevant government authorities, and subscribers. GPHIN reports constitute approximately 40% of the WHO's early warning outbreak information [25]. Several other notable web-based disease surveillance systems are Influenzanet, the Global Outbreak Alert and Response Network, and Google Flu Trends [28-30].

Regarding the COVID-19 outbreak, both the ProMED and GPHIN systems delivered early notifications in late December 2019 of what turned out to be SARS-CoV-2, the virus causing COVID-19 [31]. Subsequently, SARS-CoV-2 spread worldwide, despite the presence of these early surveillance systems. It should be noted that these systems operate mostly at the level of government and public health authorities; therefore, an active engagement of the public throughout the process, which is a requirement for the preventive measures to be of utmost effectiveness, is an ongoing concern. Administration of an individual-level, population-wide alert system would be complementary to the existing platforms by enhancing public response and engagement.

Rationale for an Individual-Level Pandemic Notification System

The COVID-19 pandemic emerged with such rapidity and lack of clarity on its transmissibility and severity that many governments implemented a cascade of changing, ad-hoc actions to address the situation [32,33]. In Canada, SARS and Ebola had primed the health care system to develop refined measures and protocols for dealing with cases, and to protect frontline health care workers [34,35]. Yet, there have been medical supply shortages and ongoing challenges to produce plans for managing incoming patients [36-40]. In the 8-week period leading up to the declaration of lockdown and social distancing measures, Canada, for example, moved from no travel restrictions and a declared low risk to the Canadian public to imposition of travel restrictions but not bans and selective banning of public gatherings [41]. These were then followed quickly by outright travel and gathering bans, coupled with stay-at-home orders [41]. This dynamic response played out across many countries around the world and continues as countries begin to lift restrictions. In the early stages, rapidly changing responses to the unfolding pandemic contributed to public confusion about expectations.

Throughout, the North American public has received communications from many sources of information, including those made by the Public Health Agency of Canada, the US Centers for Disease Control and Prevention, and regional counterparts. As we have witnessed with previous outbreaks, the COVID-19 pandemic has spawned a parallel, massive infodemic, leading to a surge of fabricated news and distorted evidence, which has increased the potential for health hazards while substantially diminishing the impact of valid information issued by health authorities about facts on all aspects of the virus, including origin, transmissibility, severity, and preventive measures [42-46]. Much like earlier trends, the presence of misinformation, rumors, and hoaxes about the novel coronavirus was also omnipresent throughout social media and the internet, which ultimately inflamed the crisis. To illustrate, there were claims about the origins of the virus (ie, bioterrorism and conspiracy theories) that led to xenophobia in many regions of the world [47,48]. Furthermore, some potentially dangerous rumors about miracle remedies spread in social media (ie, consumption of bleach, methanol, and disinfectant), which led to the deaths of people who were otherwise healthy and noninfected [49-51].

In addition, the media's sensationalistic coverage of extreme events and reports without context (eg, bodies on the streets of Ecuador, Italian military hauling coffins) exacerbated the public reaction [52,53]. A spike in fear-driven panic buying of masks and other medical supplies occurred initially [54,55], ultimately contributing to a subsequent shortage on the front lines among hospital staff in some countries [36,37]. This suggests that some of the fear-driven responses among the public may have misdirected behavior in the early stages, in part due to confusion about what constituted an appropriate response to the level of threat at a given point in time.

Ideally, the public should be informed and advised by clear communications in a manner that can rise above the buzz and chaos of the plethora of information sources in the world. It must be evidence-based and driven by public health authorities who have the expertise to understand and interpret the rapidly growing scientific studies on the novel pathogen and can synthesize the material and communicate it in ways that the public can readily understand, and to provide advice in ways that the public can readily follow [43]. This may facilitate rule-based (better than emotion-based) responding among the population and diminish the unintended affect-driven responses that may be not desirable. Considering these matters, an individual-level, graded pandemic notification system, if implemented nationwide, could provide a significant benefit complementary to existing systems by ensuring a timely and coordinated response, transmitting notification directly to the general population via mobile devices. This will likely be important during multi-wave dynamic pandemics such as COVID-19 and during oscillation between response levels (ie, imposing and lifting restrictions).

Prototype Model for an Individual-Level Pandemic Notification System

As COVID-19 has spread worldwide with catastrophic effects on both economy and human life, there is a renewed consideration of an individual-level, general-purpose pandemic notification system responsive to outbreaks of an infectious illness. Such a system would make responses more universally clear and decipherable for the average member of the population. Much like a disaster or weather notification system, a pandemic notification system would be structured as a graded level of threats. Each level would ideally provide details on three aspects of the outbreak: information about the pathogen, level of threat, and behavioral directives (eg, hygiene, physical distancing). This system, known in advance by the public, would be used to prime the public in real time with respect to changes in threat level and, equally importantly, the expected responses. For example, if the system was operational now (Textbox 1, Figure 1), level 1 or 2 would provide information about SARS-CoV-2, the impending threat nationally and locally, and hygiene measures that need to be followed; threat level 3 would advise people toward physical distancing; level 4 would push stay-at-home orders; and level 5 would be more extreme measures such as a lockdown. Overall, the threat levels would be cumulative, and the public would follow all the precautionary measures outlined in the lower threat levels on top of the precautionary measures required by the current threat level put in place. Depending on the circumstances, the threat level could vary from region to region in a given country and could be switched as a given situation required. The mode of delivering the alert would be adjusted based on the intensity of the threat. For instance, the alert for a threat level of 1 or 2 may be disseminated by simple text messaging or passive information observed only for those who look at the relevant app or website source, but the alert for threat levels 3, 4, and 5 could be push notifications directly to the mobile phones of the entire population, similar to an Amber Alert (an Amber Alert is an emergency response system that provides immediate and up-to-date information to the public about a recently missing or abducted person) in Canada and other countries.

Textbox 1. Sample operational definitions and guidelines for a graded pandemic notification system. The threat levels are cumulative. Level 3A and above must include Enhanced Hygiene by default.

Level 5: lockdown

This is the extreme level of precautionary measure, which requires a particular neighborhood to completely shut down all necessary and nonessential outdoor activities by the residents, with the exception of only law enforcement agencies, health care professionals, and personnel involved with essential services. Residents will contact the authority for emergency necessity and can go outside only with authorization. It is warranted when a large disease outbreak is confirmed in close vicinity, and the residents are exposed to severe risk of disease transmission.

Level 4: shelter in place

This is a high level of precautionary measure, which requires a particular neighborhood to completely shut down all nonessential outdoor activities by the residents. People can go outside only for necessary activities, which include but are not limited to buying food, getting medication, and essential in-person doctor’s appointments. It is warranted when a large disease outbreak is confirmed in close vicinity, and the residents are exposed to a high risk of disease transmission.

Level 3C: physical distancing (strict)

This is a high level of precautionary measure, which requires a particular neighborhood to follow strict physical distancing guidelines. Citizens must maintain a specific distance from each other while outdoors, with the exception of family members or individuals living in the same household. Any gathering of more than 2 people is prohibited, and noncompliance is subject to legal sanction. All schools and offices will be closed, and work from home protocol will be activated. It is warranted when a disease outbreak is confirmed in close vicinity, and the residents are exposed to a significant risk of disease transmission.

Level 3B: physical distancing (moderate)

This is a moderate level of precautionary measure, which requires a particular neighborhood to follow moderate physical distancing guidelines. Citizens must avoid large gatherings of a specific number (to be determined by the context of the locality). Offices can be open with caution and maintaining physical distancing guidelines. Schools will be closed except for the necessary activities. Course activities will be continued through online platforms. It is warranted when a disease outbreak is confirmed in close vicinity, and the residents are exposed to a significant risk of disease transmission, but the risk is lower than the Level 3C (to be determined by the number of cases, disease trend, and other vital information of the respective locality and surroundings).

Level 3A: physical distancing (mild)

This is a moderate level of precautionary measure, which requires a particular neighborhood to follow mild physical distancing guidelines. Citizens must avoid large gatherings of a specific number (to be determined by the context of the locality). Offices and schools can remain open with caution and maintaining adequate physical distancing guidelines. It is warranted when a disease outbreak is confirmed in close vicinity, and the residents are exposed to a significant risk of disease transmission, but the risk is lower than the level 3B (to be determined by the number of cases, disease trend, and other vital information of the respective locality and surroundings).

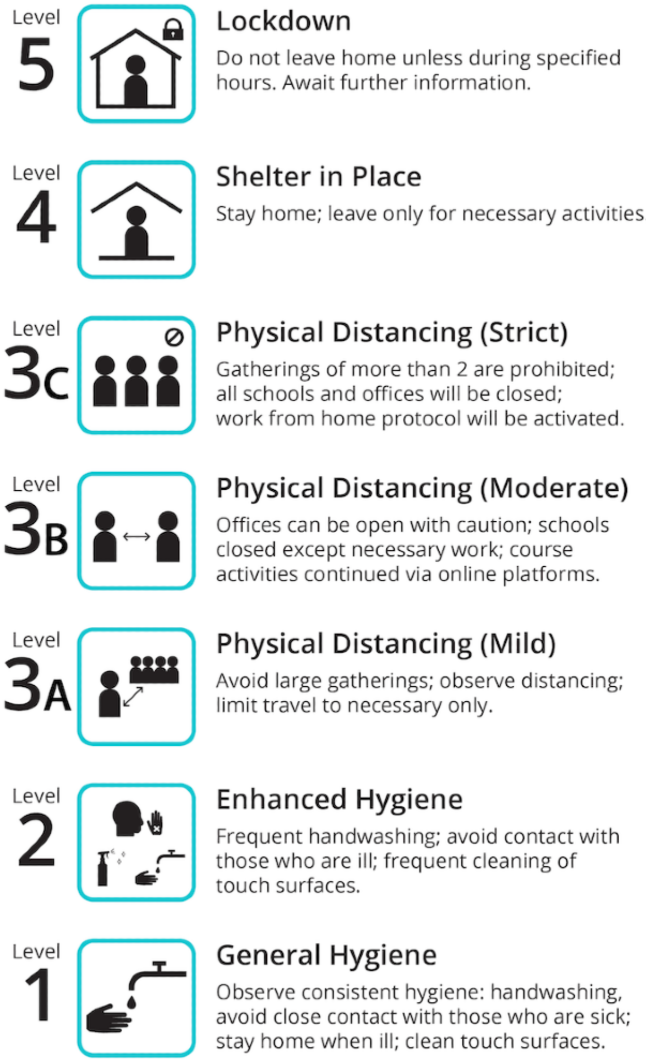
Level 2: enhanced hygiene

This is a mild level of precautionary measure, which requires a particular neighborhood to follow enhanced hygiene guidelines that include but are not limited to frequent handwashing, wearing masks where applicable, avoiding contact with people who are ill, and cleaning touched surfaces. It is warranted when a disease outbreak is suspected in close vicinity, and the residents are exposed to a general risk of disease transmission.

Level 1: general hygiene

This is a low level of precautionary measure, which requires a particular neighborhood to follow general hygiene guidelines that include but are not limited to observing consistent hygiene, handwashing, avoiding contact with people who are sick, staying home when ill, and cleaning touched surfaces. It is warranted when a disease outbreak is suspected in close vicinity, and the residents are exposed to a low risk of disease transmission.

Figure 1. Sample icon and instruction set for a pandemic alert and response notification system.



Lockdown
Do not leave home unless during specified hours. Await further information.

Shelter in Place
Stay home; leave only for necessary activities.

Physical Distancing (Strict)
Gatherings of more than 2 are prohibited; all schools and offices will be closed; work from home protocol will be activated.

Physical Distancing (Moderate)
Offices can be open with caution; schools closed except necessary work; course activities continued via online platforms.

Physical Distancing (Mild)
Avoid large gatherings; observe distancing; limit travel to necessary only.

Enhanced Hygiene
Frequent handwashing; avoid contact with those who are ill; frequent cleaning of touch surfaces.

General Hygiene
Observe consistent hygiene: handwashing, avoid close contact with those who are sick; stay home when ill; clean touch surfaces.

Figure 1 presents an example of a symbol and number-coded system that is easy to remember and interpret by members of the public, even among those with limited literacy. Features include a hierarchical arrangement of threat levels and associated responses, the latter including links to more detailed information as necessary. If this were a universal standard within a given country, health care settings, workplaces, and educational institutions would also have a common understanding with employees, students, parents, and others on a moment-to-moment basis as to what is expected. Similar approaches have been widely tested and implemented in other domains, such as Defense Readiness Condition alert states [56] and travel advisories [57]. The integration of public education efforts along with drills or simulations during the time between threats would be useful to ensure that all have some level of recent familiarity with procedures and aspects of their implementation. Each of these settings could also be encouraged to include a response plan for their own institution, such that institutional protocols are worked out in advance.

If such a platform is available in a country capable of transmitting notification directly to the population through mobile messaging, it would improve the clarity of communication about both the changing threat level (which, in the case of an emerging pandemic, can be day-to-day) and what the expected steps are at each of these threat levels, as well as data-driven tools for helping public health officials to plan and monitor interventions. This could in turn be linked to reliable website information and data visualization for the public. The technology necessary for implementing these solutions is widely available and can easily be used to deliver the proposed services. However, major challenges lie in the privacy and governance of such platforms, requiring the guidance of a team of expert researchers in public health, privacy, and public policy to facilitate the implementation of such a solution.

Expectations on the level of everyday citizens, employers, and health care professionals could be aligned more easily by proactive creation of such a system, coupled with public education as to how to interpret and act on it. This latter facet is critically important—public education about the meaning of each level and the expected sequence of actions to take in response will reduce fear by making the response more obvious when the signal comes.

The public education and infrastructure investment for a pandemic notification system may require considerable funding; however, it could provide a long-term benefit to handle future pandemics once developed. Compared to SARS and MERS, COVID-19 will be costly to some countries due to delayed response and inefficient implementation of the recommendations [58,59]. A notification system would mitigate the initial confusion and improve implementational efficiency, which could, therefore, be economical in the long run.

Prospects of Pandemic Notification Systems in Developed Countries

Developed countries have long-standing experience operating different alert systems successfully, such as the Emergency Alert System, Amber Alert, and Alert Ready. However, existing alert systems have been criticized for being inefficient for a myriad of reasons, such as the execution of false alarms, nonresponse, uneven distribution, network disruption, inadequate technology, and inappropriate timing [60-62]. Despite that, the necessity of emergency notification systems is indisputable, as a substantial number of lives could be saved and casualties could be prevented in the event of natural and human-made disasters [63,64].

Although the COVID-19 pandemic has spread pervasively, numerous strategies have been adopted by developed countries to communicate with the public about the threat and preventive measures undertaken. Some countries have excelled in their battle against COVID-19 because of prompt, coordinated, and organized actions. New Zealand, so far, is leading the battle against COVID-19 [65]. From the beginning, New Zealand has adopted the strategy of eliminating the virus rather than just containing it by imposing a national lockdown and other stringent measures [66]. In addition, a multilevel COVID-19 alert system, similar to terror alert, has been launched by the government of New Zealand to counter the ongoing crisis. This system comprises of 4 levels of alerts based on the impending risks of disease transmission: level 1"Prepare," level 2 "Reduce," level 3 "Restrict," and level 4 "Lockdown" [67]. A higher level indicates an increased risk of disease transmission, therefore, associated with more stringent measures and restrictions. Each level has a risk assessment coupled with a range of public health and social measures expected to be followed by the residents. This is an organized and efficient way to communicate with the public about day-to-day restrictions in effect. New Zealand's strategy appears to be working, as only 1504 confirmed cases and 22 deaths have been reported as of May 31, 2020, [68] and the transmissibility has been reduced to below outbreak threshold [65].

The United Kingdom has recently launched a five-tier coronavirus alert system to handle the pandemic situation more efficiently [69,70]. In this alert system, the threat levels of SARS-CoV-2 have been ranked on a scale of 1-5 with color coding for easy comprehension of the threat for the public: level 1 "Low" (green), level 2 "Moderate," level 3 "Substantial" (orange), level 4 "Severe," and level 5 "Critical" (red) [69,70]. The threat levels range from an absence of the virus corresponding to level 1 to a rapid ongoing transmission corresponding to level 5. A higher threat level indicates tougher social distancing and lockdown measures. The changes in the threat levels will be made based on medical and scientific data, such as the number of cases, the R_0, and transmission rate, and will be operated by the Joint Biosecurity Centre in collaboration with the government. This system is expected to facilitate a relatively smooth and efficient transition between threat levels. When the system launched on May 10, 2020, the United Kingdom was declared to be in level 4 (severe), which denotes partial lockdown measures, ongoing community transmission, and slightly stretched yet coping health care systems [69].

Compared to New Zealand and the UK systems mentioned, the prototype model we propose has several advantages. First, we adopted precautionary measures to define the threat levels rather than the less descriptive terms used in the existing systems. For example, if a threat level is labeled as "severe" or "restrict," it would not be readily understandable by the public unless they thoroughly study the alert system. The use of the terminology "prepare," "reduce," and "restrict" could also confuse people about which levels are being referred to if these are not accompanied by the numerical threat levels. The terms "substantial," "severe," and "critical" could mean the same intensity to the public and, therefore, always need to be followed by the level number when mentioned. In contrast, the use of precautionary measures as a level description is self-explanatory because common people understand the meaning without any additional effort. For example, if we say that the "Strict Physical Distancing" level is in effect, people would be able to visualize at which point they are in the hierarchy of the notification system. Second, the use of one logo per level could have an additional benefit, especially for people who are illiterate, as they can readily comprehend it by observing the logo. Third, as these terms of precautionary measures have become universal because of the current pandemic, any visitor in the foreign county would also be able to understand the prevention measures they must abide by for the current threat level in effect.

Aside from these newly implemented alert systems, sporadic use of the emergency notification systems has also been observed. In the province of Ontario, Canada, emergency alerts have been dispatched to inform dwellers about self-isolation and stay-home orders [71]. In addition, the use of existing disaster alert systems for the purpose of the COVID-19 pandemic was also evident. For example, Alert Bay, a remote coastal British Columbia community, has been using a tsunami warning siren to inform the residents about the COVID-19 curfew in the locality [72]. However, there is still a lack of a coordinated and systematic approach, which hinders the efficiency of the system and the effectiveness of the control measures [73]. This increases the possibility that critical recommendations, modifications, and warnings would be overlooked, especially for those who are not actively looking for the information. It might be a contributing factor that many residents ignored stay-home orders at the beginning [74]. Therefore, only imposing preventive measures would not be conducive unless citizens, for whom such measures are intended, are informed proactively. A recent survey by Calgary-based Public Emergency Alerting Services Inc is worth noting, which reported that about 84% of Canadians believe that the public should be informed about COVID-19 situations through the national public alert system [75]. It signifies the fact that citizens wish to be advised by the official sources in the event of a national crisis, at least in Canada.

Therefore, in similar developed countries where mobile phone penetration is high and wherein the trust of government is at least moderately high, a graded pandemic notification system may be a potential advantage over the status quo. The efficiency of the proposed notification system, however, would largely depend on the adherence and compliance of the citizens to the system, and how promptly the system could be activated. For instance, a measure like physical distancing would be most effective in containing an epidemic only if the public strictly complies with it and commences at the onset of the epidemic [76-79]. An organized, systematic, and coordinated approach is needed to receive the ultimate benefit from the system. The incorporation of legal enforcement could be necessary for the optimal functioning of the system, and the precautionary measures related to the threat levels should be prompt upon notification. To illustrate, when a lower threat level is expected and dispatched (level 1-2), the public would efficiently follow general or enhanced hygiene as instructed. Nonetheless, for the higher threat levels (level 3-5), additional safety measures would be expected by law and subject to sanction for noncompliance. The sanction could be a monetary penalty or other strict sanction proportionate to the severity of violation [80].

All institutions and organizations would need to develop their own logistics so that they can comply with the systems effectively upon notification. For example, when a level 4 (shelter in place) alert will be dispatched, the employees would start working from home where applicable, nonessential business and schools would be closed, and people would not leave home except for the necessary activities (among other measures) until the threat level is reduced. A change in the alert level would ideally be made either in the early morning or late evening or night to prevent road congestion and panic buying. Overall, installing such a system would operate complementary to any existing platform, and a significant benefit can be conferred by enhanced public engagement.

Given that bidirectional oscillations of threat levels over the course of a pandemic may be the norm, the proposed notification system may facilitate population response changes in the direction of increasing or decreasing precautions over time as the threat accumulates or abates. In all instances, such oscillations in response recommendation should be guided first and foremost by objective scientific advice on level of health threat rather than political objectives or other nonhealth-related agendas.

Unique Challenges for Developing Countries

The administration of the graded pandemic notification system would be more challenging in developing countries for several reasons [81]. First, the accessibility of the system could be an issue due to the lack of some infrastructure components, leading to asymmetries in the reach of warnings, which may amplify the exposure and structural response disparities. Most developing countries now have well-developed mobile network systems with a majority of the population having access to cell phones, but this issue would be an ongoing consideration. As an illustration, Bangladesh, a developing country in South Asia and home of more than 164 million people [82], has reported approximately 166 million mobile phone subscribers in February 2020 [83]. Other South Asian countries have a similar level of mobile phone penetration. India is estimated to have over 800 million mobile phone users for a population of more than 1.3 billion [82,84].

Although cell phones are ubiquitous and widespread, a large proportion of people do not have reliable data plans [85]. Consequently, a notification system may need to largely rely on simple text messaging to ensure it can reach the majority of the population. Contrary to Canada where we have Alert Ready [86], mobile phone carriers in some countries do not provide the government with channels to notify the population in cases of emergency. Some countries might not have adequate technology to provide emergency alerts. Deploying such systems in developing regions, therefore, might require changes to the current infrastructure to allow for such channels to be implemented. In addition, close collaborations with cell phone providers and public health officials are necessary for the successful implementation of such technological ecosystems.

Second, the nature of each precaution level in the notification system would have to be customized to the context of developing countries [81]. For instance, the ability of large swaths of the population to enact social distancing is questionable in some countries, simply based on population density. Bangladesh and India have a population density of 1116 and 420 per square kilometer, respectively, compared to only 4 and 35 per square kilometer for Canada and the United States [82]. Therefore, a 2-meter physical distancing guideline recommended in the ongoing COVID-19 outbreak is likely not achievable.

In a similar manner, developing countries should be judicious while imposing extreme measures like lockdowns because a large proportion of the population lives under the poverty line, and the governments have limited capacity to support their citizens amid lockdown. The recent lockdown in India is worth noting as the lives of migrant workers were under threat during their efforts to return home [87]. The creation of roadway congestion could also increase the risk of disease transmission [88].

Third, the effectiveness of the notification system could be hampered by conventional wisdom or mistrust of the government. For example, a widely held belief in Mexico is that people from low socioeconomic neighborhoods benefit from greater disease immunity because they are exposed to poor sanitation standards. This belief led the governor of the Mexican State of Puebla to recently state that poor people are immune to COVID-19 [89], contrary to the fact that low standards of living are strongly associated with impaired immunity from multiple routes (eg, malnutrition, chronic stress, unhealthy behavior), leading to a greater likelihood of morbidity and mortality from COVID-19 [90-93]. The effectiveness of any notification system is prefaced on the existence of belief systems that will make the public receptive to the messages being transmitted through the system. Mistrust of government, perhaps fostered by histories of institutionalized corruption or cronyism, may also predispose the public to ignore government warnings.

In Latin America, such mistrust has led citizens to look to international sources for information on COVID-19 [94], thereby suggesting that government-sponsored apps may be disregarded altogether.

Fourth, the lessons from existing alert systems should be scrutinized. For instance, Bangladesh has been operating their Cyclone Warning System in coastal areas for decades in collaboration with the international development partners and nongovernmental organizations. This system has been successful in reducing human casualties and property damage [95,96]. However, it has been reported that a large percentage of the residents do not follow evacuation orders and do not take necessary protective measures even after receiving warning messages and being informed about the potential consequences of not evacuating [97]. The primary reasons behind this are mistrust in the warning message and failure to understand the instructions conveyed in them [97]. Nationwide implementation of a pandemic notification system, therefore, needs to address these issues carefully. The message conveyed must be simple and concise, and will need to be tailored according to the needs of the target population. To improve compliance and penetration, the simultaneous use of other means must be considered, such as announcements from churches or prayer houses, radio, television, newspaper, and other community sources.

Source and Level Considerations

An important consideration in the implementation of any pandemic notification system would be the issuing source. In this viewpoint, we have assumed that a government agency is the primary source, given the use of reserved mobile communication channels and universal population reach within a geographic region. However, it is also possible that arms-length public health organizations within or outside of governments could be considered as a notification issuing source as well. In the COVID-19 pandemic response, many central government bodies responded in a delayed manner, which would not be helped by a notification system reliant upon their approval. On the other hand, it is difficult to envision a pandemic notification system that is permitted to operate without a substantial degree of direct input from an official government source. Ultimately along these lines, a pandemic response system that is synchronized with others around the world may be ideal, particularly given the potential for rapid spread of any contagious epidemic due to air travel. Yet, on the level of any individual country or subregion within a country, substantial negotiation and multilateral approval would be required for it to operate in a manner that could reach the population with uniformity.

A final consideration is the level at which the communication is made: national, provincial or state, or regional. Given that both outbreaks and recovery rates vary significantly by subregions within a country, an argument could be made that notifications should be delivered on that level. In some countries, such geographic units have all or most of the authority to introduce such communications and make provisions to handle changes in threat level. All of these issues must be considered on a country-by-country basis. In all cases, communications must prioritize population health first and foremost.

Limitations

The main limitation of a pandemic notification system would be the unintended consequences that could occur as a result of adverse public reactions. However, this issue could be mitigated by proper education and building trust in the government. Governments, for their part, need to ensure support for all citizens to follow any recommended precautionary measures. An additional limitation would be the lack of sensitivity to local context when deployed at the national level. This is particularly important when restrictions ease if the rate of easing is different within different regions. Several other limitations have been pointed out in previous sections (eg, privacy concerns, inadequate technology, noncompliance, mistrust); however, a detailed discussion of each point is beyond the scope of this paper.

To our knowledge, this is the first paper to describe the benefits and challenges of an individual-level pandemic notification system delivered via mobile technology. We illustrated the context of why such a system is necessary and described a simple prototype model, its prospects, and potential barriers regarding implementation. However, there are other challenges that need to be addressed with the benefit of empirical data gleaned from population attitudinal surveys and real world implementational trials.

Conclusion

Following SARS-CoV and MERS-CoV, another novel coronavirus (SARS-CoV-2) emerged and rapidly spread across the world. Despite having global public health surveillance systems (eg, ProMED, GPHIN) and their timely notification on COVID-19, many nations were unsuccessful in controlling the virus effectively. To prevent or slow the progression of future pandemics, we need a remolded system capable of facilitating effective communication and prompt activation of preventive measures. A graded, individual-level pandemic notification system could be an effective tool if customized and carefully implemented on the level of the individual country. In this system, the threat levels would be arranged hierarchically with relevant logos and a set of recommended precautionary measures for each level, which would be easily comprehensible to all citizens. Notifications provided by such a system could facilitate a prompt, timely, and coordinated response from all levels of governments and, most importantly, from the public. However, extensive preparation, advance education, and coordination by the government with all the relevant sectors involved in the dissemination of the alert are required to prevent unintended consequences. Public education and awareness are of utmost importance to ensure that the alert is understood and appreciated properly upon delivery. Under such circumstances, citizens would be able to act promptly in an organized manner relevant to the alert level without having unproductive panic and fear. It is worth noting that different countries and regions have their own limitations and challenges. Implementing a pandemic notification system would not be effective unless authorities address unique challenges in the local context. Particularly for the developing regions, careful consideration of limitations and potential unintended consequences is required.

Acknowledgments

Support for this research was provided by operating grants to PH (RGPIN-2019-04606) and PM (RGPIN-2017-05310) from the Natural Sciences and Engineering Council of Canada, as well as a foundation grant (FDN-148477) from the Canadian Institutes of Health Research, and a Senior Investigator Award (IA-004) from the Ontario Institute for Cancer Research to GTF.

Authors' Contributions

All authors contributed significantly to the conceptualization of this paper, provided critical feedback, and contributed to the drafting and revision of the article. All authors read and approved the final manuscript.

Abstract

Background: People obtain information on the coronavirus disease (COVID-19) from the internet and other sources. Understanding the factors related to such information sources aids health professionals in educating individuals.

Objective: This study used data collected from the online survey study on COVID-19 in Taiwan to examine what major COVID-19 information sources are available and which sources are significantly related to the self-confidence of people in coping with COVID-19 in Taiwan.

Methods: A total of 1904 participants (1270 non–health-care workers and 634 health care workers) were recruited from the Facebook advertisement. Their major sources of information about COVID-19, the relationships between the sources and demographic factors, and the relationships between the sources and the self-confidence in coping with COVID-19 were surveyed.

Results: Most Taiwanese people relied on the internet for COVID-19 information. Many respondents also used a variety of sources of information on COVID-19; such variety was associated with sex, age, and the level of worry toward COVID-19, as well as if one was a health care worker. For health care workers, the use of formal lessons as an information source was significantly associated with better self-confidence in coping with COVID-19. The significant association between receiving information from more sources and greater self-confidence was found only in health care workers but not in non–health-care workers.

Conclusions: Medical professionals should consider subgroups of the population when establishing various means to deliver information on COVID-19.

KEYWORDS

COVID-19; information; internet; coping; confidence; mental health; social media; Facebook; survey; online health information

Introduction

The coronavirus disease (COVID-19) emerged in Wuhan, China at the end of 2019 and rapidly spread worldwide. The World Health Organization (WHO) declared the ongoing outbreak of COVID-19 as a public health emergency demanding global concern. Early in the outbreak, Taiwan was predicted to have the second highest number of COVID-19 cases due to the many people moving to and from Taiwan and China [1]. After all, Taiwan experienced the severe outbreak of the 2002-2003 severe acute respiratory syndrome (SARS), which originated from southern China; worldwide, Taiwan had the third highest number of SARS cases, after China and Hong Kong [2]. However, the experience with SARS made many Taiwanese people vigilant against COVID-19, which has aided in COVID-19 prevention.

For information on COVID-19, timeliness and accuracy—although difficult to attain and measure—are foundational to mitigating and curing the disease for both the public and the scientific community [3]. Among the public, the internet is the most popular source of information on the etiologies and intervention models of medical illnesses [4]. Information has been proliferating on traditional and social media since the COVID-19 outbreak [5]. A recent study of 21 countries found that the number of Google searches for “wash hands” increased with the lower speed of the COVID-19 spread [6]. Misinformation on COVID-19, however, has also been proliferating on the internet, especially on social media [7,8].

In addition to the internet, traditional media are also important sources of information during disease outbreaks. However, repeated media exposure to crisis-related information elevates anxiety and stress responses among people [9]. The public may also receive information on COVID-19 from medical staff and laypeople, such as their friends, family members, and coworkers. Because people obtain information on COVID-19 from various sources, understanding the factors related to such information sources aids health professionals in educating individuals in particular and the public at large. Thus, by developing information-delivery systems that are transparent and effective, self-confidence in coping with the pandemic can be improved in their audience.

The online survey study on COVID-19 in Taiwan (hereafter referred to as the Taiwan COVID-19 survey) was conducted to assess the life experiences of people in Taiwan during the COVID-19 outbreak. Generally, the online survey is a promising method for assessing how members of the public understand and perceive a fast-moving infectious disease outbreak [10]. This study used data collected from the Taiwan COVID-19 survey to examine the following two issues: (1) what major COVID-19 information sources are available as well as the relationships between these sources and demographic factors; and (2) which sources are significantly related to the self-confidence of people in coping with COVID-19? We were particularly interested in the information sources of traditional media and the internet with regard to advice on social distancing. Furthermore, because Taiwan’s Ministry of Health and Welfare recommends that health care workers should learn about COVID-19 through online or in-person lessons, we were also interested in whether the associations of information sources with people’s self-confidence differed between health care workers and non–health-care workers.

Methods

Participants

Participants were recruited through a Facebook advertisement from April 10 to April 20, 2020. Facebook users were eligible for this study if they were ≥20 years of age and living in Taiwan. The Facebook advertisement included a headline, main text, pop-up banner, and link to the research questionnaire website. We designed the advertisement to appear in the Facebook users’ “news feeds,” which is a continually updated list from advertisers and the user’s connections such as friends and the Facebook groups that they have joined. Our advertisement only targeted users’ news feeds as opposed to other Facebook advertising locations such as on the right column because news feed advertisements are most effective in recruiting research participants [11]. We targeted the advertisement to Facebook users by location (Taiwan) and language (Chinese), where Facebook’s advertising algorithm determined which users to show our advertisement to. To ensure that health care workers were recruited, we also posted the link of the Facebook advertisement to Line (a direct messaging app) and Facebook groups joined by health care workers.

This study was approved by the Institutional Review Board (IRB) of Kaohsiung Medical University Hospital (KMUHIRB-EXEMPT[I] 20200011). Because participation was voluntary and survey responses were anonymous, the IRB ruled that this study did not require informed consent. Our study participants were given no incentive for participation. We provided links to COVID-19 information from the Taiwan Centers for Disease Control, Kaohsiung Medical University Hospital, and Medical College of National Cheng Kung University for participants to learn more about COVID-19.

Measures

In the survey, participants were asked about the following:

Sources of Information About COVID-19

We measured participants’ frequency of receiving COVID-19-related information from the following sources: the internet (including blogs, internet news, and social media, such as Facebook, Line, Twitter, and Plurk), friends, traditional media (including television, newspapers, and radio broadcasting), formal lessons on COVID-19 (whether online or in-person), medical staff in health care settings, coworkers, and family members. Participants rated their frequency for each source as never, sometimes, or frequently. Sources rated frequently were classified as major sources of information. The total numbers of sources of information about COVID-19 were summed.

Worry About COVID-19

We used the following question from the study of Liao et al [12] to assess how much respondents worried about COVID-19: “Please rate the level of your current worry toward COVID-19.” This question was rated from 1 (very mild) to 10 (very severe).

Self-Confidence in Coping With COVID-19

We used the following question adapted from the questionnaire on risk perception of an infectious disease outbreak [13] to assess how self-confident respondents were in coping with COVID-19: “How confident are you that you can cope well with COVID-19?” The question was rated from 1 (not confident at all) to 5 (very confident).

Demographic Variables

Data on respondents’ gender (female and male), age, and education level were also collected. Respondents who had high school qualifications or below and respondents who had university qualifications or above were classified into low and high education level groups, respectively. Respondents were also asked whether they were health care workers.

Statistical Analysis

Data analysis was performed using SPSS 22.0 statistical software (IBM Corp). For each participant, the frequency of information-source use is expressed in terms of percentage. The associations of demographic characteristics and worry toward COVID-19 with COVID-19 information sources were examined using logistic regression analysis. The *P* value, odds ratio, and 95% CI were used to indicate significance. Because multiple comparisons were conducted, a *P* value of <.007 (.05/7) indicated significance. The factors related to the total number of major sources of information about COVID-19 were examined using multiple regression analysis. Moreover, the associations of each information source and total number of information sources with self-confidence were examined using multiple regression analyses as well as for the subgroups of health care workers and non–health-care workers. A two-tailed *P* value of <.05 indicated statistical significance.

Results

In total, the data of 1904 respondents (1282 female and 622 male participants) were analyzed, with 70 of the original 1974 respondents excluded due to missing data. Table 1 presents the descriptive statistics for demographic characteristics, worry toward COVID-19, self-confidence in coping with COVID-19, and COVID-19 information sources. The mean age was 38.0 years (SD 10.8 years); most had a high education level; one-third were health care workers. The mean scores for worry and self-confidence were 6.1 (SD 2.2) and 3.1 (SD 0.8), respectively.

Table 1. Descriptive statistics for participants' (N=1904) demographic characteristics, worry toward COVID-19, self-confidence in coping with COVID-19, and COVID-19 information sources.

Variables	Statistic	Range
Gender, n (%)		
Female	1282 (67.3)	N/A[a]
Male	622 (32.7)	N/A
Age (years), mean (SD)	38.2 (10.8)	20-74
Education level, n (%)		
Low (high school or below)	212 (11.1)	N/A
High (university or above)	1692 (88.9)	N/A
Health care workers, n (%)		
No	1270 (66.7)	N/A
Yes	634 (33.3)	N/A
Severity of worry toward COVID-19[b], mean (SD)	6.1 (2.2)	1-10
Self-confidence in coping with COVID-19, mean (SD)	3.4 (0.8)	1-5
Sources of information about COVID-19, n (%)		
Internet	1535 (80.6)	N/A
Friends	403 (21.2)	N/A
Traditional media	1018 (53.5)	N/A
Academic lessons	391 (20.5)	N/A
Medical staff	367 (19.3)	N/A
Work colleagues	462 (24.3)	N/A
Family members	475 (24.9)	N/A
Number of information sources, n (%)		
0	200 (10.5)	N/A
1	494 (25.9)	N/A

4	196 (10.3)	N/A
5	129 (6.8)	N/A
6	66 (3.5)	N/A
7	82 (4.3)	N/A
Total number of information sources, mean (SD)	2.4 (1.8)	0-7

[a] Not applicable.

[b] COVID-19: coronavirus disease.

The major source of information on COVID-19 in a high proportion of users was the internet, followed by traditional media, family members, coworkers, friends, formal lessons, and medical staff. Furthermore, more than one-quarter of participants received their COVID-19-related information from 1 source, followed by 2 sources, 3 sources, ≥5 sources, 0 sources, and 4 sources, with 2.4 sources as the mean (SD 1.8).

Table 2 presents the multiple regression results on the associations of demographic characteristics and worry toward COVID-19 with each information source. The results indicated that women were more likely to obtain information from traditional media and family members; older people were more likely to obtain information from traditional media and were less likely to obtain information from the internet and their work colleagues; and health care workers were more likely to obtain information from formal lessons, medical staff, and coworkers. For all information sources, except for formal lessons and medical staff, worry was significantly associated with information-source use.

Table 2. Factors related to COVID-19 information sources.

[a] OR: odds ratio.

[b] Female as reference.

[c] High school or below as reference.

[d] Non–health-care worker as reference.

[e] COVID-19: coronavirus disease.

Table 3 presents the multiple regression results on the associations of demographic characteristics and worry toward COVID-19 with the number of information sources each respondent used. The results indicated that women and health care workers tended to use more information sources relative to their counterparts. Worry was also significantly associated with the number of information sources used.

Table 3. Factors related to number of COVID-19 information sources.

Variables	Beta	*t* test	*P* value
Males[a]	–.066	–2.909	.004
Age	–.037	–1.585	.11
High educational level[b]	–.024	–1.067	.29
Health care workers[c]	.117	5.218	<.001
Worry toward COVID-19[d]	.230	10.132	<.001

[a] Female as reference.

Discussion

Principal Findings

This online survey study found that most Taiwanese people relied on the internet for COVID-19 information, followed by traditional media. Many respondents also used a variety of sources of information on COVID-19; such variety was associated with sex, age, and the level of worry toward COVID-19, as well as if one was a health care worker. For health care workers, the use of formal lessons as an information source was significantly associated with better self-confidence in coping with COVID-19. The significant association between receiving information from more sources and greater self-confidence was found only in health care workers but not in non–health-care workers.

The Internet and Traditional Media as COVID-19 Information Sources

Approximately 80% of participants received COVID-19 information online. The internet makes information on COVID-19 more accessible, especially for those staying indoors due to the pandemic, with the websites of official public health organizations being the highest-quality source of online information on COVID-19 and how to prevent it [14]. We found that age was positively and negatively related with receiving COVID-19 information from traditional media and from the internet, respectively. This result suggests a cohort effect on the information source related to major health issues. Because the internet is a popular and accessible information source, medical professionals should consider subgroups of the population, especially with respect to internet access, when delivering information online. Despite the popularity and accessibility of the internet, we did not find a significant association between use of the internet as an information source on COVID-19 and self-confidence in coping with COVID-19. Misinformation on COVID-19 is rife, especially on social media. The WHO and Taiwan's Ministry of Health and Welfare made efforts to dispel such misinformation [7,8].

Sources of Information About COVID-19 Among Health Care Workers

Because Taiwan's Ministry of Health and Welfare recommended health care workers attend formal lessons (whether online or in-person) on COVID-19, they were more likely to receive COVID-19 information from formal lessons, which resulted in greater self-confidence. A study in China reported depression, anxiety, insomnia, and distress in a high proportion of health care workers who were never exposed to information on COVID-19 [15]. It was the uncertainty surrounding COVID-19, in addition to physical and psychological exhaustion, that resulted in such mental health problems [16]. Thus, our study and previous studies have demonstrated the necessity of providing timely and transparent formal lessons on COVID-19 for health care workers.

Worry About COVID-19 and Sources of Information

We noted that more severe worry about COVID-19 was significantly associated with using more information sources. More sources of information about COVID-19 were also associated with higher self-confidence to cope with COVID-19 in health care workers. Overall, these results imply the benefits of using multiple information sources during the COVID-19 pandemic. However, the direction of the association is unclear: greater self-confidence can lead one to access information from multiple sources. Clarifying this direction of association warrants further study.

Limitations

This study has some limitations. First, although recruiting participants through Facebook is a promising research method to target the public during fast-moving infectious disease outbreaks [10], Facebook users may not be representative of the population. A review of a study that recruited participants through Facebook reported a bias in favor of women, young adults, and people with higher education and incomes [17]. Second, the cross-sectional design of this study limited causal inference between sources of information, worry about COVID-19, and self-confidence. Third, this study was conducted during the period of COVID-19 mitigation but not during the period when COVID-19 first emerged in Taiwan.

Conclusion

People may use a variety of sources to search for information on COVID-19, and various sources of information had various relationships with the confidence in coping with COVID-19. Medical professionals should consider subgroups of the population when establishing the various means to deliver information on COVID-19.

Acknowledgments

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Authors' Contributions

C-FY and N-YK designed and conducted the study. Y-LC and D-JL analyzed the data. P-WW, C-FY, W-HL, and Y-PC drafted the manuscript. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: On March 12, 2020, the World Health Organization declared the coronavirus disease (COVID-19) outbreak a pandemic. On that date, there were 134,576 reported cases and 4981 deaths worldwide. By March 26, 2020, just 2 weeks later, reported cases had increased four-fold to 531,865, and deaths increased five-fold to 24,073. Older people are both major users of telehealth services and are more likely to die as a result of COVID-19.

Objective: This paper examines the extent that Australia, the United Kingdom, and the United States, during the 2 weeks following the pandemic announcement, sought to promote telehealth as a tool that could help identify COVID-19 among older people who may live alone, be frail, or be self-isolating, and give support to or facilitate the treatment of people who are or may be infected.

Methods: This paper reports, for the 2-week period previously mentioned and immediately prior, on activities and initiatives in the three countries taken by governments or their agencies (at national or state levels) together with publications or guidance issued by professional, trade, and charitable bodies. Different sources of information are drawn upon that point to the perceived likely benefits of telehealth in fighting the pandemic. It is not the purpose of this paper to draw together or analyze information that reflects growing knowledge about COVID-19, except where telehealth is seen as a component.

Results: The picture that emerges for the three countries, based on the sources identified, shows a number of differences. These differences center on the nature of their health services, the extent of attention given to older people (and the circumstances that can relate to them), the different geographies (notably concerned with rurality), and the changes to funding frameworks that could impact these. Common to all three countries is the value attributed to maintaining quality safeguards in the wider context of their health services but where such services are noted as sometimes having precluded significant telehealth use.

Conclusions: The COVID-19 pandemic is forcing changes and may help to establish telehealth more firmly in its aftermath. Some of the changes may not be long-lasting. However, the momentum is such that telehealth will almost certainly find a stronger place within health service frameworks for each of the three countries and is likely to have increased acceptance among both patients and health care providers.

Introduction

Context

In March 2020, the nature and virulence of the coronavirus disease (COVID-19) became a matter of urgent debate. This brought telehealth into focus as a potential tool to help provide services without the need for direct face-to-face contact. Older people, as major users of telehealth services and the age group most likely to die as a result of a COVID-19 infection, were positioned to become beneficiaries of any expanded range of these services. This may especially be the case since older people in isolation may be at risk of depression and anxiety [1,2].

The focus of this paper is on the 2-week period beginning March 12, 2020, when the World Health Organization announced that the COVID-19 outbreak was a pandemic. Notably, on this date, there was high or accelerating numbers of cases and related deaths in China (where the disease was first reported), South Korea, Iran, Italy, and Spain. Worldwide there were 134,576 reported cases and 4981 deaths. By March 26, just 2 weeks later, there were 397,289 reported cases and 24,073 deaths, both reflecting increases of over 300% [3]. These global increases were reflected in increases for each of the three countries (see Table 1).

Older people have the highest risk of mortality from COVID-19. The risk may vary per country or per region depending on various factors such as screening strategies and population distributions. The Chinese Center for Disease Control and Prevention reported that, from 72,314 cases, there was a case-fatality rate (CFR) of 8.0% for those aged 70-79 years and a 14.8% CFR for those 80 years or older [4]. The highest CFR was for people with cardiovascular disease, diabetes, chronic respiratory disease, hypertension, and cancer. Men had a higher risk of death than women (2.8% vs 1.7%). Italy has shown higher CFRs for people aged 70-79 years (19.1%) when compared to China (8.0%) [5]. Gender differences for cases and deaths were indicated for Italy and Germany, where men were, according to initial statistics, over 30% more likely to have the disease or die from it [6,7]. Such differences were noted as coming with provisos that relate to, for example, lifestyles and the extent of people's employment in relevant caring tasks [8,9]; overall (ie, for all projections at this early stage of the disease), there is further statistical uncertainty in view of data relating solely to "confirmed" cases and the omission of an "unknown" number of people who are asymptomatic [10].

Table 1. Coronavirus disease cases and deaths worldwide in Australia, the United Kingdom, and the United States from March 12 to 16, 2020.

Country	March 12, 2020		March 26, 2020		Increase	
	Cases, n	Deaths, n	Cases, n	Deaths, n	Cases, n (%)	Deaths, n (%)
Australia	156	3	3050	13	2894 (1955)	10 (433)
United Kingdom	590	10	11,658	578	11,068 (1976)	568 (5780)
United States	1697	41	85,435	1295	83,737 (5034)	1254 (3159)
World	134,576	4981	531,865	24,073	397,289 (395)	19,092 (483)

Definition of Telehealth

A note on the definition of telehealth is necessary in view of its uneasy position in relation to telemedicine, telecare, technology-enabled health, and digital health—terms that may overlap and are sometimes used interchangeably. Mobile health (mHealth; and the use of apps) are also included. Differences in understanding are indicated in the country profiles below.

The definition of telehealth offered here is encompassed by the term digital health. Its origin lies in the European Code of Practice for Telehealth Services [11]. Telehealth, it affirms, is "the means by which technologies and related services concerned with health and well-being are accessed by people or provided for them irrespective of location." This definition fits with Wootton's [12] description of telemedicine as "health care carried out at a distance," with both reflecting a person- (or patient-) centered, as opposed to a technology-driven, approach. Either can be viewed as suitable to underpin potentially new norms for health service provision, in part forced by the COVID-19 pandemic.

Benefits and Barriers of Telehealth

The reported benefits of telehealth have focused on cost, choice, and convenience. In respect to cost, much debate has taken place on the extent of financial savings that might be realized. The most substantial study of telehealth interventions, that of the "Whole System Demonstrators" (WSDs), started in 2010 and involved 3000 patients in England. It was reported that, although there was a reduction in hospital admissions, telehealth did not "seem to be a cost-effective addition to standard support and treatment" [11,13]. An ensuing study in Northern Ireland, with just under 4000 patients, noted "no evidence within the dataset of any marked impact of telehealth services on hospitalisations and hospital-based service usage" [14]. Both studies related to interventions involving the use of devices such as vital sign monitors linked to home hubs characteristic of "telecare" services that operate throughout the United Kingdom.

In contrast, an Australian study in 2013-2014 that involved nearly 300 telehealth patients explored the benefits of both vital signs monitors and technologies that included participant videoconferencing capabilities and messaging features. It, like the WSDs in the United Kingdom, found a reduction in hospital admissions but, importantly, also found a significant improvement in participants' health literacy and health behaviors, together with reported improvements in anxiety, depression, and quality of life [15,16]. The Australian study, by taking a more person-focused approach, at least *touched* on some of the potential benefits of telehealth that are not concerned with cost-effectiveness (as seen by provider organizations and funding bodies).

Other small-scale studies have taken this further, emphasizing the convenience of such services, especially when accessed by people in rural areas and, therefore, obviating the need to travel [17]. Although personal contact in the form of *presence* and *touch* is beyond telehealth, at least there is some help toward addressing the twin scourges of loneliness and social isolation that can afflict some older people. Linked with this is a real ability to make connections that give comfort and companionship to (older) people when they are dying, access to interpreters and signers where necessary, and even provide cognitive behavioral therapy.

Prominent among telehealth technologies are health apps, with their ubiquity increasing in the context of smartphone use, including messaging for mindfulness-based therapy for patients with cancer [18] or providing "digital therapy" for people with mental health needs [2]. There is an immense range of health-related apps, totaling over 300,000 in iTunes and Google Play in 2017, though the quality of most apps was considered as leaving much to be desired [19].

Known barriers to uptake of telehealth, aside from cost-effectiveness, center around the lack of (suitable) information technology and the security of communication links regarding personal (including health) data [2,20]. In addition, there are concerns regarding the impact on patient rapport, workforce, liability and legal issues, and time constraints [21]. Other barriers include the need to rethink business models and to overcome financial barriers including incentives, billing, and both initial and longer-term funding. Finally, some are concerned that telehealth is of lower efficacy; this clearly being the case where *face-to-face* contact with patients is necessary, for example, to undertake clinical examinations [17]. It is also of concern if there would be any deferring (by older people in the context of COVID-19) of making contact with health services that could assist in relation to, for example, pain, weight loss, and diminution of strength, or if any circumstances were overlooked that could relate to, for example, isolation and its consequences (eg, lack of food intake, depression, and even suicidal thoughts). Additionally, the COVID-19 outbreak could lead to a "mental health spike" [2].

Finally, there are the twin technological barriers that relate to the limitations or unreliability of internet connections (a matter that relates, in part, to the geographies of each country but also to the capacity and, therefore, the efficacy of remote connections) and the interoperability of the technologies concerned.

In relation to the positive aspects of telehealth, the need for future research has been called for by Dinesen et al [22] who affirmed the need to "identify...factors that *promote* [our emphasis] telehealth acceptance, such as human-technology interaction, organization of the health care system and social factors."

COVID-19 and Telehealth

The COVID-19 pandemic casts telehealth in a new light because it is accessed by people directly from their homes. The use of telehealth "may reduce the likelihood of viral transmission by limiting person-to-person contact, while enabling people with the virus to be treated for viral symptoms and their normal medical conditions" [23]. Health professionals meanwhile (as is already the case for extant telehealth services) are able to undertake more work from home. In addition, telehealth can be seen as safeguarding both health and social care workers, and (older) people who access such services *at least for those tasks that do not require physical contact*.

Hollander and Carr [24] pointed to the merits of telehealth enabling the diversion of people, where appropriate, from centers that deal with "emergencies" to "nurse triage lines" or for scheduled video consultations. They affirmed that remote screening and diagnosis (or referrals) can potentially reduce exposure for health care workers and other patients, as it will allow patients "to bypass the ED (Emergency Department) and be placed directly in a hospital bed." Technologies (whether via tele- or video consultations) can, they argued, inform and motivate people in relation to their lifestyles or the (self-) management of different conditions.

We can envisage, furthermore, the increased use of self-test kits with these and other vital sign measurement devices (eg, for blood pressure and respiratory function), contributing to a devolution of more traditional health care to the home. At least some of the matters that tie us to "the delivery of services in bricks-and-mortar campuses and clinics," where infection transmission is too easily facilitated, could be loosened and even make such institutions "largely unusable" [25].

It is only a small additional step to recognize the potential of telehealth through the use of artificial intelligence (AI) with, for example, remote screening via video that can recognize and record voice, facial expressions, attention, skin pallor, movement, and other signs for assessment and diagnostic purposes. However, published work in English on the use or potential use of AI in the context of both telehealth and COVID-19 is currently absent except for identifying disease outbreaks and learning from patterns of spread [26].

Particular barriers in relation to telehealth development in response to COVID-19 for three countries are noted in the Results section. Some are being addressed by changes to legislation and regulation, finance, and support programs. Protocols to guide at least video consultations were either already in place or under review. Most health and social care professionals, faced with the new demands of COVID-19, are therefore on a steep learning curve relating to the virus itself and necessary operational changes.

This paper examines the extent to which Australia, the United Kingdom (consisting of England, Scotland, Wales, and Northern Ireland), and the United States have, as a consequence of the pandemic, implemented telehealth as a tool to help older people who may live alone, are frail, or are self-isolating; identify those who may have a COVID-19 infection; and give support and facilitate treatment where necessary.

Methods

Three countries were explored: Australia, the United Kingdom, and the United States. The focus is on the 2-week period starting on March 12, 2020, when the World Health Organization announced the COVID-19 pandemic. This paper reports on the activities and initiatives taken by governments or their agencies (at national or state levels) in the three countries and the publications or guidance issued by professional, trade, and charitable bodies. Different sources of information are drawn upon that point to the perceived likely benefits of telehealth in fighting the pandemic.

Accessing the relevant sources of information for each of the countries was facilitated in large part by the knowledge and networks of the coauthors. It involved internet searches, scrutiny of media reports, and the use of contacts who work in practice or are involved in consultancy (including those who are acknowledged at the end of this paper). The focus of attention was on national (or federal) policy initiatives that would impact, through changes in funding frameworks or other strategic measures, on practice within regional, state, or territory jurisdictions.

During the period of study, the coauthors explored the burgeoning range of publications online (in the form of newsletters and blogs), some of which bore testimony to the escalation in use of tele- and video consultations, and reactions (mainly of service providers) to the funding and policy changes that were being enacted or signaled. In the wake of these a smaller but important number of academic articles were accessed—these, in general, revisited earlier work and began to re-evaluate the potential of telehealth in the new context.

The different governmental structures of the three countries, and the fragmented nature of telehealth services therein, means that they cannot be taken as representative of any wider range of countries. This must be a matter for future study.

Results

Australia

On March 11, 2020, the Australian government announced an AUS $2.4 billion (US $1.6 billion) health package to combat COVID-19. AUS $100 million (US $68 million) was promised to fund a “new Medicare service,” at no cost for patients, concerned with telehealth consultations via phone or video (eg, Skype) by general practitioners (GPs), specialists, nurses, and mental health allied health workers. The service would be available for COVID-19–related consultations and, more widely, to people at greater risk of COVID-19 infection, including those older than 70 years (or older than 50 years for Aboriginal or Torres Strait Islanders), people with chronic conditions or who are immunosuppressed, women who are pregnant, and parents with new babies. A free 24/7 national triage phone line was also to benefit from additional funding of AUS $50.7 million (US $34.4 million). In addition, AUS $25 million (US $17 million) was earmarked to fund Australians in isolation and at-risk groups to file their medication prescriptions online and have medicines home delivered free-of-charge [27].

This urgent initiative followed a call from the Royal Australian College of General Practitioners (RACGP) on March 6, 2020, for the government to “relax current restrictions around telehealth services by removing geographical constraints and permitting GPs to interact with their patients irrespective of location” [23]. Other bodies such as the Australian Medical Association, Australian College of Rural and Remote Medicine (ACRRM), and the Rural Doctors Association of Australia added their voice. Snoswell et al [23] noted that previous government telehealth funding had been made in response to droughts and bushfires, and on March 23, the Australian Government allowed vulnerable health care professionals who were authorized to use telehealth “item numbers” (ie, reimbursable) for all consultations with all their patients [28].

Australia already had relatively well-established telehealth services with some 150,000 “visits” having taken place from “rural and remote communities” in 2018 [23]. This is despite that fact that medical students are not exposed much to telehealth in their training, despite a realization of its potential benefits. In a 2018 study, they expressed preference for face-to-face consultations [17].

The ACRRM had published a standards framework (in 2016) that promoted the use of telehealth services for remote communities [29]. Guidelines for operating videoconference calls were already in place, such as from the Royal Australasian College of Physicians [30]; although, these required a GP, practice nurse, or Aboriginal health worker to be present with the patient during consultations. There remain barriers, however, to service operation in view of people having to have “access to a videoconferencing platform and internet connection” despite, as noted by Snoswell et al [23], that these could be freely or cheaply done via a “tablet or PC”. The broader context for Australia had been set in the nation’s digital health strategy that called for “widening access to telehealth services” [31].

Finally, on March 30, 2020, the Australian government announced funding of AUS $669 million (US $454 million) for the rollout of a universal telehealth model for all Australians to enable health care access through tele- or video consultations from home until September 30, 2020 [32]. There were multiple benefits: the new model enabling a reduction in COVID-19 exposure for both patients and health care providers, a maintaining of the primary health care frontline, and a reduction in the demand for personal protective equipment and emergency departments. It also helped people to stay at home, therefore, supporting compliance with self-isolation and quarantine requirements. Providers were expected to adopt either a 100% remote business model or a hybrid model of service provision. Face-to-face consultations were recognized as still being needed where physical examination was required or where technology could not be used (eg, for a confused patient without support). Practices would need to create new workflows, and some local primary health networks were guided in these tasks [33].

In addition, on March 30, 2020, further funding (AUS $74 million [US $50 million]) was provided to support telehealth consultations for those with mental health needs, including the development of a digital mental health portal and a “coronavirus hotline” for well-being and online support for health workers.

Specifically for older people, AUS $10 million (US $6.8 million) was assigned to the existing community visitors scheme (and to train volunteer visitors) to combat social isolation caused by COVID-19–imposed visiting restrictions. Such volunteer visitors will connect with older people both online and by phone.

Elsewhere, the growth in the use of apps was noted by Scott et al [19], who recognized their usefulness in relation to certain health conditions. They set out a comprehensive framework by which their merits could be assessed. An "App Evaluation Model" for mental health apps is available from the American Psychiatric Association [34]. Apps were already being trialed within some local primary health networks in Australia [35] and in the United Kingdom [36]. By March 27, 2020, a European Commission funded project had pointed to 19 mHealth "solutions" to help with the COVID-19 outbreak [37].

Given the role of apps as a means that people can self-manage and at the same time share information (eg, on heart rate and respiration) with health services, their *potential* importance as a tool of telehealth in the context of the COVID-19 pandemic is clear. Research has demonstrated that, if health care providers discuss the use of health apps with their patients, they are generally willing to use them to manage their chronic conditions [38], but such use in Australia is still in its infancy. COVID-19 might accelerate their uptake and use.

Furthermore, well-developed "aged care" services are important throughout Australia. These include the usual range of services in care homes and the wider community (home care), and have often been underpinned by "social alarms" (personal response systems) or telecare. In this sector, although not clinician-led, there is a rapidly growing awareness of telehealth's potential in supporting older people at home and of the tools that are available to help with this. The Aged Care Industry IT Council (ACIITC; that draws together Aged Care Services Australia and Leading Age Services Australia) mapped and documented recent technology changes [16]. This helped multiple aged care services to re-evaluate their roles in the context of such technologies and, where they had not already done so, to look at service cultures, operational procedures, and related training.

A leading Australian example of an *aged care* service that crosses over from the social to health care sectors is provided by Feros Care. This *aged care* service provider has partnered, for its home care services, with Google to facilitate older people's use of Google Assist, thus, giving them (and caregivers) access to the organization's portal and a widening range of information and other services. Information gathered regarding service use is envisaged as a prelude to using AI to monitor well-being [16].

The range of technologies documented in the work of the ACIITC was substantial and carries importance in the COVID-19 context. It ranged from apps and voice assistants (including Google Assist, Amazon's Alexa, and Apple's Siri) to fall-detection devices and socially assistive robots—with consideration also being given to related developments around smart homes and the internet of things. Importantly the report recognized "touch points" with clinicians. This is because of the extent that such technologies are now able to provide lifestyle and physiological data that can both help people to remain in good health and safely manage any health conditions, a matter that carries greater importance when self-isolating. It is only a small step thereafter to consider (as previously noted) how AI can be used [39] to facilitate not just monitoring (with necessary safeguards around privacy) but also diagnosis and treatment.

In the meantime, levels of awareness of the role of telehealth in relation to COVID-19 are rapidly rising. Helping this was the Digital Health Cooperative Research Centre webinar on March 18, 2020, titled "COVID-19 and Digital Technology: the Roles, Relevance and Risks of Using Telehealth in a Crisis" [40].

The resources, guidelines, training, online forums, and directory of telehealth care specialist and generalists maintained by the ACRRM may, in this context, assist health care organizations in setting up, reshaping their services, and supporting their workforces through the transitions [41]. The RACGP, furthermore, was poised to release a checklist on how to set up good clinical care in the age of telemedicine. More broadly, the Australian Digital Health Agency, having consulted on the issue of interoperability in 2019, aimed to publish a "National Health Interoperability Roadmap" [42].

However, as for all three countries, the *reach* of new telehealth initiatives to older people in Australia, despite the urgency around COVID-19, is uncertain. Many people, disproportionately those with the greatest needs, may not have (or cannot afford) smartphones or computers. Some, depending on location, have poor (or no) connectivity—albeit alleviated by the fact that many can use a landline to consult with their health care provider. Others, maybe many, may find it hard to consult over the phone and could forgo their health care *visits* until the pandemic is finished, with this potentially leading to other health care complications, the implications of which have not yet been adequately considered.

In summary, there is a good range of operational telehealth services in Australia (that offer tele- and video consultations), notably in rural areas, and such services may be able to further develop their wares as a consequence of the government's investment promise. Furthermore, the existing range of aged care services and the extent of their recognition in the role of new technologies is significant. This makes Australia relatively well positioned to respond to the COVID-19 challenge and to develop telehealth services in ways that respond to both health and social care needs.

United Kingdom

On March 12, 2020, the United Kingdom was moving to a "containment" phase in its response to the COVID-19 pandemic. The Prime Minister affirmed that, in this phase, "many more families will lose loved ones before their time" [43]. Telehealth did not have a place in the UK government's plans at this point; although Scotland had announced on March 10 that they were "accelerating" an investment of £1.24 million (US $1.5 million) plus £8 million (US $10 million) "implementation" costs to support video consultations, already used in rural areas, more widely, including for GP consultations [44].

Impetus for the UK action was added to through a publication from the Imperial College London. On March 16, 2020, Ferguson et al [45] modeled the potential of nonpharmaceutical interventions for the United Kingdom and the United States, aimed at reducing contact rates and disease transmission. It pointed to the possibility that 81% of both populations would catch the disease if control measures were not put in place. The control measures included in the modeling were "case isolation in the home," "voluntary home quarantine" of *all* household members, and "social distancing." These, of course, have a severe impact on older people.

On March 17, 2020, NHS England issued a notice to health trusts, health service commissioners (procurers), and providers, including GP services. This called for the agencies in question to "support the provision of telephone-based or digital- and video-based consultations, and advice for outpatients," and for general patient consultations to be undertaken by GPs and other health care staff. For the latter, the "roll out" of such practices would, it was considered, be accompanied by increased use of email and text messaging. "Face to face appointments," the notice stated, "should only take place when absolutely necessary."

The limited promotion of telehealth on a UK-wide basis in response to COVID-19 is likely because of the general lack of developed services (the exception being Scotland). This is despite what has been recognized as a sizeable market for such services—a major part of which was relating to mHealth and the use in the United Kingdom of apps and smart phones [46]. There are, however, many established social alarm (personal response systems) and telecare services. A leading UK example (in the north of England) of a telehealth service that crosses over from the health care to the social care sector is that provided by the Airedale NHS Foundation Trust. The "hub" provides varied services including telemonitoring, tele-coaching, the provision of advice, home visit scheduling, and (where appropriate) clinical assessments enabled through video consultations. Furthermore, is the "Gold Line" service that provides video contact for people "approaching or in the last year of life" [47,48].

The Digital Health and Care Institute, based in Scotland and financially supported by the Scottish Government, reported that some 1.8 million (mainly older) people in the United Kingdom use such services, with some also benefiting from vital sign monitoring. Most of these services, it can be noted, have their origins in housing and social care services. The TSA (formerly the Telecare Services Association) meanwhile called for their service provider members to "engage with health and social care partners" to plan for the COVID-19 response and be ready "for increased demand from vulnerable service users" [49]. It follows that many telecare services in the United Kingdom have quickly reshaped their offerings to enable staff, normally located at their monitoring and control centers, to work from home; implement new practices for visiting staff (eg, to undertake assessments or respond to urgent circumstances); and adopt, where possible, self-installation procedures (where home "hubs" are delivered for simple connection to a telephone line or internet connection).

Telehealth service development in relation to COVID-19 in the United Kingdom appears, therefore, to be initially slow. The Scottish exception, similar to Australia, will build on experience that was driven by the needs of rural, remote, and island communities. Its program includes several recognized elements of telehealth such as "home and mobile health monitoring," videoconferencing, and telecare. It also includes the use of a "bespoke" videoconferencing system for people at home (with internet-linked computers) or who are "on the move" (via smartphones). These services are not just concerned with health-related consultations but also links, at least for Scotland's most rural health service, with dispensing practices to facilitate "better pharmaceutical management" [50,51].

For the United Kingdom overall, therefore, the COVID-19 outbreak was a major "jolt" to the National Health Service (NHS) that had been and remains, in part, reluctant to embrace telehealth. A recent harbinger of necessary change was offered, however, in the Topol Review [39] that called, in the context of technological changes, for dramatic improvements in the England's health and social care infrastructure (including the workforce) and associated changes in culture. In the review, telemedicine (a subset of telehealth) topped the list of the most relevant and necessary technological advances, followed by smartphone apps and remote monitoring facilitated (in part) through sensors, including those embedded within wearable devices. Relevant also is NHSX, established in 2019 [52] as an NHS "spin-off," that is intended to lead, for England, the "largest digital health and social care transformation programme in the world," with foci that include the interoperability of systems and an intent to guide ways in which benefits for the NHS can be harnessed from "big data" analytics. Their "tech plan," including attention to apps, was under development in 2020. NHSX is, according to the NHS England notice of March 17, 2020, leading work relating to telehealth developments in the primary care sector.

In response to the question as to why telehealth had not (to date) been developed further in the United Kingdom, Professor Trish Greenhalgh put it succinctly in a webinar on March 18, 2020 [40]. She affirmed, referring to clinicians, that they "*didn't have any particular reason to use [telehealth]. They didn't see a clinical need,*" adding that "*running a service with video-consultations as a main component involves major changes in workflows and also changes in professional interactions. And it feels a bit weird* [for them] *to be consulting either by telephone or video when you could just bring the patient in and look at them - as you were taught*." Other work by Greenhalgh is relevant in exploring video consultations [53] and remote assessments [54].

Useful in this context is the release by the (UK) Royal College of General Practitioners of "top tips" for telephone consultations in the context of COVID-19 [55] and preliminary "video-consultation information" for GPs developed by the NHS in collaboration with the University of Oxford and drawing on guidance produced by the Scottish Government [56].

In summary, the *reach* of new telehealth initiatives to older people in the United Kingdom is uncertain. Many (older) people do not have smartphones or computers. Some, depending on location, will have poor (or no) connectivity. In the United Kingdom, furthermore, although there is good NHS *intent* to reach all those in need (as part of their universal service obligation), the rollout of telehealth services, despite the urgency of COVID-19, may be slow—though lessons will be learned from both Scotland and outside of the United Kingdom.

United States of America

On March 17, 2020, the United States announced the "dramatic" expansion of telehealth services via tele- and videoconferencing, with people able to use these services over the ensuing 6 months through such platforms as Skype or Facetime and with the waiving of "other" normal requirements [57]. The waiving of regulations applied to the state authorized Medicare funded services that operate throughout the United States [58] and followed growing concerns about the COVID-19 outbreak. A further US $2 trillion (of which US $200 million was earmarked for telehealth) was promised through the Coronavirus Aid, Relief, and Economic Security Act that passed through the Senate on March 25, 2020, [59] and was signed into law on March 27.

Realization of the need for such urgent action was partly prompted by an article, published on March 11, 2020, by Hollander and Carr [24]. This affirmed that, in the context of COVID-19, "direct to consumer (or on-demand) telemedicine...is both patient-centered and conducive to self-quarantine, and it protects patients, clinicians and the community from exposure." In place, furthermore, was an infrastructure in the United States that would, they envisaged, facilitate telehealth's (telemedicine's) greater use, with programs already in place for 50 of the country's state health systems.

That initial week (commencing around March 11, 2020) was marked in the United States by an "explosion of demand" that "slammed into hospitals [that were] used to delivering telehealth consults for only a handful of patients a day." Cleveland Clinic and Jefferson Health were reported as having fifteen- and twenty-fold increases, respectively, in telehealth visits in a week. In addition, Penn Medicine, because of their increased demand, "increased the number of practitioners delivering remote consults from six to 60" [25]. Further increases were expected. Additional impetus was added to the moves because of the applicability of the Imperial College London report that pointed to the equal (though far bigger in population terms) threat of deaths to the United States [45].

By March 17, 2020, the American Association of Retired Persons, the largest representative body of older people worldwide, had posted an item on their website that explained, in reassuring terms, what to expect in a virtual visit [60]. The author of the item affirmed that a virtual visit was "very similar to what would happen in person," advising people to be ready to respond to questions, "to have a pen and paper handy," and to be increasingly equipped to take physiological measures at home, notably blood pressure and temperature. The Centers for Disease Control and Prevention [61] had published interim guidance for community health staff that included the need to "explore alternatives to face-to-face triage and visits" and "identify staff to conduct telephonic and telehealth interactions," with "protocols so that staff can triage and asses patients quickly." The American Hospital Association [62] had, a year prior to the COVID-19 pandemic, called for "widespread elimination of geographical and setting locations requirements" and an expansion of "types of technology," including remote monitoring, that could be used.

The new Medicare rules began retrospectively, starting on March 6, 2020. The telehealth services in question were required to consult in "real-time" (ie, asynchronous and store and forward communication was not included), and the prior restriction to beneficiaries in rural and remote areas was removed. Reimbursement rates for service providers were set at the same rate as for face-to-face visits. Importantly, all eligible Americans became able to link to telehealth services "through video chat and online patient portals" referred to as "virtual check-ins" [59].

The range of staff engaged by service providers (at "originating" sites) was widened, overall including doctors, nurse practitioners, licensed clinical social workers, and clinical psychologists, with ordinary consultations, as well as health screening and mental health counselling, being able to be undertaken. Health staff (including nurse practitioners and physician assistants, where necessary, at "distant" sites) became eligible for payment [63]. Although the focus was on Medicare, it can be noted that several of the private insurance service providers were starting to waive costs for remote assessments and consultations, reckoning on the health benefits that would ensue [64].

What superficially may look like a consistent approach in the United States (focused mainly on videoconferencing) hides variation between the funding and administrative frameworks that operate in different states. Dinesen et al [22] reported on a "fragmented" system in the United States where the "use of technologies can create jurisdictional conflicts, policy conflicts and remain tangential to care practices rather than integrated in [the] health care infrastructure." In 2019, the Center for Connected Health Policy [65] affirmed that "no two states are alike in how telehealth is treated, despite some similarities in the language used."

A useful fact sheet for telehealth was, however, provided by the American Hospital Association [62]. This noted that, in 2017, three-quarters of US hospitals connected "patients and consulting practitioners at a distance," albeit that there were barriers to wider adoption. All states provided reimbursement under Medicaid "for some form of live video," but less than half were reimbursed for "store and forward" [62]. There are many people, furthermore, who were recognized as "low-income or uninsured" and who "may have no choice but to pay out-of-pocket for these services" [66]. Only a minority of Americans, in fact, are on Medicare, with Cahan [67] arguing that "telehealth must also reach these 281 million individuals in the under-resourced nooks and crannies of the US."

A US example of a telehealth service is provided by St Luke's Health, which operates a "virtual care center" in Boise, Idaho. The center and its staff provide video consultations and remote patient monitoring for people at other linked health care facilities, in their homes, or (via mHealth) on the move. Importantly, the service approach is seen as evolving from one that is more reactive and responsive to health needs as they arise to one that is proactive in supporting people's day to day health [68].

Finally, mention must be made of the fact that the United States has well developed personal response services (social alarms) that are frequently in place to support patients after hospital discharge or are otherwise used to enable people to contact responders after a fall or in other necessitous circumstances. Most of these are private sector services and some are seeking to evolve as telehealth services. They echo in their form the social alarm services in Australia and the United Kingdom.

As for all three countries, the *reach* of telehealth initiatives to older people in the United States, despite the urgency around COVID-19, is uncertain. Many people do not have smartphones or computers. Some people, depending on their location, will have poor (or no) connectivity. In the United States there are, furthermore, issues around the cost of services where (older) people are not eligible for Medicare.

Discussion

This paper has exposed differences in the way that Australia, the United Kingdom, and the United States responded, in the 2-week period beginning March 12, 2020, to the promotion and use of telehealth to combat the COVID-19 pandemic. These differences relate to their prior experiences with telehealth, the different health, and to some extent, social care, contexts, and cultures; the extent that specific attention was given to older people; the respective geographies (most notably in relation to rural areas); and the linked funding frameworks. Differences in understandings of definitions or the breadth of telehealth were also indicated, reflecting the nature of extant services within the countries in question.

Regarding the health context, a strong link to long-standing universal welfare models is signaled for both Australia and the United Kingdom. In the United Kingdom, a major part of telehealth and related service provision is via public and third sector (charitable or nonprofit) organizations. In Australia, provision is both from these and the private sector. The welfare element is, however, also there for the United States where Medicare and Medicare programs seek to ensure that the needs of at least some of those who are most vulnerable are met, albeit with most people normally accessing services through private providers.

All three countries give attention to older people. An interesting aspect of this, especially in Australia and the United Kingdom, are the moves toward cultural change within services, being reflected in an increased understanding of the potential of technologies to empower their users. The use of apps (notable in the United Kingdom) and voice assistant devices in the home are pointers to this, with indications in all three countries of some moves, within the context of telehealth, toward encouraging greater self-management.

The different geographies of the three countries have been observed as influential. This, in part, reflects the fact that some (often pioneer) telehealth services, were born of necessity—arising from rurality, remoteness, and island locations, and workforce shortages [69]. This is particularly the case for Australia. It is interesting to note, therefore, the actions by governments in both Australia and the United States that waived restrictions on financial support for service provision in nonrural areas. In addition, regardless of the future of telehealth, there is no doubt as to its real achieved benefits as perceived by (older) people living in rural and remote regions.

Understandings of the meaning of telehealth in the three countries were clearly influenced by the nature of services that had been established, this then being consolidated by what was determined as eligible for funding. Hence the US "model" based around video consultations can be contrasted with the less rigidly framed, but arguably more inclusive, services in Australia and the United Kingdom. The US model may, nevertheless, prove to be a useful foundation for extended services that are able to respond to the COVID-19 pandemic. By contrast, the rapid building or strengthening of telehealth services in Australia and the United Kingdom as a response to COVID-19 could prove more problematic, in the sense that greater attention will be necessary to establishing or putting in place adjustments to staffing and operational procedures able to both ensure reasonable quality standards (for technologies and services) and to respond to the certain increase in demand.

As noted in STAT [25], for the United States, "the administrative challenges are numerous. They include training doctors to deliver virtual care...there are also technology set up challenges for new users as well as a shortage of bandwidth as the internet groans under the strain of increasing use." All three countries, meanwhile, could consider the extent to which "nurse-practitioners" and "physician assistants" could play a greater part together with social care staff (and assisted by the technologies) in the operation of telehealth services. There are, in addition, all kinds of related challenges for information governance and the inevitably time-consuming tasks associated with quality testing of both the technologies and the related services. In addition, even though funding may be provided in this extraordinary time, the questions remain as to whether this will prove adequate to support the running of viable telehealth businesses in the COVID-19 context.

Common to all three countries is their commitment to at least basic service quality safeguards. These are essential and will need to be built upon if telehealth is to take its place within established health services. The COVID-19 pandemic is forcing the changes, and the question of service sustainability will, therefore, remain. We are some way from what Cahan [67] referred to as telehealth becoming "finally mainstream – overnight(ish)," and we are some way away from loosening the ties that bind us to "the delivery of services in bricks-and-mortar campuses and clinics" and face-to-face consultations and care, "where infection transmission is too easily facilitated" [25].

What begins to come through, however, is a sense of an increasing and shared recognition of how the technologies that we associate with telehealth are not only vehicles for the provision of services but also offer a means for people's empowerment. This empowerment applies to all, including older people for whom there is an imperative for equal effort to be expended in ensuring both the form of the technologies and services is appropriate to facilitate their use. Although with telehealth, the extent of personal contact in the form of *presence* and *touch* has been noted as currently out of reach; tele- or video consultations may offer a route toward helping address the twin scourges of loneliness and social isolation that can afflict some older people. Linked with this is the ability, in the context of COVID-19, of telehealth to make the links that give comfort to (older) people when they are ill, self-isolating, or being confined. In addition, for (older) people who are more mobile, there is the often-cited telehealth benefits of not needing to travel to health facilities, with the concomitant inconvenience and cost to themselves and, frequently, accompanying persons.

Further than this, the empowerment of older people living with mild dementia and their caregivers during COVID-19 has been demonstrated in Spain through television-based health and social support interventions, and the provision of telephone-based support [70]. Telehealth in the form of television-based support went, therefore, beyond an initial objective of home support and is concerned with promoting "active aging" at home. The program has enabled caregivers to provide remote support and improved cognitive function with online memory exercises.

In summary, the picture that emerges is one of uncertainties and differences for the three countries but with an increasing awareness of the part that can, and probably must, be played by telehealth in the context of COVID-19. That part will potentially have a great benefit for older people who, it has been noted, are disproportionately impacted by the virus.

However telehealth services develop in this context, there is the reassurance, of a shared concern in the three countries for at least basic quality standards to be maintained. To do this, and whether or not the immediate impact on telehealth services is sustained after the pandemic, there will be a commensurate need for telehealth (or, rather, the broader realm of digital health) to become integrated within health and social care service frameworks. In other words, telehealth must not be seen as an "alternative" form of health care. It follows that telehealth, regardless of the impact of COVID-19, must also become integrated within the training curricula for both health and social care professionals and practitioners.

Acknowledgments

The authors are grateful to Dr Kevin Doughty, T-Cubed (Bangor, Wales, UK); Kevin McSorley, Radius Connect 24 (Holywood, Northern Ireland, UK); and Karen Moore, Simple Shared Healthcare Ltd (Stafford, England, UK) for providing information regarding relevant technologies and services, and to Dr Hugh McIntyre, East Sussex Healthcare NHS Trust (Hastings, England, UK); Dr Marlene Maheu, Telebehavior Institute Inc (San Diego, CA, United States); Dr Drago Rudel, MKS Electronic Systems Ltd (Ljubljana, Slovenia); and Mark VanderWerf, Telehealth Consultant (Phoenix, AZ, United States) who provided insights and commented on earlier drafts. MF is grateful for the financial support of the Aged Care Industry Information Technology Council in his study visit to Australia during March 2020.

Authors' Contributions

MF designed the research, drafted the manuscript, and analyzed the content. SP and AL contributed to manuscript drafting and provided critical analyses of the content. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The coronavirus disease (COVID-19) was discovered in China in December 2019. It has developed into a threatening international public health emergency. With the exception of China, the number of cases continues to increase worldwide. A number of studies about disease diagnosis and treatment have been carried out, and many clinically proven effective results have been achieved. Although information technology can improve the transferring of such knowledge to clinical practice rapidly, data interoperability is still a challenge due to the heterogeneous nature of hospital information systems. This issue becomes even more serious if the knowledge for diagnosis and treatment is updated rapidly as is the case for COVID-19. An open, semantic-sharing, and collaborative-information modeling framework is needed to rapidly develop a shared data model for exchanging data among systems. openEHR is such a framework and is supported by many open software packages that help to promote information sharing and interoperability.

Objective: This study aims to develop a shared data model based on the openEHR modeling approach to improve the interoperability among systems for the diagnosis and treatment of COVID-19.

Methods: The latest Guideline of COVID-19 Diagnosis and Treatment in China was selected as the knowledge source for modeling. First, the guideline was analyzed and the data items used for diagnosis and treatment, and management were extracted. Second, the data items were classified and further organized into domain concepts with a mind map. Third, searching was executed in the international openEHR Clinical Knowledge Manager (CKM) to find the existing archetypes that could represent the concepts. New archetypes were developed for those concepts that could not be found. Fourth, these archetypes were further organized into a template using Ocean Template Editor. Fifth, a test case of data exchanging between the clinical data repository and clinical decision support system based on the template was conducted to verify the feasibility of the study.

Results: A total of 203 data items were extracted from the guideline in China, and 16 domain concepts (16 leaf nodes in the mind map) were organized. There were 22 archetypes used to develop the template for all data items extracted from the guideline. All of them could be found in the CKM and reused directly. The archetypes and templates were reviewed and finally released in a public project within the CKM. The test case showed that the template can facilitate the data exchange and meet the requirements of decision support.

Conclusions: This study has developed the openEHR template for COVID-19 based on the latest guideline from China using openEHR modeling methodology. It represented the capability of the methodology for rapidly modeling and sharing knowledge through reusing the existing archetypes, which is especially useful in a new and fast-changing area such as with COVID-19.

(J Med Internet Res 2020;22(6):e20239) doi:10.2196/20239

KEYWORDS

coronavirus disease; COVID-19; openEHR; archetype; template; knowledge modeling; clinical guidelines

Introduction

The coronavirus disease (COVID-19) is a severe infectious disease that has been confirmed to lead to human-to-human transmission since December 2019 [1]. Considering the sudden outbreak of the disease as a challenging threat, it was brought into the Class B of infectious diseases defined in the Law of the People's Republic of China on the Prevention and Control of Infectious Diseases, but management and policies were adopted according to the Class A of infectious diseases [2,3]. All of the challenges have brought great pressure on medical institutions and professionals, including the lack of medical equipment and the complexity of diagnosis. At the same time, the fear of the disease has a negative impact on both the psychological and physiological well-being of affected individuals.

Although, most cases of the disease occurred in mainland China in the beginning, other areas have also confirmed cases of the same disease, and the number of cases continues to increase. The World Health Organization (WHO) has declared the 2019-20 coronavirus outbreak to be a Public Health Emergency of International Concern [4]. So far, the United States is the most seriously affected country in the world. In addition to China, many cases were found in the Western Pacific Region, such as South Korea and Japan. Russia and Great Britain were relatively seriously affected areas in Europe [5] according to the latest data reported by the WHO.

Symptoms include fever, cough, or shortness of breath, and even pneumonia, multi-organ failure, and death in the most severe cases. The latent period can be between 1 and 14 days, and on average is between 3 and 7 days according to the epidemiological investigation. What is even worse is that some patients may be asymptomatic at the beginning, which results in some undetected errors [6]. Given the severity of the infectious disease and urgency of diagnosis and treatment, a large number of studies related to disease prevention and control have been carried out with the support of various countries according to the WHO [7].

Considering the rapid spread of the disease, the transferring of knowledge of diagnosis and treatment of the disease and newly updated achievements of research are important, especially from areas with improved epidemics like mainland China, the area where the epidemic had begun. Although some efforts have been made through teleconsultation and medical staff assistance, they are still limited due to a lack of experts. Using decision support tools is an efficient way to transfer the knowledge of experts to clinical practices. Epic (Epic Systems), which is a health care software company with electronic medical record software application, has sent out an update to its customers to detect potential cases of COVID-19 [8]. DIPS, which is a major openEHR vendor, released open source components to assist software developers creating apps to fight COVID-19 [9]. Although Epic provided a complete solution for medical information systems where the clinical decision support tools have already been embedded, most other systems still need to integrate with medical information systems to be used in clinical practice. The interoperability of disease-related data has become an important issue.

Many studies on terminology standardization have been conducted to improve the interoperability. Systematized Nomenclature of Human Medicine International has issued an interim release to promote the analysis with the most up-to-date terminology [10]. The Observational Health Data Sciences and Informatics has also committed vocabulary about COVID-19 into GitHub [11]. These efforts have been focused on the shared representation of the concepts related to COVID-19 but are not enough for data exchanging, with the shared data model being the key issue. It specifies not only the data structures but also the attributes of data elements. Although there exist many methods [12-15] to develop a data model for certain requirements, the rapidly updating knowledge for COVID-19 makes it a challenge to achieve a flexible model constantly with the requirement evolution.

An open, semantic-sharing, and collaborative-modeling framework is needed to meet the dynamic change of data requirements. openEHR specifications can be used to create standards and build information and interoperability solutions for health care as a multilevel modeling framework [16]. In the approach suggested by openEHR, the reference model (RM) focuses on the logic structures and attributes required to express data, so it is stable and provides basic components for building concrete medical information models. The archetype model is comprised of archetypes and templates. Based on the RM, archetypes can be developed to define all the attributes about specific clinical concepts. Different archetypes can be organized into context-specific data sets, templates that are mostly developed and used locally. Only the RM is implemented in apps, while clinical information (archetypes and templates) is independent of specific implementations. The approach allows data models to be flexible and extensible within the constraints of the RM, which can keep up with the development of the clinical knowledge and meet the requirements of the complicated clinical environment [17]. The knowledge obtained in clinical practice in mainland China can be sharable and beneficial for other countries and regions by being formalized as openEHR archetypes and templates.

As a goal, we developed an openEHR template to promote interoperability among clinical systems for the diagnosis and treatment of COVID-19. The remainder of this paper is organized as follows: the Methods section introduces the knowledge source and methodology we used to develop and review the template, the Results section illustrates our results step-by-step according to the proposed methodology, and the Discussion section discusses the contributions of this paper and limitations.

Methods

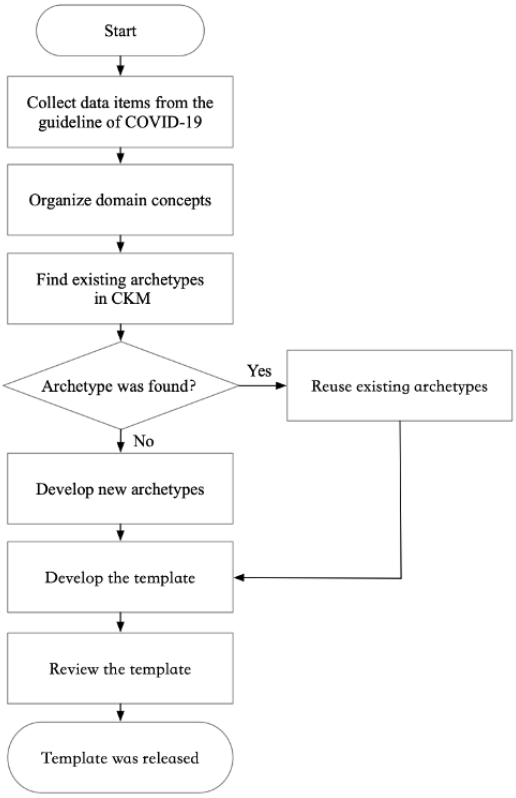
Knowledge Sources

Given that the outbreak of the disease happened within a short time frame, the involved knowledge is limited. To make them justified and believed, the Guideline for Diagnosis and Treatment of COVID-19 released by the National Health Commission of the People's Republic of China was adopted as the knowledge source. At present, the guideline has evolved to the 7th edition [18] (the English translated version is also available [19]). The guideline can be divided into 13 sections: (1) Pathogenic Characteristics; (2) Epidemiological Characteristics; (3) Pathological Changes; (4) Clinical Characteristics; (5) Diagnostic Criteria; (6) Clinical Classifications; (7) Clinical Warning Signs for Severe and Critical Cases; (8) Differential Diagnosis; (9) Discovery and Reporting of Cases; (10) Treatment; (11) Criteria for Discharge and Notes After Discharge; (12) Transportation Principles; and (13) Prevention of Infection in Medical Establishments. Since only the contents related to conditions and recommendations for diagnosis and treatment will be used for data exchanging, sections 4-9, section 11, and part of section 10 were selected as the knowledge source. There are three reasons for excluding other sections. First, sections 1-3 describe the general knowledge of COVID-19, most of which will not be directly used as the condition for the judgment of diagnosis, treatment, and management. Second, sections 12 and 13 illustrate the regulations and policies for transportation and infection prevention, and will also not be used for diagnosis and treatment. Third, in another part of section 10, traditional Chinese medicine and herbal medicine are regarded as a kind of alternative medicine, which is a supplement to evidence-based medicine and has only regional characteristics.

The Process of Development

To develop an openEHR template for COVID-19, our method consists of six steps. These steps include collecting data items, organizing domain concepts, searching corresponding archetypes, developing an openEHR template, and reviewing and releasing the template (see Figure 1).

Figure 1. The method of developing an openEHR template about COVID-19. CKM: Clinical Knowledge Manager; COVID-19: coronavirus disease.



Collecting Data Items

In this step, data items related to diagnosis and treatment were extracted from sections 4-9, section 11, and part of section 10 of the guideline, and further organized in Excel (Microsoft Corporation) with three columns. The first and the second column corresponded to the sections and subsections of the guideline, and the third column corresponded to the data items extracted from the subsection. The extracted original data items in Chinese have been translated from Chinese to English. Although extraction of data items was done manually, two principles were followed to lower the bias of extraction and reduce the errors.

First, considering that the composition of the guideline is hierarchical and segmented, which is the inherent knowledge of grouping data items, the extracted data items were organized in the same hierarchical structure as the guideline to not only lay the foundation for further organization of domain concepts but also provide a much easier correspondence for reviewers when verifying the correctness of the extraction.

Second, two members of our team extracted these data items separately. After the extraction, both of them exchanged and reviewed the opponent's results. For the results acknowledged by both of them, they were included in the Excel file directly. For the results acknowledged by only one of them, they were reviewed by another member to confirm the final results. For the results that were acknowledged by both of them but needed to be refined, they were re-extracted by both team members.

Organization of Domain Concepts

The organization of domain concepts is the basis for the development of archetypes and templates. Five steps were performed to organize domain concepts from the extracted data items.

1. If the data items from different subsections were the same semantically, they were merged into a single-data item. For example, coagulopathy and blood coagulation disorder can be merged into blood coagulation disorder.
2. If the data items from different subsections belong to the same domain concept, they were regrouped into a more suitable group other than the sections or subsections. For example, symptoms such as fever and difficulties in breathing found in different sections will be regrouped together.
3. According to practices from clinical decision support with the clinician participants, medical concepts that are encountered and used commonly were selected and organized as a supplement. For example, in diagnosis and treatment, operations such as surgery are generally mentioned, such as pneumonectomy or splenectomy, but similar medical concepts are not mentioned in the guideline, so this step is a significant supplement to the knowledge extracted from the guideline.
4. All domain concepts were then organized as a tree structure according to the inherent correlation among them and were represented into a mind map using XMind (XMind Ltd) as a tool. The extracted data items can be either the data elements themselves or one value in the value set of the data elements within domain concepts. For example, respiratory failure and blood coagulation disorder are each treated as a single value within the value set of diagnoses.
5. Finally, the domain concepts were further classified into three categories according to the different stages in the process of clinical diagnosis and treatment; they are "Instruction, Evaluation, and Observation."

Searching in Clinical Knowledge Manager and Archetype Development

To avoid developing archetypes repeatedly and to facilitate semantic interoperability, the adoption of existing archetypes is of much significance. The openEHR Foundation provides a website called Clinical Knowledge Manager (CKM) [20], which supports international domain knowledge governance and collaborative development of clinical knowledge resources beyond a library of openEHR archetypes and templates.

This step mainly focused on performing a search in the repository to find the archetypes with similar semantics. The name of domain concepts and data items were used as keywords to identify the archetypes. On account of polysemy and synonym, extra manual work was carried out to find the related archetypes. Some archetypes can be used directly, which means the data elements can be represented in these archetypes exactly, and there is no difference on a semantic level among them.

If no corresponding archetypes exist or existing archetypes cannot represent the data elements fully, developing new archetypes or extending existing archetypes is necessary according to the syntax of openEHR Archetype Definition Language [21].

Development of openEHR Template

After the required archetypes were found and developed, the template can be built based on them. This task can be performed with the support of Ocean Template Editor [22] to set constraints on these archetypes to fit the requirements for data exchanging. In this step, two issues come in to focus. First, constraints about terminology for certain data elements in the archetype should be made, such as medication. For example, the name of drugs can be generic names that can be identified around the world and aliases, which can be used in specific countries or regions. A unified value domain can be significant for data sharing and interoperability. Second, from the perspective of diagnosis and treatment, time series problems should be taken into consideration. For example, "patients whose chest imaging shows a significant progression of lesions (>50%) are managed as a severe case within 24-48 hours" was mentioned in the guideline. To support the diagnosis decision, the occurrence of the data elements in the template should be more than one so that they can contain the required two elements including the first chest imaging and the second chest imaging within 24-48 hours.

Review and Release of the Template

The review process is necessary to achieve a template with high quality. Two aspects of the template have been reviewed. First, the representation of the domain knowledge, such as correctness of the semantics, classification of data elements, and logic structure of archetypes, was reviewed. Second, the template was reviewed from informatics, such as the data types of data elements and relationships among different archetypes. The study has designed two review phases to achieve the goal.

1. Internal review phase: the internal review group includes a total of four persons, with one person that is familiar with the COVID-19 guideline, two persons who are developers of clinical data repositories (CDRs) and decision support tools, and one person that is familiar with openEHR specifications.
2. Outreach review phase: the participation of two domain experts beyond the research team was involved in this

phase. One has the expertise of openEHR modeling and the other has the expertise of medical informatics.

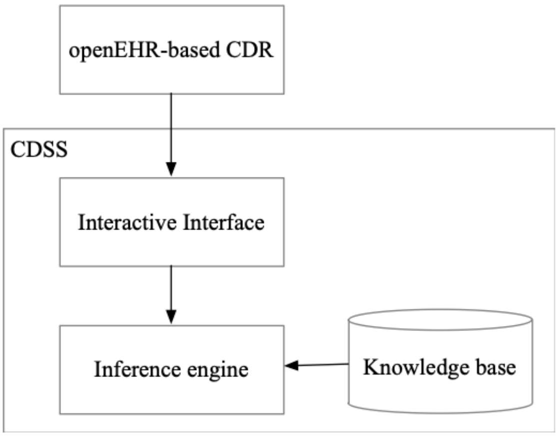
After the review, the template and the used archetypes have been uploaded and shared in the Healthcare Modeling Collaboration [23] and in the project of the CKM.

Verification of the openEHR Template COVID-19

The study has designed a test case to verify the feasibility of the template. The case was conducted in a hospital located in Wuhan, which has already implemented openEHR-based CDR and accepted a large number of patients with COVID-19. The CDR in the hospital was built based on the solution we have proposed, which can be found in [24,25]. With a developed openEHR model, the storage structure can be generated easily. The decision support tool for diagnosis and treatment of COVID-19 has been developed and is planned to be used in the practice. There is great demand for data sharing and interoperability between CDR and the decision support tool.

The test case was designed to include two steps: (1) the template was applied to the openEHR-based CDR, which can provide template-specific data query and storage service through application programming interfaces (APIs); and (2) the decision support tool used these APIs to query the data useful for the judgment of the diagnosis and treatment. The interaction diagram is shown in Figure 2.

Figure 2. The interaction diagram between CDR and decision support tool. CDR: clinical data repository; CDSS: clinical decision support system.



Results

Based on the methodology previously described, 203 data items were extracted from the guideline in China, including 8 sections and 15 subsections (see Multimedia Appendix 1). After the classification and merge of these data elements, 16 domain concepts (16 leaf nodes in the mind map) were organized for diagnosis and treatment of COVID-19. The results in this step are illustrated in the mind map in Figure 3 (full results can be found in Multimedia Appendix 2).

Among these domain concepts, only 2 archetypes were classified into Instruction, and 3 of them were classified into Evaluation. The archetypes of Observation include 11 items. A total 22 archetypes have been developed to represent all data elements about COVID-19, and all of them can be referred to from the CKM directly. These archetypes found in the CKM, which are adapted to our requirements, are shown in Textbox 1. Finally, a template was developed with the constraint of these archetypes as shown in Figure 4.

In addition, it has been deployed in a hospital, which has accepted many cases of COVID-19, to support data sharing between CDRs and clinical decision support systems (CDSS). Because the CDR is developed based on openEHR, the storage structure is consistent with the template. Although there exist many storage implementations of openEHR [25,26], they are transparent for the invocation of data services as a result of openEHR two-level modeling. Data elements in the template can be uniquely identified by paths and attributes. In this way, data for each data element can be transferred in representational state transfer (REST)ful API. The rules in CDSS were also built based on the template. The template was used in both CDR and CDSS. The data from RESTful API was parsed, extracted, and used in the inference engine to produce the decision for the case. The user interface for the data view whose data was from openEHR-based CDRs is shown in Figure 5. Textbox 2 shows the part of the content of the data that is in the RESTful API from CDR.

In the end, the template (COVID-19 Pneumonia Diagnosis and Treatment [7th edition]) has been uploaded into the CKM [27].

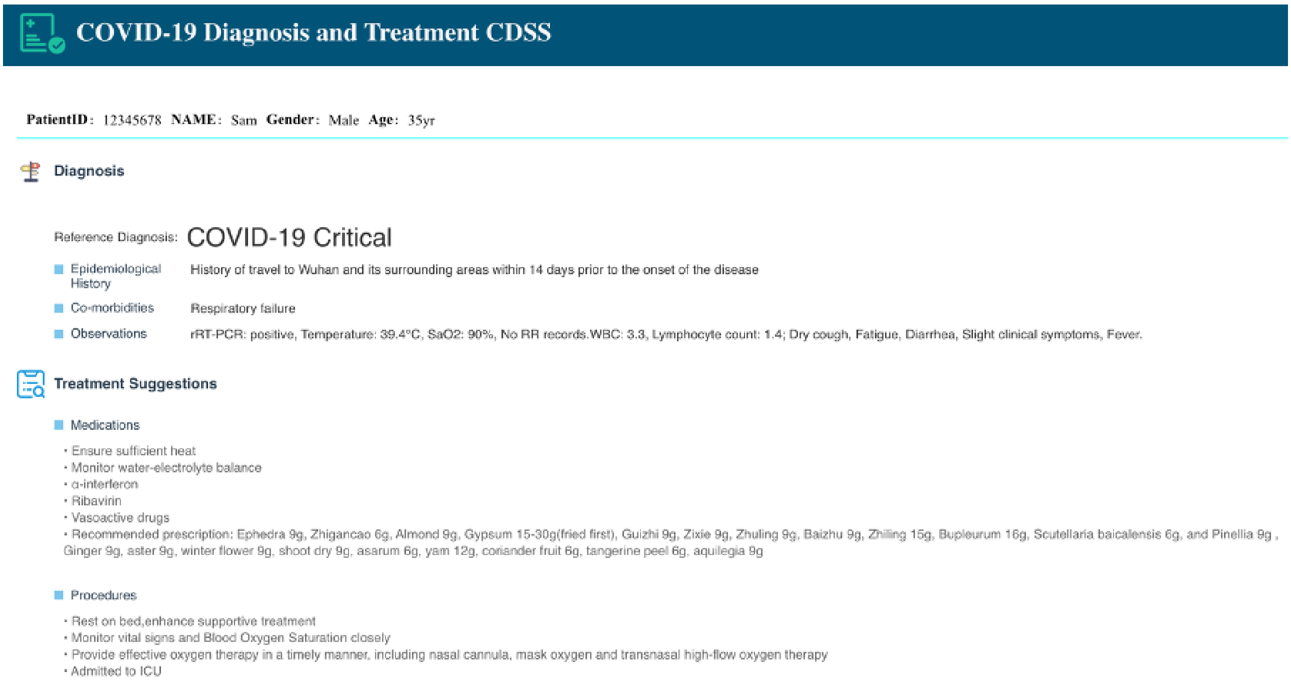

Figure 5. The data view of COVID-19 Diagnosis and Treatment CDSS. CDSS: clinical decision support system; COVID-19: coronavirus disease; ICU: intensive care unit; rRT-PCR: real time reverse transcription-polymerase chain reaction; WBC: white blood cell.

COVID-19 Diagnosis and Treatment CDSS

PatientID: 12345678 **NAME:** Sam **Gender:** Male **Age:** 35yr

Diagnosis

Reference Diagnosis: COVID-19 Critical

Epidemiological History	History of travel to Wuhan and its surrounding areas within 14 days prior to the onset of the disease
Co-morbidities	Respiratory failure
Observations	rRT-PCR: positive, Temperature: 39.4°C, SaO2: 90%, No RR records.WBC: 3.3, Lymphocyte count: 1.4; Dry cough, Fatigue, Diarrhea, Slight clinical symptoms, Fever.

Treatment Suggestions

Medications

- Ensure sufficient heat
- Monitor water-electrolyte balance
- α-interferon
- Ribavirin
- Vasoactive drugs
- Recommended prescription: Ephedra 9g, Zhigancao 6g, Almond 9g, Gypsum 15-30g(fried first), Guizhi 9g, Zixie 9g, Zhuling 9g, Baizhu 9g, Zhiling 15g, Bupleurum 16g, Scutellaria baicalensis 6g, and Pinellia 9g , Ginger 9g, aster 9g, winter flower 9g, shoot dry 9g, asarum 6g, yam 12g, coriander fruit 6g, tangerine peel 6g, aquilegia 9g

Procedures

- Rest on bed,enhance supportive treatment
- Monitor vital signs and Blood Oxygen Saturation closely
- Provide effective oxygen therapy in a timely manner, including nasal cannula, mask oxygen and transnasal high-flow oxygen therapy
- Admitted to ICU

Textbox 2. The part of the content of data in representational state transfer application programming interface from clinical data repositories.

Discussion

The Template Facilitates the Interoperability in Different Clinical Scenarios

Since the openEHR template developed in our study covered the contents related to clinical characteristics, diagnosis criteria, clinical classification, warning signs for severe and critical cases, differential diagnosis, diagnosis of suspected cases, treatment, and discharge from the latest guideline, it could be used for data exchanging among systems in different clinical scenarios such as screening patients in outpatient clinics, where the diagnosis of suspected cases will be the main focus; the routine round in the wards, where the diagnosis and warning signs for severe or critical cases will be more important; and the intensive care unit, where the treatment recommendation will be the most necessary. Although some hospital information system vendors [8] provided the monolithic solution, the applications for different scenarios with an integrated solution were still encouraged to fully use the expertise of different vendors, which is the norm in the health care institutions. For this reason, the data interoperability is an important issue, and the results of our study can play a significant role.

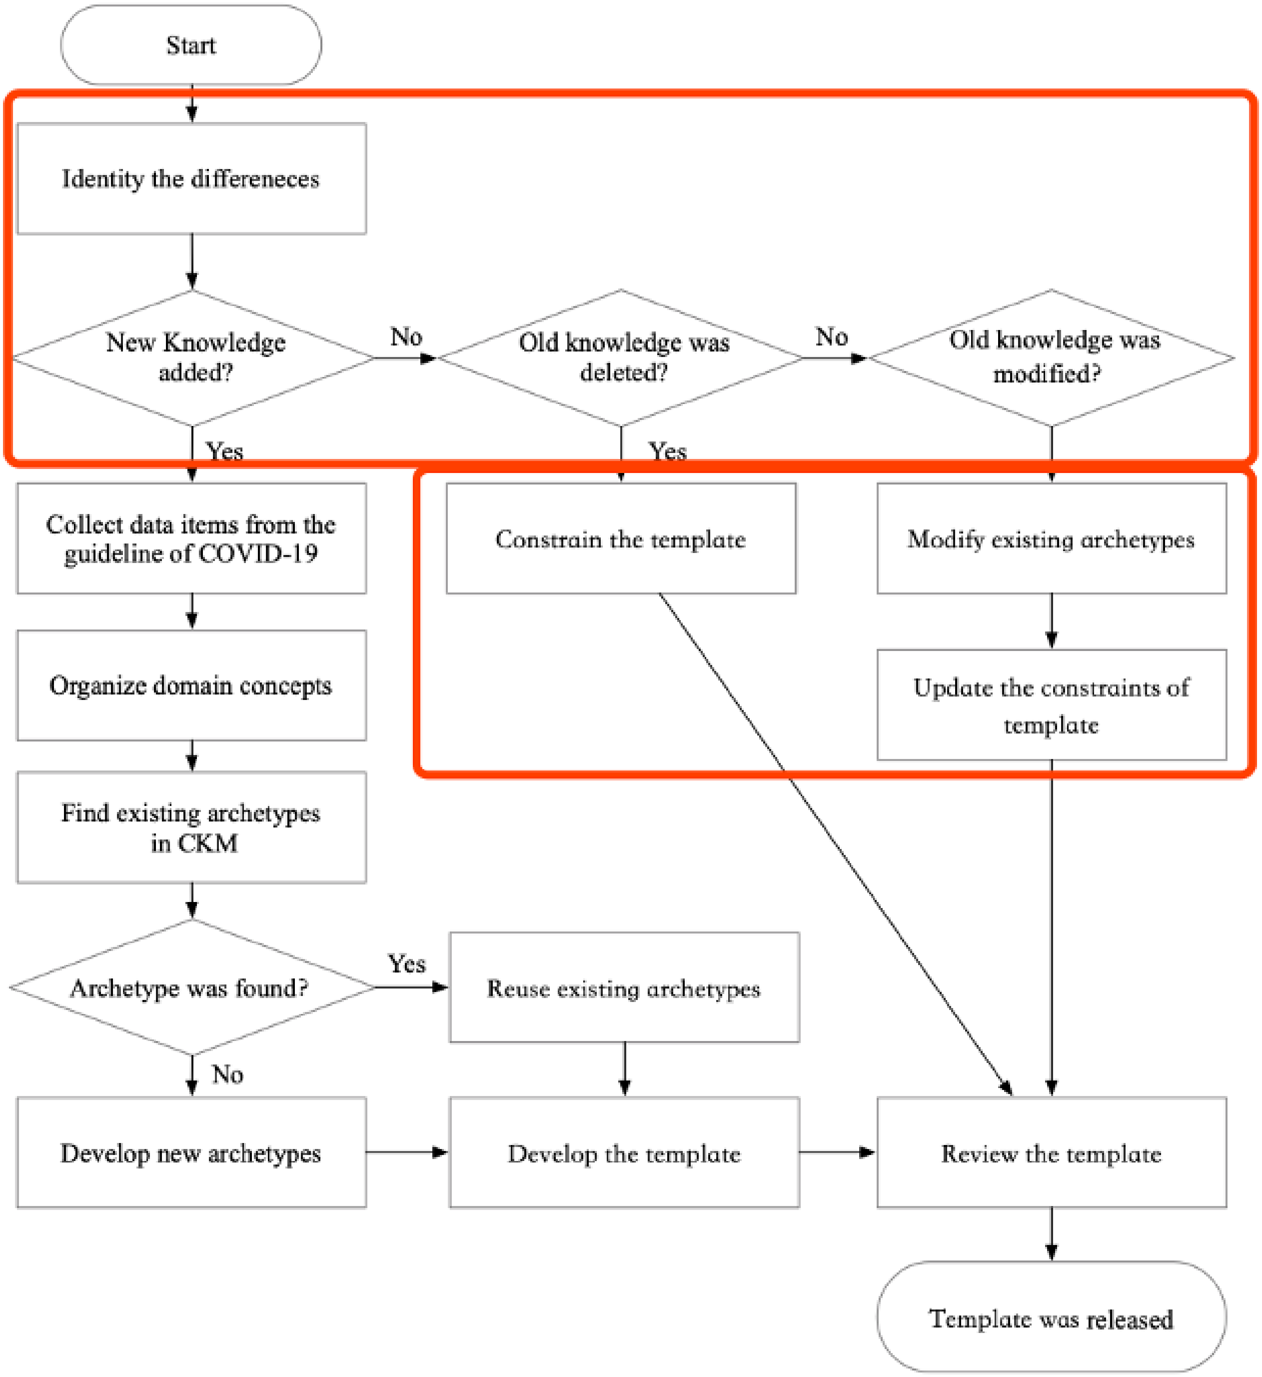
Furthermore, the results of our study can be used for purposes other than the diagnosis and treatment of COVID-19. It can help to develop scales according to severity at different levels and be used for risk assessment of COVID-19. Meanwhile, it is also significant for the prevention and control of the disease in the community. The questionnaires can be designed for people who are under closed management to monitor their physical conditions.

openEHR Modeling Approach Is Flexible for Rapidly Changing Knowledge

COVID-19 was a new threatening infectious disease that brought great pressure on medical systems around the world and with limited previous knowledge in the domain. The methods of diagnosis and treatment have been updated rapidly to reflect the achievement of the latest research since the outbreak of the disease, which sets the challenge for data exchange among systems. The openEHR modeling approach perfectly meets the requirement since the multilevel modeling is especially suitable for the knowledge evolution. In the openEHR ecosystem, when the knowledge of diagnosis and treatment has been updated, only the template needs to be updated and the apps can be kept unchanged. This enables the latest knowledge to be applied to clinical practice at the fastest speed.

In our study, once the latest guideline has been released, the new knowledge can be incorporated into the existing template according to the flowchart shown in Figure 6. Compared with starting from scratch as in the first round, only a few steps need to be performed when the knowledge has been updated, which is shown in the red box (Figure 6).

Figure 6. The updating process of the template. CKM: Clinical Knowledge Manager; COVID-19: coronavirus disease.



The Purpose of Modeling Needs to be Refined for Modeling Precisely

The purpose of the template needs to be refined before modeling since it will largely affect the final results. First, although the purpose of the study is to develop the template for diagnosis and treatment, it still needs to be refined based on whether it is for rule-based decision support tools only or general decision support. As an example, the guideline only mentioned that pregnancy status may affect the intervention without specifying the exact rules, so it is not necessary to be modeled if only for the rule-based decision support tool, but it will still be useful information for professionals to make the decision. Second, the refined purpose should also clarify whether it is used for exchanging the original data from EMR or the condition points for the final decision support. Data items extracted from the guideline usually did not exist in CDR, so they need to be abstracted from the existing data. For instance, the guideline may describe the “Two consecutive negative nucleic acid tests using respiratory tract samples (taken at least 24 hours apart)” as a condition point for discharge, but it has to be calculated from two data items of the nucleic acid test.

Is it Enough to Use the Latest Guideline as the Only Knowledge Source?

This study has used the guideline released by the National Health Commission of the People's Republic of China as the only knowledge source for modeling since the authoritative knowledge was limited at the beginning of the outbreak. However, with the ever-increasing research results and experiences of diagnosis and treatment, there are and will be more knowledge sources, such as the handbook developed by the First Affiliated Hospital, Zhejiang University School of Medicine jointly sponsored by the Jack Ma Foundation and Alibaba Foundation [28], which could be taken as complementary to the guideline. Our modeling approach makes it much easier to apply new or updated knowledge in the template quickly.

More Case Studies and Reviews Aare Needed

Although the template has been reviewed and verified in our study, it still has limitations. First, due to the reason that most of the experienced medical professionals were prioritizing clinical care of patients with COVID 19, it was difficult to have the template reviewed by professionals. Second, since there are not many cases that have been conducted, there may exist some points not appropriate for specific cases (eg, the patient may need to be treated with extra intervention that is not represented in the template). Therefore, further case studies and reviews are necessary to improve the template.

Limitations of Using openEHR Template in an Actual Hospital

The template can be easily deployed in the openEHR-based CDR as shown in this study. However, not all institution's implemented systems are based on openEHR, so there will be a limitation for the use of the template in such scenarios. However, since the infrastructure of openEHR has been designed to be compatible with other existing industry standards, the template can be easily transferred to other popular accepted industry standards like JavaScript Object Notation (JSON), XML, and Health Level 7. To take JSON as an example, the template can be expressed in this format within the support of the JSON schema [29]. The JSON schema is similar to the XML schema to help describe the data format and provide the constraints for the data expression.

Conclusions

This paper developed and released the openEHR template based on the latest guidelines of COVID-19 in China. Most of the archetypes used in the template can be covered by existing archetypes in the CKM. This study proved that the openEHR approach has advantages in modeling a new medical application field and meeting the requirements of rapidly updating knowledge. The template developed in this study could be used to transfer the experience and knowledge achieved from China to other countries and regions as soon as possible from the perspective of improving data exchange among applications to defeat COVID-19.

Abstract

Background: We developed a self-assessment and participatory surveillance web application for coronavirus disease (COVID-19), which was launched in France in March 2020.

Objective: Our objective was to determine if self-reported symptoms could help monitor the dynamics of the COVID-19 outbreak in France.

Methods: Users were asked questions about underlying conditions, sociodemographic status, zip code, and COVID-19 symptoms. Depending on the symptoms reported and the presence of coexisting disorders, users were told to either stay at home, contact a general practitioner (GP), or call an emergency phone number. Data regarding COVID-19–related hospitalizations were retrieved from the Ministry of Health.

Results: As of March 29, 2020, the application was opened 4,126,789 times; 3,799,535 electronic questionnaires were filled out; and 2,477,174 users had at least one symptom. In total, 34.8% (n=1,322,361) reported no symptoms. The remaining users were directed to self-monitoring (n=858,878, 22.6%), GP visit or teleconsultation (n=1,033,922, 27.2%), or an emergency phone call (n=584,374, 15.4%). Emergency warning signs were reported by 39.1% of participants with anosmia, a loss of the sense of smell (n=127,586) versus 22.7% of participants without anosmia (n=1,597,289). Anosmia and fever and/or cough were correlated with hospitalizations for COVID-19 (Spearman correlation coefficients=0.87 and 0.82, respectively; *P*<.001 for both).

Conclusions: This study suggests that anosmia may be strongly associated with COVID-19 and its severity. Despite a lack of medical assessment and virological confirmation, self-checking application data could be a relevant tool to monitor outbreak trends.

Trial Registration: ClinicalTrials.gov NCT04331171; https://clinicaltrials.gov/ct2/show/NCT04331171

COVID-19; anosmia; epidemiological surveillance; self-assessment; web application; outbreak; symptoms; self-assessment; surveillance; epidemiology

Introduction

Web-based self-reporting of symptoms is a growing field and has been used to improve survival in oncology [1,2]; it can be used as a participatory surveillance tool for coronavirus disease (COVID-19) or other influenza-like illnesses as well [3,4]. We thought of applying the same technology to optimize patient triage for COVID-19 patients in France and alleviate the burden on emergency call centers. A self-assessment and participatory surveillance website [5] was developed and launched during the growing phase of the COVID-19 epidemic in France in March 2020. Our objective was to determine if self-reported symptoms could help monitor outbreak dynamics in France. We report here the analysis of the first 13 days of web application usage.

Methods

Users were recruited via national media campaigns in France, including social media, radio, and magazine campaigns, between March 17-29, 2020. Participants were recruited through the maladiecoronavirus.fr website [5]. Respondents provided information on sociodemographic data, zip code, and coexisting disorders anonymously. They were asked about nine symptoms associated with possible COVID-19 infection—fever (body temperature >37.7°C), unusual cough, shortness of breath, sore throat, muscle aches, diarrhea, anorexia, and asthenia. Anosmia, a loss of the sense of smell, was added on March 21, 2020. Following symptom reporting, a notification was sent, recommending the user either to stay at home and use the website again in case of evolving symptomatology (self-monitoring), or to contact a general practitioner (GP), or to call an emergency number if they reported dyspnea or anorexia. A questionnaire was built according to Chinese reports and French experience [6]. The website was not considered a medical device by regulatory authorities since no tracking was performed and data were anonymous. We compared the distribution of web-based, self-reported symptoms to that of hospitalized COVID-19 patients according to Ministry of Health reports. Spearman correlation coefficients were used for statistical analysis.

Results

Between March 17-29, 2020, the website was accessed 4,126,789 times; 3,799,535 electronic questionnaires were filled out; and 2,477,174 users had at least one out of the nine symptoms included in the questionnaire (Figure 1). In total, 1,322,361 (34.8%) participants reported no symptoms. The remaining patients (median age 37 years; range 15-99 years) were directed to self-monitoring (858,878, 22.6%), GP visit or teleconsultation (1,033,922, 27.2%), or an emergency phone call (584,374, 15.4%).

Of all symptomatic patients, anosmia was reported by 17.1% (325,910/1,903,741), fever was reported by 33.5% (828,952/2,477,174), and cough by 61.2% (1,515,557/2,477,174). Emergency warning signs (dyspnea or complete anorexia) were reported by 39.1% of participants with anosmia (n=127,586) versus 22.7% of participants without anosmia (n=1,597,289; *P*<.001; Table 1). Anosmia and fever and/or cough were correlated with COVID-19–related hospitalizations (Spearman correlation coefficients=0.87 and 0.82, respectively; *P*<.001 for both; Figure 2).

Figure 1. Flowchart of the study population.

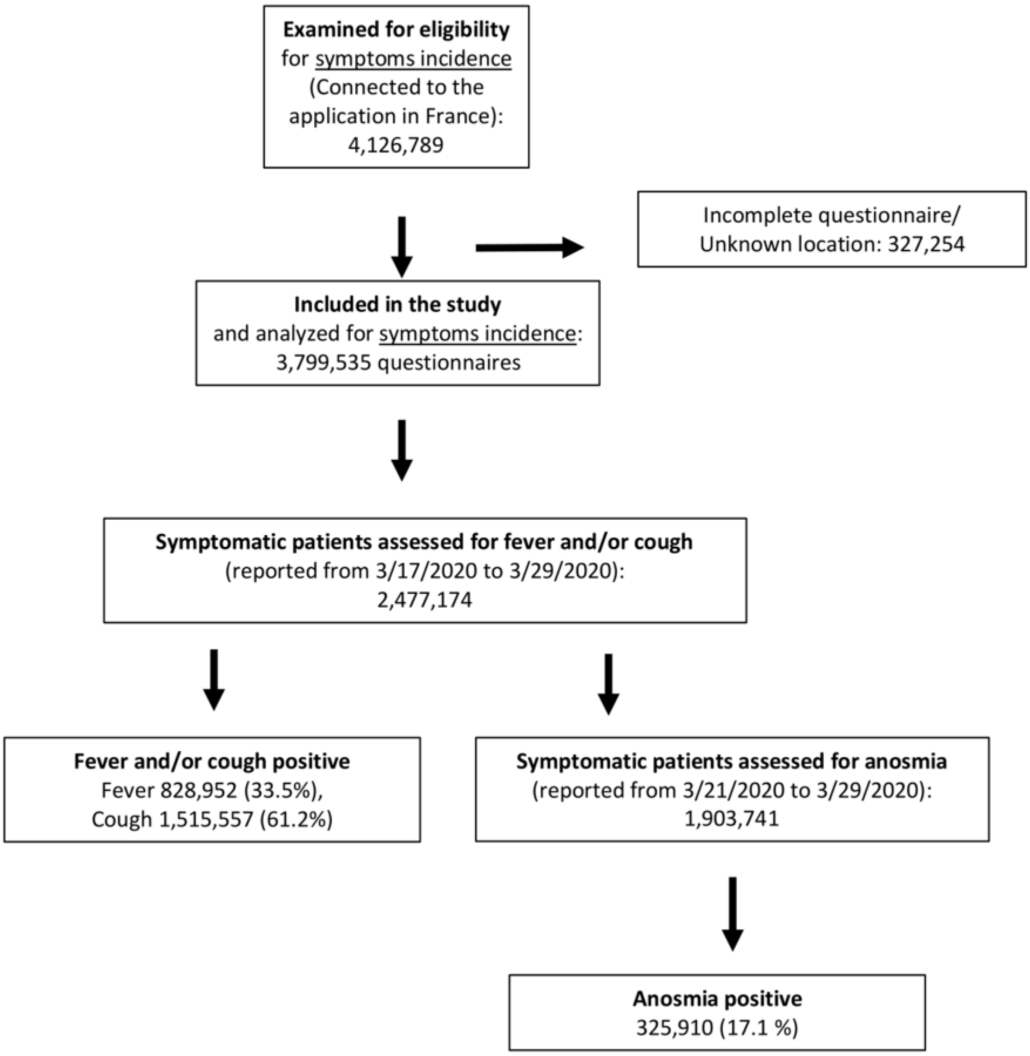

Table 1. Users characteristics.

Characteristic	Value (n=2,477,174[a])
Age (years), average (range), median	39.12 (15-99), 37
Sex	—[b]
Body mass index (kg/m^2)	
≥30	436,609 (17.6)
<30	2,040,555 (82.4)
Comorbidities	
Cardiovascular disease / uncontrolled hypertension	401,888 (16.2)
Diabetes	78,354 (3.2)
Malignancy	72,577 (2.9)
Pulmonary disease	243,247 (9.8)
Chronic kidney disease	11,333 (0.5)
Chronic liver disease	36,677 (1.5)
Pregnancy	40,766 (1.6)
Immunodepression	135,624 (5.5)
Immunosuppressive ongoing therapy	70,927 (2.9)
Reported symptoms	
Fever (body temperature greater >37.7°C)	828,952 (33.5)
Cough	1,515,557 (61.2)
Dyspnea	658,442 (26.6)
Asthenia	1,155,297 (46.6)
Complete anorexia	103,122 (4.2)
Sore throat or muscle aches	1,837,286 (74.1)
Diarrhea	497,665 (20.1)
Anosmia or dysgeusia[c]	325,910 (17.1)
Patient triage after questionnaire completion[d]	
No symptoms	1,322,361 (34.8)
Self-monitoring	858,878 (22.6)
General practitioner / phone call	1,033,922 (27.2)

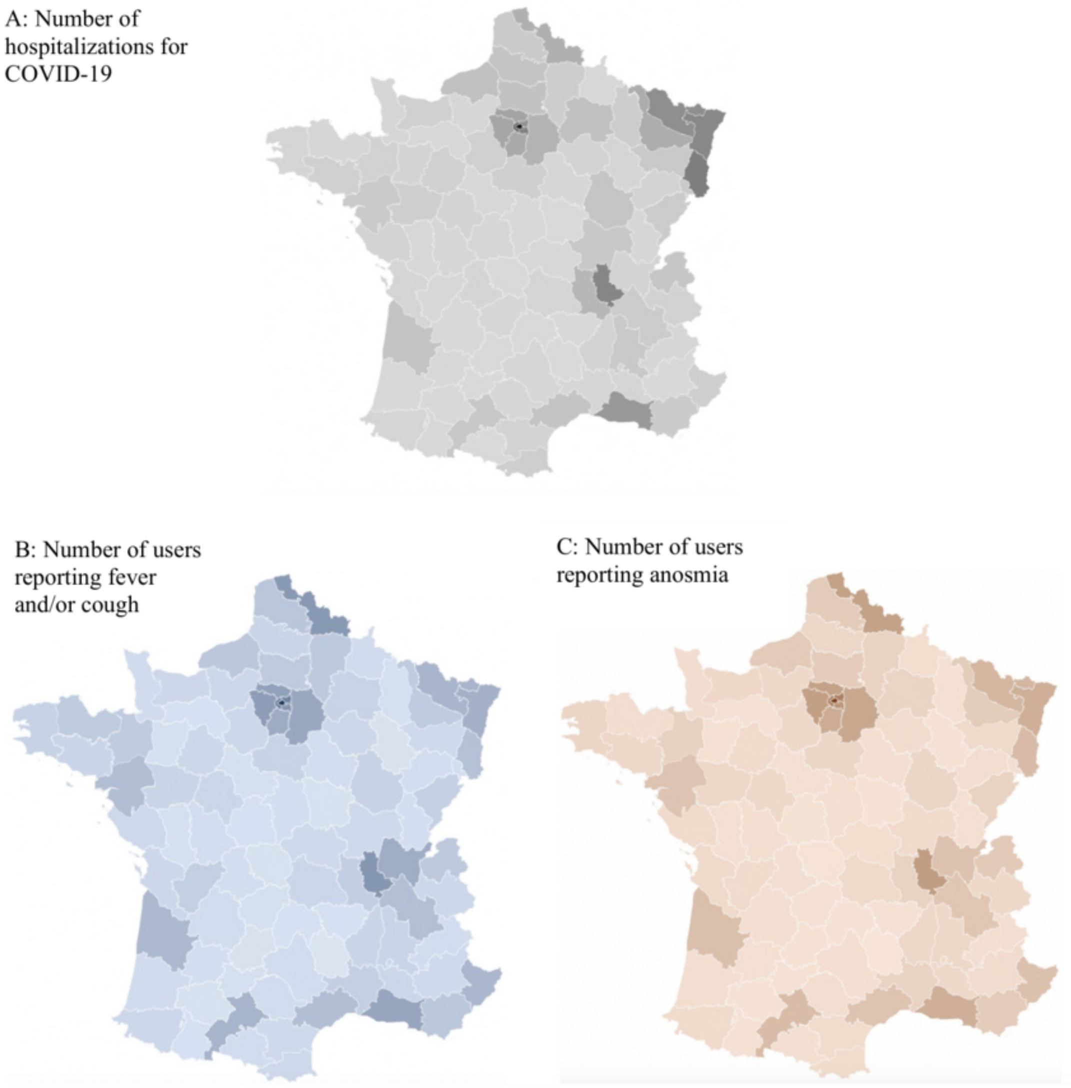
[a] Symptomatic patient (reported at least one symptom).

[b] Sex was not asked to protect the identity of the user.

[c] Anosmia was reported from March 21, 2020; the number of symptomatic patients during this period was 1,903,741.

[d] Denominator is N=3,799,535 (all respondents; symptomatic or not).

Figure 2. Maps displaying the correlation between fever and/or cough and anosmia with hospitalizations for COVID-19. (A) The cumulative number of hospitalized COVID-19–positive patients in France on March 29, 2020. (B) Fever and/or cough reported by users via the application; cumulative amount in French counties from March 17-29, 2020: 3,799,535 respondents (828,952 with fever and 1,515,557 with cough). (C) Anosmia reported by users; cumulative number from March 21-29, 2020: 325,910 positive respondents.



A: Number of hospitalizations for COVID-19

B: Number of users reporting fever and/or cough

C: Number of users reporting anosmia

Discussion

This study suggests that self-reported symptoms of COVID-19 are correlated with COVID-19–related hospitalizations and that anosmia may be strongly associated with COVID-19. This could be explained by a greater specificity compared to other reported symptoms that could result from other respiratory viruses [7,8].

Limitations include lack of medical assessment and virological confirmation of COVID-19 and comparison of application-retrieved data with a distinct set of data from the Ministry of Health reports on hospitalizations. Self-checking application data could be a relevant tool to monitor the dynamics of an outbreak and thus can be a real-time health system response to the epidemic.

Conflicts of Interest

FD received personal fees from AstraZeneca, Ipsen, Sivan Innovation, Pfizer, Chugai, Takeda, and Roche. All other authors declared no conflicts of interest.

Abstract

Background: South Korea took preemptive action against coronavirus disease (COVID-19) by implementing extensive testing, thorough epidemiological investigation, strict social distancing, and rapid treatment of patients according to disease severity. The Korean government entrusted large-scale hospitals with the operation of living and treatment support centers (LTSCs) for the management for clinically healthy COVID-19 patients.

Objective: The aim of this paper is to introduce our experience implementing information and communications technology (ICT)-based remote patient management systems at a COVID-19 LTSC.

Methods: We adopted new electronic health record templates, hospital information system (HIS) dashboards, cloud-based medical image sharing, a mobile app, and smart vital sign monitoring devices.

Results: Enhancements were made to the HIS to assist in the workflow and care of patients in the LTSC. A dashboard was created for the medical staff to view the vital signs and symptoms of all patients. Patients used a mobile app to consult with their physician or nurse, answer questionnaires, and input self-measured vital signs; the results were uploaded to the hospital information system in real time. Cloud-based image sharing enabled interoperability between medical institutions. Korea's strategy of aggressive mitigation has "flattened the curve" of the rate of infection. A multidisciplinary approach was integral to develop systems supporting patient care and management at the living and treatment support center as quickly as possible.

Conclusions: Faced with a novel infectious disease, we describe the implementation and experience of applying an ICT-based patient management system in the LTSC affiliated with Seoul National University Hospital. ICT-based tools and applications are increasingly important in health care, and we hope that our experience will provide insight into future technology-based infectious disease responses.

Introduction

The coronavirus disease (COVID-19) pandemic has become a major concern worldwide since the first report from Wuhan, China in December 2019 [1-4]. According to the World Health Organization, up to 4 million patients and 277,000 deaths have been reported [5,6]. In South Korea, the first confirmed case of COVID-19 was diagnosed on January 20, 2020; as of May 10, 2020, 10,874 patients have been diagnosed, 9610 have been released from isolation, and 256 have died [7].

South Korea has earned recognition worldwide for its tackling of the pandemic. The number of infections dropped from 900 a day in late February to less than 20 per day in late April. South Korea acted preemptively against COVID-19 with robust testing, vigorous tracing, strict social distancing, and rapid treatment of patients according to severity. In late February, a super-spreader, "Patient 31," caused a regional outbreak in the southern city of Daegu and Gyeongsangbuk Province by attending religious services. Health authorities conducted contact tracing and decided to test every close contact irrespective of whether they showed any symptoms [8]. Up to 80% of patients tested were clinically healthy, and due to the substantial number of tests performed, medical institutions were highly saturated. To provide appropriate treatment and to reduce the burden on the medical institutions of Daegu and Gyeongsangbuk Province, the government established a new treatment system based on severity on March 1, 2020 [9]. Every patient was classified based on severity into mild, moderate, severe, or extremely severe cases. Patients identified as moderate, severe, and extremely severe were immediately hospitalized for treatment [9,10].

Asymptomatic patients testing positive for COVID-19 and mild symptomatic patients were isolated and accommodated at government-sponsored facilities called living and treatment support centers (LTSCs) to be monitored by health care staff at least twice a day [9]. Patients can be discharged from the LTSC after two consecutive negative tests. In case of emergencies, patients are transferred to nearby hospitals [9]. The government asked several tertiary hospitals to operate LTSCs. The first LTSC opened in Daegu; Seoul National University Hospital (SNUH) opened the third LTSC at the SNUH Human Resource Development Center in Mungyeong, Gyeongsangbuk Province, 180 kilometers southeast of Seoul and 100 kilometers northwest of Daegu.

In this study, we introduce the experience of operating a LTSC for the management of mild COVID-19 patients and introducing information and communications technology (ICT)–based solutions tailored to the characteristics of the patients' clinical pathways.

Methods

We implemented new electronic health record (EHR) templates for the hospital information system (HIS), dashboards, an electronic prescription (e-prescription) system, and cloud-based medical image sharing. A newly developed mobile app enabled effective and accurate communication between health care providers and patients, and wearable vital sign monitoring devices facilitated management of clinically healthy COVID-19 patients.

The SNUH HIS

SNUH is a non-profit, academic referral government hospital with 1778 beds. SNUH treats approximately 600,000 inpatients and 2.3 million outpatients per year and employs about 1400 physicians and 2200 nurses. SNUH internally developed a computerized physician order entry system in 1999, implemented a picture archiving and communication system (PACS) in 2001, and started using an EMR in 2004. In 2001, SNUH's internal information technology (IT) department was spun off as a separate company, ezCaretech, which is now the largest HIS company in Korea [11]. The current version of the HIS, BESTCare 2.0, which integrates and manages all services needed by the hospital, was built by ezCaretech and implemented in 2016. The HIS was modified to support the LTSC.

Patient Management Systems to Support a LTSC in Mungyeong

Health authorities screened and designated clinically healthy COVID-19 patients to be admitted to LTSCs; however, patient management was entirely the responsibility of the entrusted hospital. Patients were considered clinically healthy if their vital signs were stable (blood pressure, heart rate, and oxygen saturation within normal limits), if they were afebrile, and if they were asymptomatic or had mild COVID-19 symptoms. Clinical health status was determined by directly evaluating the patient at the time of diagnosis. Blood pressure monitors, pulse oximeters, and thermometers were placed in each room for the patient to measure their blood pressure, oxygen saturation, and temperature. In some rooms, a wearable continuous vital sign monitoring device was placed alongside conventional devices for continuous remote monitoring. To protect the medical staff, exposure was minimized via the use of remote communication methods and self-monitoring by the patients.

User Survey

We conducted online surveys to measure satisfaction with the systems modified for the LTSCs. Three separate online surveys were conducted: patient satisfaction with the mobile app, patient satisfaction with the wearable device, and satisfaction of the medical staff. Only participants who voluntarily agreed to participate were included. Responses were measured using a 5-point Likert scale. The questionnaires were administered using an online survey form. Participants accessed questionnaires via a URL and were able to complete the survey at any time or place. The study was approved by the Institutional Review Board of SNUH (IRB number: H-2004-026-1115). The ethics committee waived the need for informed participant consent.

Results

Patient Management in the LTSC

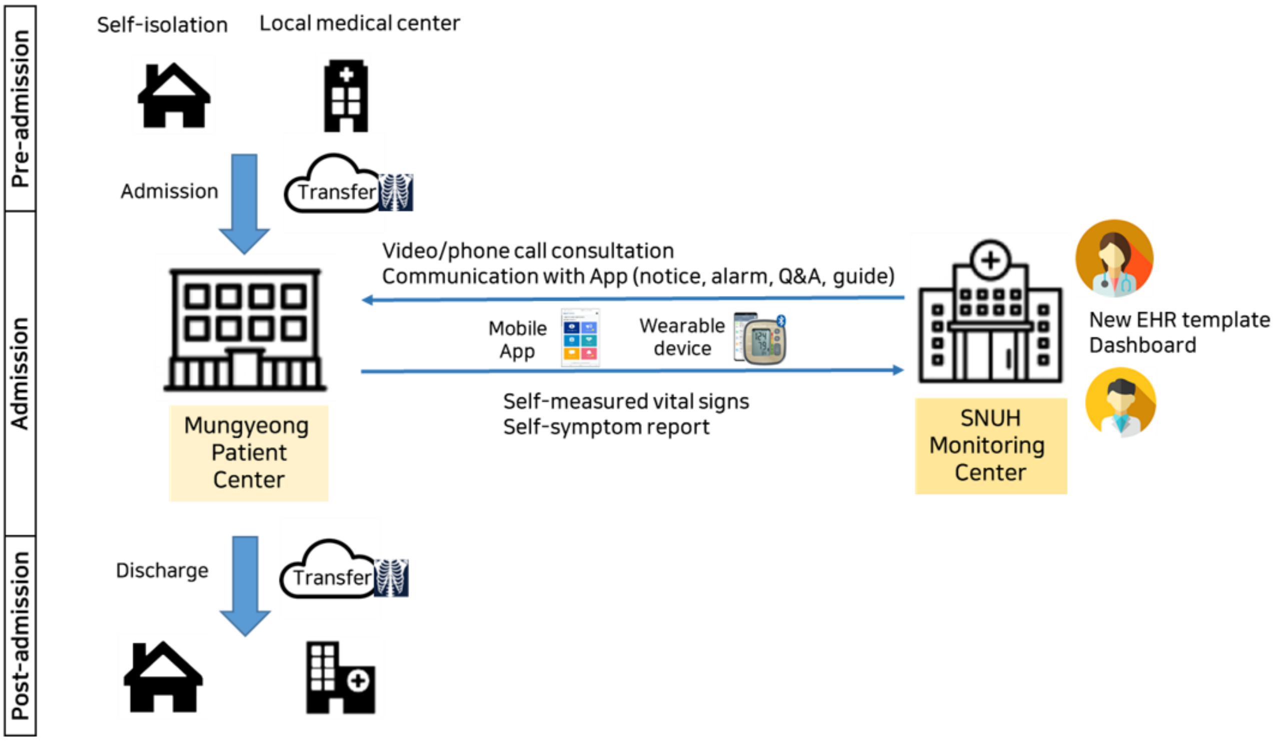
Patients who were positive for the COVID-19 real time polymerase–chain reaction (RT-PCR) test but were asymptomatic or had mild symptoms were subject to LTSC admission. Upon disease confirmation, a group of experts from public authorities triaged the patient and determined treatment depending on the severity of the patient's symptoms. Patients with severe symptoms were hospitalized and treated in negative pressure isolation units, and mild and asymptomatic patients were designated to be admitted to LTSCs [7-9]. Patients were initially admitted to the LTSC from self-isolation in their homes or were transferred from other local hospitals.

As of April 20, 2020, a total of 18 LTSCs were operational in Korea. 2948 patients were admitted to the centers, of whom 155 were transferred to another hospital due to worsening symptoms [12]. Because the number of newly diagnosed patients decreased and the number of people who were released from quarantine increased, the 18 LTSCs were consolidated into 5 centers in May 2020.

The SNUH facility in Mungyeong was originally constructed as a human resource development center used to train SNUH personnel. It was not a medical facility and therefore did not contain any medical equipment. After the decision was made to adapt the facility at Mungyeong into a LTSC, the necessary equipment, including personal computers, monitors, a portable chest x-ray machine, medical devices, and the hospital network, was installed in 2 days. Since the LTSC opened on March 5, 2020, a total of 118 patients have been admitted.

Figure 1 shows the overall flow of ICT operations according to the patient journey. A cloud system was used for instant medical image sharing in cases of patient transfer. Patients self-reported vital signs and subjective symptoms through a mobile app. These data were automatically linked to the newly introduced semistructured EHR template for mild COVID-19 patients in the HIS to help the medical staff obtain patient-reported data conveniently and accurately. In addition, in some rooms equipped with wearable devices, vital signs were transmitted to the HIS in real time. Through the mobile app, medical staff were able to notify and alert individual patients and communicate with them when needed. The Korean government temporarily permitted virtual patient management to minimize COVID-19 transmission on February 22, 2020 [7]. Each patient self-measured vital signs and reported symptoms through the mobile app at 9:00 AM and 4:30 PM every day, and they spoke with the nurse in charge via remote video consult twice a day from 9 AM-12 PM and 5 PM-8 PM and once a day with a physician in Seoul. If the patient had a concern or problem, the assigned nurse could be contacted by text or telephone. To respond to emergencies, more than two medical staff members (physicians or nurses) were always present in the patient center at Mungyeong.

Figure 1. Overall ICT operation flow according to the patient's journey. EHR, electronic health record. ICT: information and communications technology. Q&A: question and answer. SNUH: Seoul National University Hospital.



Patients were discharged if they had two consecutive negative COVID-19 tests. The RT-PCR test used by SNUH is the STANDARD M nCov Real-Time Detection Kit (SD Biosensor), which was issued an emergency use authorization by the United States Food and Drug Administration and the Korea Food and Drug Administration. The sensitivity of the test is 100% and the specificity is greater than 97% [13,14]. Chest x-rays were performed periodically to check for progression to pneumonia after admission [7-9].

The Korean government funded the operation of the LTSCs through reimbursement of medical fees. The conditions for reimbursement were as follows: medical personnel are dispatched to the LTSC, patients are seen twice a day, and necessary medical equipment, such as an x-ray machine, is available. The fee of about US $30 per patient per day could be claimed if the conditions were met [15].

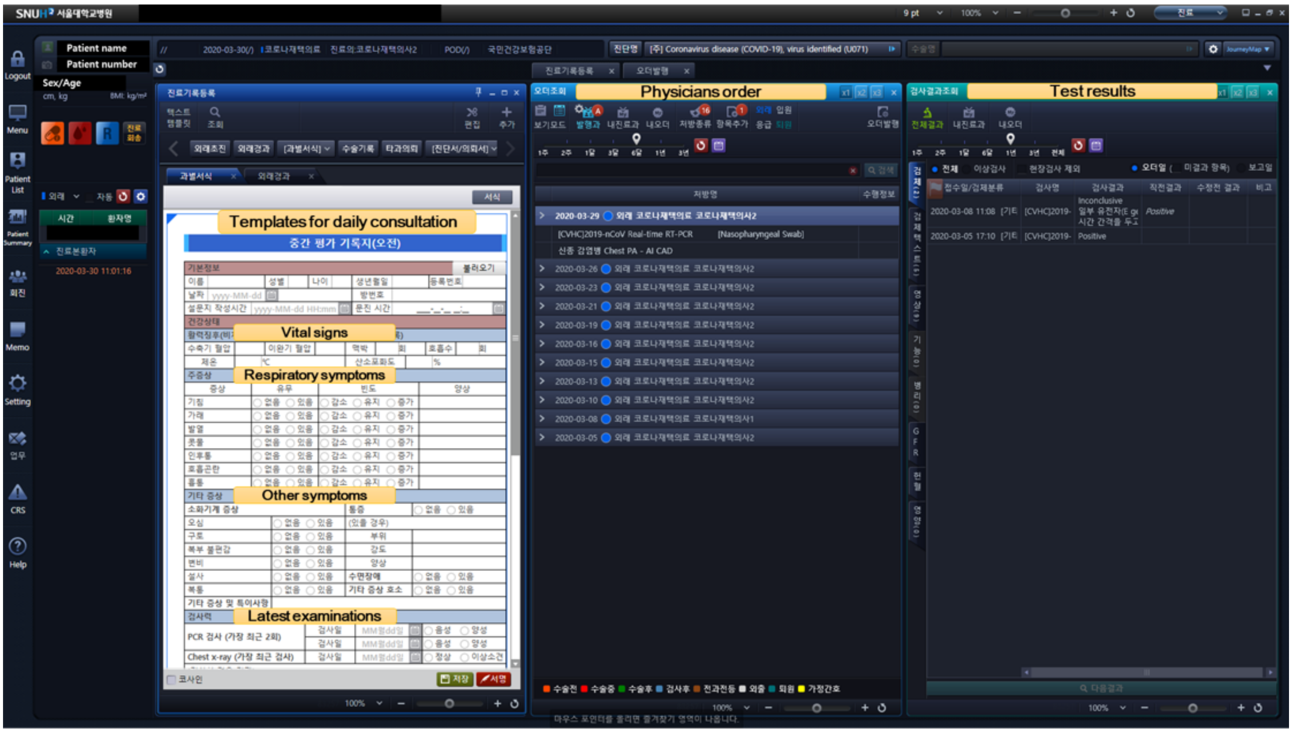
Enhancements to the HIS

A multidisciplinary task force of physicians, nurses, infection specialists, epidemiologists, and IT experts headed by the chief information officer of the hospital was convened to direct and manage the modifications to the IT systems to support the LTSC. First, we customized and enhanced our HIS to support the LTSC.

New EHR Templates and Order Codes

To use the SNUH HIS in the LTSC, a hospital network was installed in addition to the usual internet service. An LTSC department was established in the HIS for efficient and independent patient management. Only chest x-rays and RT-PCR using a nasopharyngeal swab or sputum samples were performed at the LTSC; new order codes were created for these tests. Moreover, we developed three new EHR templates for admission, progression, and discharge, which were used to track the symptoms and general status of the patients (Figure 2). The EHR templates for the LTSCs were constructed in a semistructured form that combined a free text section for medical staff to freely record observations during consultation and a structured form that was configured to include patients' subjective respiratory, gastrointestinal, and psychological symptoms, objective vital signs, previous medical history, contact history of COVID-19, and allergies. When a patient entered self-reported symptoms or vital signs on the mobile app, the data were automatically linked to the EHR template to be viewed during remote video consultation.

Figure 2. Modified EHR template for daily consultation at the LTSC.



Dashboard

A dashboard for the medical staff was developed to display real time information for all patients at central monitoring centers at Seoul and Mungyeong. The dashboard displayed each patient's vital signs (heart rate, body temperature, respiratory rate, blood oxygen saturation) and information on whether the patient has any symptoms or chest x-ray abnormalities (Figure 3).

Figure 3. Dashboard of the EHR displaying real time information for patients at the LTSC.

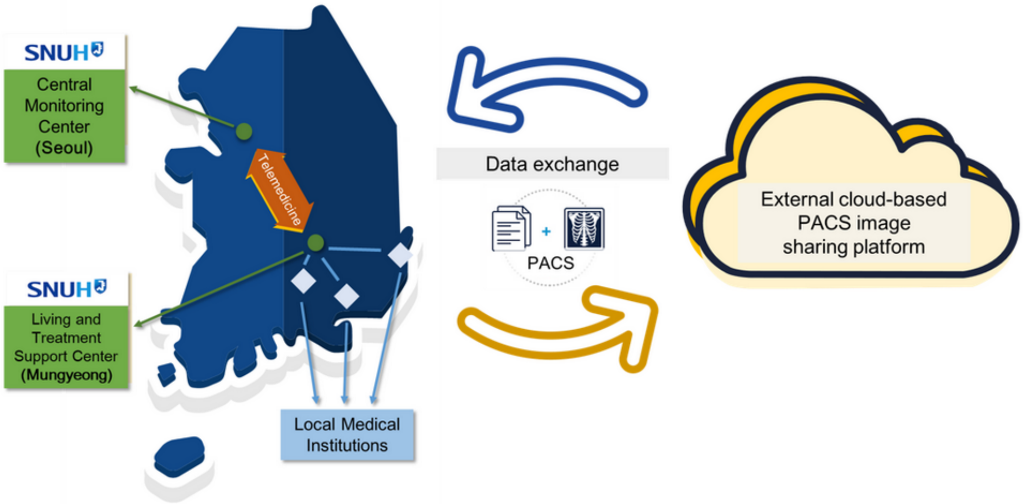
e-Prescription System

Basic medications were prepared at SNUH and transported to the LTSC facility. Plans were made for sourcing other medications from local pharmacies by sending prescriptions electronically. A mobile app–based e-prescription system was added to the SNUH app for patients on March 1, 2020. The patient could send the prescription information through the app to a nearby pharmacy selected by the user. There were two cases of e-prescription system usage in the LTSC. A 25-year-old female patient taking propranolol regularly for palpitation was admitted but did not bring the medication with her. During the stay, she complained of palpitations with tachycardia. The physician at the central monitoring center in Seoul prescribed propranolol, and the prescription was electronically sent through the app to a local pharmacy about 1.8 km from the LTSC. Another case was a 25-year-old male patient with hyperthyroidism who was prescribed and received methimazole using the e-prescription system.

Cloud-Based Medical Image Sharing

Seamless medical image interoperability is not available in Korea. Generally, medical images are copied to CDs and carried by the patient from one institution to another. Clearly, this process is inadvisable due to the nature of the disease. In addition, SNUH decided to review the chest x-ray and computerized tomography images taken by radiologists at SNUH before a to the LTSC. Also, producing a CD copy for patients in need of transfer to another hospital due to emergent or worsening conditions was not practical. Thus, we decided to establish a simple cloud-based system for instant and effective medical image sharing (Figure 4). Users from other hospitals would upload the patient's medical images to the cloud, which were then transferred to the SNUH PACS for physician review. All medical images were shared using the Digital Imaging and Communications in Medicine (DICOM) format. Twelve patients used this system when they were admitted. Two patients who had no symptoms at the time of admission developed difficulty breathing and were transferred to a nearby hospital. Chest x-rays taken at LTSC were quickly shared with medical staff in the receiving hospital using this system.

Figure 4. The cloud-based medical image sharing platform. PACS: picture archiving and communication system. SNUH: Seoul National University Hospital.



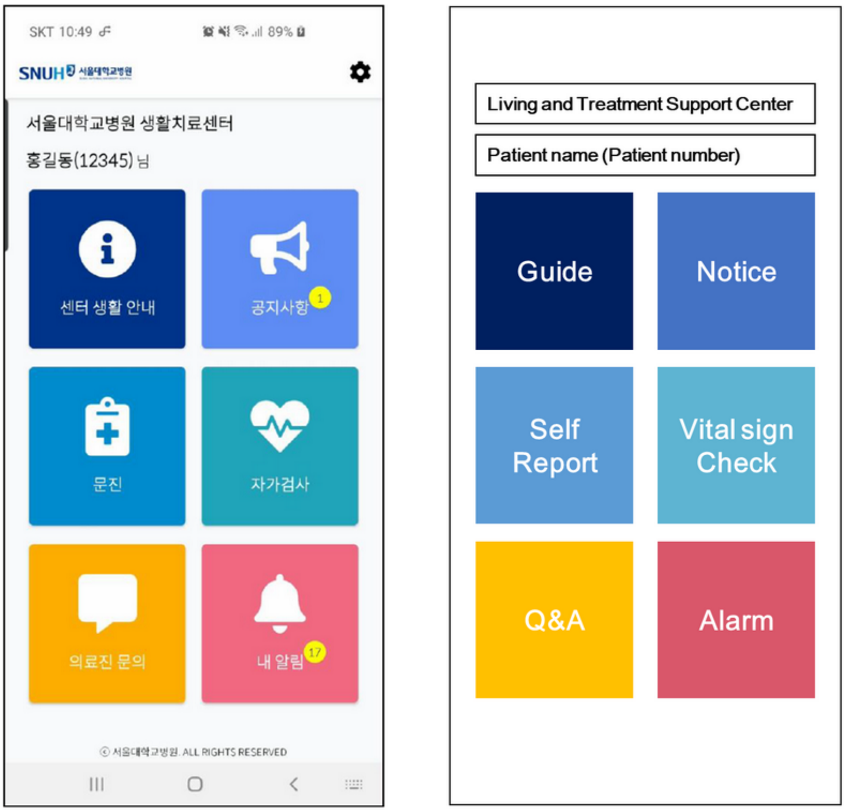
Wearable Vital Sign Monitoring Device

Some patients were asked to use a wearable device to measure their vital signs and enable the medical staff to monitor them remotely. The Vital-sign Data Recorder (VDR-1000) from Tribell Labs is a wearable medical multi-function measurement device that can be easily used by patients (Multimedia Appendix 1). It can directly measure the patient's electrocardiogram, pulse rate, blood oxygen saturation, respiratory waveform, respiratory rate, and body temperature. The measured data are transmitted to the central monitoring system (CMS) using Wi-Fi and are then forwarded to the HIS. Medical staff in Mungyeong and Seoul can monitor vital signs of patients using both the CMS monitor and HIS (Multimedia Appendix 2). The CMS software can set alarms with different thresholds for each patient. An alarm sounds when a value outside the threshold range is measured, assisting the medical staff to respond quickly (Multimedia Appendix 3).

Mobile App

To enable efficient patient management and communication between the patients and medical staff, an Android-based mobile app was developed for patients in the LTSC. The app consisted of six functions: general guides for patients admitted to the LTSC, notice board, symptom questionnaire, vital sign reporting, question and answer (Q&A), and push reminders. The app was released on March 27, 2020 (Figure 5).

Figure 5. Interface of the mobile app for patients admitted to the LTCS. Q&A: question and answer.



General Guides for the LTSC

General information on admission to the LTSC and frequently asked questions by patients were organized for patient reference. Administrators could edit or register additional content directly through the app management web portal.

Notice Board

The notice board was used to send announcements to the patients. A push alarm was triggered when a new announcement was registered.

Symptom Questionnaire

Patients were asked to self-report their symptoms using the questionnaire in the mobile app. The questionnaire focused on the presence and frequency of symptoms most relevant to COVID-19 (cough, sputum, fever, rhinorrhea, sore throat, dyspnea, and chest pain) but also asked patients to report other more general symptoms (nausea, vomiting, abdominal discomfort, constipation, diarrhea, abdominal pain, insomnia, pain, and others). The self-reported data automatically populated the health record template.

Vital Sign Self-Reporting

In addition to the self-reporting of symptoms, patients were instructed to measure their vital signs twice a day, in the morning and afternoon, with the devices provided in each room and to enter the values into the mobile app. The vital sign measurements were also sent to the HIS to be reviewed by the medical staff.

Q&A

The Q&A function was a secure messaging platform for patients to submit questions to the medical team. The staff members replied through the app management web portal, and when a question was answered, a push notification was sent to the patient's mobile phone.

Push Alarms

Patients received a push alarm as a reminder to fill out the self-reporting questionnaires for symptoms and vital signs, when their question was answered, or when the medical staff posted a new announcement to the notice board.

Usability Survey

Twelve patients participated in the online surveys. The mean age of the respondents was 25 years (SD 6.25 years), and 7 (58%) were college students. For the mobile app, out of 5 points, the perceived usefulness showed the highest score at 4.62 points (SD 0.48), followed by satisfaction at 4.08 points (SD 1.41) and perceived ease of use at 3.81 points (SD 0.41) (Supplemental Table 1 in Multimedia Appendix 4). When patients rated the experience of using the wearable vital sign monitoring devices out of 5, perceived usefulness scored the highest at 4.45 points (SD 0.57), followed by perceived ease of use at 4.30 points (SD 0.59) and satisfaction at 3.98 points (SD 0.70) (Supplemental Table 2 in Multimedia Appendix 4).

A simple satisfaction survey regarding the usability of the mobile app was also conducted with the medical staff. Of the 24 participants who answered the questionnaire, 20 (83%) were nurses and 4 (17%) were physicians. The overall satisfaction score for the mobile app out of five points was 4.10 (SD 0.64) (Supplemental Table 1 in Multimedia Appendix 4).

Discussion

Principal Findings

The ICT-based patient management system introduced in this study was applied to the LTSC for clinically healthy COVID-19 patients operated by SNUH. Due to the infectious nature of the disease, it was difficult for medical staff to directly perform patient care; therefore, noncontact management was essential. SNUH introduced an ICT-based care system for the management of clinically healthy COVID-19 patients at the LTSC that fit the entire care flow, from preadmission and admission to discharge or transfer. The process started on March 1, 2020, and was completed in 4 weeks. Korea’s strategy of aggressive mitigation through early detection based on extensive diagnostic testing thorough epidemiological investigation and transparent management of COVID-19–related information has “flattened the curve” of the rate of infection [7]. The Ministry of Health and Welfare of Korea has tailored treatment policies and guidelines to match the disease profile of COVID-19 and the available medical resources. As part of their multifaceted approach to COVID-19, the Ministry relaxed regulations and temporarily approved the limited use of telemedicine and e-prescriptions [9]. Because direct telemedicine visits between health care professionals and patients were previously prohibited, the infrastructure and ecosystem around telemedicine were not fully developed [16]. Another approach was the decision to isolate patients with mild symptoms in designated LTSCs from March 1, 2020 [9]. The LTSCs were public or private facilities that were modified to accommodate and quarantine patients. SNUH, as a national hospital of Korea, was also asked to operate an LTSC at the SNUH Human Resources Development Center in Mungyeong. Most of the medical staff were located in the central monitoring center in Seoul and led patient care using telemedicine tools; meanwhile, some staff worked at the Mungyeong site in supportive roles and in preparation for emergencies.

The authors recognized the importance of a multidisciplinary approach to develop a system to support patient care and management at LTSCs as quickly as possible [17-19]. The Office of Hospital Information of SNUH, composed of several medical faculty members, nurses, pharmacists, medical record technicians, and IT experts, manages the IT services of the hospital and was well placed to lead this effort. Moreover, ezCaretech, the company that developed our HIS, is under contract to maintain the HIS and has a team located at SNUH; this team could make timely improvements to the system in a straightforward manner. In addition, HealthConnect, a health care application development company, has been working on a mobile app with SNUH for a project to collect patient-reported outcomes and enable viewing of the data in the HIS. This familiarity with the hospital interfaces and data structures enabled rapid development and deployment of the LTSC app.

Role of Health Care Information Exchange in the Pandemic Era

Health care information exchange between health care institutions plays an important role during pandemics and disasters [20-24]. In Korea, where the population has high accessibility to health care resources due to the national health insurance program, any patient can visit any hospital. Health records are fragmented among the health care institutions that the patient visits, as the EHR systems used by each institution are different and most are not interoperable [25]. To alleviate this problem, the Ministry of Health and Welfare initiated a nationwide healthcare information exchange (HIE) project in 2017. This service electronically and securely sends and receives medical records and image data of patients who have consented to provide personal information to medical institutions for patient care [26]. However, in the current HIE system, electronic information is generated only when the patient is referred to another medical institution; thus, it is difficult to use it in this situation. Furthermore, the project is not gaining traction as expected due to the cost burden to small and medium-sized hospitals to connect their EHRs with the national HIE system as well as the conflict between health care institutions and the government on reimbursement and penalty policies [27]. As most institutions were not prepared to share image data through the national HIE system, we developed a simple cloud-based image sharing platform to enable efficient exchange. This platform was immediately used for a 55-year-old woman who had no underlying disease and no symptoms at initial presentation but who progressed to pneumonia 3 days after admission. Her physician decided to transfer her to a local general hospital and shared her chest x-ray images through this system.

Lessons From the MERS Outbreak and Application for COVID-19 in South Korea

South Korea learned important lessons from its 2015 Middle East respiratory syndrome (MERS) outbreak, including the importance of increased transparency, early detection, and rapid diagnosis [28-30]. The Korea Centers for Disease Control and the Health Insurance Review & Assessment Service developed the international traveler information system and provides the service to all health care institutions in Korea [31]. When the patient has visited countries that are being screened, the international traveler information system sends out a real time alert to allow staff to recognize and prevent possible exposure. Similarly, to minimize exposure, the system was used to inform the physician or nurse whether the patient was arriving from the epicenter of the COVID-19 epidemic in Korea, Daegu and Gyeongsangbuk Province, since February 18, 2020.

Although the current pandemic is ongoing, we should also learn from this experience. Telemedicine is ideal for proper triage, early diagnosis, isolation, and treatment of patients [32]. Even in the United States, where access to telemedicine services, coverage, and reimbursement is available, telemedicine use is relatively uncommon [33]. Telemedicine use is even rarer in Korea, which is one of the few countries where patient-facing telemedicine is explicitly banned [16]. All stakeholders involved, including the government, medical communities, civic groups, and politicians, have different opinions. Some believe that Korea should approach this issue differently from other countries due to the nature of the medical system in Korea, which has excellent accessibility and low costs [34]. However, to limit community transmission during the COVID-19 pandemic, the Ministry of Health and Welfare has temporarily approved the limited use of telemedicine with e-prescriptions [9]. With recent studies reporting the advantages of proactive use of IT systems and strategies in infectious patients [35-37], we hope that this experience provides an impetus for the stakeholders of the health care system to improve and expand on the use and application of ICT in health care.

Conclusions

Faced with a novel infectious disease, we describe the implementation and experience of applying an ICT-based patient management system in the LTSC by SNUH. ICT-based tools and applications are increasingly gaining importance in health care, and we hope that our experience can provide insight into future technology-based infectious disease responses.

Acknowledgments

We would like to gratefully acknowledge our excellent team members, Suhyeon Kim, Jisu Ha, Buri Lee, and Sanghee Lim from the Hospital Information Development team, Myeonghee Song and Gyeongran Hong from the Medical Records team, Taewoo Kim and Donggyu Lee from the Hospital Information Strategy team, and Hyesook Lee from the Hospital Information System and Security team for their profound dedication and excellence. We would like to thank our colleagues Hyuck Kim from HealthConnect, Jinmo Kim and Sanghak Lee from Tribell Labs, and the IT specialists from ezCaretech. Above all, we would like to express deep gratitude to all experts and volunteers who are still fighting COVID-19. This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute, funded by the Ministry of Health and Welfare, South Korea (grant number: HI19C0790).

Authors' Contributions

KHK had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis. YSB, KHK, CWJ, BC, MSK, and EK conceived and designed the study. YSB acquired, analyzed, and interpreted the data. YSB, SWC, and TK drafted the manuscript. Critical revision of the manuscript was provided by YSB and SWC. YSB and KHK provided administrative, technical, or material support.

Abstract

Since the World Health Organization declared the coronavirus disease (COVID-19) outbreak a pandemic, significant changes have occurred in the United States as the infection spread reached and passed its exponential phase. A stringent analysis of COVID-19 epidemiologic data requires time and would generally be expected to happen with significant delay after the exponential phase of the disease is over and when the focus of the health care system is diverted away from crisis management. Although much has been said about high-risk groups and the vulnerability of the elderly and patients with underlying comorbidities, the impact of race on the susceptibility of ethnic minorities living in indigent communities has not been discussed in detail worldwide and specifically in the United States. There are currently some data on disparities between African American and Caucasian populations for COVID-19 infection and mortality. While health care authorities are reorganizing resources and infrastructure to provide care for symptomatic COVID-19 patients, they should not shy away from protecting the general public as a whole and specifically the most vulnerable members of society, such as the elderly, ethnic minorities, and people with underlying comorbidities.

(J Med Internet Res 2020;22(6):e19934) doi:10.2196/19934

KEYWORDS

coronavirus; COVID-19; African American; mortality; race; virus; minority; infectious disease

Although it has only been a short time since March 11th, 2020, when the World Health Organization officially announced that the coronavirus disease (COVID-19) outbreak had reached the level of a pandemic [1], things have changed significantly for the United States. The country has reached and passed the exponential phase of the COVID-19 pandemic, with over 1.7 million confirmed cases and close to 105,000 COVID-19–related deaths [2]. These numbers seem to reflect only the tip of the iceberg; the figures would be much higher if we are to include asymptomatic carriers and mildly symptomatic untested cases in the population. As shown in a study by Ing et al [3], testing all of the passengers of a cruise ship revealed a ratio of asymptomatic COVID-19–positive patients to symptomatic patients to be 4:1. Furthermore, a second wave of COVID-19 infection is always a possibility.

A stringent analysis of COVID-19 epidemiologic data requires time and would generally be expected to happen with some delay after the exponential phase of the disease is over and when the focus of the health care system is not on crisis management. Although much is said about high-risk groups and the vulnerability of the elderly and patients with underlying comorbidities (eg, hypertension, diabetes, malignancies, cerebrovascular disease, and underlying pulmonary/cardiovascular disease like chronic obstructive pulmonary disease and asthma [4-6]), the impact of race on the susceptibility of ethnic minorities living in indigent communities has not been discussed in detail worldwide and in the United States. Myers [7] and Dyer [8] brought up this issue and discussed as to why, in their opinion, ethnic minorities, in particular African American or black populations, are more vulnerable to COVID-19 infection and mortality. Dyer [8] also brought up the same issue with other “invisible communities” (ie, Navajo Nations communities of Arizona, New Mexico, and Utah and “undocumented immigrants”) and proposed delayed health care seeking behavior, inferior care, difficulty in trusting authorities (eg, fear of charges against those without legal immigration documents upon receiving care or being tested for COVID-19) as possible explanations. Dyer [8] believes that African Americans are generally suspicious of the health care system following the Tuskegee syphilis scandal (1932-1972), where black participants with a syphilis diagnosis were monitored for almost 40 years and left untreated despite the availability of treatment for syphilis at the time; this mistrust continues to impact medical advice–seeking behaviors among black populations in the United States [8].

Knowledge of comorbid risk factors as well as vulnerable groups can be useful for clinicians in directing early and appropriate medical management and allocating resources when handling patients with COVID-19. As “ethnicity” is still considered a sensitive/controversial topic in the United States, its inclusion as a research topic as well as patients’ demographic data should be cautiously evaluated; even the Centers for Disease Control and Prevention does not include race and ethnicity information in their publicly available data when presenting the demographic and geographic distributions of COVID-19 cases. Myers [7] provided invaluable, practical recommendations to health care authorities and hospital administrations caring for vulnerable populations with COVID-19, including patients with comorbidities and ethnic minorities. Cooney [9] presented examples from Illinois, Michigan, and Milwaukee County in Wisconsin to show disparities and the overrepresentation of COVID-19 cases and mortalities among African Americans compared to other ethnic groups, especially Caucasians. Although these areas do not constitute the majority of the United States, these are a handful of exceptional areas where the local government agencies have included race as part of the shared information when presenting the most vulnerable and affected segments of society “hardest hit by the virus” [9,10]. While African Americans in Illinois, as an example, account for 17% of confirmed COVID-19 cases and 29.7% of attributed deaths, they make up only 15% of the state’s population [10]. In Louisiana, based on the 2019 US census, 33% of the population is African American, but this group accounts for 55% of COVID-19–related deaths, according to data from the Department of Health [11]. North Carolina, Michigan, St Louis, New York City, and Alabama are other examples of disparities in COVID-19–related deaths and ethnicity, with higher death rates reported in African Americans compared to Caucasians [12-15].

This disparity is not a confirmed fact across the board, but it is present in some states as mentioned above. There are some possible explanations for this pattern. The proposed association between COVID-19 and angiotensin-converting enzyme II (ACE-II) secondary to ACE-II being a co-receptor for respiratory viral entry, along with potential innate ACE-II receptor differences in function, response to medications, and gene polymorphism in the African American population compared to other ethnic groups [16,17] could be an explanation that needs further investigation. Having higher incidence of hypertension, diabetes, malignancies, heart failure, cerebrovascular disease, and underlying pulmonary/cardiovascular disease could also make the African American community a potential high-risk group for COVID-19 [7,8,18,19]. Higher BMI among African Americans compared to other groups, particularly Caucasians, has been shown to be present in children and adults [20,21]. This contributes to a general decrease in self-rated health among older African Americans and can even interfere with the protective effects of education and income [22]. Higher average BMI in African Americans could potentially decrease their survival rate in cases with COVID-19–related acute respiratory distress syndrome and increase the rate of associated complications [23]. Other possible contributing factors to COVID-19 susceptibility among African Americans include lower socioeconomic status, crowded living conditions, living in densely populated parts of cities, reduced access to hygienic products and personal protection equipment, unemployment, employment in the more virus-exposed fields of the job market, along with cultural habits that hinder medical advice seeking (although their exact role warrants further investigations) [24]. Myers [7] went a step further and proposed the influence of “systemic racism on baseline health” as a compounding factor influencing the health of ethnic minorities including African American people. While health care authorities are reorganizing resources and infrastructure to provide care for symptomatic COVID-19 patients [25], they should not forgo protecting the general public as a whole and specifically the most vulnerable members of society, such as the elderly, ethnic minorities, and people with underlying comorbidities. We agree with Myers [7] and Fouad et al [26] that the following are essential steps toward a fairer and more effective health care system when battling COVID-19 infection: collecting data on patient care during the COVID-19 era including race, implementation of social policies to reduce economic burden, culturally sensitive and appropriate messaging tailored to certain communities, increased accessibility of testing and vaccination (after vaccine development) for vulnerable communities, real-time reporting of disparities and reflective redistribution of resources, aggressive treatment of comorbidities simultaneously while treating COVID-19 infections, and prioritization of community-based health care systems that primarily serve ethnic minorities. We can turn this crisis into an opportunity to reduce disparities in care in our health care system [26].

Abstract

Background: Social media has become increasingly important as a source of information for the public and is widely used for health-related information. The outbreak of the coronavirus disease (COVID-19) has exerted a negative impact on dental practices.

Objective: The aim of this study is to analyze the nature and diffusion of COVID-19–related oral health information on the Chinese social media site Weibo.

Methods: A total of 15,900 tweets related to oral health and dentistry information from Weibo during the COVID-19 outbreak in China (December 31, 2019, to March 16, 2020) were included in our study. Two researchers coded 1000 of the total tweets in advance, and two main thematic categories with eight subtypes were refined. The included tweets were analyzed over time and geographic region, and coded into eight thematic categories. Additionally, the time distributions of tweets containing information about dental services, needs of dental treatment, and home oral care during the COVID-19 epidemic were further analyzed.

Results: People reacted rapidly to the emerging severe acute respiratory syndrome coronavirus 2 threat to dental services, and a large amount of COVID-19–related oral health information was tweeted on Weibo. The time and geographic distribution of tweets shared similarities with epidemiological data of the COVID-19 outbreak in China. Tweets containing home oral care and dental services content were the most frequently exchanged information (n=4803/15,900, 30.20% and n=4478, 28.16%, respectively). Significant differences of public attention were found between various types of bloggers in dental services–related tweets ($P<.001$), and the tweets from the government and media engaged the most public attention. The distributions of tweets containing information about dental services, needs of dental treatment, and home oral care information dynamically changed with time.

Conclusions: Our study overviewed and analyzed social media data on the dental services and oral health information during the COVID-19 epidemic, thus, providing insights for government organizations, media, and dental professionals to better facilitate oral health communication and efficiently shape public concern through social media when routine dental services are unavailable during an unprecedented event. The study of the nature and distribution of social media can serve as a useful adjunct tool to help make public health policies.

Introduction

The outbreak of the coronavirus disease (COVID-19) caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), first identified from Wuhan, Hubei Province, China, has almost swept across the whole world and constituted a public health emergency of “pandemic” proportions [1]. SARS-CoV-2 is the third zoonotic human coronavirus emerging in this century after severe acute respiratory syndrome–related coronavirus and Middle East respiratory syndrome–related coronavirus (MERS-CoV) [2]. As a global pandemic, COVID-19 has affected people from more than 200 countries and regions, leading to 2,719,897 laboratory-confirmed cases and 187,705 deaths as of April 25, 2020 [3]. The total cases outside of China has outnumbered China more than 20 times. Strict prevention measures and effective therapeutics are urgently needed for the control of the pandemic.

COVID-19 has posed a particular threat to the practice of dentistry. With the identification of SARS-CoV-2 in the saliva of patients who are infected [4] and the transmission of COVID-19 through asymptomatic carriers [5-7] or potential patients in incubation status [8], awareness of the risk of COVID-19 spreading during dental procedures was of considerable concern among dental professionals [9-11]. Moreover, droplets and aerosols generated from high-speed dental handpieces, ultrasonic instruments, or 3-way syringes has the potential for direct or indirect cross transmissions of coronavirus between patients and dental care providers [12]. Therefore, during the early and outbreak stages of the COVID-19 epidemic in China, a majority of dental practices were suspended and most of the routine dental services were not available for the public, resulting in the inconvenience for potential patients to seek dental treatment. During this special period, social media played an important role in the exchange of dentistry- and oral health–related information among the public.

The internet, especially social media, is becoming increasingly important as a source of information for public health issues since it provides free and immediate access to large volumes of data [13]. In the past decade, social media has not only changed the pattern of spread for health-related information and the communication mode between patients and health care providers, but also drawn great attraction from researchers to study the distribution of diseases [14], the diffusion of health-related information and misinformation [15,16], the public reactions to health events [17-19], and more. Accumulating studies using social media for health care research have been published annually, providing insights for public health surveillance or helping develop health policy [14,20-23]. During the COVID-19 epidemic, the social media search index was identified as a promising predictor of new cases of COVID-19 infections [24].

Sina Weibo, similar to Twitter, is the most popular online microblog platform in China. Weibo allows its users to tweet or retweet messages optionally with links, pictures, or videos attached. The public reactions of Chinese people to the MERS-CoV and H7N9 outbreaks were significantly strong on Weibo [17]. Considering that the COVID-19 outbreak has exerted an impact on dental practices, we proposed the following research question: how was dentistry- or oral health–related information during the COVID-19 epidemic “tweeted” and communicated about on Weibo? The aim of this study was to investigate the nature and diffusion of COVID-19–related dentistry or oral health information on Weibo and determine the public reactions to tweets with this content, thus, providing an overview and reflection of the supply and demand of dental services under the epidemic on social media.

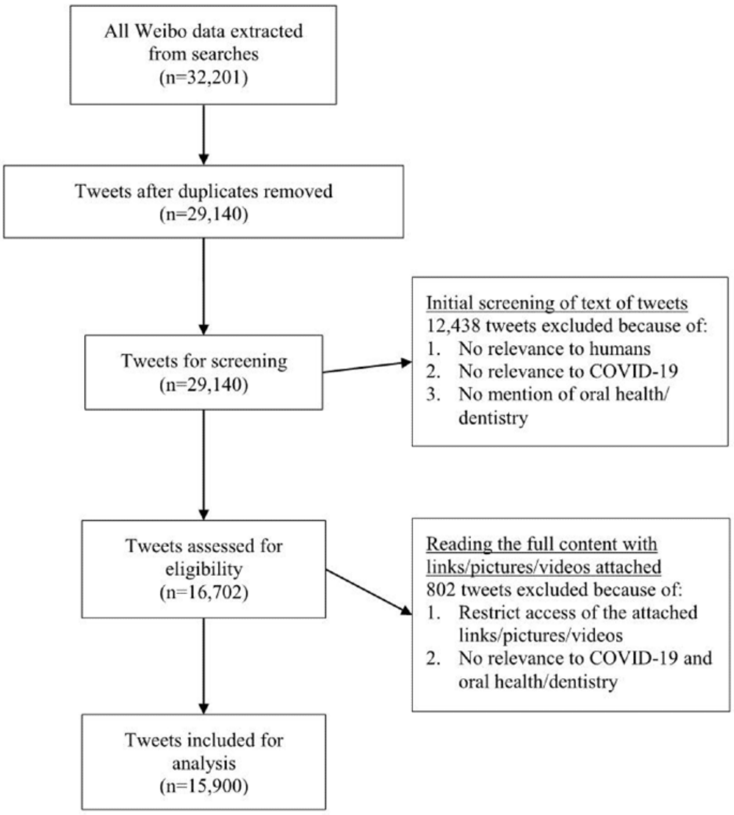
Methods

Study Design and Search Strategy

A study of “COVID-19-related oral health information” tweets on Sina Weibo was performed. A new anonymous Weibo account was created with only the name, gender, and date of birth provided upon registration. Using a new account without search histories, previous likes, or friends can avoid preferential links promoted by Weibo. Four keywords related to COVID-19 (pneumonia of unknown cause, coronavirus, COVID-19, and epidemic) and two keywords for dentistry (stomatology and dentistry) in Chinese characters were employed to search tweets about COVID-19 and dentistry or oral health on Weibo. Eight independent searches with a combination of one keyword for COVID-19 and the other for dentistry were carried out on March 17, 2020, through the new account. We selected December 31, 2019, as the start date of tweets since, on this day, the pneumonia of unknown cause (the name of COVID-19 at the time) in Wuhan was officially reported to the World Health Organization, and the first group of epidemiologists were dispatched by the Chinese Center for Disease Control and Prevention (CCDC) to support the control of this emerging infectious disease (EID) in Wuhan.

Figure 1 is the flow diagram used in our study. In total, 32,201 tweets in the first 77 days (December 31, 2019, to March 16, 2020) of the COVID-19 epidemic were identified. All Weibo data, including the full-text content; post time; numbers of likes, shares, and comments; and blogger information (name, ID, homepage website, number of followers, and personal introduction) of each tweet were extracted with a Python-based platform *Gooseeker*, which could retrieve all the tweets from each independent research through the account we created. A total of 29,140 tweets after removal of duplicates were scanned to exclude non–human-related and irrelevant results. After screening, there were 16,702 tweets included for further eligibility assessment, namely, reading the full content and the links, pictures, or videos attached to tweets as well. Restricted access of links, pictures, or videos were also excluded since only the information available for the public was assessed. Finally, the remaining 15,900 tweets were included for further analysis. The initial screening work and eligibility assessment was conducted by two researchers (ZT and GC) together.

Figure 1. Flow chart of the study. COVID-19: coronavirus disease.



Coding Procedure

Two researchers (ZT and GC) with expertise in dentistry completed the coding. First, the two coders were asked to pilot the project by coding 1000 (6.28%) of the total 15,900 tweets to develop and refine the coding schemes for thematic categories. Two main thematic categories for all tweets were determined initially: COVID-19–related and oral health–related information. The information related to COVID-19 was further subtyped into five domains: epidemiology, pathology, symptoms, diagnosis, and prevention; the information related to oral health was subtyped into three domains: dental services, needs of dental treatment, and home oral care information. The tweets that were related to oral health and COVID-19 but inappropriate to be sorted into any of the categories were labelled “others.” The definition and examples of each category are shown in Multimedia Appendix 1.

Second, to test the feasibility and reliability of categories, a weighed Kappa test was used to assess interrater and intrarater agreement of coding between two researchers. Two researchers were asked to classify 200 randomly selected tweets and reclassify 2 weeks after the first coding. The results of the weighed Kappa test of the two researchers were 0.983 for interrater agreement and 0.994 (ZT) and 0.983 (GC) for intrarater agreement, which indicated excellent reliability of coding procedure.

Third, after agreement for the coding of the tweets was confirmed, all 15,900 tweets were randomly separated into two groups and classified by two researchers. The tweets were coded to more than one category if containing miscellaneous information. Tweets in each thematic category were divided into two types according to the numbers of followers (less than 1000 followers and 1000 or more followers).

Postanalysis of the Included Tweets

The tweets of each day were counted and compared with COVID-19 daily new cases and deaths in China for time distribution analysis. Among 15,900 tweets, 1682 tweets with location information were analyzed for geographic distribution and compared with the regional distribution of total COVID-19 cases by March 16, 2020. The epidemiological data were obtained from the official website of the CCDC [25]. In addition, the tweets and retweets conveying similar information were extracted and grouped to analyze the topics of interest. The mean and SD of the numbers of likes, shares, and comments in each group were calculated.

Meanwhile, the tweets related to oral health information were further analyzed. Specifically, the time distribution of tweets containing information about the risks of COVID-19 transmission during dental procedures, notices of stopping all or part of dental services, need for dental treatment, home oral care, protective measures during dental services, and notices of restoring dental services during the COVID-19 epidemic were analyzed. The public needs for dental treatment and home oral care information tweeted on Weibo were further categorized and counted. The Kruskal-Wallis test was used to determine the differences of public reactions (numbers of likes, shares, and comments) to tweets from different types of bloggers (governments, media, dental clinics or hospitals, dentists or dental nurses, online health platforms, and others). In addition, the Mann-Whitney U test was used to compare the public reactions to tweets related to oral health information tweeted by the same types of bloggers.

All statistical analyses were carried out with Microsoft Excel (Microsoft Corporation) and SPSS software 18.0 (SPSS Inc), and *P*<.05 was considered significant.

Results

Time and Geographic Distribution of Weibo Tweets

As shown in Figure 2, the time distribution of the Weibo data was similar to the distribution of new cases and deaths during this period of time. From December 31, 2019, to March 16, 2020, the daily count of tweets in Weibo was low during the first 20 days, then increased with fluctuations starting on January 20, 2020, presented three major peaks before mid-February, and finally gradually decreased and kept at a steady low level until March 16, 2020. The first peak on January 22, 2020, was between two milestone events of the COVID-19 outbreak in China, namely, official confirmation of human-to-human transmission of COVID-19 on January 20 and the start of the lockdown in Wuhan on January 23, 2020. The second peak on January 28, 2020, was composed of tweets and retweets refuting the misinformation for COVID-19 prevention. The highest peak of 1316 tweets on February 8, 2020, followed the death of Dr Wenliang Li, one of the first doctors who flagged the new coronavirus outbreak and raised alarms to the public. This peak occurred because retweets of the news that aerosol acts as a transmission route for COVID-19 as disseminated in a press conference of the Shanghai government office at 2 PM that day.

Further analyses were conducted on 1682 tweets whose geographic distribution could be identified and compared to the regional distribution of total cases. The geographic location was optional for the users when posting tweets on Weibo. Therefore, only 1682 tweets included geographic location information. As demonstrated in Figure 3, the provinces (Zhejiang, Jiangsu, Guangdong, Shandong, Sichuan, and Henan) that witnessed the most tweets (>100) had more than 500 COVID-19 cases, higher than most of the other provinces in China. In northwest China, with no more than 100 confirmed cases in each province, tweets were less frequently distributed. More tweets were posted from central and eastern coastal provinces. However, tweets posted from Hubei, which was the original epicenter of the COVID-19 outbreak and had the most cumulative number of cases, surprisingly, were no more than 100.

Figure 2. Time distribution of tweets and new cases and deaths of COVID-19 in China. COVID-19: coronavirus disease.

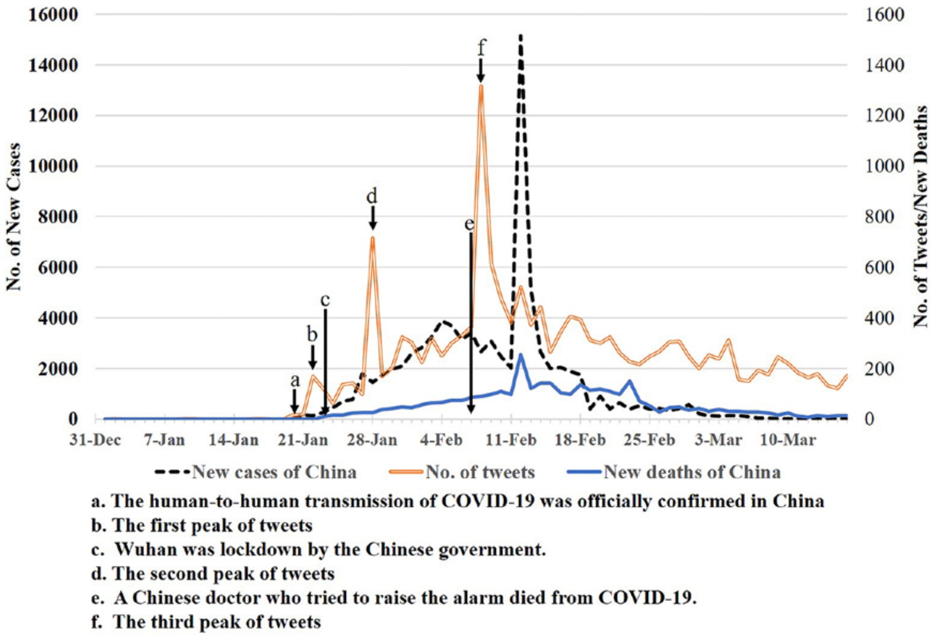


Figure 3. The geographic distributions of Weibo tweets (left) and total coronavirus disease cases (right) in the region.

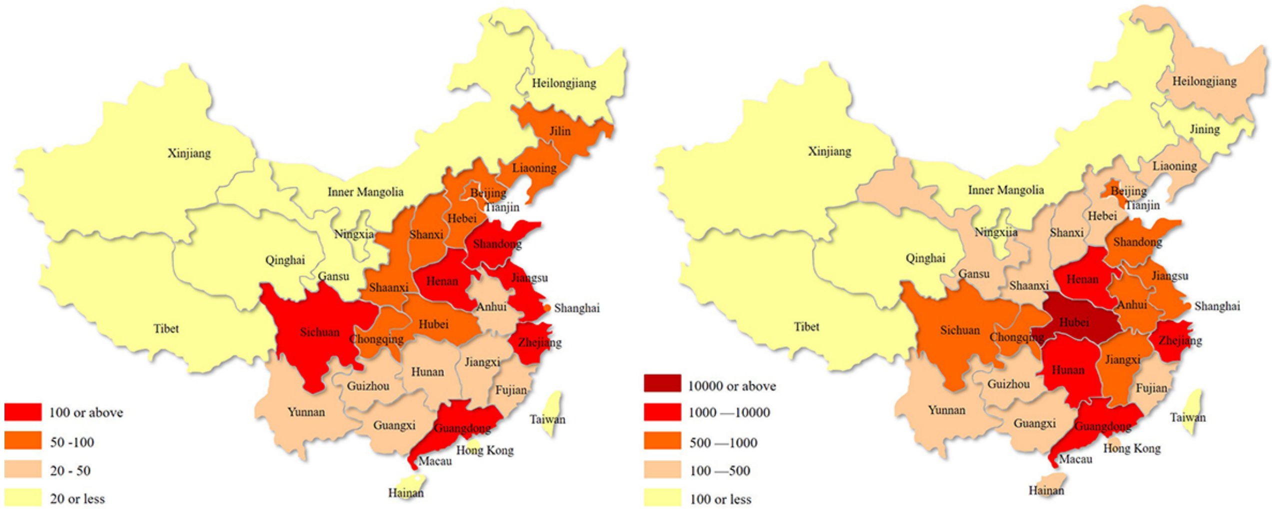

Thematic Distribution of Tweets and Highly Retweeted Information

Among 15,900 tweets included in our study, 79.81% (n=12,690) were oral health–related information and 38.86% (n=6180) contained background knowledge of COVID-19. As shown in Figure 4, the most commonly exchanged types of tweets related to oral health was home oral care information (n=4803, 30.20%), followed by dental service–related information (n=4478, 28.16%), the need for dental treatment (n=2793, 17.57%) during the epidemic, and other information about oral health or dentistry and COVID-19 (n=616, 3.87%). In terms of background knowledge about COVID-19, information about the prevention of COVID-19 (n=3404, 21.40%) witnessed the most tweets and retweets on Weibo, and epidemiology of COVID-19 (n=2390, 15.04%) was also common, while only a relatively small proportion of tweets mentioned aspects of pathology and symptoms (n=139, 0.87%) or diagnosis (n=247, 1.54%). The background information of COVID-19 (except the pathology and symptoms) was mostly tweeted by bloggers with more than 1000 followers. The dental services and home oral care information were highly tweeted by bloggers with 1000 or more followers, whereas the need for dental treatment were tweeted mostly by bloggers with followers less than 1000 (Figure 4).

Some information was frequently tweeted or retweeted on Weibo and the top five pieces of widely diffused information were selected for evaluating the public reactions (Table 1). The most tweeted information was the news that aerosol acts as a transmission route of COVID-19, officially announced by the government office of Shanghai on February 8, 2020. There were 1406 tweets or retweets of this news or related aerosol information, and it gained 321.28 likes, 24.85 shares, and 19.70 comments on average. The second most tweeted information related to the risks of COVID-19 spread in dental clinics due to the aerosol generation, widely exchanged by dentists and dental clinics and hospitals, which averagely garnered 4.72 likes, 1.92 shares, and 1.31 comments. The next 3 groups of tweets were refutations of three pieces of widely spread misinformation of prevention measures for the coronavirus. As shown in Figure 5, the first misinformation that gargling with saltwater or mouthwash can prevent COVID-19 by lowering the level of coronavirus in the saliva spread among the public at an early stage of the epidemic (around the end of January). Soon the refutation of this misinformation was tweeted by the official platform “Weibo Refutes Rumours” and retweeted by others much more than the misinformation itself. A similar pattern was seen in another 2 groups of misinformation, namely, that eating garlic or applying oral spray or disinfectants can kill the coronavirus in oral cavities to protect from COVID-19 infection (Figure 5).

Figure 4. Thematic distributions of tweets with COVID-19–related oral health information. COVID-19: coronavirus disease.

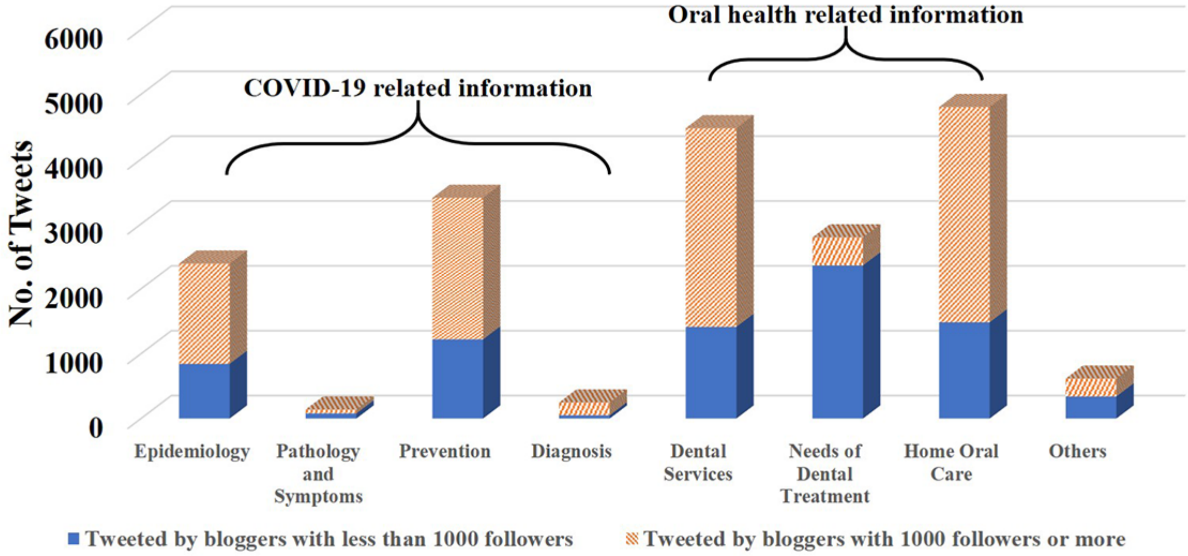

Table 1. Public reactions to highly tweeted information on Weibo.

Most highly tweeted information	Count, n	Public reactions		
		Likes, mean (SD)	Shares, mean (SD)	Comments, mean (SD)

Misinformation 1: Gargling with saltwater/mouthwash can prevent COVID-19.

Misinformation 2: Eating garlic can prevent COVID-19.

Misinformation 3: Buccal spray/disinfectants can prevent COVID-19.

Disruption of Dental Services During the Epidemic

Tweets with different types of oral health–related information were distributed differently during the COVID-19 epidemic. As shown in Figure 6, the risk of COVID-19 spread during dental procedures was proposed during the early stage of the epidemic, and the associated tweets and retweets peaked on January 25 and 26, 2020, after the start of the Wuhan lockdown on January 23. During the first half of February, under the first level emergency response to COVID-19 in China, the government, public hospitals, and private dental clinics delivered notices to stop all or part of dental services to the public. Followed by this was the peak of information about home oral health care in the second half of February. From late February to early March, tweets associated with notices of restoring dental services and protective measures during dental treatment gradually increased due to the control of COVID-19 in China.

When the dental services were not available from the end of January to early March, many bloggers complained of oral problems and sought dental care on Weibo. There were a steady number of tweets (around 40-80 tweets/day; Figure 6) during this time period. As shown in Table 2 those complaining of toothaches or wisdom tooth problems (eg, pericoronitis, decay) were most common, followed by orthodontic-related problems, oral ulcers, and pediatric oral diseases; oral cancer and implants or prostheses only occupied a small proportion. Additionally, the rest of the tweets were related to seeking oral care for other dental diseases including tooth decay and gingival bleeding or without specific reasons.

Interestingly, numerous tweets with home oral care content were found on Weibo when the majority of dental services were not available for the public, much more than the tweets seeking oral health care as previously mentioned (4803 vs 2973 tweets). Information about daily oral care, how to deal with dental emergencies at home, and online consultation services shared similar proportions among these tweets (n=1684/4803, 35.06%; n=2092, 43.56%; and n=2029, 42.24%, respectively; Figure 7). Notably, 21.50% (n=362/1684) of daily oral care–related tweets presented commercial advertisements of oral hygiene products including toothbrushes, toothpastes, and dental floss.

As for the public responses to dental services and home oral care–related tweets from different types of bloggers, the number of likes, shares, and comments for tweets from governments, media, dental clinics and hospitals, dentists and dental nurses, online health platforms, and other nondental bloggers were counted and analyzed (only bloggers with >1000 followers were included; Table 3). Significant differences of public attention were found between various types of bloggers in dental service–related tweets (χ^2_4=113.883, 99.037, 49.544 for numbers of likes, shares, and comments, respectively, and P<.001 for all of them). The same findings were seen in tweets with home oral care content (χ^2_5=292.817, 186.265, 264.250, respectively, and P<.001 for numbers of likes, shares, and comments). The governments and media tweeted a large number of tweets related to dental services but fewer related to home oral care content (492 vs 98 tweets from governments, 805 vs 87 tweets from media, respectively) and received public responses with high average numbers of likes, shares, and comments in both categories. The government-generated tweets with dental service information received significantly more shares and comments but less likes than with home oral care content (dental services vs home oral care, *P*<.001 for numbers of likes, shares, and comments), while the media-tweeted information related to dental services garnered much less public attention compared to home oral care content (*P*<.001 for numbers of likes, shares, and comments). As for the tweets from dental clinics and hospitals, the public seemed to pay more attention to the tweets associated with home oral care information than dental services (*P*=.001 for numbers of likes and comments), though tweets in both categories were intensive. Dentists and dental nurses tweeted a mass of information related to oral health, and there were no significant differences between public responses for tweets with home oral care information and dental services (*P*=.37, *P*=.30, and *P*=.81 for numbers of likes, shares, and comments, respectively). Notably, nearly one-fifth of tweets with home oral care information were provided by online health platforms and garnered 4.05 likes, 1.28 shares, and 0.59 comments on average.

Figure 6. Time distributions of oral health–related tweets during the COVID-19 epidemic. COVID-19: coronavirus disease.

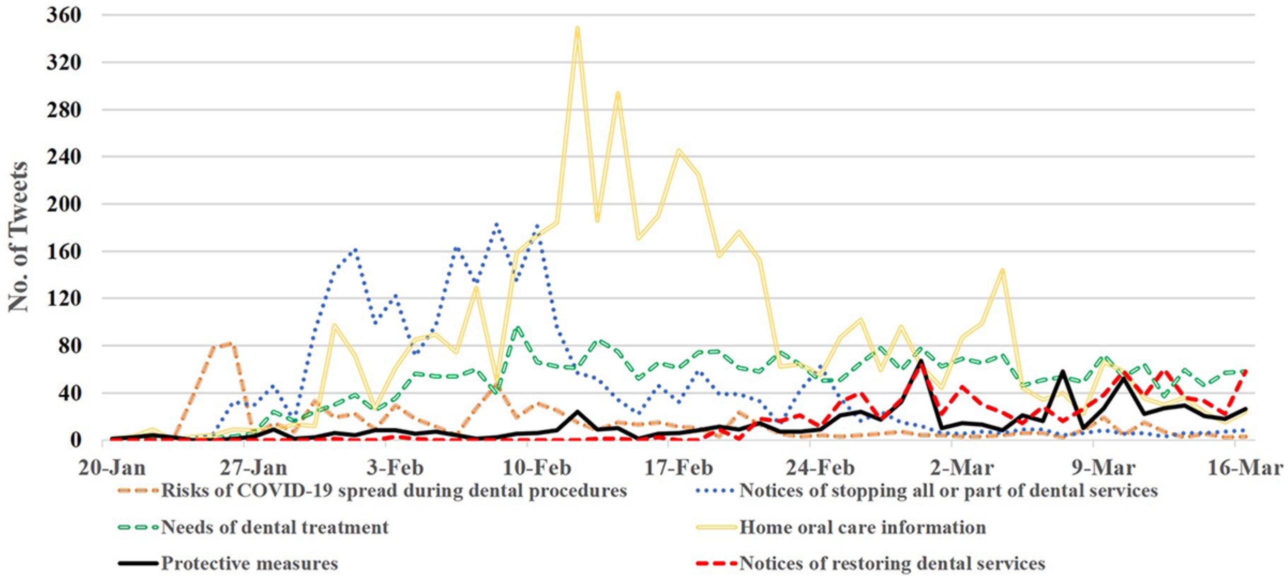

Table 2. Needs for dental treatment during COVID-19 epidemic.

Needs of dental treatment	Number of tweets (n=2793), n (%)[a]
Toothache or wisdom tooth problem	1132 (40.53)
Oral ulcer	264 (9.45)
Orthodontic problem	536 (19.19)
Implants or prostheses	31 (1.11)
Pediatric oral diseases	81 (2.90)
Oral cancer	41 (1.47)
Others or not specific	788 (28.21)

[a] The sum value of all parts is over 100% because some tweets mentioned more than one need of dental treatment.

Discussion

Principal Results

Since the COVID-19 outbreak exerted a negative impact on dental practices [12], the Chinese online community reacted rapidly and tweeted considerable information associated with COVID-19 and dentistry and oral health. This is the first study to analyze COVID-19–related oral health information that was presented on Chinese social media and evaluate the public interaction with this information. As shown in our study, COVID-19–related oral health content tweeted on Weibo may serve as a key indicator of the supply and demand of dental services under the epidemic in China.

The Distribution of Tweets and the Epidemiology of COVID-19

It was interesting to note that the time distribution of the Weibo data was approximately consistent with the trend of both daily new cases and deaths. Our finding is similar to a previous study on H7N9–related tweets on Weibo, which identified a positive correlation between the number of daily tweets and the cumulative case fatality rate of H7N9 [26]. Accordingly, the time distribution of social media may help predict the trend of new cases and deaths during the epidemic, thus, serving as a cost-effective and useful tool for epidemiology study.

Additionally, the peaks of tweets were influenced by some milestone events of COVID-19, including the official confirmation of human-to-human transmission of COVID-19, lockdown of Wuhan, and the death of Dr Wenliang Li. The possible explanation for this phenomenon is that social media engages more public attention during outbreaks of EIDs, especially when important news about the epidemic is released [27]. Similarly, during the H1N1 pandemic in 2009 and the outbreaks of MERS-CoV in 2012 and H7N9 in 2013, the time distribution of related tweets on social media were impacted by milestone events, such as the official announcement of the first case diagnosed and the level of the epidemic [17,28].

Although our results show that the geographical distribution of the tweets was roughly consistent with the distribution of total COVID-19 cases, Hubei Province was an exception. As the first epicenter of a newly identified infectious disease in the world, people may have been overwhelmed, and the concerns for oral health problems and demands for dental services were unavoidably suppressed. This phenomenon should attract more attention from public health policy makers.

Social media should not only provide true and useful information for the public, but also possess self-correction function for misinformation [29]. As illustrated in our study, during the early stage of the COVID-19 outbreak, some misleading information for prevention of COVID-19 was diffused among the online community, which attributed to a natural fear for the unknown and unexpectable disaster. This phenomenon is quite common during outbreaks of emerging diseases. When yellow fever re-emerged during 2015-2017, nearly two-thirds of tweets associated with yellow fever contained misinformation including some improper treatments [30]. After the first Zika infection case confirmed in the United States, grassroots users on Twitter amplified social concerns and even tweeted conspiracy theories [31]. A systemic review about social media and outbreaks of EIDs showed that 20%-30% of the EID–related YouTube videos contained inaccurate or misleading information [27]. In our study, the refutations of misinformation were tweeted by the official platform “Weibo Refutes Rumours” and immediately exchanged by other users with a larger scale on Weibo. This may contribute to calming the public panic with scientific knowledge.

Dental Services and Dental Care Needs During the COVID-19 Outbreak

Social media can amplify the spread of contents compared to traditional mass media [32]. In this study, the most widely diffused information was about aerosol as a transmission route of COVID-19 and its effect on dental practices, which was first tweeted on January 25, 2020, on Weibo (earlier than scientific publications). The study that first confirmed SARS-CoV-2 existed in saliva was published on February 12, 2020 [4], and the study that first announced the possibility of COVID-19 transmission by aerosol-generating dental procedures was published on February 20, 2020 [9]. The updates and spread of information on social media are updated to the minute, and the communication on social media is in real time, much faster than traditional media and online scientific publications. Moreover, increasing numbers of bloggers in public health professions are active on social media and tweet scientific knowledge on epidemics of infectious diseases, which plays a crucial role in shaping public awareness and response to an emerging disaster [33].

The analysis of the COVID-19–related oral health contents on Weibo provided an overview of the supply and demand of dental services during the COVID-19 outbreak. The public concern about the risks of spreading coronavirus by aerosols was disseminated earlier than the official notices of stopping part of or all dental services. With insufficient dental services, the public needs for oral care could not be satisfied, and an increased number of users complained of oral diseases or sought for consultation on Weibo. Our study showed dynamic changes of information related to supply and demand of dental services during this period, indicating that social media can serve as a useful tool for the monitoring of medical and health demands during an unprecedented time [34].

Social media plays an increasingly important role in health policy making [20,21,35]. As shown in our review, the urge of stopping dental services to avoid potential risks of coronavirus transmission between patients and dental care providers was tweeted by dental professionals and retweeted by other bloggers at the end of January, which may contribute to the public health policy about suspension of dental practices from the governmental agencies at the beginning of February. This important function of social media benefits from the multidirectional conduit of social networks, leading to more efficient and wide diffusion of information on social media than on traditional media [36] and more frequent interactions between individuals and public health organizations and policy makers [37]. Regarding social media as a rapidly maturing channel of communication, the policy makers can obtain evidence to help make health policy decisions, disseminate the policies on social media, and monitor the public reactions to the policies [38].

In response to perceived unmet dental care needs from the online community, home oral care information was highly tweeted on Weibo to satisfy the public needs for both daily oral care and dental emergencies. Remote dental consultations were also achieved through Weibo, not only providing diagnosis and suggestions for patients with oral health problems but also avoiding risks of coronavirus transmission. This correlation between dental service disruption and an increased use of social media as a means of communication is not uncommon during a disaster or emergency [39]. Previous studies have also recommended social media for dental public health surveillance due to its potential in monitoring episodes of dental pain [40,41]. The active exchange of information related to oral care and the interaction between patients and dental professionals were found from our Weibo data, presenting a promising communication mode between health care providers and patients as a supplement for the traditional doctor-patient relationship.

The Variation of Public Reactions to Tweets From Different Bloggers

In our study, the online community reacted variously to the tweets from different bloggers. The tweets posted by governments and media attracted more responses from the public due to their authority [42]. The government and media should take the responsibility to tweet true and real time information. Surprisingly, the influence of dental clinics and hospitals, and dentists and dental nurses was not strong enough despite tweeting high-quality information of oral health. The important role of the emerging online health platforms was identified in this study. The online health platforms with more followers than individual dental professionals can transmit health-related information more efficiently and benefit more people [43]. From the perspective of social equality, the services from online health platforms can also cover those hard-to-reach populations, making it an equitable access to health care for the public. Therefore, our results suggest that the online health platform has potential to be a promising solution for cost-efficient health care information and medical consultations.

Limitations

Several limitations of our study should be acknowledged. First, there was inevitable bias of information in the data collection process. For example, Weibo is more popular among young people rather than the aged and is more accessible for economically developed regions. Therefore, the impact of age and regional distribution of users may need to be considered when interpreting the results. As a real time social media, some tweets were deleted by bloggers and some bloggers' accounts were suspended by Sina Weibo, which led to direct information loss. In the geographic analysis of tweets, around 90% did not provide location information, thus affecting the overall objectivity and accuracy of results to a certain extent. Second, our study did not provide any data on the characteristics of Weibo users who viewed and shared these tweets, and the complete diffusion route of tweets were not extracted and analyzed. Therefore, the audience of the information and the diffusion scale of tweets could not be accurately evaluated. Third, the information provided by online consultation services was not available, and thus, the quality of online consultations and the effects on the patients remained unknown.

Conclusions

To the best of our knowledge, this is the first study to comprehensively overview and analyze social media data on the dental services and oral health information during the COVID-19 epidemic in China. Based on our results, it is evident that social media users reacted immediately to the emerging SARS-CoV-2 threat to dental practices. Social media not only contributed to public health surveillance and policy making but also served as a bridge between oral health information providers and the patients. The findings illustrate the relationship between social media information with the supply and demand of dental services during the outbreak of the COVID-19 epidemic in China. In addition, the study provides insights for government organizations, media, and dental professionals to efficiently affect and shape public awareness, and disseminate dental public health information through social media.

Abstract

Background: During the coronavirus disease (COVID-19) pandemic, engagement in preventive behaviors and getting tested for the virus play a crucial role in protecting people from contracting the new coronavirus.

Objective: This study aims to examine how internet use, risk awareness, and demographic characteristics are associated with engagement in preventative behaviors and testing during the COVID-19 pandemic in the United States.

Methods: A cross-sectional survey was conducted on Amazon Mechanical Turk from April 10, 2020, to April 14, 2020. Participants' internet use (in terms of the extent of receiving information pertaining to COVID-19), risk awareness (whether any immediate family members, close friends or relatives, or people in local communities tested positive for COVID-19), demographics (sex, age, ethnicity, income, education level, marital status, and employment status), as well as their engagement in preventative behaviors and testing were assessed.

Results: Our data included 979 valid responses from the United States. Participants who received more COVID-19–related health information online reported more frequent effort to engage in all types of preventive behaviors: wearing a facemask in public (odds ratio [OR] 1.55, 95% CI 1.34-1.79, *P*<.001), washing hands (OR 1.58, 95% CI 1.35-1.85, *P*<.001), covering nose and mouth when sneezing and coughing (OR 1.78, 95% CI 1.52-2.10, *P*<.001), keeping social distance with others (OR 1.41, 95% CI 1.21-1.65, *P*<.001), staying home (OR 1.40, 95% CI 1.20-1.62, *P*<.001), avoiding using public transportation (OR 1.57, 95% CI 1.32-1.88, *P*<.001), and cleaning frequently used surfaces (OR 1.55, 95% CI 1.34-1.79, *P*<.001). Compared with participants who did not have positive cases in their social circles, those who had immediate family members (OR 1.48, 95% CI 8.28-26.44, *P*<.001) or close friends and relatives (OR 2.52, 95% CI 1.58-4.03, *P*<.001) who tested positive were more likely to get tested. Participants' sex, age, ethnicity, marital status, and employment status were also associated with preventive behaviors and testing.

Conclusions: Our findings revealed that the extent of receiving COVID-19–related information online, risk awareness, and demographic characteristics including sex, ethnicity, age, marital status, and employment status are key factors associated with US residents' engagement in various preventive behaviors and testing for COVID-19.

KEYWORDS

COVID-19; coronavirus; preventive behaviors; testing; online health information; risk awareness

Introduction

Since its initial outbreak in late December 2019, the coronavirus disease (COVID-19) pandemic has caused and is continuing to cause a severe, large-scale impact on individuals and societies across the world, including the United States [1,2]. As of May 29, 2020, there were over 1.7 million confirmed COVID-19 cases and more than 100,000 deaths in the United States [3]. In the face of a rapidly growing pandemic such as COVID-19, prompt and up-to-date assessment of the public's behavioral responses to the pandemic is critical if the findings are to be informative to public health policies and responses at local, regional, and national levels [4]. Compared with previous pandemics, the COVID-19 pandemic poses unprecedented challenges to public health responses due in part to its unique epidemiological characteristics. For example, the incubation period of COVID-19 can be as long as 24 days, and studies have found that a significant proportion of individuals infected with COVID-19 were asymptomatic but highly contagious, thus, posing enormous challenges for containing the spread of COVID-19 [5,6]. For the time being, there are no vaccines or antiviral medicine to treat or prevent this novel coronavirus [7]. Given all these factors, it is imperative for the public to actively engage in preventive behaviors and testing for the virus [8]. Correspondingly, research that identifies potential predictors of engagement in preventive behaviors and testing will generate urgently needed insights into social responses to the pandemic and inform targeted interventions to promote preventive behaviors and testing.

At the time of writing, we are aware of only one study that examined engagement in preventive measures (eg, avoiding in-person social interactions, staying home, washing hands) during the early stage (early March 2020) of the pandemic in the United States [9]. Although another study examined the use of masks as a behavioral response during the pandemic, this behavior was not examined as a preventive measure but instead as a behavioral response against the Centers for Disease Control and Prevention (CDC) and National Institute of Health (NIH) recommendations [10]. To our knowledge, no research has examined testing behaviors during the pandemic. Large-scale testing, followed by contact tracing and isolation of those with positive test results, is an essential measure for preventing a large fraction of possible transmission chains [8,11,12].

As a new infectious disease, COVID-19 has triggered a massive spike in uncertainty among the public. To learn more about the disease and to better cope with the pandemic, people are motivated to acquire relevant information through various sources. The internet has become a particularly important source of health information [13]. Recent research shows that people rely heavily on the internet to search for relevant COVID-19 health information [14]. Besides acquiring information through active search, people are also incidentally exposed to health information online [15]. Health information received online not only fills an information gap but also influences people's health decision making [16,17]. Besides the internet, personal experiences serve as a prominent means to acquire information. Because the virus is primarily transmitted through personal contacts, awareness of infection in one's social surroundings, including immediate family, friends and relatives, and local communities, are likely to affect people's risk perceptions and their engagement in preventive behaviors and testing. Past research has also shown that different demographic characteristics tend to be correlated with preventive behaviors during a pandemic [18]. A newly published article noted that demographic characteristics such as age and sex were associated with COVID-19 fatality rates [19], suggesting a necessary role of demographic factors in the investigation of behavioral responses during the COVID-19 pandemic. In this study, we examine internet use, risk awareness, and demographic characteristics associated with preventive behaviors and testing during the COVID-19 pandemic in the United States. Internet use is primarily examined via the amount of COVID-19–related information one has received online, including information received from both active search and passive exposure. Risk awareness is conceptualized as the extent that people have knowledge of infections in their social surroundings. Major demographic characteristics including sex, age, ethnicity, income, education, marital status, and employment status were also examined in this study.

Methods

Sampling Participants

This study received ethical approval from the corresponding author's university. Participants for the study were recruited from Amazon Mechanical Turk (MTurk), an online crowdsourcing labor marketplace operated by Amazon. There is evidence showing that MTurk samples provide data equivalent in quality to the data generated from alternative samples [20]. The survey was constructed and administered using Qualtrics (version 12; Qualtrics International Inc). Qualtrics records individual responses to the survey but not the MTurk account information, so participants remain anonymous. Each participant received US $0.75 for their participation.

Data Collection

Data collection started on April 10, 2020, and was completed on April 14, 2020. Upon consent, participants were instructed to complete a survey asking about their perceptions and behaviors related to the COVID-19 pandemic. Specifically, each participant was asked about whether or not they got tested for the virus, their engagement with different types of preventive behaviors, the extent to which they received information related to COVID-19, the amount of time they spent on the internet on a daily basis, and risk awareness regarding others' COVID-19–related health status (see Textbox 1). For engagement in preventative behaviors against COVID-19, items were measured on a 5-point scale (1=never, 2=sometimes, 3=about half the time, 4=most of the time, 5=always) and were prefaced with the question "Over the past month, how often have you engaged in the following practices to minimize the risk of contracting the coronavirus (COVID-19)?" For receiving COVID-19–related health information online, items were measured on a 5-point scale (1=didn't receive at all, 2=received rarely, 3=received occasionally, 4=received regularly, 5=received a great deal) and were prefaced with the question "Over the past month, to what extent have you received the following types of informational support online?” Extent of receiving COVID-19–related information was calculated based on the average of the four items (Cronbach alpha=.84). Based on the recommendations from the World Health Organization and the CDC in the United States [7,21], seven types of preventive behaviors were examined in this study: wearing a facemask, washing hands, covering nose and mouth when sneezing and coughing, social distancing, staying home, avoiding public transportation, and cleaning frequently touched surfaces. Risk awareness of others’ COVID-19–related health status was assessed by asking if the participants were aware of any positive cases in their immediate family, among close friends and relatives, or in local communities. The survey also obtained participants’ basic demographic information including sex, age, ethnicity, income, marital status, educational level, and employment status.

In total, 1080 MTurk workers filled out the online questionnaire. To ensure data quality, we included attention checks in the questionnaire. At three different places in the questionnaire, participants were asked to select a designated answer without giving a specific content question (eg, “Please select ‘Never’ for this question,” “Please select ‘Disagree’ for this question”). Failure to select the designated answer for any of the three questions was considered an indication of random clicking. This resulted in the exclusion of 101 participants. The final data set included 979 participants’ survey responses.

Textbox 1. Measurement of engagement in preventive behaviors and online information reception.

Engagement in preventive behaviors against the coronavirus disease (COVID-19)

- Wear a facemask in public even if I am not sick
- Wash hands regularly for 20 seconds, with soap and water or alcohol-based hand rub
- Cover nose and mouth with a disposable tissue or flexed elbow when coughing or sneezing
- Keep safe social distance with others
- Stay home
- Avoid using public transportation
- Clean and disinfect frequently touched surfaces such as doorknobs, phones, and keyboards daily

Received COVID-19–related health information online

- Information regarding the scientific facts (eg, symptoms, causes of the disease) related to the pandemic
- Information regarding how to prevent contracting the virus
- Information regarding the spreading of the virus
- Information regarding the sources and resources to give and receive social support during the pandemic

Data Analysis

To assess the effects of internet use, risk awareness, and demographic characteristics on engagement in preventive behaviors and testing of COVID-19, we conducted ordinal logistic regression for the 5-level self-reported engagement in preventive behaviors and binomial logistic regression analysis for the binary testing behavior. In both ordinal and binomial logistic regression analyses, participants’ *demographic characteristics* (ie, sex, age, ethnicity, income, education level, marital status, employment status) were entered in step 1 (see Model 1s in Multimedia Appendix 1), *internet use* (time spent on the internet and the extent of receiving COVID-19–related information online) was entered in step 2 (see Model 2s in Multimedia Appendix 1), and *risk awareness* (whether any immediate family members, close friends or relatives, and people in the local community tested positive for COVID-19) was entered in step 3 (see Model 3s in Multimedia Appendix 1). Detailed results are reported in Multimedia Appendix 1. SPSS 26 (IBM Corp) was used to perform the analyses.

Reported in the Results section, the findings pertaining to the effects of each demographic characteristic reflect their independent effects controlling for other demographic characteristics (ie, based on Model 1s in Multimedia Appendix 1). Findings pertaining to the effects of internet use or risk awareness reflect their independent effects controlling for all other predictors (ie, based on Model 3s in the Multimedia Appendix 1).

Results

Participant Characteristics

Demographic characteristics of the 979 participants are provided in Table 1.

Table 1. Sample characteristics (n=979).

Demographics	Participants
Female, n (%)	466 (47.6)
Age groups (years), n (%)	
18-27	210 (21.5%)
28-37	391 (39.9%)
38-47	196 (20.0%)
48-57	104 (10.6%)
≥58	78 (8%)
Age (years), mean (SD)	36.94 (11.93)
Marital status, n (%)	
Single	**449 (45.9)**
Single	376 (38.4)
Widowed	8 (0.8)
Divorced	54 (5.5)
Separated	11 (1.1)
Married/domestic partnership	530 (54.1)
Employment status, n (%)	
Working	**793 (81.0)**
Self-employed	134 (13.7)
Working full time for wages	568 (58)
Working part time for wages	91 (9.3)
Not working	**186 (19.0)**
Out of work	97 (9.9)
Not able to work or disabled	18 (1.8)
Retired	25 (2.6)
Other	46 (4.7)
Race, n (%)	
White	677 (69.2)
Black or African American	112 (11.4)
Hispanic or Latino American	46 (4.7)
Asian or Asian American	96 (9.8)
Other	48 (4.9)
Education level, n (%)	
Less than high school degree	4 (0.4)
High school graduate	63 (6.4)
Some college but no degree	148 (15.1)
Associate degree in college	104 (10.6)
Bachelor’s degree in college	447 (45.7)
Master’s degree	176 (18.0)
Doctoral degree	21 (2.1)
Professional degree (JD, MD)	16 (1.6)
Education year[a], mean (SD)	15.62 (2.15)
Household income (US $), n (%)	

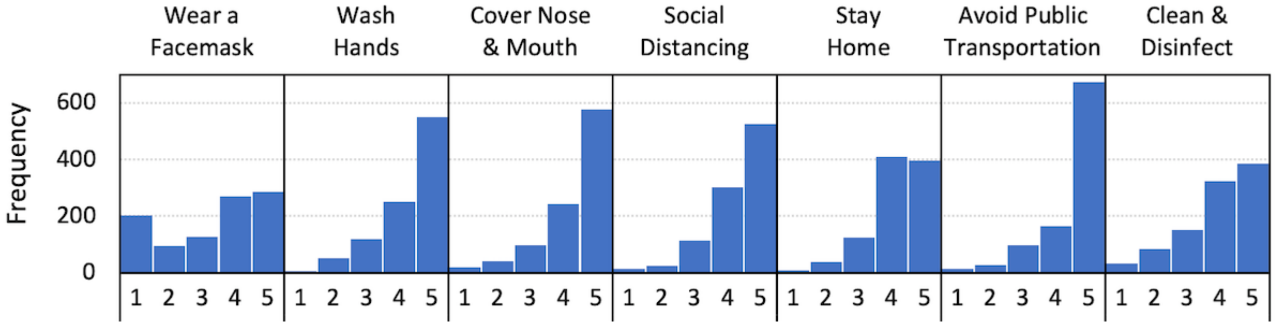
Demographics	Participants
<10,000	45 (4.6)
10,001-20,000	76 (7.8)
20,001-40,000	183 (18.7)
40,001-60,000	222 (22.7)
60,001-80,000	201 (20.5)
80,001-100,000	106 (10.8)
100,001-120,000	64 (6.5)
>120,000	82 (8.4)

[a] Education year is transformed from education level based on typical years of completion.

Engagement in Preventive Behaviors

As shown in Figure 1, participants reported less frequent engagement in wearing a facemask in public than other preventive measures (mean 3.35, SD 1.50), and a fair number of participants reported that they never wore a facemask during the pandemic. A large number of participants reported that they frequently washed hands (mean 4.31, SD 0.93), covered nose and mouth when sneezing and coughing (mean 4.35, SD 0.95), kept social distance (mean 4.33, SD 0.87), stayed home (mean 4.17, SD 0.86), avoided using public transportation (mean 4.49, SD 0.89), and cleaned frequently touched surfaces (mean 3.97, SD 1.09) to protect themselves from COVID-19.

Figure 1. Response distributions of the self-reported preventative behaviors. Responses were coded from 1 (Never) to 5 (Always).



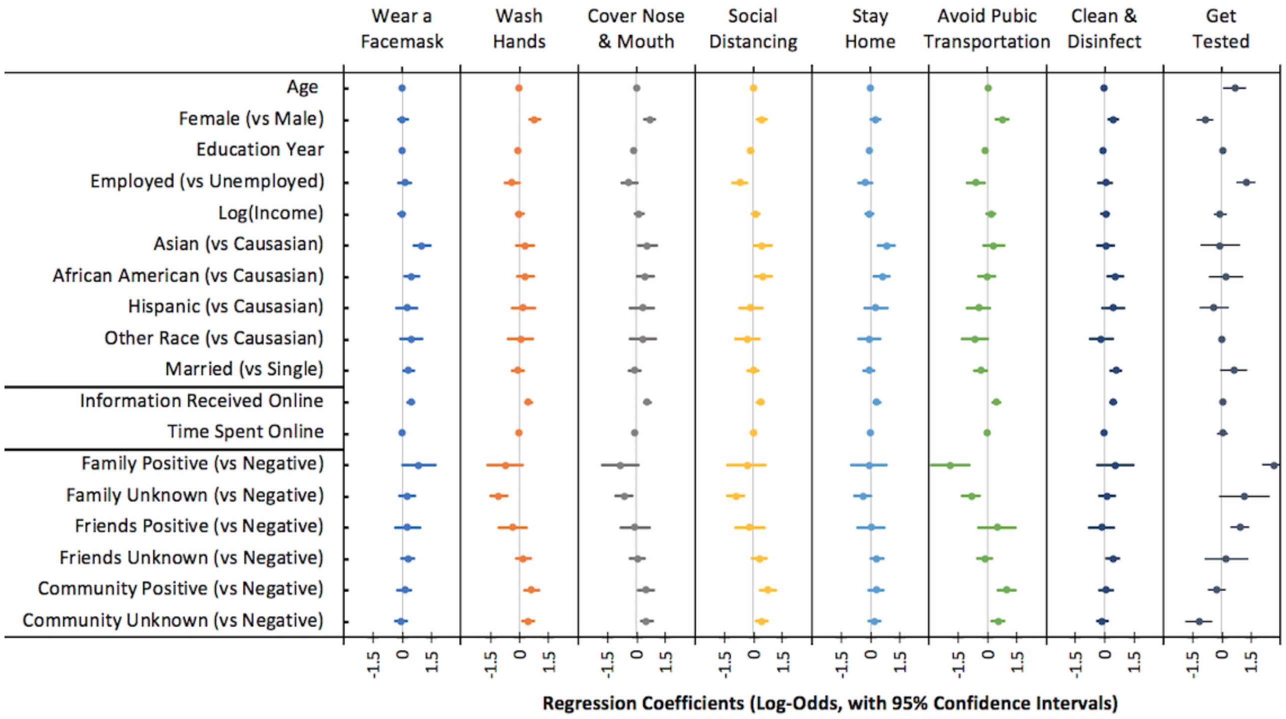
Internet Use and Engagement in Preventive Behaviors

Our data showed that the amount of COVID-19–related health information received online was positively associated with engagement in all types of preventive behaviors: wearing a facemask in public (odds ratio [OR] 1.55, 95% CI 1.34-1.79, *P*<.001), washing hands (OR 1.58, 95% CI 1.35-1.85, *P*<.001), covering nose and mouth when sneezing and coughing (OR 1.78, 95% CI 1.52-2.10, *P*<.001), keeping social distance with others (OR 1.41, 95% CI 1.21-1.65, *P*<.001), staying home (OR 1.40, 95% CI 1.20-1.62, *P*<.001), avoiding using public transportation (OR 1.57, 95% CI 1.32-1.88, *P*<.001), and cleaning frequently used surfaces (OR 1.55, 95% CI 1.34-1.79, *P*<.001).

Risk Awareness and Engagement in Preventive Behaviors

Our data revealed that awareness of immediate family members' test results was associated with participants' engagement in preventive behaviors (see Figure 2 and Model 3s in Multimedia Appendix 1). Specifically, compared with participants who did not have immediate family members with positive test results, those who had immediate family members with positive results less often washed hands (OR 0.35, 95% CI 0.23-0.52, *P*<.001), covered nose and mouth when sneezing and coughing (OR 0.53, 95% CI 0.35-0.80, *P*=.003), kept social distance with others (OR 0.40, 95% CI 0.26-0.61, *P*<.001), and avoided using public transportation (OR 0.42, 95% CI 0.28-0.65, *P*<.001).

Figure 2. Summaries of effect estimates (standardized) and 95% CIs based on logistic regression models predicting self-reported preventative behaviors (ordered log-odds) and testing behaviors (log-odds).



Participants reported more frequent effort in cleaning frequently touched surfaces if they had close friends or relatives who tested positive (OR 1.52, 95% CI 1.10-2.10, *P*=.01). In addition, participants who were aware of positive cases in their local communities reported more frequent hand washing (OR 1.54, 95% CI 1.15-2.06, *P*=.004), covering nose and mouth when sneezing and coughing (OR 1.68, 95% CI 1.25-2.26, *P*=.005), keeping social distance (OR 1.51, 95% CI 1.13-2.02, *P*<.001), and avoiding using public transportation (OR 1.71, 95% CI 1.24-2.37, *P*=.001) than those who reported no positive cases in their communities.

Demographic Characteristics and Engagement in Preventive Behaviors

As shown in Figures 2 and 3, several demographic characteristics were found to be associated with engagement in preventive behaviors (also see Model 1s in Multimedia Appendix 1). Compared with males, females more frequently washed their hands (OR 2.39, 95% CI 1.85-3.09, *P*<.001), covered their nose and mouth when sneezing and coughing (OR 2.12, 95% CI 1.63-2.74, *P*<.001), kept social distance with others (OR 1.64, 95% CI 1.28-2.11, *P*<.001), stayed home (OR 1.34, 95% CI 1.05-1.70, *P*=.02), avoided using public transportation (OR 2.30, 95% CI 1.72-3.07, *P*<.001), and cleaned frequently touched surfaces (OR 1.58, 95% CI 1.25-2.00, *P*<.001).

Compared with younger participants, older participants reported more frequent efforts to wash hands (OR 1.01, 95% CI 1.00-1.02, *P*=.04), cover nose and mouth when sneezing and coughing (OR 1.01, 95% CI 1.00-1.03, *P*=.02), keep social distance (OR 1.02, 95% CI 1.01-1.03, *P*=.001), stay home (OR 1.01, 95% CI 1.00-1.02, *P*=.02), and avoid public transportation (OR 1.02, 95% CI 1.01-1.04, *P*<.001) than younger participants.

Ethnic differences were also observed in engagement with preventive behaviors. Compared with whites, African Americans and Asians more frequently wore a facemask in public (OR 1.81, 95% CI 1.26-2.59, *P*<.001; OR 2.47, 95% CI 1.65-3.69, *P*<.001, respectively) and stayed home (OR 1.88, 95% CI 1.28-2.77, *P*=.001; OR 2.23, 95% CI 1.47-3.37, *P*<.001, respectively). In addition, compared with whites, Asians covered their noses and mouths when sneezing and coughing more often (OR 1.78, 95% CI 1.13-2.80, *P*=.01), and kept social distance more often (OR 1.61, 95% CI 1.04-2.48, *P*=.03). African Americans reported more frequent effort in cleaning frequently touched surfaces than whites (OR 2.00, 95% CI 1.36-2.94, *P*<.001).

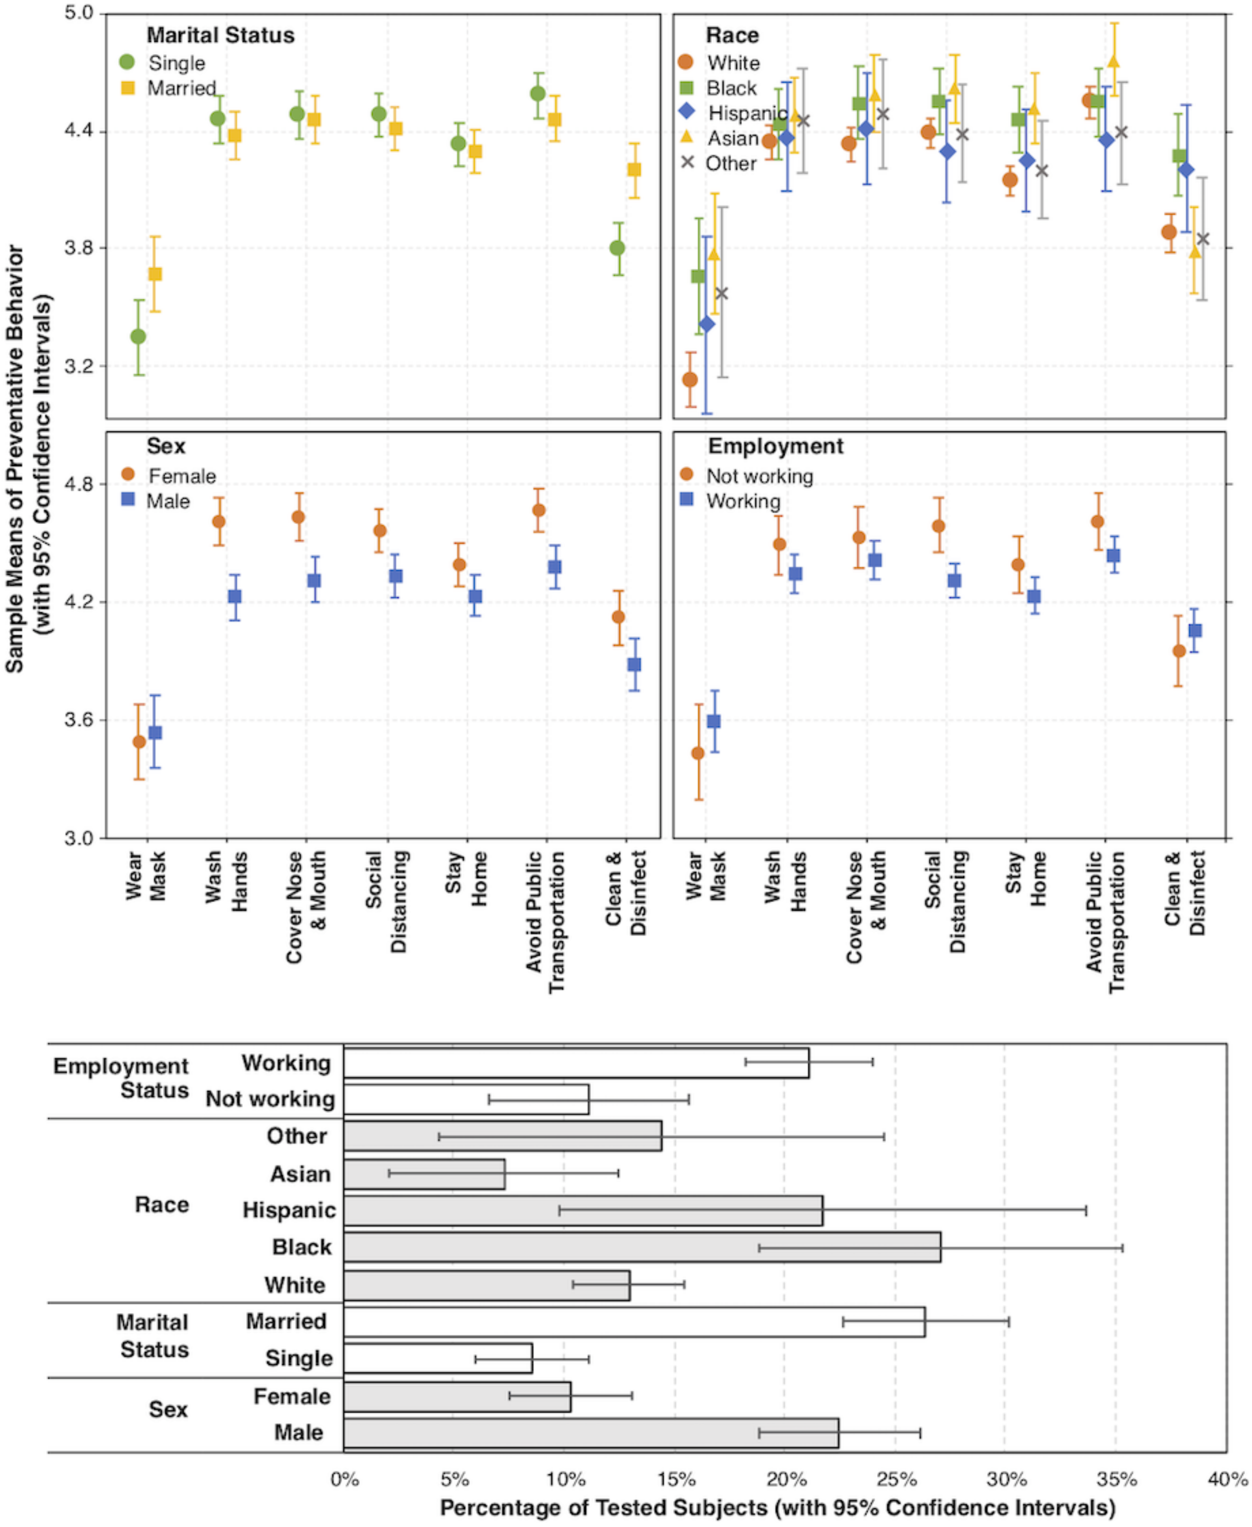
More educated participants less frequently engaged in the following preventive behaviors: washing hands (OR 0.93, 95% CI 0.87-0.99, *P*=.03), covering nose and mouth when sneezing and coughing (OR 0.87, 95% CI 0.81-0.93, *P*<.001), keeping social distance (OR 0.90, 95% CI 0.84-0.96, *P*=.001), avoiding using public transportation (OR 0.88, 95% CI 0.82-0.95, *P*<.001), and cleaning and disinfecting touched surfaces (OR 1.25, 95% CI 1.04-1.50, *P*=.02).

Participants who are married or have domestic partners more frequently wore a facemask in public (OR 1.43, 95% CI 1.11-1.84, *P*=.01), kept social distance with others (OR 1.64, 95% CI 1.28-2.11, *P*<.001), and cleaned frequently touched surfaces (OR 1.84, 95% CI 1.42-2.38, *P*<.001) than their single counterparts. However, compared to single participants, participants who are married or have domestic partners less frequently avoided public transportation (OR 0.90, 95% CI 0.84-0.96, *P*=.001).

Compared with unemployed participants, employed participants less frequently kept social distance (OR 0.50, 95% CI 0.35-0.72, *P*<.001) or avoided using public transportation (OR 0.56, 95% CI 0.36-0.86, *P*=.01).

Compared to the participants who reported having lower income, the ones reported to have higher income covered their noses and mouths more often (OR 1.25, 95% CI 1.04-1.50, *P*=.02), and avoided public transportation more often (OR 1.29, 95% CI 1.06-1.58, *P*=.01).

Figure 3. Sample means of self-reported preventative behaviors and proportions of testing (with 95% CIs) across categorical demographic characteristics.



Testing Behavior

Out of the 979 participants, 22.7% (n=222/979) reported that they had tested for COVID-19, including 23.0% (n=51/222) who reported positive results, 72.5% (n=161/222) who reported negative results, and 4.5% (n=10/222) who did not know the results at the time of participation. Of the 222 participants who got tested, 44.6% (n=99) had at least one positive case in their immediate family, 45.5% (n=101) had at least one positive case among close friends or relatives, and 51.3% (n=114) had at least one positive case in their local communities.

The extent of receiving COVID-19–related health information online was not associated with their odds of testing (OR 1.03, 95% CI 0.81-1.32, *P*=.79). Awareness of COVID-19 infection in one's social surroundings was associated with odds of testing, although the patterns slightly differed between close and distant social circles. For participants who had positive cases in their immediate family, their odds of testing were much higher than those who did not have any positive cases in their immediate family (OR 1.48, 95% CI 8.28-26.44, *P*<.001). Similarly, for participants who had any close friends or relatives that tested positive, their odds of testing were much higher compared with those who had no close friends or relatives with positive test results (OR 2.52, 95% CI 1.58-4.03, *P*<.001). Participants who were aware of positive cases in their local communities did not appear to differ in testing from those who were not aware or uncertain if there were any positive cases in local communities.

Results of the logistic regression showed that several demographic characteristics were associated with testing for COVID-19. Specifically, the odds of females getting tested were only 39.75% (95% CI 28.12%-56.20%) of those of males (*P*<.001). The odds of African Americans getting tested were 249.98% (95% CI 156.95%-398.14%) of those of white Americans (*P*<.001) and 275.45% (95% CI 118.73%-639.01%) of those of Asian Americans (*P*=.02). Older participants' odds of testing were 96.39% (95% CI 94.76%-98.05%) of those who were 1 year younger (*P*<.001). The odds of testing among participants who are married or have domestic partners were 383.92% (95% CI 260.70%-565.36%) of those of singles (*P*<.001).

Discussion

Principal Findings

This study examined if internet use, risk awareness, and demographic characteristics were associated with engagement in preventive behaviors and testing for COVID-19 in the United States. Taken as a whole, our data revealed several notable patterns of findings pertaining to preventive behaviors.

First, consistent with findings from other studies on individuals' engagement in preventive measures against COVID-19 [9,22,23], our data showed that there is a greater tendency for people to engage in some preventative behaviors than others. Although there is evidence showing that, as the pandemic progresses, individuals develop greater awareness of the health risk posed by the virus and engage in protective behaviors with increasing frequency [9], we found that this development is unequal across different types of preventive behaviors. Specifically, people seemed to be more active in adopting the preventive measures of washing hands, covering mouths when sneezing, keeping social distance, and avoiding public transportation than wearing a facemask, staying home, or cleaning frequently touched surfaces. This finding is consistent with several recent studies that assessed the public's perceptions or knowledge about COVID-19 [9]. In particular, people have different perceptions of the effectiveness or necessity of various preventive measures. For example, although wearing a facemask in public has been a mandatory preventive measure in some countries [23] and many states in the United States, its utility as a preventive measure against the coronavirus is still highly controversial [24]. In addition, as some scholars have noted, the practice of mask wearing is an evolving and cultural phenomenon [10]. Although older people in the United States were found to be less likely to wear a mask during the early stage of the pandemic, which is likely due to their higher knowledge of CDC and NIH recommendations against mask use [10], our survey showed that they seemed to have quickly adapted their behaviors following nationwide revised recommendations for mask use. At the same time, different levels of engagement in preventive behaviors during the COVID-19 pandemic can be attributed to the fact that some preventive measures require greater effort (eg, cleaning frequently touched surfaces) or pose greater difficulties (eg, staying home) than others and are thus deemed less feasible.

Second, we observed positive associations between the extent of receiving COVID-19–related information online and engagement in all types of preventive behaviors. It is possible that a good proportion of the COVID-19–related information people received or sought online involved recommendations on preventive measures [25], leading to more frequent engagement in preventive behaviors. At the same time, this finding suggests that receiving pandemic-related information online, despite vast variation in information content, may enhance people's concerns about the pandemic and motivate them to actively take preventive measures [26].

Third, risk awareness regarding infection in one's immediate family, close friends and relatives, and local communities was differentially associated with engagement in preventative behaviors. Compared with participants who did not have positive cases in their immediate family, those who had positive cases in their immediate family reported less frequent engagement in almost all preventive behaviors. Although this finding is somewhat counterintuitive, it also implies that a lack of prevention may lead to higher risk of infection in a family. Immediate family members, as the closest contacts, are at high risk of transmitting the virus within the household. This finding suggests that taking preventive behaviors not only helps one protect themself but also reduces risks of their immediate families becoming infected. Awareness of positive cases among friends and relatives seemed to have limited influence on one's preventative behaviors. A possible explanation is that many people do not live in close proximity with their friends and relatives, and thus do not perceive high risk of infection from them. One's local communities appeared to have a positive impact on engagement with preventive behaviors. Compared with participants who reported no positive cases in their communities, those who were aware of positive cases in their communities more frequently washed hands, covered nose and mouth when coughing, kept social distance, and minimized using public transportation. This finding suggests that one's behavioral responses to a pandemic is influenced by immediate risk factors in one's surroundings.

Fourth, subgroups tend to differ in their engagement in preventive behaviors. For example, consistent with many past studies, our data showed that being older, female [27-32], or nonwhite [33] is associated with a higher chance of adopting preventive behaviors during a pandemic involving respiratory type diseases. This finding is also consistent with recent research on COVID-19 showing that older people and females were more knowledgeable about COVID-19 [10].

In addition, working people reported less frequent engagement in terms of avoiding public transportation and keeping social distance. This finding suggests that working individuals, especially those who cannot work from home, face greater challenges in implementing certain preventative measures. In particular, for individuals who work in essential businesses (eg, supermarkets, health care, post office, food processing factories), it may not be feasible for them to employ preventive measures such as keeping social distance or avoiding public transportation.

Our findings pertaining to testing behaviors seemed less straightforward. The extent of receiving health information online was not associated with testing. This may be largely due to the fact that during the early stage of the pandemic eligibility criteria for testing were highly stringent, and testing capacity was limited in most parts of the country. Although individuals can request a test for COVID-19, whether or not one will get tested is a decision ultimately made by health departments and health professionals. In other words, unlike many preventive behaviors that can be performed based on one's own volition, individuals have much less power in decision making regarding testing.

Not surprisingly, individuals who had confirmed COVID-19 cases in their immediate family were more likely to get tested. Individuals who had confirmed COVID-19 cases among their close friends and relatives were also likely to get tested. On the other hand, positive cases in one's local communities did not seem to have a significant influence on one's testing. These findings are consistent with CDC's guidelines for testing, one of which is close contact with patients who are infected. As testing capacity increases and testing criteria become less stringent, it is reasonable to expect that awareness of positive cases in local communities would motivate more individuals to request testing.

Our study also reveals some subgroup differences in testing. For example, we found that working individuals were twice as likely as nonworking individuals to get tested for COVID-19. In addition, individuals who are single were much less likely than those who are married or have domestic partners to get tested. Given that individuals may contract the coronavirus at virtually any setting with others around (eg, grocery stores, parks, social gatherings), this finding suggests that some nonworking individuals or those who live by themselves might have underestimated their risk of COVID-19 infection.

Our findings offer several implications for interventions, communication strategies, and future research. First, in light of recent research showing that many health care workers had poor knowledge of the mode of transmission and the incubation period of COVID-19 [33], both of which can affect health care workers' recommendations to their patients regarding preventive behaviors and testing (eg, asymptomatic patients often do not get tested), there is an urgent need to provide health care workers with up-to-date information about the disease. Second, as shelter-in-place orders remain in effect in most states in the United States, greater efforts should be put into increasing household internet coverage so that more people will have easy and prompt access to information related to the pandemic [34]. Third, our findings suggest a need for more public health education programs and interventions targeting certain subgroups that have consistently shown to be less likely to adopt preventive measures during a pandemic. Identifying more effective strategies that can be used to induce self-protective behaviors in groups such as young males, for example, can help slow down the spread of the virus. At the same time, as other scholars have noted, although demographic characteristics are generally immutable, future research needs to obtain a deeper understanding of the root causes of differential behavioral responses, which can help inform the development of dissemination strategies directed at different subgroups [28].

Limitations

This study has several limitations. First, given the cross-sectional nature of our data, we are not in a position to empirically assess and demonstrate causal relationships among the variables. For instance, confirmed cases in one's social surroundings may prompt people to engage in more active preventive behaviors, and one's engagement in preventive behaviors during a pandemic like COVID-19 can certainly influence the health of families, friends, and people in local communities.

Second, given the urgency of the research needs and limited access to nationally representative samples, we elected to recruit our participants from an online crowdsourcing platform. Although the composition of ethnicity, sex, and marital status in our data largely mirrored the demographics profile in the US population [35-37], our sample included more young, educated, and working participants. Ideally, a randomly selected sample of the public should be surveyed and comparisons made with the known distribution of key variables in the population.

Third, although social desirability bias has been found to be lower in anonymous online surveys than in telephone or in-person surveys [38], we cannot rule out the possibility of some response bias in the self-reported data. In particular, potential group variations in response bias may have influenced some findings. For example, past research suggests that females tend to show more social desirability than males in survey responses [39]. Although the observed pattern of gender differences in this study is largely consistent with past research, we still cannot rule out the possibility that female participants reported more frequent engagement in preventive behaviors than male participants due, in part, to social desirability. Despite this limitation, a recent study [4] has validated the use of rapid surveys to examine COVID-19–related perceptions and behaviors.

Conclusions

During the ongoing and rapidly evolving COVID-19 pandemic, we have seen a bourgeoning amount of research pertaining to the pathophysiology, diagnosis, and treatment of the novel disease, which is urgently and rightfully needed. Research examining the public's behavioral (and cognitive, psychological) responses to the pandemic, however, also deserves attention, as it can help inform formulation and implementation of public health policies and control measures. This study offers useful insights into factors that are associated with engagement in preventive behaviors and testing of COVID-19. Our findings revealed that the extent of receiving COVID-19–related information online, risk awareness, and demographic characteristics including sex, ethnicity, age, marital status, and employment status are key factors associated with individuals' engagement in various preventive behaviors and testing for COVID-19.

Abstract

Background: The fatality rate of coronavirus disease (COVID-19) in Italy is controversial and is greatly affecting discussion on the impact of containment measures that are straining the world’s social and economic fabric, such as instigating large-scale isolation and quarantine, closing borders, imposing limits on public gatherings, and implementing nationwide lockdowns.

Objective: The scientific community, citizens, politicians, and mass media are expressing concerns regarding data suggesting that the number of COVID-19–related deaths in Italy is significantly higher than in the rest of the world. Moreover, Italian citizens have misleading perceptions related to the number of swab tests that have actually been performed. Citizens and mass media are denouncing the coverage of COVID-19 swab testing in Italy, claiming that it is not in line with that in other countries worldwide.

Methods: In this paper, we attempt to clarify the aspects of COVID-19 fatalities and testing in Italy by performing a set of statistical analyses that highlight the actual numbers in Italy and compare them with official worldwide data.

Results: The analysis clearly shows that the Italian COVID-19 fatality and mortality rates are in line with the official world scenario, as are the numbers of COVID-19 tests performed in Italy and in the Lombardy region.

Conclusions: This up-to-date analysis may elucidate the evolution of the COVID-19 pandemic in Italy.

(J Med Internet Res 2020;22(6):e19825) doi:10.2196/19825

KEYWORDS

COVID-19; SARS-CoV-2; fatality rate; swab tests; Italy; Lombardy region

Introduction

Since February 2020, the severe acute respiratory syndrom coronavirus 2 (SARS-CoV-2) pandemic has generated much concern among citizens and mass media in Italy regarding the real and official numbers provided by the Italian Government and the Italian Department of Civil Protection [1-4]. One of the most discussed topics is why the case fatality rate in Italy appears to be much higher than in other countries. Another main topic of debate is why inappropriate numbers of COVID-19 tests appear to have been performed on citizens of Italy in general and the Lombardy region in particular, thus underrepresenting the infected population.

The purpose of this study is to use a set of statistical and data analyses to clarify both the actual and official case fatality rate in Italy in comparison to those in other countries as well as the actual size of the tested population.

Methods

We examined data regarding coronavirus disease (COVID-19) case fatality rates and numbers of throat swab and nasal swab tests using real time polymerase–chain reaction assay methods conducted in world populations to describe the actual global picture of the case fatality rate of COVID-19 in Italy compared to other industrialized countries and the number of tests performed since the first outbreak in Italy (Codogno, Lodi province, and the Lombardy region) between February 24 and April 14, 2020. This time interval was selected to cover most of the COVID-19 epidemic curve. Raw data for the case fatality rate and swab tests were obtained as comma-separated value (.csv) open files from the Italian Department of Civil Protection [1] and from the Worldometer portal [5]. Data regarding the critical situation in the Lombardy region were obtained as open data directly from [1]. It is important to highlight that at the time of writing, the March 22, 2020 decree (Implementation of the decree 23 February 2020 No. 6: Urgent measures for the containment and management of the COVID-19 epidemiological emergency (20A01807), Official Gazette: General Series No.76 of 22-03-2020 [6]) is in action to temporarily stop all unnecessary industrial and commercial production activities. Currently, all of Italy is in a quarantine red zone.

To compare the situations in Italy and in other countries, the analysis was limited to the Group of Ten (G10) industrialized countries: Belgium, Canada, France, Germany, Japan, Italy, the Netherlands, the United Kingdom, the United States, and Sweden. For the Lombardy region analysis, the most affected regions and areas in each G10 country were identified and compared. The case fatality rate trend in Italy was plotted using Excel software (Microsoft Corporation), while all the other statistical analyses (absolute values, mean values, and normalized values) are reported in tables.

Results

COVID-19 Fatality Rate in Italy

To clarify both actual and official case fatality rates in comparison to those of other countries as well as the actual extent of the tested population, it is important to differentiate the case fatality rate from the actual fatality rate (infection fatality rate). The case fatality rate is the ratio of the number of deaths to the total number of positive tests, while the infection fatality rate is the ratio of the number of deaths to the total infected population. However, because the entire population (symptomatic and asymptomatic) cannot be tested with sufficient speed, it is necessary to rely on case fatality rates for epidemiology measures and policy planning. Moreover, as the epidemic escalates, the tested population represents the emergent cluster of patients who, by seeking care, turn to and contact national health systems.

At present, the COVID-19 case fatality rate in Italy is 12.80% [5]. In China, the case fatality rate shows a nonlinear trend, with a high rate at the start of the outbreak (17.3%) that decreased to 0.7% at the end of the emergency. China hit the infection curve plateau on February 20, 2020. At the time of writing, the Chinese case fatality rate is approximately 4.1% [5].

The current Italian case fatality rate is comparable with that of other European countries, such as Belgium (12.80%), the United Kingdom (12.70%), France (11.20%), and Spain (10.44%). To date, the worldwide case fatality rate is 6.40% [5]. In Germany, the case fatality rate is 2.7%; however, the Robert Koch Institute has stated that this rate is expected to grow greatly [7]. Furthermore, general misalignment with other European countries is observed for other German indices related to COVID-19, such as the distribution of deaths per age of infected people and the distribution of deaths per gender [8,9].

The Lombardy region is the region most affected by COVID-19 worldwide; data indicate that this region represents 38% of the total infections in Italy, with a regional case fatality rate of 18.08% [1]. No other countries have such unbalanced distribution and variability among their regions [5]; therefore, we can perform the statistical exercise of considering the Lombardy region value as an outlier (ie, a data point that differs significantly from the other regional observations). Hence, if we attempted to disaggregate the contribution of the Lombardy region proportionally to the national datum, we would obtain an Italian case fatality rate of 9.60%. The Italian case fatality rate value would decrease even further to 7.9% if data from the Emilia-Romagna region (the second most affected Italian region) were also excluded.

This statistical exercise stems from the consideration that the very first COVID-19 outbreak in Europe occurred in the Lombardy region, and the National Health System was realistically unprepared to face a pandemic.

Ultimately, it is important to note that the case fatality rate trend is not linear over time due to the number of total infected people depending on the daily number of new infections combined with the numbers of recovered and discharged patients. As shown in Figure 1, the trend line (ie, the 5-day moving average) of daily recoveries grows strongly over time, whereas the trend line for COVID-19 fatalities decreases with a different slope function.

Figure 2 also shows that the curve of total recovered/discharged patients grows much faster than the curve of total deaths. The difference in the slopes of the two curves could enable a reliable prediction of a decrease in the national case fatality rate at the end of the first wave of the epidemic.

Furthermore, as officially reported in the available open data [1], the occupancy of beds in COVID-19–dedicated intensive care units is steadily decreasing, with increasingly diverging curves between the number of new infections and the number of patients with severe symptoms that could lead to death in the near future. At the time of writing, there are more than 3000 patients with severe symptoms out of 104,000 total active positive cases.

Figure 1. Graphical plot of COVID-19 daily fatalities versus recoveries in Italy. COVID-19: coronavirus disease.

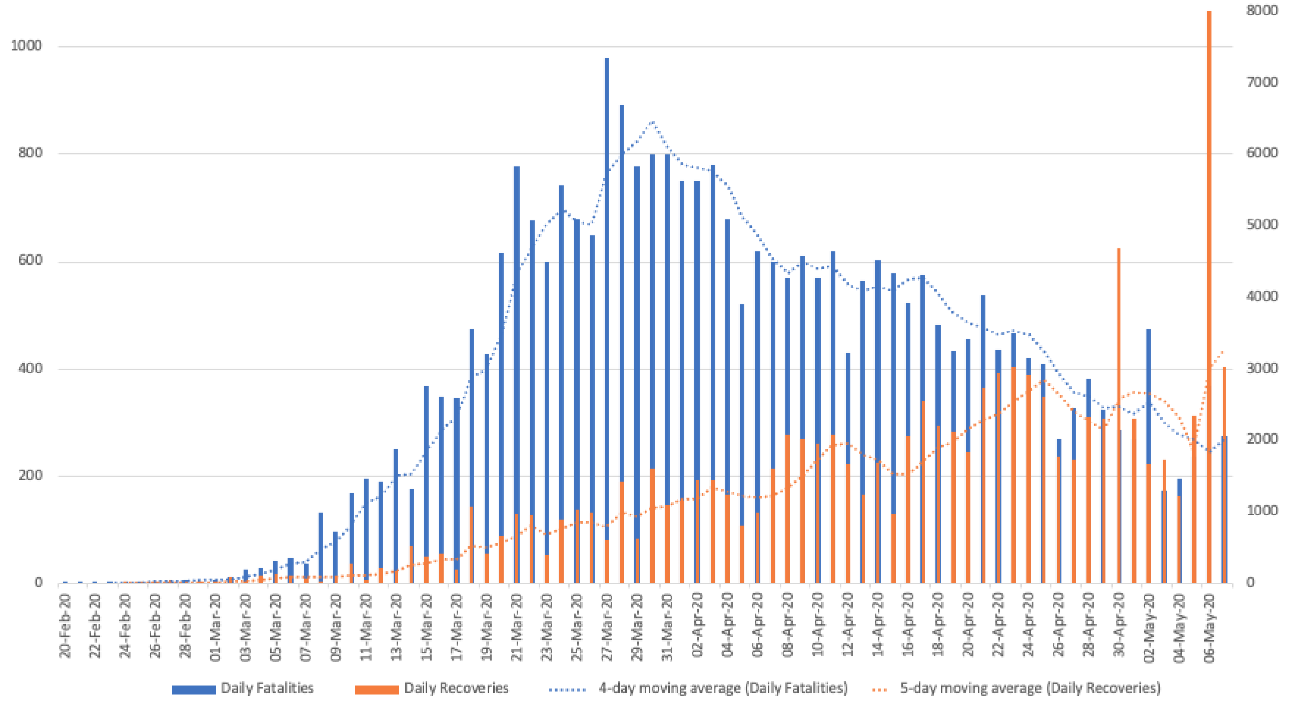

Figure 2. Graphical plot of COVID-19 cumulative total fatalities versus recoveries in Italy. COVID-19: coronavirus disease.

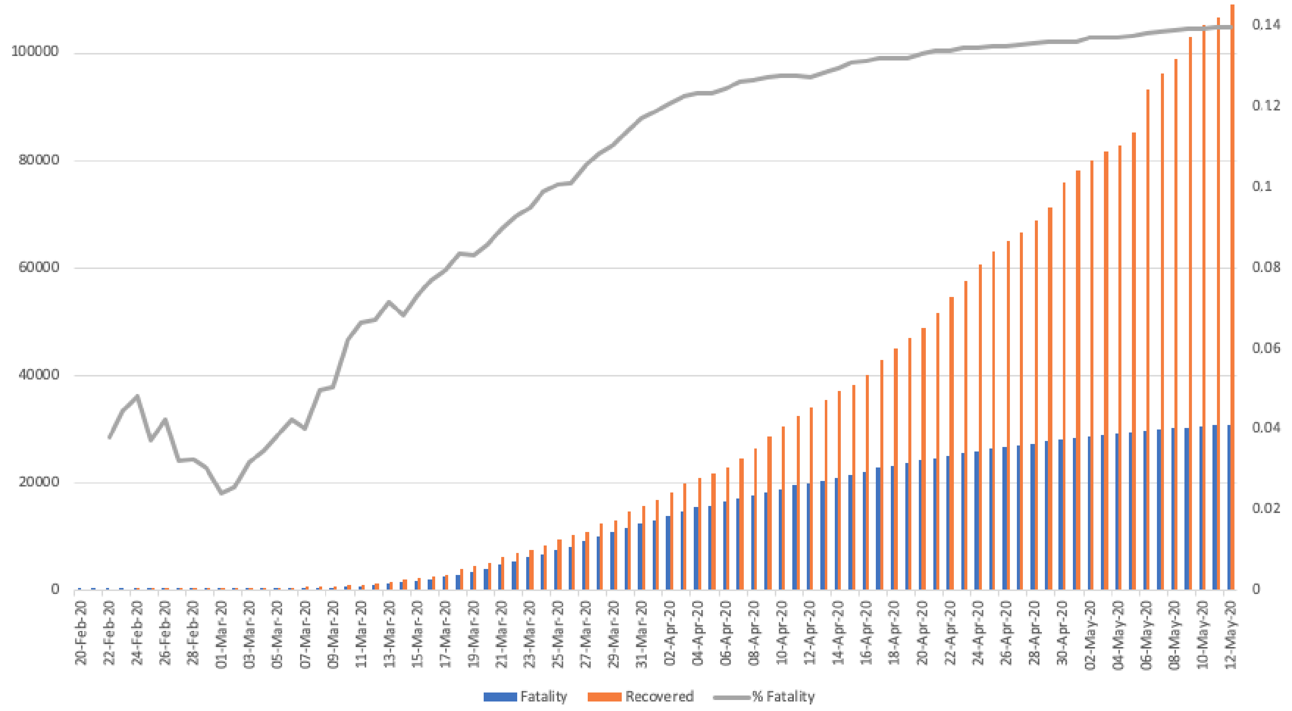

Table 1 shows the COVID-19 case fatality rates and mortality rates (the ratio of deaths of patients who tested positive for COVID-19 to the total number of citizens) on April 14, 2020 among the industrialized countries in the G10: Belgium, Canada, France, Germany, Japan, Italy, the Netherlands, the United Kingdom, the United States, and Sweden [5]. Comparing the Italian data to those of the other G10 countries, the COVID-19 mortality in Italy is approximately 358 per 1 million inhabitants, which is not the highest value in the set. Belgium, for instance, has a mortality rate of 419 per 1 million inhabitants, and the rate in Spain is 409 per 1 million inhabitants. Following the model of the statistical exercise above, if we excluded the Lombardy region mortality rate of 1000 per 1 million inhabitants, the Italian mortality rate would decrease to 220 per 1 million inhabitants.

Table 1. Comparison of the case fatality rate and mortality rate in Italy and the Lombardy region with those of the other G10 countries.

Country	Case fatality rate, %	Mortality rate, deaths per 1 million inhabitants
Belgium	12.80	419
Canada	4.00	32
France	11.20	263
Germany	2.70	46
Italy	12.80	358
Japan	2.12	2
Lombardy region	18.08	1,000
Netherlands	11.40	193
United Kingdom	12.70	190
United States	5.50	86
Sweden	10.50	132
Spain	10.44	409

COVID-19 Test Coverage in Italy

One of the most debated issues in Italy is the number of COVID-19 tests performed [1]; the scientific community is divided by suggestions of a hypothetical high number of undiagnosed cases that would lower the national case fatality rate. This aspect can be easily assessed from the officially declared world data [5]. As reported in Table 2, at the time of writing (April 15, 2020), approximately 1,100,000 COVID-19 tests had been performed in Italy. In the United States, where over 600,000 COVID-19 cases had been confirmed to date, 3,300,000 tests were performed. In Spain (the second most affected country in the world, with over 170,000 total cases), only 600,000 tests were performed; 330,000 tests were performed in France, 1,300,000 in Germany, and 380,000 in the United Kingdom. Therefore, in absolute terms, the nation of Italy has performed the third largest number of tests in the world.

After weighting the number of tests by the population of each nation, Italy has a ratio of 17,800 tests per 1 million inhabitants, ranking first among the G10 countries in terms of tests per 1 million inhabitants (column 3 of Table 2) [5]. This gap is even more evident for the Lombardy region, which has a ratio of 25,000 tests per 1 million inhabitants.

Conversely, if we consider the total of patients who tested positive and the number of swabs performed in the equation, we find that the lower the percentage ratio, the more effectively the nation has tested its citizens.

It is important to observe the temporal misalignment between all the countries because the COVID-19 outbreak started in different countries on different dates. Hence, these values should be normalized by the cumulative number of days since the first outbreak in each country. However, it should be noted that the Lombardy region suddenly discovered the first outbreak with a delay of at least 18 days (ie, 2 weeks of average SARS-CoV-2 incubation time plus 4 or 5 days to develop severe symptoms). In contrast, other European Union countries were able to prepare in advance and may have benefited from a significant advantage in managing the diffusion of COVID-19 by observing the behavior of the COVID-19 spread in Italy, particularly in the Lombardy region.

Table 2. COVID-19 testing data for Italy and the Lombardy region and for the other G10 countries.

Country	Total tests	Tests per 1 million inhabitants	Positive cases/tests, %
Belgium	134,000	11,000	26.0
Canada	450,000	12,000	6.7
France	330,000	5,000	44.3
Germany	1,300,000	16,900	8.0
Japan	100,000	800	9.0
Italy	1,100,000[a]	17,800[b]	14.8[c]
Netherlands	140,000	8,500	20.0
United Kingdom	380,000	6,000	24.6
United States	3,300,000	10,000	19.8
Sweden	70,000	7,000	16.6
Lombardy region	230,000	23,000	27.9
Spain	600,000	17,500	19.7

[a] Third place.

[b] First place.

[c] Fourth place.

Additional Considerations in the Lombardy Region

As already discussed, the Lombardy region has a very significant impact on the national data in Italy. Hence, it may be worthwhile to explore additional considerations to better understand the impact of the Lombardy region on the global data. The Lombardy region has 10,000,000 inhabitants in a territory of 23,800 square kilometers and has a population density of 425 inhabitants/km^2. Its capital city, Milan, is one of the most dynamic alpha cities in the world, with a population of 1,350,000 people and a population density that reaches 7600 units/km^2. The Lombardy region also contains the largest logistics hubs in Italy (close to the first outbreak in Codogno [5]) and some of the largest in Europe. It is also one of the regions in Europe with the greatest flow of people and goods by air, rail, or road [10].

In this context, the analysis can be further extended by comparing the Lombardy region data with the most important regions/areas of the other G10 countries (see Table 3). If we focus on the total cases reported, the Lombardy region is the region with the second highest absolute value of COVID-19–positive cases (Lombardy region=59,000; New York City=123,000). If we normalize this value by the total number of inhabitants, New York, Antwerp, and Madrid have the highest numbers of positive cases per 1 million inhabitants. Regarding case fatality rates, the Lombardy region is the region with the highest number of fatalities (18.08%), followed by Île-de-France (17.99%) and Antwerp (14.20%). When we normalize the regional case fatality rate with the national datum (ie, the ratio of the regional case fatality rate to the national case fatality rate), New York City appears to have the highest multiplication factor (9.50%/5.50%) of ×1.73.

Table 3. COVID-19 statistics for the Lombardy region and for the most affected regions in the other G10 countries.

Country	Region	Total cases	Cases per 1 million inhabitants	Case fatality rate, %	Ratio of regional case fatality rate to national case fatality rate
France	Île-de-France	23,500	2000	17.00	1.52
Germany	Bayern	36,000	2800	3.20	1.18
Italy	Lombardy region	59,000	5900	18.08	1.41
Belgium	Antwerp	4500	9500	14.20	1.25
United Kingdom	London	19,500	2200	—[a]	—
Sweden	Stockholm County	7100	7500	14.10	1.34
Spain	Community of Madrid	48,000	8000	14.00	1.34
United States	New York City	123,000	13,700	9.50	1.73

[a] Not available.

Discussion

The case fatality rate and mortality rate of COVID-19 in Italy are in line with the official world scenario. It is also evident that the numbers of COVID-19 tests performed in Italy and in the Lombardy region are comparable with those in the rest of Europe and the rest of the world.

Abstract

Background: Full level 1 personal protective equipment (PPE) is used in various domains and contexts. Prior research has shown influences of such equipment on performance, comfort, and contamination levels. The coronavirus disease (COVID-19) pandemic forced a pervasive requirement of PPE, with little preparation, rushed deployment, inadequate time for training, and massive use by personnel who are inexperienced or not qualified in its effective use.

Objective: This study aims to examine the key human factors (physical and ergonomic, perceptual and cognitive) that influence the use of level 1 PPE when attending to patients with suspected or confirmed COVID-19.

Methods: The research approach consisted of a short survey disseminated to health care professionals in two countries, Israel and Portugal, with similar demographics and health care systems. The survey included 10 items with a 5-point Likert scale regarding the key human factors involved in level 1 PPE, as identified in prior research.

Results: A total of 722 respondents from Israel and 301 respondents from Portugal were included in the analysis. All the respondents reported using level 1 PPE with patients with COVID-19 in the range of several hours daily to several hours weekly. The Cronbach α was .73 for Israel and .75 for Portugal. Responses showed high levels of difficulty, with medians of 4 for items related to discomfort (n=539/688, 78% in Israel; n=328/377, 87% in Portugal), hearing (n=236/370, 64% in Portugal; n=321/642, 50% in Israel), seeing (n=697/763, 89% in Israel; n=317/376, 84% in Portugal), and doffing (n=290/374, 77% in Portugal; n=315/713, 44% in Israel). A factor analysis showed a set of strongly related variables consisting of hearing, understanding speech, and understanding the situation. This suggests that degradation in communication was strongly associated with degradation in situational awareness. A subsequent mediation analysis showed a direct effect of PPE discomfort on situational awareness (*P*<.001); this was also influenced (mediated) by difficulties in communicating, namely in hearing and understanding speech.

Conclusions: In 2020, the COVID-19 pandemic is paving the way for updating PPE design. The use of already deployed technology affords ample opportunities to improve, adapt, and overcome caveats. The findings here suggest that the use of level 1 PPE with patients with COVID-19 has perceptual and cognitive effects, in addition to physical and ergonomic influences. Efforts should be taken to mitigate the harmful effects of such influences, both regarding the performance of medical actions and the risk of contamination to health care workers. Such efforts involve the design of PPE; the introduction of technologies to enhance vision, hearing, and communicating during the use of PPE; and training staff in using the equipment and in effective communication and teamwork protocols.

KEYWORDS

COVID-19; personal protective equipment; PPE; human factors; cognitive functioning; multinational survey; pandemic; protection; infectious disease; infection; survey

Introduction

Starting in December 2019 and during the first months of the year 2020, the global outbreak of the coronavirus disease (COVID-19) has forced health care professionals of various disciplines in hospital and community settings to use full level 1 personal protective equipment (PPE) to avoid contamination from patients with suspected or confirmed COVID-19 [1]. Such PPE typically consists of a completely encapsulated suit and a self-contained breathing apparatus, such as the N95 face mask, which can provide full skin, eye, and respiratory protection.

The pervasive requirement to use PPE due to the COVID-19 pandemic emerged with little preparation and rushed deployment, inadequate time for training, and massive use by personnel who are inexperienced or not qualified in the effective use of PPE. Such unique and urgent circumstances call for an examination of the use of the full PPE. Moreover, the current widespread use of PPE is not limited to contact with patients with COVID-19 in dedicated and isolated units, but rather in a variety of contexts, and in the general community.

Previous research on using full PPE in various contexts (chemical, biological, radiological, nuclear and explosive incidents, firefighting, health care, and the military) has shown several human factor problems. Much of the research addressed procedural problems, including failures to effectively put on (don) or remove (dof) the PPE [2-5], and ergonomic problems such as poor fit and discomfort while having it on [6-9]. Problems of ineffective use or decreased adherence to using the PPE were found to be associated with insufficient training and lack of prior experience [10-13], and with the appropriateness of organizational culture [12,14-16].

The use of PPE can also influence perceptual and cognitive functioning, although less research has been conducted about such influences. PPE can degrade visual perception [17]; auditory perception [18,19]; gait and balance, which are related to vision and hearing [20,21]; and cognitive functioning [22,23], communication, and teamwork [8,17,24]. Finally, according to some research, the use of PPE can result in ineffective protection against contamination [25,26]. Moreover, even effective use of PPE can influence medical actions including lifesaving procedures [13,27-29].

Taken together the use of PPE, whether effective or ineffective, has been shown to influence the user's functioning and performance, as well as protection from contamination. Yet, the COVID-19 pandemic has introduced unique circumstances and challenges regarding the use of PPE, which prompt a critical need to re-examine the influences. This study explored these influences by means of a binational survey. In particular, we set out to identify relations of physical and ergonomic factors with perceptual and cognitive factors in the use of PPE during the COVID-19 pandemic. For this study, we considered two small developed countries that used equivalent PPE levels to deal with the COVID-19 pandemic: Israel and Portugal. The countries are similar in population, median age, and life expectancy, and have well-ranked national health care systems (NHS), 25th and 31st, respectively, in a 2018 report by the UK Health Foundation [30].

Methods

The Two Countries

Israel has an area of 22,145 km^2, a population of 9,190,000, and a current density of 400 inhabitants per km^2. The median age is 30.5 years and the life expectancy is 83.5 years. The Israeli Ministry of Health is responsible for managing the NHS by means of a public health system. The national emergency medical service is called Magen David Adom. Activated by the emergency number 101 under the coordination of the dispatch centers, specialized resources operate after triage of prehospital levels of care: basic or advanced life-support motorcycles (1 emergency medical technician [EMT] or 1 paramedic), basic life support ambulances (1 or 2 EMTs), intensive care ambulances or helicopters (1 or 2 paramedics and 1 EMT in an ambulance) [31].

Portugal has an area of 92,212 km^2, a population of 10,202,166, and a current density of 111 inhabitants per km^2. The median age is 46.2 years and the life expectancy is 81.5 years. The Portuguese Ministry of Health is responsible for managing the NHS, tendential and free for all residents. The main emergency medical service is managed by the National Medical Emergency Institute. Activated by the emergency number 112 under the coordination of the dispatch centers, specialized resources operate after triage of prehospital level of care: basic life support motorcycles (1 EMT), basic life support ambulances (2 EMTs), intermediate life support ambulances (1 EMT and 1 nurse), advanced critical care fast cars (1 physician and 1 nurse), and helicopter ambulances (1 physician and 1 nurse plus 2 pilots) [32].

Similar level 1 PPE is used in the two countries as is shown in Figure 1.

Table 1 presents the COVID-19 status in each country on May 1, 2020.

Figure 1. Typical level 1 personal protective equipment used in Portugal (left) and Israel (right).

Table 1. Coronavirus disease summary statistics for Israel and Portugal, as of May 1, 2020.

Statistic	Israel	Portugal
Total confirmed cases, n	16,101	25,351
New cases[a], n	58	306
Total deaths, n	225	1007
New deaths[a], n	1	18
Total recovered, n	9156	1647
Active cases, n	7023	22,697
Intensive care unit cases, n	103	154
Total tests, n	390,022	395,771

[a] During the last 24 hours, as of May 1, 2020.

Survey Design

The survey consisted of ten items relating to factors that have been found to have influence during the use of full PPE. The survey included general information about the objective of the study and a photo of a person wearing level 1 PPE.

Each item of the survey stated either the difficulty or ease of an influencing factor. Half the statements were worded as a difficulty and half as an easing influence so as to mitigate response bias. The statements were as follows in this order: (1) it is easy to put on (don) the full PPE; (2) wearing the full PPE is very uncomfortable; (3) it is hard to see everything around me while wearing the full PPE; (4) it is easy to hear sounds and speech around me while wearing the full PPE; (5) it is easy to understand what is said to me while wearing the full PPE; (6) it is easy to understand my surroundings while wearing the full PPE; (7) it is hard to think clearly while wearing the full PPE; (8) it is easy to make decisions while wearing the full PPE; (9) it is hard to remove (dof) the full PPE; and (10) it is very important to wear the full PPE.

Responses were according to a Likert scale ranging from 1, completely disagree, to 5, completely agree. The questionnaire included three demographic questions regarding gender, profession, and the frequency of using the full PPE. All statements and demographic questions were presented in Hebrew to participants in Israel and in Portuguese to participants in Portugal.

The survey was administered through the Qualtrics (Qualtrics International Inc) online platform. It was available for participants from April 12 in Israel and from April 16 in Portugal, to May 1, 2020. This platform ensured that there were no multiple entries from the same individual.

The study was approved by the Institutional Review Board of the Israel Institute of Technology, Haifa, Israel. Participants received a general introduction to the study and then presented with an informed consent form. In that form, participants were informed that the study does not pose any risk, that their participation is completely voluntary, and that they can quit at any time. In addition, they were informed that no personal data or identifying details were required nor collected, and that the data was secure and their participation remained anonymous. Participants had to select the "I Agree" option before entering the survey itself.

Recruitment

We used a combination of criterion-based purposive and convenience sampling. The criterion for the purposive sampling was prehospital and hospital health care professionals involved in the care of patients with COVID-19 and using level 1 PPE. Using professional email lists and closed professional WhatsApp and Facebook groups, we recruited 1013 participants in Israel. In a similar fashion, we recruited 519 participants in Portugal.

Statistical Analysis

Data Exclusion

Of the original 1013 persons who entered the survey in Israel, 189 did not proceed with responding and were thus excluded from the analyses. Of the original 519 who entered the survey in Portugal, 104 did not proceed with responding and were thus excluded from the analyses. We assume that many who consented to participate and entered the survey may have realized that the questions focused only on the use of level 1 PPE and elected not to continue. In addition, the goal of the study was to examine the influences of using the PPE based on extended and intensive use typical of the COVID-19 situation. Consequently, participants who reported rarely or never using the level 1 PPE may have responded to the questions based on their training or other sources but not necessarily based on personal experience and were thus excluded from the final survey analysis. In the Israeli sample, this amounted to 102 (12% of the participating respondents), and in the Portugal sample, this amounted to 114 (27% of the participating respondents).

Scoring the Responses

To achieve uniform direction of the responses on the 5-category Likert scale, the responses on items worded as a statement of ease were reversed. The objective was that all high responses would indicate greater difficulty and low responses would indicate greater ease. Specifically, the responses to item 1, 4, 5, 6, and 8 were reversed for the subsequent analyses.

Results

Respondent Statistics

A total of 722 respondents from Israel (of a total of 824 who participated) were included in the analysis. This sample consisted of 346 (48%) who reported using the level 1 PPE for at least a few hours daily and 376 (52%) who reported its use for at least a few hours weekly. This sample included 524 (72%) males and 198 (28%) females. In addition, 66 (9%) were physicians, 46 (6%) were from nursing professions, 299 (41%) were paramedics, 269 (37%) were medics, and 42 (7%) were of other occupations.

A total of 301 respondents from Portugal (of a total of 415 who participated) were included in the analysis. This sample consisted of 150 (49%) who reported using the level 1 PPE for at least a few hours daily and 151 (51%) who reported its use for at least a few hours weekly. This sample included 168 (55%) males and 133 (45%) females. In addition, 69 (24%) were physicians, 130 (43%) were from nursing professions (which in Portugal includes prehospital emergency work, parallel to the paramedics in Israel), 64 (21%) were medics, and 37 (12%) were of other occupations.

Reliability

To assess reliability of the questionnaire items, a Cronbach α was computed for each of the samples. Cronbach α for the sample from Israel was .73 and, for the sample from Portugal, .75. This reliability index indicates an acceptable internal consistency of the responses.

Overall Responses on the Questionnaire Items

Medians and their corresponding ranges were computed for each of the questionnaire items, stratified by health care profession, for each of the two countries. In addition, the percentage of respondents indicating an agreement and a strong agreement with a given questionnaire statement were computed. These percentages represented the proportion of respondents that expressed more difficulty with a given PPE factor. These statistics are presented in Table 2.

Table 2. Medians for each of the survey items, together with the proportions of respondents who agreed and strongly agreed with the difficulty, stratified by profession, for each of the countries.

[a] The emergency medical services in Portugal do not include paramedics; nurses working in prehospital settings fulfill parallel functions.

Responses to items relating to the physical and ergonomic aspects showed high agreement across professions and in both countries that the use of the PPE is highly uncomfortable: 78% (n=539/688) in Israel and 87% (n=328/377) in Portugal. Only 27% (n=188/684) of the respondents from Israel and 45% (n=163/365) from Portugal, of all the professions, indicated that donning the PPE was difficult. Agreement was high across professions and the two countries regarding difficulty in seeing what is going on around while using the PPE: 89% (n=697/763) in Israel and 84% (n=317/376) in Portugal. Finally, almost all the respondents of all the professions, 99% in both countries, expressed the importance of using the PPE.

Significantly higher proportions of respondents from Portugal than Israel reported difficulties in doffing the PPE: 77% (n=290/374) vs 44% (n=315/713; $\chi^2_1=110$, $P<.001$); in hearing: 64% (n=236/370) vs 50% (n=321/641; $\chi^2_1=25.2$, $P<.001$); in understanding speech: 65% (n=243/372) vs 47% (n=314/661; $\chi^2_1=22.1$, $P<.001$); in understanding the situation: 69% (n=253/367) vs 54% (n=325/599; $\chi^2_1=20.4$, $P<.001$); in being able to think clearly: 57% (n=183/323) vs 43% (n=275/644; $\chi^2_1=16.8$, $P<.001$); and in being able to make decisions: 50% (n=158/317) vs 39% (n=218/552; $\chi^2_1=8.8$, $P<.001$).

Discovery of Common Factors

When variables of a certain set correlate with each other, a certain factor may exist that correlates with the set of variables. To discover such possible underlying factors in the data, an exploratory factor analysis (EFA) was performed to reduce the data set into a smaller number of variables. Factor analysis identifies factors that may explain correlations among variables. Accordingly, each variable has a relative weight, or loading, within a given factor. Statistical indices of the analysis indicate that our data were suitable for factor analysis and suitable for the specific factor analysis reduction technique. The detailed statistics of the factor analysis for each country are included in Multimedia Appendix 1 for Israel and Multimedia Appendix 2 for Portugal.

The factor analysis uncovered two factors, which are presented for both countries in Table 3. For both countries, the first factor showed high loadings for three questionnaire items: difficulty in hearing, difficulty in understanding speech, and difficulty in understanding the situation. This factor suggests that when the full PPE is on, increased difficulties in hearing and understanding speech imply difficulties in spoken communication, which were related to difficulties in understanding the surroundings, that is, situational awareness.

Table 3. Relative weights (loading coefficients) of all the questionnaire items according to the two factors identified for each country[a].

Questionnaire items	Israel		Portugal	
	Factor 1	Factor 2	Factor 1	Factor 2
Donning	0.05	*0.65* [b]	0.29	0.53
Discomfort	0.33	0.56	0.19	*0.70*
Seeing	0.40	0.43	0.07	*0.71*
Hearing	*0.87*	0.02	*0.84*	0.07
Understanding speech	*0.89*	0.04	*0.87*	0.16
Understanding the surroundings	*0.64*	0.36	*0.80*	0.13
Thinking clearly	0.11	*0.63*	0.10	0.55
Making decisions	0.42	0.45	0.44	0.18
Doffing	0.02	*0.61*	0.06	*0.67*

[a] The analysis did not include the last item of the questionnaire, regarding the significance of having the personal protective equipment, since there was little variation in the responses to that question.

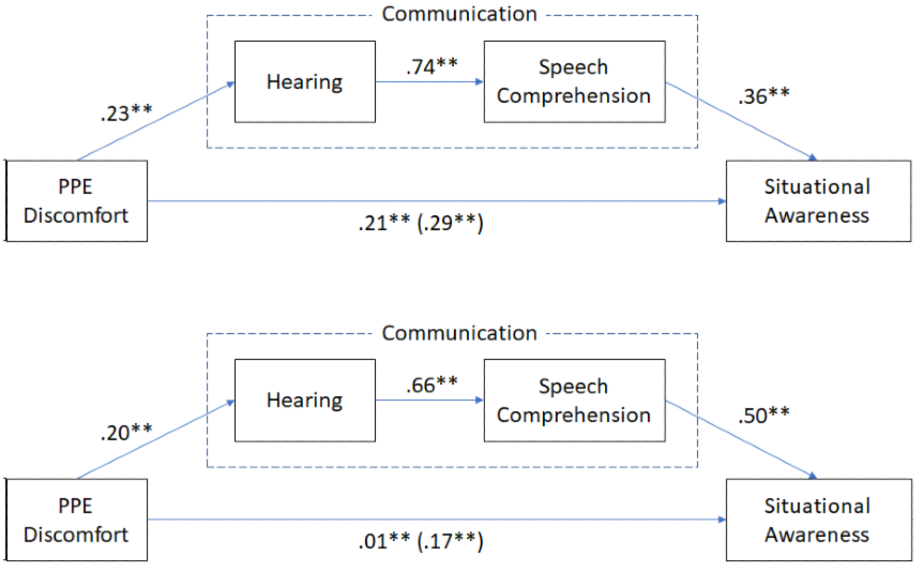
[b] Relative weight values higher than 0.6 are in italics.

Less similarity was observed between the two countries in the second factor. The Israeli data show loadings slightly higher than 0.6 for the items of difficulty of donning the PPE, difficulty in thinking clearly, and difficulty of doffing, with discomfort being close to a loading of 0.6. The Portuguese sample showed loadings higher than 0.6 for the items of discomfort, difficulty in seeing, and difficulty of doffing. Taken together, this factor implies a construct relating to the physical aspects of having the PPE, primarily related to doffing, discomfort, and donning. Interestingly, the second factor in the Portuguese sample includes the item of difficulty in seeing.

PPE Discomfort, Communication, and Situational Awareness: Relations Between the Constructs

We further explored the possibility that wearing the PPE influences communication, as manifested through difficulties in hearing and understanding speech, which in turn influences situational awareness. Specifically, we examined the extent that discomfort influenced communication (ie, hearing and understanding speech), which in turn influenced situational awareness. We employed a mediation analysis based on [33], using the Process Macro in SPSS v21 (IBM Corp). Specifically, we used model 6, which assumes two mediators between an independent variable and the outcome. In this study, the extent of difficulties in hearing while having the PPE on was the independent variable, and the outcome was the extent that one understands the surroundings. We explored the extent of hearing and understanding what is spoken while wearing the PPE, as possible mediating variables in the influence of PPE discomfort on situational awareness. This mediation analysis was performed on the data of each country. Both mediation analyses are presented in Figure 2.

Figure 2. Mediation models of the responses in Israel (top model) and Portugal (bottom model). Each link is associated with its corresponding standardized coefficient, together with the significance indication (** indicates a significance level of $P<.01$). The direct link between PPE discomfort and situational awareness shows the total effect, including the presence of the mediating variables; the direct effect without the mediating factors is in parenthesis. PPE: personal protective equipment.



As shown in Figure 2, discomfort had a significant direct effect on situational awareness, as evident by the significant coefficients in parenthesis, for both countries. This effect decreased significantly when mediation by hearing and understanding speech was considered. This implies a significant indirect effect of discomfort on situational awareness, as mediated by hearing and understanding speech. Increased discomfort with the PPE was related to increased difficulties in hearing and speech comprehension, which were related to increased difficulties in understanding the surroundings. According to this analysis, the mediating variables of hearing and understanding speech could account for 31% of the total effect of discomfort on situational awareness in Israel and 94% in Portugal. Although the effect size in the Portuguese data was much stronger than in the Israeli data, the same relations were demonstrated significantly in both countries.

Discussion

Principal Results

During the period this study was conducted, level 1 PPE was used extensively to mitigate contamination of health care professions treating patients with suspected or confirmed COVID-19. A survey of health care workers in two countries, Israel and Portugal, showed that the use of level 1 PPE is uncomfortable and entails difficulties in removing (doffing) it. Moreover, the discomfort appeared to be associated with difficulties in perceptual and cognitive functioning. Specifically, the equipment was found to be associated with difficulties in visual and auditory perception, and difficulties in understanding speech, situational awareness, and thought and decision making.

The findings of the survey uncovered strong relations between difficulties in auditory perception, the ability to understand speech, and situational awareness. Auditory perception and the ability to understand what is being said are fundamental and critical to speech communication. Communication is critical to teamwork [34] and to situational awareness [35]. Additional analysis of the survey responses shows associations of increased discomfort with the PPE with greater difficulties in communication, namely hearing and understanding speech; these in turn were associated with degraded situational awareness.

The mediation of communication in the influence of PPE discomfort on situational awareness has both interesting theoretical and practical implications. Theoretically, this implies that perceptual and cognitive processes play a significant role in the influence of a physical factor, discomfort in this case, and on a cognitive factor, situational awareness in this case. However, beyond these theoretical implications, practical implications can and should be drawn from such findings.

Practical Implications

Effective design of PPE and adequate sequence and training of donning and doffing are aimed at two major objectives: (1) protect health care workers from contamination; and (2) minimize interference with performing medical and nursing tasks. This section discusses practical implications of the similarities and differences in the responses between the two countries in terms of PPE design, donning and doffing procedures, training, and culture. It also addresses the findings in terms of short- and long-term implementations.

The results showed overall agreement across professions and the two countries concerning the discomfort of the PPE. Accounting for these similar responses is the fact that the components of the PPE, and the steps and sequences of donning and doffing PPE are similar for Israel and Portugal, with both following the CDC and WHO recommendations [36]. The donning sequence is: (1) gown or coverall; (2) mask or respirator; (3) goggles; (4) face shield; and (5) gloves. The doffing sequence is the reverse. Improper use of PPE is known to spread infection among health care workers [4,5]. All these steps can be sources of errors. This is especially true in the context of long work shifts and harsh environmental settings, as the design of PPE materials does not yet account for user temperature and hydration homeostasis. Both reusable and disposable PPE should be clearly designated such as with color coding and designed for easy donning and doffing [37,38]. The simpler the system (with fewer parts), the more likely it will avoid human distractions that may lead to contamination. Regarding contamination protection, although PPE is often only worn for short periods of time, pathogenic viruses such as influenza, severe acute respiratory syndrome, and Ebola can survive for extended periods of time on surfaces and be sources of transmission via surface-to-hand and hand-to-face or -mucous membrane contact. Despite two layers of protective clothing and sometimes two pairs of gloves, hand hygiene remains an essential aspect of PPE.

Full-face covers can provide adequate mucous membrane protection, such as the nasal cavities, lips, and mouth [39]. Whether by using positive pressure systems or only barrier filters, we believe that full-face integrated systems may widen the field-of-view and offer advantages for situational awareness. Such system should be designed to minimize condensation. In addition, a single system is simpler to maintain and minimizes efforts in donning and doffing.

Much of the research on influences of using PPE has focused on influences of the equipment on the motoric aspects of user performance [27,29,40]. The findings here suggest that the use of level 1 PPE also has perceptual and cognitive influences. Relating to communication and situational awareness, some key technological directions and advancements can be considered, such as audio and communication-enhancing technologies. These should be hands-free technologies under the PPE, such as headsets and microphones or throat microphones based on Bluetooth, Wi-Fi, or radio ultra-high frequency. These can be interfaced with dedicated mobile phone apps and facilitate effective hearing and talking among health care workers.

Longer-term consideration of technologies that promote more effective use of level 1 PPE and that facilitate perceptual and cognitive functioning can include:

- Virtual reality technology: the use of virtual reality for training purposes, such as was previously proposed [41], can facilitate training in effective communication,

teamwork, and situational awareness during the use of the equipment.
- Augmented reality technology: this single key aspect may boost the ergonomics of a full-face system and act synergistically when connected with a hands-free voice-activated communication device.
- Internet of Things (IoT): capable 5G IoT devices coupled with mesh framework solutions and cheap microcomputers (or even smartphones) can contribute to a solution. Ultrafast transmission rates and processing power, allied with powerful cloud servers, will eliminate bandwidth problems and eventually clear the way for artificial intelligence “Wingmen.” This should help overcome the previously mentioned limitations in PPE while providing advanced advice immediately [42].

The responses from Portugal reflected more difficulties in hearing, understanding speech, and understanding the situation in addition to more difficulties in thinking clearly and making decisions compared with the responses from Israel. These differences could be accounted for by the differences in training and overall culture. Specifically, the prehospital professionals in Israel, paramedics and medics, undergo more extensive training in using PPE as an overall preparedness to various chemical, biological, radiological, nuclear, and explosive materials incidents. This is in addition to the training at the breakout of the COVID-19 crisis. In contrast, the health care professionals in Portugal received training only when the crisis started. Thus, beyond considering the redesign of level 1 PPE and implementation of newer technologies to facilitate visual and auditory perception, more periodic training and procedures related to cognitive functioning can be implemented immediately. These can include practicing and adopting visual scanning patterns, and communication protocols with coworkers to facilitate teamwork situational awareness.

Another factor that could account for some of the differences between the countries are cultural and overall political considerations. Israel thus far is in a constant state of preparedness to multi-casualty incidents, and consequently health care professionals are in a different mindset when encountering a crisis compared with other countries. Thus, when dealing with a global crisis such as the COVID-19 pandemic, cultural and political characteristics should be considered.

Limitations and Future Research

The research has some limitations that should be addressed in follow-up and future studies. First, the definition of a paramedic differed between the two countries. In Israel, paramedics are all prehospital emergency workers; in Portugal, the nursing profession includes prehospital and in-hospital emergency workers. This distinction was not captured in the data and analyses. Second, the sampling method was indeed purposive but also comprised convenience sampling through the professional networks in each of the countries. This sampling approach may not have included other health care workers who used level 1 PPE during the pandemic, such as community health care workers. Such data would have enriched the data, findings, and conclusions. Third, the survey instructions specified the details of level 1 PPE, including a photo to visualize it. Nevertheless, we acknowledge the availability of a variety of level 1 PPE in the world, of different brands and including different components. The exact PPE used by each respondent was not captured in the data and should be documented and analyzed in future studies.

Future studies should include simulation-based experiments in which various PPE designs and procedures can be compared in terms of their influence on potential contamination and on physical, perceptual, and cognitive functioning. In addition, analytic techniques such as failure mode and effects analysis along with the risk priority ratings should accompany empirical studies.

Conclusions

From 2014 to 2016, a global epidemic of the Ebola virus made proper use of PPE a paramount concern in health care settings [43]. Nevertheless, almost no innovations were implemented in terms of PPE ergonomics to address limitations in hearing, vision, or even comfort. The COVID-19 pandemic serves as a “field test” for PPE technology, as every health care system in the world must adapt its use on a daily basis. Our binational study found that health care workers from different countries and cultures, yet similar NHS and PPE level approaches, shared the same difficulties and felt their situational awareness undermined by outdated PPE designs.

In 2020, the COVID-19 pandemic is paving the way for updating PPE design. The use of already deployed technology provides abundant opportunities to improve, adapt, and overcome problems. This should be done in a practical and aesthetically pleasing way, as well as appropriately to endure future epidemics of this century.

Abstract

Background: The vast majority of people worldwide have been impacted by coronavirus disease (COVID-19). In addition to the millions of individuals who have been infected with the disease, billions of individuals have been asked or required by local and national governments to change their behavioral patterns. Previous research on epidemics or traumatic events suggests that this can lead to profound behavioral and mental health changes; however, researchers are rarely able to track these changes with frequent, near-real-time sampling or compare their findings to previous years of data for the same individuals.

Objective: By combining mobile phone sensing and self-reported mental health data among college students who have been participating in a longitudinal study for the past 2 years, we sought to answer two overarching questions. First, have the behaviors and mental health of the participants changed in response to the COVID-19 pandemic compared to previous time periods? Second, are these behavior and mental health changes associated with the relative news coverage of COVID-19 in the US media?

Methods: Behaviors such as the number of locations visited, distance traveled, duration of phone usage, number of phone unlocks, sleep duration, and sedentary time were measured using the StudentLife smartphone sensing app. Depression and anxiety were assessed using weekly self-reported ecological momentary assessments of the Patient Health Questionnaire-4. The participants were 217 undergraduate students, with 178 (82.0%) students providing data during the Winter 2020 term. Differences in behaviors and self-reported mental health collected during the Winter 2020 term compared to previous terms in the same cohort were modeled using mixed linear models.

Results: During the first academic term impacted by COVID-19 (Winter 2020), individuals were more sedentary and reported increased anxiety and depression symptoms (*P*<.001) relative to previous academic terms and subsequent academic breaks. Interactions between the Winter 2020 term and the week of the academic term (linear and quadratic) were significant. In a mixed linear model, phone usage, number of locations visited, and week of the term were strongly associated with increased amount of COVID-19–related news. When mental health metrics (eg, depression and anxiety) were added to the previous measures (week of term, number of locations visited, and phone usage), both anxiety (*P*<.001) and depression (*P*=.03) were significantly associated with COVID-19–related news.

Conclusions: Compared with prior academic terms, individuals in the Winter 2020 term were more sedentary, anxious, and depressed. A wide variety of behaviors, including increased phone usage, decreased physical activity, and fewer locations visited, were associated with fluctuations in COVID-19 news reporting. While this large-scale shift in mental health and behavior is unsurprising, its characterization is particularly important to help guide the development of methods to reduce the impact of future catastrophic events on the mental health of the population.

Introduction

Coronavirus Disease

An outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the virus that causes coronavirus disease (COVID-19, also known as 2019-nCov), was first reported in Wuhan, China in December 2019, and SARS-CoV-2 was identified as a novel coronavirus in January 2020. On March 11, 2020, the World Health Organization (WHO) declared COVID-19 a global pandemic; as of April 27, 2020, COVID-19 was responsible for over 200,000 deaths and 3,000,000 confirmed cases worldwide [1]. COVID-19 is not only a grave public health issue; it also carries severe political, economic, educational, and social ramifications. COVID-19 continues to impact millions of people worldwide every day. Understanding the behavioral and mental health implications for individuals during this unprecedented period of high stress and crisis is critical for informing current public policies and ensuring preparedness for future pandemics.

Mental Health and Behaviors in Pandemics and Disasters

Initial survey-based research on the psychological impact of the COVID-19 outbreak in China suggested that the mental health impact was moderate to severe for the majority of respondents in the general population, with increased anxiety, depression, and stress attributed to the outbreak by participants [2]. In initial research investigating the impact of the COVID-19 outbreak on college students in China, increased levels of anxiety and depression were observed as well as a willingness to engage in social isolation [3,4]. A limitation of these studies is that they used cross-sectional data; better understanding of the timeline of onset of anxious and depressive symptoms is critical if we are to understand how mental health changes in response to different stages of the pandemic (eg, initial reports, the first national infections, and shelter-in-place).

A handful of studies have employed ecological momentary assessments (EMAs) to assess depression and anxiety more frequently and in near-real-time [5-8]. EMA surveys are sent at predetermined frequencies to the participants' phones as they go about their daily life. This method enables the collection of dense longitudinal data with minimal participant effort relative to in-person research. An initial study in which EMAs from 80 undergraduate students were used to investigate the influence of COVID-19 on mental health and social contact found increased mental health problems but no change in social contact [9].

Our current work combines longitudinal smartphone sensing and EMAs collected from a cohort of Dartmouth College undergraduates to determine the impact on mental health and behaviors during the COVID-19 pandemic. Dartmouth College has four academic terms per year, which are roughly split into 10-week terms followed by 2-week (or longer) breaks. Self-reported mental health has been observed to vary across typical academic terms [8,10]. During the Winter 2020 academic term, Dartmouth College began implementing new policies in response to COVID-19 (Table 1). Beginning on February 4, individuals returning from China were asked to self-isolate for 14 days upon their return to campus. On March 2, the first local COVID-19 case was diagnosed at nearby Dartmouth-Hitchcock Medical Center. On March 10, during the final examination period, the College requested that all students scheduled to leave campus for spring break depart upon completion of their final examinations and further requested that students who were planning to stay on campus during spring break instead depart campus by March 16. Consequently, students were required to rapidly change their travel plans, complete final examinations sooner than expected, or take final examinations online. On March 11, the WHO officially declared COVID-19 a pandemic, at which time all college-sponsored athletic competitions were cancelled. Just one day later, on March 12, the US government implemented policies limiting travel to and from European countries. By the next day, March 13, COVID-19 had been declared a national emergency by the President of the United States. Dartmouth College's spring break started on March 14. On March 16, the college cancelled all gatherings of groups larger than 50 people. Finally, on March 17, the college announced that there would be no in-person, on-campus option to attend classes during the Spring 2020 term. This timeline is particularly relevant because it allows us to identify periods during which we might expect additional changes in mental health and behaviors due to the stress of the pandemic and in light of potential adherence to the "Stay Safe, Stay Home" policies mandated by local and national governments. News coverage in the United States can also serve as a proxy for the perceived severity of the situation, given the rapid transition from a localized outbreak in a country several thousand miles away (China) to an outbreak within a few miles of campus along with a rising number of cases nationally (Figure 1). Increases in anxiety and depression are frequently observed after traumatic events [11-14].

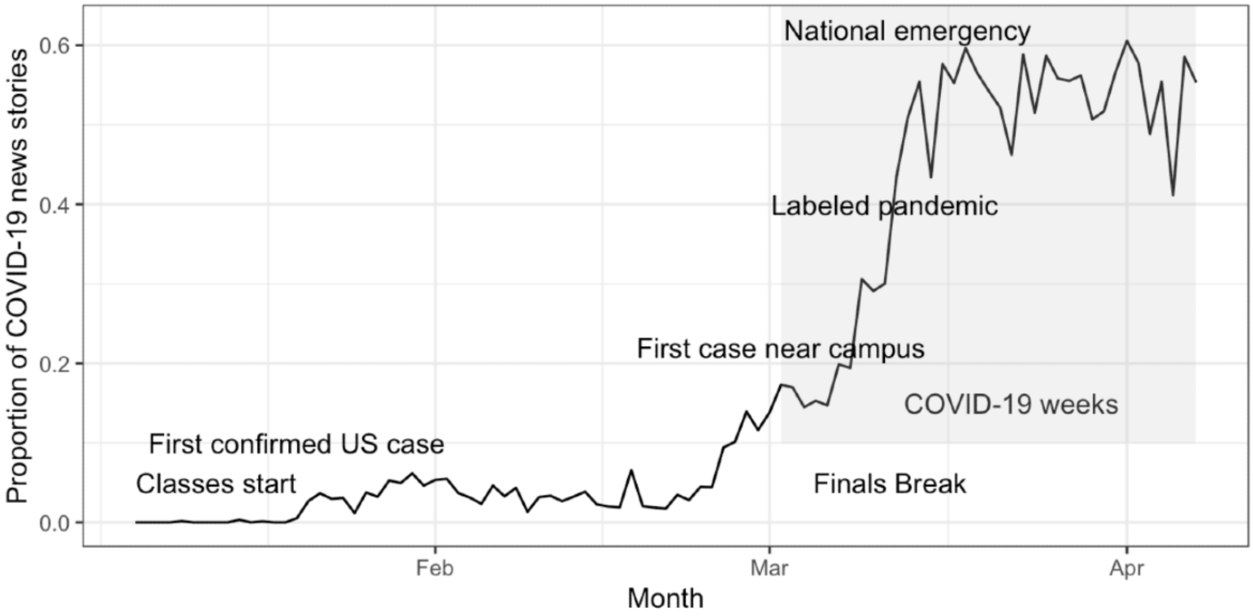
Table 1. Key Dartmouth College academic dates for the Winter 2020 term and relevant COVID-19 events.

Date	Event	Term week
January 6	First day of classes	1
January 20	First confirmed COVID-19[a] case in the United States	3
February 4	Travelers from China asked to self-quarantine	5
March 2	First COVID-19 case near campus	9
March 6	Last day of classes	9
March 9	First day of final examinations	10
March 10	Students asked to leave campus as soon as possible (March 16 at the latest)	10
March 11	WHO[b] labels COVID-19 a pandemic; all Dartmouth College athletics cancelled	10
March 12	Travel between the United States and Europe restricted	10
March 13	COVID-19 declared a national emergency; last day of final examinations	10
March 14	Start of spring break	11 (Break)
March 16	Gatherings of more than 50 individuals cancelled	11 (Break)
March 17	Online-only off-campus learning for Spring 2020 term announced	11 (Break)

[a] COVID-19: coronavirus disease.

[b] WHO: World Health Organization.

Figure 1. Proportion of US news and media stories containing the term *coronavirus* with key COVID-19 and Dartmouth academic term events labeled. Data were obtained from Media Cloud. COVID-19: coronavirus disease.



Objectives

The current work seeks to answer the following questions. First, how and when was the mental health of college students impacted by the COVID-19 epidemic, and were changes in depression and anxiety statistically different from those in previous terms in the same student cohort? Second, how are daily behaviors (as measured by smartphone sensing) and changes in depression and anxiety impacted by COVID-19 media coverage?

Methods

Study Design

All data in the current study were obtained from the second iteration of the StudentLife study [11], which is a longitudinal multimodal study that is designed to follow the experiences of undergraduate students throughout their academic tenure, with a focus on mental health. Study components include smartphone mobile sensing through the StudentLife app [6], EMAs and surveys focusing on a variety of college experience components, and functional neuroimaging [12].

Participants

Data were collected from 219 participants who agreed to provide mobile sensing data via the StudentLife app [6]. One participant was removed from the study because their mobile phone was incompatible with the app, and one participant withdrew within a week of starting the study. Data for both subjects were excluded from further analyses. Of the remaining 217 participants, 147 (67.8%) were female, with an age range for all participants of 18 to 22 years at the time of enrollment. Recruitment for this study began in August 2017 and concluded in November 2018. This study was approved by Dartmouth's Committee for the Protection of Human Subjects.

Academic Terms

At Dartmouth College, the academic calendar consists of a flexible, year-round calendar that is approximately divided into four academic terms, or quarters. Each term consists of 10 weeks, typically followed by 2 (or more) weeks of break. The Winter 2020 academic term (January 6 start date) includes the progression of the COVID-19 pandemic, ranging from the first confirmed case in the United States (Table 1) to the identification of COVID-19 as a global pandemic; these events resulted in policy and regulatory changes at the college, local, and national levels. Academic terms prior to the Winter 2020 term, including the subsequent 2 weeks of break, were included as control terms.

Mobile Sensing and EMAs

Smartphone sensing data and EMA surveys were administered using the StudentLife application (iOS and Android) [6]. The StudentLife app collects data from several of the phone's sensors, including but not limited to the GPS, accelerometer, and lock/unlock status. Anonymized data from the StudentLife app are uploaded to a secure server when a participant is both using WiFi and charging their phone. Data from these sensors are used to assess factors such as the day-to-day and week-by-week impact of workload on the stress, sleep, activity, mood, sociability, mental well-being, and academic performance of the students [6]. Students are prompted weekly by the StudentLife application to complete a few short surveys, administered as EMAs [5]. These EMAs include the Patient Health Questionnaire-4 (PHQ-4), a brief measure of depressive and anxious symptoms [13] that assesses how often individuals were bothered by specific symptoms over the last 2 weeks with values ranging from 0 to 6 for each subscale. The PHQ-4 combines the Patient Health Questionnaire-2 (PHQ-2) and the Generalized Anxiety Disorder-2 (GAD-2). Data coverage was 19.7/24 hours for location, 22.3/24 hours for all other indices, and 80.1% for EMA responses across the duration of the study.

Sedentary Time

Sedentary time, or stationary duration, is computed to measure students' activity or, more precisely, their lack of activity. The app continuously infers physical activities using the Android activity recognition application programming interface [14,15] or iOS Core Motion [16].

Sleep

Sleep was inferred through a combination of passive sensing features (ambient light, movement activity, screen on/off). In this way, 3 features were computed: sleep onset, wake time, and sleep duration. These measures of sleep have been shown to be accurate within 30 minutes for total sleep duration [6].

Location

Density-based spatial clustering of applications with noise (DBSCAN) [17] was used to cluster GPS coordinates to determine the number of locations visited and distance traveled during a given time period. Locations were detected when 3 GPS samples (1 sample every 10 minutes) were within a radius of 30 meters. Distance was calculated in meters traveled between all locations throughout the day.

Phone Usage

Unlock duration is a measurement of time during which a mobile phone is unlocked and the screen is on; it is calculated from the time the user unlocks the phone until they either manually relock the phone or it autolocks due to disuse (the iOS default is 30 seconds, while Android defaults vary by manufacturer; users can also alter this by changing their phone settings). Notification and system services do not influence the measurement of unlock duration. While unlock duration is not an absolute measurement of phone usage, it is the closest approximation implemented in StudentLife. From the start of the study in September 2017 until September 2018, the unlock duration was measured by remotely triggering the mobile phones every 10 minutes, sampling 1 minute every 10 minute period (minimum 10% temporal coverage). If conversation was detected during the 1-minute sampling period, the sampling was extended to 3 min for a maximum of 30% temporal coverage. After September 2018, the mobile phones were remotely triggered every 3 minutes, with subsequent sampling for 1 minute. Lock/unlock behaviors within that minute were recorded in real time, while lock/unlocks for the remaining 2 minutes were logged during the next remote trigger.

COVID-19 News Coverage

To obtain an unbiased measurement of media exposure to COVID-19, the number of news articles published with the term *coronavirus* and the number of all news articles were pulled for the duration of the entire study (August 2017 to 2 weeks after the end of the Winter 2020 academic term). Articles were pulled from a variety of US news outlets, including newspapers and online sources, on the Media Cloud website [18]. The ratio of articles mentioning *coronavirus* to the total number of articles was computed to create a variable indexing the amount of COVID-19 reporting in the media landscape and is presented alongside notable timepoints in the academic term (Figure 1).

Data Processing, Modeling, and Visualization

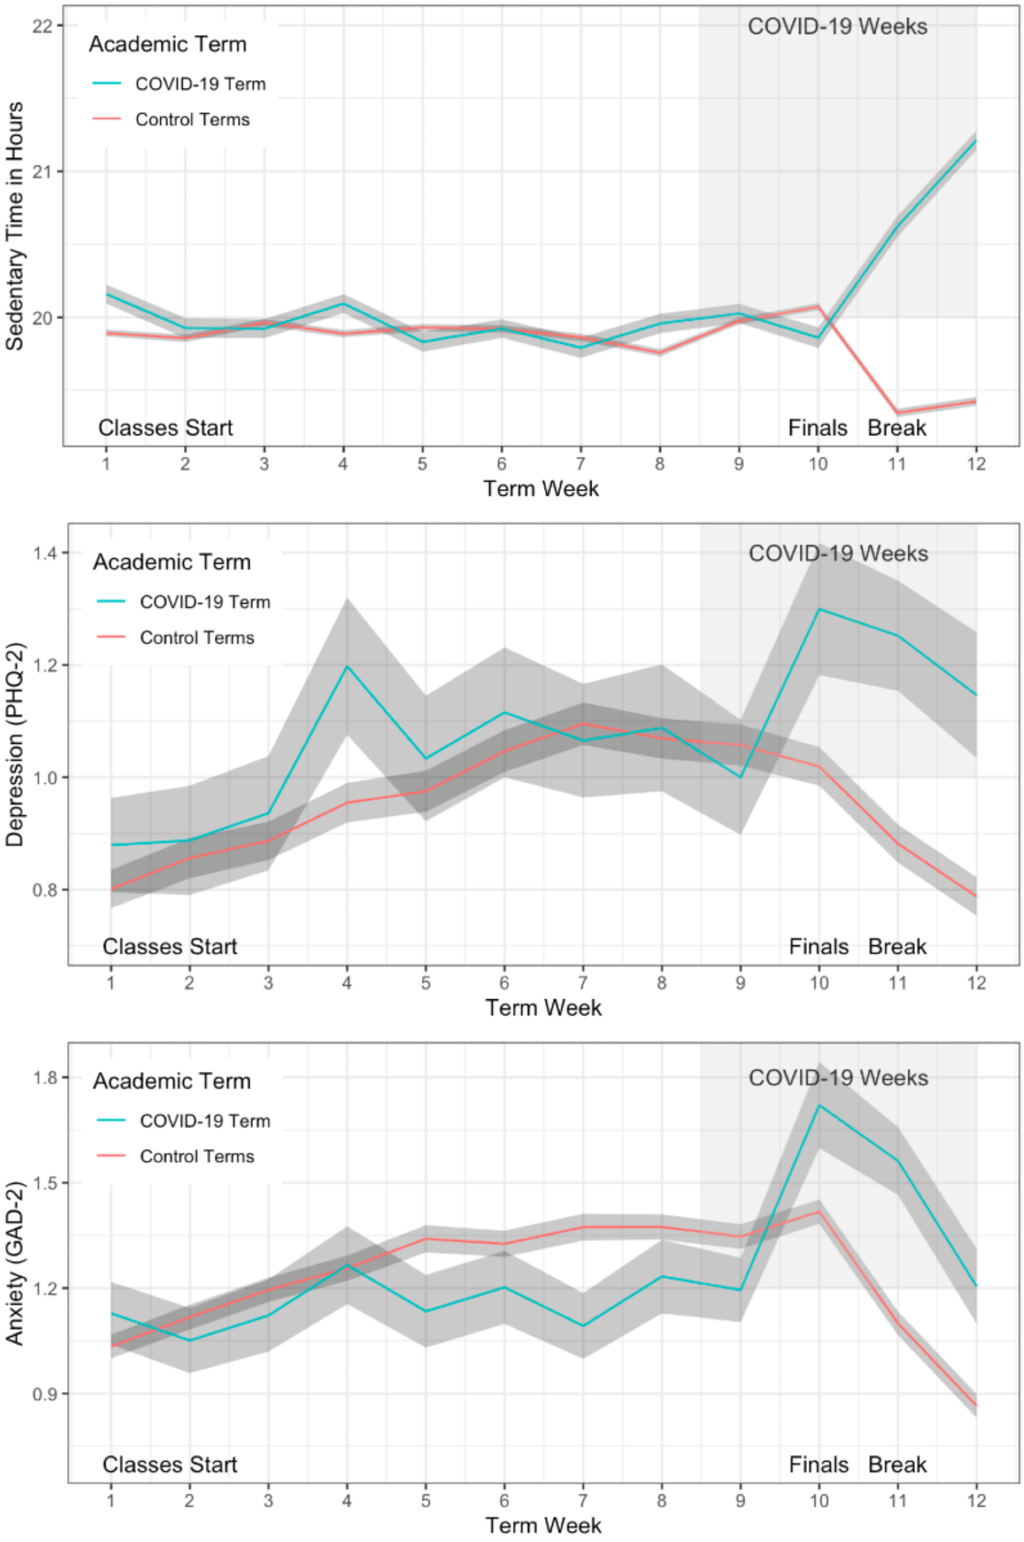
Data processing was performed in R [19] with formatting and development in R Markdown using RStudio [20]. Modeling was implemented in the lme4 [21] and lmerTest [22] packages. Plots were generated using ggplot2 [23]. Result tables were produced using the stargazer package [24]. The objective of the first analysis was to model sedentary time, depression, and anxiety. To observe trends in these domains across the academic term, the mean values of the variables of interest were plotted by week of the term; data were combined from all study participants from all terms except for the Winter 2020 term, which was plotted as a separate line. Standard error was plotted as a shaded ribbon surrounding the mean. Visual representations of the sedentary time and self-reported depression and anxiety can be observed in Figure 2. Linear mixed models fit by log-likelihood were compared to determine if the values were indeed different from prior terms with respect to sedentary time, anxiety, and depression. The terms in each model included a binary factor, “COVIDTerm,” to label whether the term was influenced by COVID-19. The term week was modeled as linear and quadratic factors, along with interactions between the COVIDTerm factor and the term week variables (ie, COVIDTerm×Term Week (Linear)) in subsequent models. Random intercepts were set per subject in all models. Term week variables were scaled to aid model convergence.

Each variable of interest (sedentary time, depression, and anxiety) was individually modeled with COVIDTerm, term week (linear), and random intercepts per subject. The next model added an interaction term between COVIDTerm and term week (Linear). The third model added the term week (quadratic) variable, and the fourth model added an interaction between COVIDTerm and term week (quadratic). For each of the variables of interest, these four models were compared using the analysis of variance function from the base stats package in R. For each variable, the model with the lowest deviance was selected. *P* values were calculated using the Satterthwaite method as implemented in lmerModLmerTest as part of the lmerTest package.

To obtain a daily variable mirroring possible exposure to COVID-19–related news content, a *coronavirus* topic was created on Media Cloud with dates spanning the duration of the study. The proportion of stories including *coronavirus* was downloaded and scaled. Modeling of COVID-19 news was first performed by combining smartphone sensing features and the week of the academic term. Each feature was scaled before being submitted to the model. Each variable, except for the COVIDTerm factor and subject, was scaled to aid model convergence and allow for regression coefficients that can be compared for relative importance. COVID-19 news was inferred with fixed effects of unlock duration, unlock number, sedentary time, sleep duration, number of locations visited, and term week (linear and quadratic) variables, as well as random intercepts for each subject.

To determine if mental health was associated with the COVID-19 news ratio, self-reported depression and anxiety variables were added to the daily model above. Given that individual participants only answered mental health EMAs on a weekly basis, the subsequent models include far fewer time points than the smartphone-sensing only model above; again, this limits the statistical comparability between the models.

Figure 2. Sedentary time (top), depression (middle), and anxiety (bottom) scores across an academic term and the first 2 weeks of break, with the term influenced by the outbreak of the COVID-19 pandemic as a separate line. The shaded ribbons represent the standard error for each week. Weeks influenced by policy changes related to COVID-19 are represented with a shaded box from weeks 9 to 12. Sedentary time was calculated using data from the StudentLife app. Depression and anxiety were measured with the PHQ-2 and GAD-2 scales through the StudentLife app. Control terms include data from the same group of individuals across previous academic terms. COVID-19: coronavirus disease; Finals: final examinations; GAD-2: Generalized Anxiety Disorder-2; PHQ-2: Patient Health Questionnaire-2.



Results

Behavioral and Mental Health Changes Associated With the COVID-19 Pandemic

Compared with all other academic terms, we observed differences in both behavior and mental health between weeks 9 and 12 of the Winter 2020 term, which correspond to the last week of classes, the week of final examinations, and the 2-week spring break. Sedentary time appeared to be very similar across the Winter 2020 and previous terms until week 11 (first week of break), when individuals spent over one hour more per day sedentary compared with a typical term; the sedentary time increased further through the second week of break (Figure 2). Self-reported symptoms of depression and anxiety spiked noticeably in week 10, which corresponds to widespread policy changes at the college, local, and national government levels. Week 10 is 1 week after the first case of COVID-19 was confirmed proximal to Dartmouth College, which occurred on the first day of week 9 of the academic term. Week 10 also corresponds to the time when students were asked to leave campus as soon as possible and when the switch to a remote learning model for the Spring 2020 term was announced. After week 10 in the Winter 2020 term, both depression and anxiety remained consistently elevated above the levels in other terms; however, they decreased at similar rates.

Multiple models for sedentary time, anxiety, and depression were tested (see the Methods section for specific details). For each of these variables, superior fit (measured by lowest deviance) was observed with the most complex model. This model included the COVID-19 term, linear term, and quadratic term week trends as well as the interaction of the COVID-19 term with each of the term week trends; the model also allowed for random intercepts for each participant's data (random effects). Modeling of the academic term affected by COVID-19 compared with academic terms prior to the COVID-19 pandemic identified significantly increased sedentary time, depression, and anxiety (*P*<.001; Table 2). Interactions of the COVID-19 term and quadratic term week regressor for all three variables (*P*<.001) and significant interactions between the COVID-19 term and the linear term week regressor for sedentary time and depression were also observed (*P*<.001 and *P*=.004, respectively).

Table 2. Models of sedentary time, depression, and anxiety by week and by presence of COVID-19 during the academic term.

Variable	Dependent variables					
	Sedentary time (observations=113,864)		Depression (observations=20,323)		Anxiety (observations=113,864)	
	Parameter (SD)	*P* value	Parameter (SD)	*P* value	Parameter (SD)	*P* value

[a] COVID-19: coronavirus disease.

COVID-19 News Coverage, Mental Health, and Mobile Sensing

After establishing broad differences in sedentary time, depression, and anxiety between the Winter 2020 term and previous terms, the next goal was to determine if these behaviors changed in a finer-grained fashion, particularly mirroring the relative news coverage of COVID-19. The proportion of new stories including the term *coronavirus* remained at baseline until early January, with an unsurprisingly large increase appearing at the beginning of March (Figure 1). To ascertain which behaviors changed with increasing proportion of COVID-19 news reports, we included fixed effects for phone usage (unlock duration and unlock number), sedentary time, sleep duration, number of locations visited, and linear and quadratic academic term week regressors. Random intercepts per subject were included in the model. Each variable was scaled to aid convergence of the restricted maximum likelihood model and to obtain regression coefficients that could be compared for relative importance. All variables except sleep duration and distance traveled were significantly associated with the proportion of COVID-19 news reports (*P*<.001, Table 3 [left column], Figure 3 [top]). Phone usage (unlock duration) has the largest positive standardized coefficient, closely followed by the linear term week variable. The number of locations visited has the largest negative standardized coefficient.

In the second model of the COVID-19 news ratio, we again attempted to make inferences with mobile sensing features plus the addition of self-reported anxiety and depression scores. When anxiety and depression were added to the previously used sensing model, we observed that increased anxiety but not depression was significantly associated with a higher COVID-19 news ratio (*P*<.001, Table 3 [right column], Figure 3 [bottom]). The number of phone unlocks (unlock number) is significant in the first model but not in the second model. Since the standardized beta weights are relatively stable across all other variables, it appears that anxiety may have absorbed some of the variance associated with the unlock number in the first model; however, we cannot directly make this comparison due to the different subset of data in the second model. Again, we observed increased phone usage (unlock duration), increased sedentary time, and decreased number of locations visited, with standardized beta weights stable across both models. Both linear and quadratic term weeks were positively associated with the COVID-19 news ratio.

Table 3. Inferences of the proportion of COVID-19 news reports with smartphone features and self-reported mental health variables.

Variable	Dependent variables			
	COVID-19[a] news model 1 (observations=100,300)		COVID-19 news model 2 (observations=18,432)

Discussion

Principal Findings

During the outbreak of a pandemic, the primary focus is on the pathogen and its influences on physical health. Mental health and behavioral changes are often considered secondary concerns. In the present study, we leveraged longitudinal data in a cohort of 217 college students to demonstrate the impact of the COVID-19 pandemic on mental health and behavior compared to previous academic terms. During the Winter 2020 academic term, sedentary time increased along with symptoms of anxiety and depression. Subsequent analyses examined the association between increased COVID-19 news coverage and behavior (inferred from mobile sensing data) and mental health. We found that with increasing COVID-19–related news, individuals were more sedentary, visited fewer locations (as inferred from GPS tracking), and showed increases in anxiety and depression. These analyses identified behavioral changes from smartphone sensing that are consistent with individuals adhering to the "Stay Safe, Stay Home" policies implemented by local and national governments.

During the Winter 2020 academic term, increased depression, anxiety, and sedentary time were observed, suggesting a large mental health and behavioral impact beyond the actual reach of the SARS-CoV-2 pathogen. The days and weeks leading up to and including the final examination period are a particularly stressful time for students [10]. We typically find that participants report relatively high scores of depression and anxiety during this time; however, these scores recover to baseline over the break [8]. The cyclical nature of college students' mental health within a typical academic term provides a unique control in our study that might be otherwise difficult to untangle from periodic rises and falls in stress and anxiety during March as colleges across the United States conduct final examinations. Understanding behaviors during typical academic cycles can be fruitful for determining how everyday events impact students' mental health and behaviors. Rare events such as the COVID-19 pandemic provide a unique opportunity to examine how mental health and behaviors deviate from baseline. To account for the cyclical nature of mental health throughout the academic term, we used linear and quadratic week of academic term variables, then looked for interactions and the main effects of the most recent (COVID-19–related) term. The increased depression, anxiety, and sedentary time, which were above and beyond what would normally be observed during a typical term, were attributed to the COVID-19 pandemic. Additionally, we did not observe a return to baseline for any of these 3 variables over the break, which stands in stark contrast to our previous study of this same cohort in prior academic terms. We did observe decreases in anxiety and depression that paralleled the typical post–final examination drop, which suggests some resilience in the face of COVID-19; however, the overall values remained elevated above those observed during typical academic breaks. This may also be consistent with the adjustment period to the rapidly changing landscape of social media, policies, and media coverage [25].

Individuals are generally more active over break periods; however, we observed a large increase in sedentary behavior, which can be attributed to the COVID-19 pandemic. Studies show that physical activity, particularly aerobic activity, reduces self-reported depressive symptoms with a similar efficacy to that of low-dose antidepressants [26]. Other studies have shown that increased sedentary time along with increased phone usage is implicated in depression and anxiety [12,27,28]. Taken as a whole, these findings suggest that during stay-at-home orders, individuals should increase physical activity and limit screen time in an attempt to lessen depressive symptoms.

As COVID-19 news reporting intensified, we observed increased sedentary behavior and duration of phone usage along with decreases in the number of locations visited and a decreased number of phone unlocks. Initially, the number of phone unlocks was somewhat surprisingly inversely associated with COVID-19 news; however, this is likely due to increased phone unlock duration (ie, screen time), which would otherwise span multiple phone unlocks. The decreased number of locations visited is consistent with the "Stay Home, Stay Safe" polices many governments have implemented; it also stands in contrast to initial work on social distancing among college students in the Netherlands, where social distancing policies were not implemented during the examined time period [9]. In the combined sensing and mental health model, the addition of depression and anxiety to the sensing model showed a strong inferential link between anxiety and COVID-19 news, while depression was marginally significant. In the combined model, the number of unlocks, sleep duration, and distance traveled were again not significant.

Primary takeaways from models inferring the proportion of COVID-19 news stories suggest that during the start of the COVID-19 pandemic, students were more depressed and anxious, used their phones more, visited fewer locations, and spent more time sedentary. At this critical time of increased depression and anxiety, we issue a call to public health officials and individual citizens to raise public awareness about the benefits of aerobic exercise and unplugging from technology (moderating phone usage), as each of these has previously been shown to have positive effects on alleviating anxiety and depression [8,26,28,29]. COVID-19 arrived locally during week 9 of the academic term. By the onset of the COVID-19 pandemic (academic term week 10), a significant deterioration in mental health and multiple behavioral changes were observed, which synchronizes with the implementation of rapid policy changes at the college, local, and national levels. These findings suggest a greatly expanded scope of the impact of the COVID-19 pandemic beyond the illness and deaths directly associated with the SARS-CoV-2 pathogen.

Limitations and Future Directions

The current study has a variety of limitations, although most provide incentives for future research. First, our participants are approximately the same age, are undergraduate college students with smartphones compatible with the StudentLife app, and are willing to participate in a multiyear longitudinal research study; this limits the generalizability of the current findings to the general population. Simultaneously, it provides distinct advantages, such as longitudinal measurement across behavioral cycles, wherein previous academic terms can be compared to the term affected by COVID-19. A second limitation is the moderate number of individuals included in the study, with 217 total participants across all terms and 178 across the COVID-19 term (83%). Despite the moderate sample size, strong significant effects on mental health and behavior were observed, suggesting robust effects.

While smartphone sensing is quite robust, there are some limitations to the interpretation of the available data. When mobility is decreased, such as during a stay-at-home order, individuals may not have their mobile phones with them at all times, which could lead to overestimation of sedentary time. Additionally, participants may be preferentially accessing larger screens (eg, tablets or laptops); therefore, phone usage (as measured by screen unlock duration or number of unlocks) may underestimate the total amount of screen time. Even so, we observed increased phone usage despite the possibility of underestimated changes in the total amount of screen time. Future work should also identify the types of screens used during this increased consumption period and quantify the relative amounts of news, social media, and other content consumed. In further work, we could also use smartwatches to improve the measurement of behaviors such as sedentary time and allow for more frequent sampling of phone usage, location, and other measures.

While this work primarily focuses on the initial days of the COVID-19 pandemic, future work would be well suited to investigating differences in mental health and behaviors between typical residential academic terms and terms that have been shifted from residential to online coursework due to COVID-19. Furthermore, identifying causal patterns between the pandemic, policy changes on national, local, and college levels, mental health, and behavior could provide further insight into the optimal development of interventions designed to mitigate mental health crises in the face of global crises. These findings suggest a greatly expanded scope of the impact of the COVID-19 pandemic beyond that directly associated with the SARS-CoV-2 pathogen.

Conclusions

Understanding behaviors during typical academic cycles can be fruitful for determining how everyday events impact students' mental health and behaviors. Fringe events such as the COVID-19 pandemic provide opportunities to examine how mental health and behaviors deviate from baseline.

This study provides preliminary insight into mental health and related behaviors during the initial phases of the COVID-19 pandemic. Depression, anxiety, and sedentary time increased as the COVID-19 pandemic encroached on a college campus in parallel with large-scale policy changes. Using a mixed linear model of smartphone mobile sensing and self-reported mental health questions, we were able to infer the proportion of COVID-19–related news stories; moreover, we could validate that participants' mental health and related behaviors changed in lockstep with increased media coverage and proximity of the pandemic. For these college students, the early days of the pandemic coincided with what is typically a time of increased time and depression, and we observed altered behavioral patterns and a decrease in mental health above and beyond typical academic terms. Much more work remains to be done to understand how behaviors and mental health change and interact in the face of monumental adverse global events.

Abstract

Background: In the context of home confinement during the coronavirus disease (COVID-19) pandemic, objective, real-time data are needed to assess populations’ adherence to home confinement to adapt policies and control measures accordingly.

Objective: The aim of this study was to determine whether wearable activity trackers could provide information regarding users' adherence to home confinement policies because of their capacity for seamless and continuous monitoring of individuals’ natural activity patterns regardless of their location.

Methods: We analyzed big data from individuals using activity trackers (Withings) that count the wearer’s average daily number of steps in a number of representative nations that adopted different modalities of restriction of citizens’ activities.

Results: Data on the number of steps per day from over 740,000 individuals around the world were analyzed. We demonstrate the physical activity patterns in several representative countries with total, partial, or no home confinement. The decrease in steps per day in regions with strict total home confinement ranged from 25% to 54%. Partial lockdown (characterized by social distancing measures such as school closures, bar and restaurant closures, and cancellation of public meetings but without strict home confinement) does not appear to have a significant impact on people’s activity compared to the pre-pandemic period. The absolute level of physical activity under total home confinement in European countries is around twofold that in China. In some countries, such as France and Spain, physical activity started to gradually decrease even before official commitment to lockdown as a result of initial less stringent restriction orders or self-quarantine. However, physical activity began to increase again in the last 2 weeks, suggesting a decrease in compliance with confinement orders.

Conclusions: Aggregate analysis of activity tracker data with the potential for daily updates can provide information regarding adherence to home confinement policies.

KEYWORDS

wearable activity trackers; pandemic; COVID-19; home confinement; lockdown; monitoring; wearables; tracking

Introduction

Nationwide total home confinement is the most significant measure that has been taken to prevent the spread of coronavirus disease (COVID-19) infection [1]. Currently, over 3 billion people worldwide, one-quarter of the world's population, are confined to their homes. However, the timing and stringency of governmental decisions have been heterogeneous; some governments have imposed total lockdown, while others have required partial or no confinement. Objective, real-time measures to assess populations' adherence to confinement are essential to adapt policies and control measures accordingly.

We asked whether wearable activity trackers could provide this information because of their capacity for seamless and continuous monitoring of individuals' natural activity patterns regardless of their location [2]. Data from activity trackers enable the compilation of synchronized big data resources on human behavior with high geographical and temporal resolution. In the context of the COVID-19 pandemic, activity trackers provide a valuable data set that objectively documents the time course of adherence to home confinement worldwide in response to the outbreak.

Methods

We analyzed data from approximately 742,000 individuals using activity trackers that count the wearer's average daily number of steps (Withings) in a number of representative nations that adopted different modalities of restriction of citizens' activities. We selected the nations according to a compromise between exposure to the COVID-19 pandemic, rules of lockdown, and availability of data from a large number of activity tracker users.

The pre-pandemic period was used as a reference. For each individual, we calculated the average daily number of steps between December 1, 2019, and the date of lockdown, representing the pre-pandemic period, and the average daily number of steps between the date of lockdown and the analysis time point (4 weeks for China). These data were then aggregated across countries or regions. The paired Wilcoxon nonparametric test was used to compare the number of steps per day before and during lockdown. The data presented extend to April 13, 2020, and are averaged by days and over countries or provinces/states.

The activity tracker used in this study was a wristwatch with an embedded accelerometer that counts steps. The performance of this tracker is reported to be one of the best among available devices [3]. The activity tracker provides the most accurate measures of step count under all three important physiological conditions (ie, treadmill, over-ground, and 24-hour conditions). The same accelerometer and algorithm were used for all individuals included in the analysis. All activity tracker wearers were informed that the anonymized data collected from them could be used for research purposes, and they provided informed consent before starting to use the activity tracker. They were allowed to withdraw their consent at any time and request deletion of their individual data.

Results

Table 1 shows the number of users per country or province/state, percentage of female users, lockdown initiation dates, rules, and percentage of decrease in steps during lockdown. The most demonstrative countries are presented in Figure 1, illustrating the time course of the step count and enhancing the data in Table 1. Before the epidemic, all countries showed a stable mean number of steps per day, with periodic and reproducible decreases during weekends. In countries adopting a total lockdown, a marked decrease (from 25% to 54%) in the number of steps following the official dates of home confinement can be clearly identified (Figure 1A). Partial lockdown (characterized by social distancing measures such as school closures, bar and restaurant closures, and cancellation of public meetings but without strict home confinement) does not appear to have a significant clinical impact on people's activity compared to the pre-pandemic period (Figure 1B), with similar activity patterns to those in nations without any restriction orders (Figure 1C).

[a] The number of users having activity data on a given day is subject to variation; the numbers given in the table are representative orders of magnitude of the daily number of users having activity data.

[b] Not applicable.

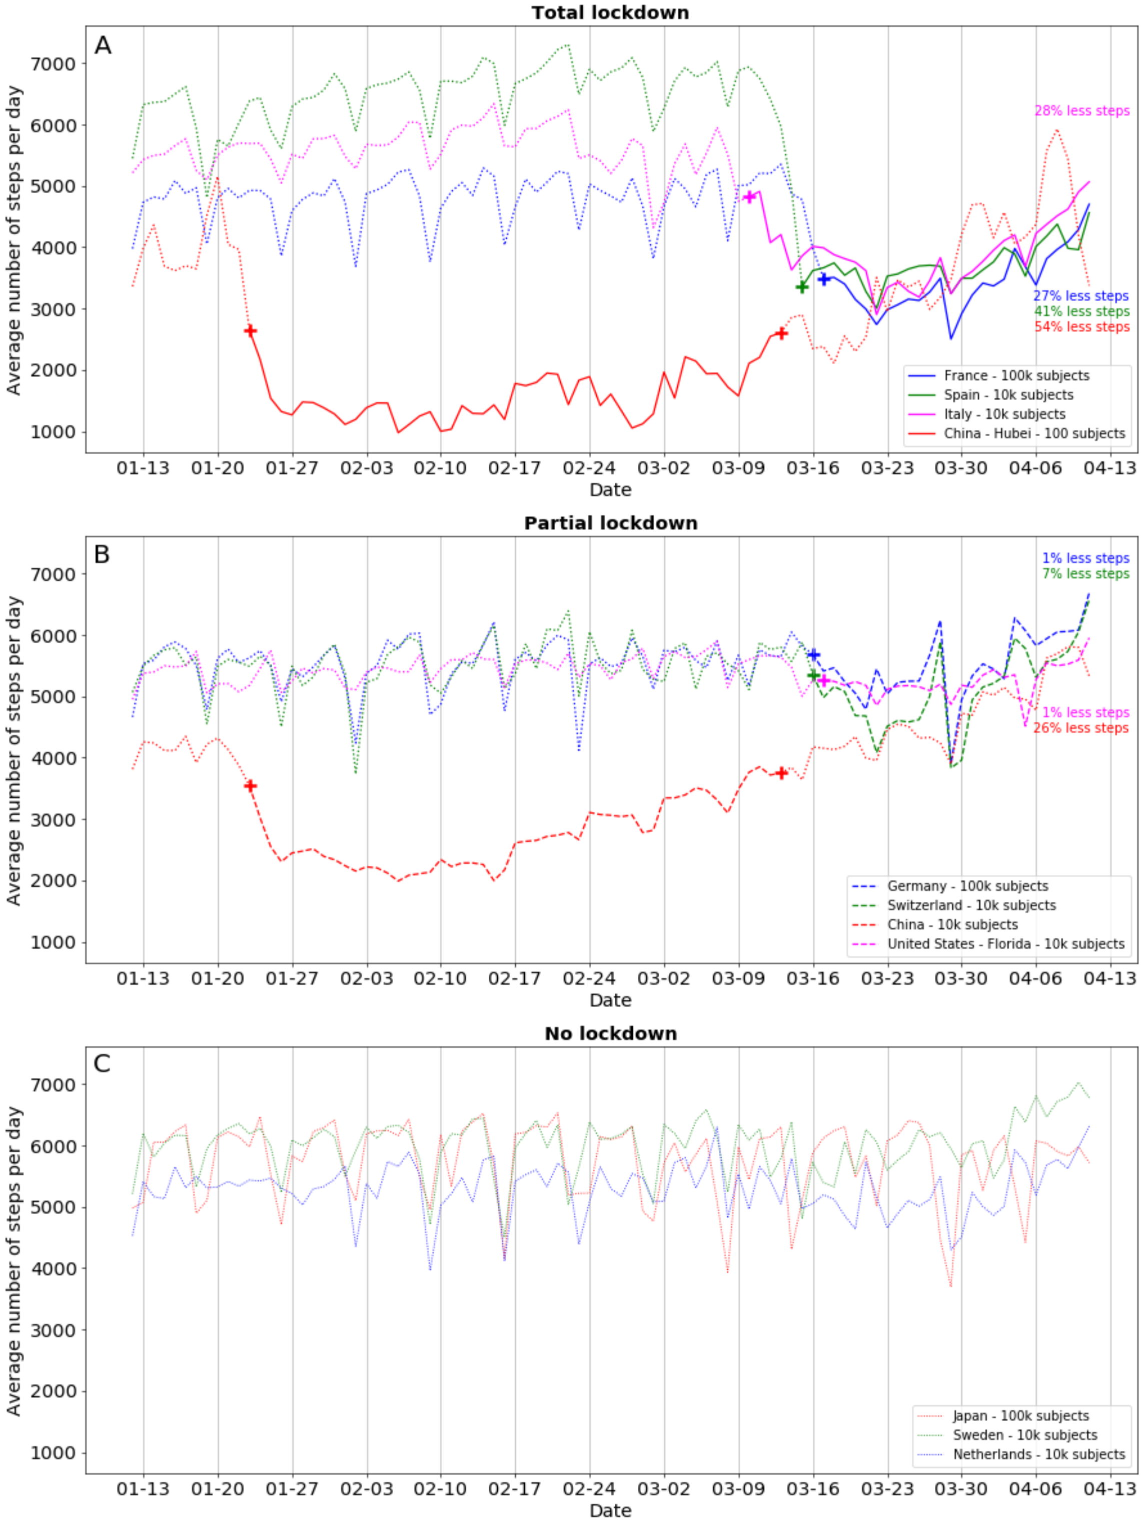

Figure 1. Trajectories of average daily number of steps recorded by activity trackers from January 13, 2020, to April 13, 2020, in a number of representative countries worldwide adopting total (A), partial (B), or no (C) lockdown. Solid lines indicate total lockdown periods, dashed lines indicate partial lockdown periods, and dotted lines indicate no lockdown. Crosses indicate the start and end dates of lockdown in the different countries.

Discussion

Principal Findings

The absolute level of physical activity under total home confinement in European countries is around twofold that in China (Table 1); this may be due to stricter governmental rules in China or different national temperaments. Interestingly, in some countries, such as France and Spain, physical activity started to gradually decrease even before official commitment to lockdown as a result of initial less stringent restriction orders or self-quarantine. However, physical activity began to increase again in the last 2 weeks, suggesting a decrease in compliance with confinement orders. Countries with partial or no lockdown policies had marginal or no changes in walking habits. Ireland was the only country with enforced confinement that showed no change in step counts. Regarding the magnitude and significance of the changes, all differences were highly significant in statistical terms (*P*<.001) because of the large number of users and because of consistent trends among users (the vast majority of users changed their step counts in the same direction, even for small changes). Clinical significance is thus arbitrary, and the weekly trends suggest spontaneous group changes (decreases on weekends). In fully locked-down countries, with the exception of Ireland, the number of steps decreased below the maximum on weekends; this shows overall good compliance with lockdown rules.

Conclusion

Aggregate analysis of activity tracker data, with the potential for daily updates, can inform governments and stakeholders on adherence to home confinement policies as well as their efficacy without violating citizens' privacy [4]. The data allow comparison of the effectiveness of different government policies. Finally, quantification of physical activity patterns, particularly leisure versus occupational patterns, and their consequences on cardiometabolic health are important because sport and leisure physical activities have been shown to have positive effects on cardiometabolic health, whereas occupational physical activity has not [5]. Data emerging from studies conducted during lockdown will help to address this issue.

Acknowledgments

We thank Alison Foote, Grenoble Alpes University Hospital, France, for critically editing the manuscript. JLP is supported by a research grant from the French National Research Agency (ANR-12-TECS-0010) in the framework of the "Investissements d'avenir" program (ANR-15-IDEX-02) and the "e-Health and Integrated Care" and "Trajectories Medicine" Chairs of Excellence at Université Grenoble Alpes (MIAI Grenoble Alpes, ANR-19-P3IA-0003).

Authors' Contributions

JLP and PB conceived the study; RY, VV, and PJ acquired and analyzed the data; and JLP, RMB, PE, and PB drafted and significantly revised the manuscript.

Conflicts of Interest

RY, VV, and PJ are employees of Withings, a manufacturer of wearable activity tracking systems; PE is a remunerated scientific advisor to Withings; and JLP and PB are informal unpaid scientific advisors to Withings.

Abstract

Background: Frontline health care workers, including physicians, are at high risk of contracting coronavirus disease (COVID-19) owing to their exposure to patients suspected of having COVID-19.

Objective: The aim of this study was to evaluate the benefits and feasibility of a double triage and telemedicine protocol in improving infection control in the emergency department (ED).

Methods: In this retrospective study, we recruited patients aged ≥20 years referred to the ED of the National Taiwan University Hospital between March 1 and April 30, 2020. A double triage and telemedicine protocol was developed to triage suggested COVID-19 cases and minimize health workers' exposure to this disease. We categorized patients attending video interviews into a telemedicine group and patients experiencing face-to-face interviews into a conventional group. A questionnaire was used to assess how patients perceived the quality of the interviews and their communication with physicians as well as perceptions of stress, discrimination, and privacy. Each question was evaluated using a 5-point Likert scale. Physicians' total exposure time and total evaluation time were treated as primary outcomes, and the mean scores of the questions were treated as secondary outcomes.

Results: The final sample included 198 patients, including 93 cases (47.0%) in the telemedicine group and 105 cases (53.0%) in the conventional group. The total exposure time in the telemedicine group was significantly shorter than that in the conventional group (4.7 minutes vs 8.9 minutes, *P*<.001), whereas the total evaluation time in the telemedicine group was significantly longer than that in the conventional group (12.2 minutes vs 8.9 minutes, *P*<.001). After controlling for potential confounders, the total exposure time in the telemedicine group was 4.6 minutes shorter than that in the conventional group (95% CI −5.7 to −3.5, *P*<.001), whereas the total evaluation time in the telemedicine group was 2.8 minutes longer than that in the conventional group (95% CI −1.6 to −4.0, *P*<.001). The mean scores of the patient questionnaire were high in both groups (4.5/5 to 4.7/5 points).

Conclusions: The implementation of the double triage and telemedicine protocol in the ED during the COVID-19 pandemic has high potential to improve infection control.

Introduction

Background

Since the beginning of the 20th century, various infectious diseases have repeatedly threatened both population health and health care systems worldwide. The rapid growth of international transportation has paved the way for the transmission of infectious diseases across regions, including severe acute respiratory syndrome (SARS), H1N1 influenza, Middle Eastern respiratory syndrome (MERS), and Ebola virus [1-4]. In 2020, coronavirus disease (COVID-19) was first reported in Wuhan, China; this virus spread globally through large-scale transmission and continues to pose great challenges to medical, public health, and socioeconomic systems worldwide [5]. Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), identified as the causative pathogen of COVID-19, is highly contagious [6]. It is primarily transmitted through droplets and close contact, even in the early course of the disease, as well as from asymptomatic patients [6]. The response strategies for controlling COVID-19 outbreaks include early diagnosis, patient isolation, symptomatic monitoring, and quarantine [7].

During the response to the COVID-19 pandemic, a considerable number of frontline health care workers have been infected with the new coronavirus. In China, the first COVID-19 case among health care workers was reported on January 20, 2020; as of February 11, 2020, health care workers represented 1716/44,672 (3.8%) of all patients with laboratory-confirmed COVID-19 and 247/1668 (14.8%) of critical cases, with 5 deaths [8]. In Italy, health care workers accounted for 2026/22,512 (9.0%) of confirmed cases as of March 15, 2020 [9]. According to a recent report from the US Centers for Disease Control and Prevention (CDC), this figure in the United States was 9282/315,531 (2.9%); 2.1%-4.9% of health care workers required intensive care unit admission, and 27 deaths were reported [10]. By April 8, 2020, COVID-19 had affected 22,073 health care workers in 52 countries [11]. The transmission of SARS-CoV-2 among frontline health care workers may result from their long, direct exposure to many infected patients and from a lack of personal protective equipment (PPE) [12]. Therefore, further infection control measures should be undertaken to minimize the direct exposure of health care workers to patients suspected of having COVID-19 [7].

Importance

Emergency departments (EDs) are at the frontline of the health care response to the COVID-19 pandemic and are responsible for rapid and safe triage of patients and isolation of suspected patients with COVID-19 from patients with noninfectious diseases. Therefore, establishing a screening protocol for patients with suspected COVID-19 and isolating them in a separate, well-ventilated space for clinical interviews can facilitate infection control [7]. Moreover, due to the shortages of PPE worldwide, its use should be optimized and prioritized based on critical requirements at health care facilities. Additional strategies to minimize exposure risk, such as implementing alternatives to face-to-face triage and hospital visits, can not only prevent health care workers from being exposed to COVID-19 but can also reduce PPE use. The combination of a specialized triage approach and telemedicine may be an alternative to reach this goal.

Telemedicine can be defined broadly as the use of telecommunications technology to provide medical information and services [13]. With the evolution in technology and online services, telemedicine may prove a compelling alternative to conventional acute, chronic, and preventive care [14-17]. Telemedicine, particularly video consultations, has been promoted to reduce the risk of disease transmission [18-23]. Certain reports have recently described potential benefits and applications of telemedicine during the COVID-19 pandemic [24-27]. However, the effectiveness of telemedicine in improving infection control has not been well studied, as most evidence has been obtained from clinical cases, and some studies merely propose theoretical assumptions.

Goal of This Study

As of May 2, 2020, Taiwan had 432 confirmed COVID-19 cases, and a total of 63,713 patients were tested. Nearly 97% of the Taiwanese population have access to the health care system and are covered by the National Health Insurance; hence, they can readily access health care [28]. EDs were the first units that responded to the COVID-19 pandemic in Taiwan, and most confirmed patients underwent screening and evaluation in EDs [29]. To provide essential care with optimized infection control in the ED, a double triage and telemedicine protocol was developed at our hospital. This study was conducted to evaluate the benefits and feasibility of the novel protocol for reducing the risk of COVID-19 infection among health care workers who manage COVID-19 patients.

Methods

Study Setting and Design

The National Taiwan University Hospital (NTUH) is a 2700-bed teaching hospital that provides both primary and tertiary care. It was designated as a COVID-19 response hospital in Taiwan. From March to April 2020, the number of average daily visits was 211, and the number of average daily visits to the NTUH ED by patients posing a risk of COVID-19 transmission was 12.

We conducted a retrospective study using prospectively collected data of patients who visited the ED between March 1 and April 30, 2020. The study was approved by the Institutional Review Board of the NTUH (REC No. 202003043RINA), and the requirement to obtain informed consent was waived.

The Double Triage and Telemedicine Protocol

In the course of the health care response to the COVID-19 pandemic, we developed a double triage and telemedicine protocol for the ED to manage patients suspected of having COVID-19. The protocol comprised two major components:

1) streamlining and diverting patient inflow using a double triage method and 2) evaluating suspected COVID-19 patients using telemedicine (Figure 1).

Regarding the double triage method, the first triage (Triage 1) was set up outside the entrance of the ED to screen patients based on their likelihood of posing a risk of COVID-19 transmission. The double triage helped examine the patients' history of travel, occupation, contact, and cluster (TOCC) based on the guidelines issued by the Taiwan Centers for Disease Control and available epidemiological data [29]. The Triage 1 nurse used the Taiwan Triage and Acuity Scale (TTAS) to carry out a second triage (Triage 2) for patients who posed a risk of COVID-19 transmission to health care workers [30]. TTAS is a computerized triage system with a 5-level scale that classifies patients in descending order of acuity from Triage Level I (resuscitation) and Triage Level II (emergent) to Triage Level V (nonurgent). The TTAS assesses triage level according to existing chief complaints, vital signs (eg, degree of respiratory distress, hemodynamic stability, conscious level, change in body temperature, and pain severity), and mechanism of injury (for patients with trauma) to determine the triage level of a patient. The patients who triaged as TTAS level I usually had life-threatening diseases and needed immediate resuscitation. Those patients who triaged as TTAS level II usually had potential life-threatening diseases or organ dysfunction and needed management quickly. The recommended reassessment time was less than 10 minutes. For patients triaged as TTAS levels III to V, the recommended reassessment times were 30, 60, and 120 minutes, respectively. If a patient was triaged as TTAS Level I or II, they would be directed to an isolated COVID-19 resuscitation room for further management. Patients classified as TTAS levels III to V were referred to the COVID-19 emergency clinic, which is located in a structure that is separated from the main ED building. The COVID-19 resuscitation rooms and COVID-19 emergency clinics are equipped with new ED infrastructure that was constructed in response to emerging infectious diseases [31]. Patients with no risk of COVID-19 would be diverted by the Triage 1 nurse into an internal triage facility inside the ED and receive routine emergency care.

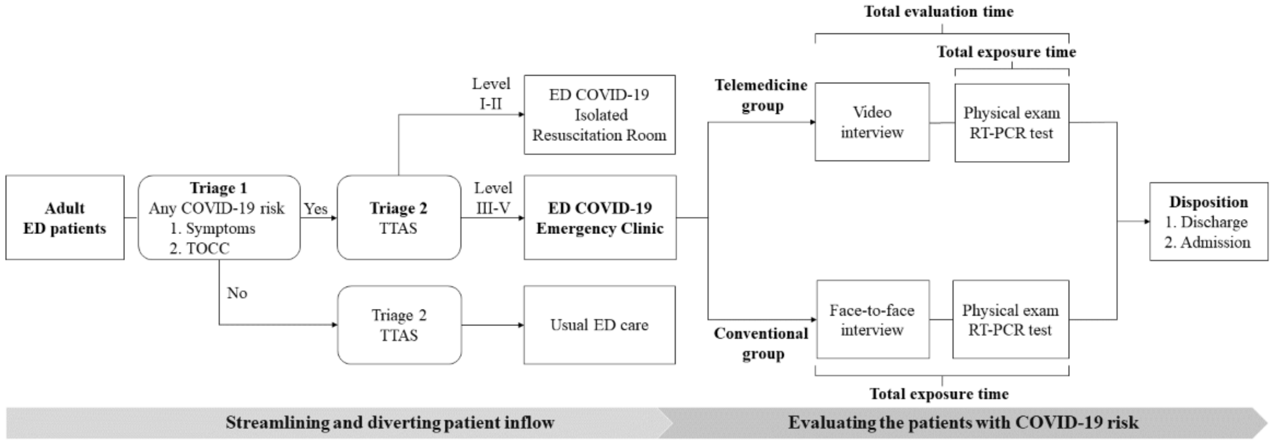
The health care workers in the COVID-19 emergency clinic were instructed to don appropriate PPE, including an N95 face mask, a waterproof gown, a non-disposable face shield, a hair cap, shoe sleeves, and two layers of gloves, when working in the clinic. A nurse was assigned to verify the appropriateness of the PPE and record the times of donning PPE, doffing PPE, and entering and exiting the clinic. In the COVID-19 emergency clinic, physicians performed face-to-face interviews with patients before performing physical examinations and collecting specimens for COVID-19 reverse transcription–polymerase chain reaction (RT-PCR) tests. In our study, patients evaluated using face-to-face interviews were assigned to the conventional group.

To improve infection control in the ED, we established a COVID-19 telemedicine team of nine attending physicians and four senior residents and provided them with training in the telemedicine interview system (TIS) on March 27, 2020. On April 1, 2020, the TIS was introduced in the COVID-19 emergency clinic (Multimedia Appendix 1) using U Meeting (CyberLink Corp) as the communication software. The TIS protects the privacy and security of patient data through end-to-end encryption and data transmission through an intranet governed by the firewall of the hospital's information system. Furthermore, the TIS is in compliance with the government regulations for telemedicine. If a patient who was diverted to the COVID-19 emergency clinic agreed to attend a video interview, the patient's attending physician on the COVID-19 telemedicine team would first use the TIS to conduct that interview. The physician would then share the patient's chest radiography findings and disease information on a screen located at the patient's side while explaining them to the patient. After the TIS interview, the physician would don appropriate PPE before entering the clinic to complete all the other necessary evaluations and obtain specimens for the COVID-19 RT-PCR test. We designated patients who underwent TIS evaluation as the telemedicine group. In both the telemedicine group and the conventional group, physicians would then decide the disposition of patients (ie, either discharging them or admitting them to quarantine wards).

The total exposure time was defined as the time that a physician remained in contact with a patient during their face-to-face interview. The total evaluation time was defined as the time the physician took to interview and assess the patient and collect specimens for laboratory testing. Both these time intervals were prospectively recorded.

Furthermore, we conducted a survey using a 10-item questionnaire in both groups upon completion of the clinical evaluation. The questionnaire was modified from a questionnaire for evaluating patient satisfaction with telemedicine [32]. It was also simplified to assess the immediate impression of the study participants because the survey was conducted in an isolated room and the response time was limited. The questionnaire helped us obtain information on the global rating of the interview, the quality of the interview, the mutual understanding between the patient and the physician, and perceptions of stress, discrimination, and safety. To assess the feasibility of telemedicine, we asked 3 additional questions to survey the participants' acceptance, perception of safety, and satisfaction with the evaluation protocol. The level of agreement was assessed using the 5-point Likert scale, ranging from 1 point (extremely agree) to 5 points (extremely disagree). The questionnaire was validated by 4 emergency physicians and the director of the Center of Quality Management at the study center. Data on the patients' admission, discharge, and clinical and personal backgrounds were obtained from the hospital's health information system.

Figure 1. Diagram of the double triage and telemedicine protocol. COVID-19: coronavirus disease; ED: emergency department; TOCC: travel, occupation, contact, and cluster history; TTAS: Taiwan Triage and Acuity Scale.



Recruitment

We included adult patients aged ≥20 years who were diverted to our COVID-19 emergency clinic during the study period. Patients who refused TIS in the telemedicine group were excluded from this study. Furthermore, to control the confounding effect of evaluation by different physicians, patients not evaluated by the COVID-19 telemedicine team were excluded from the analysis dataset.

Outcomes

The primary outcomes of interest included physicians' total exposure time and total evaluation time. The secondary outcomes were the mean scores of the questionnaire survey used to evaluate the double triage and telemedicine protocol.

Statistical Analysis

Descriptive statistics are presented as mean (SD) for continuous variables, and the intergroup differences in means were analyzed using the independent sample *t* test. The chi-square test was used to assess the associations between categorical variables, namely sex, marital status, education, TOCC history, chronic health conditions, and primary care physician level. To compare the total exposure time and total evaluation time between the two groups, we calculated their intergroup mean differences and 95% CIs. Multiple linear regression models were constructed to adjust for potential confounders and determine the effect of the telemedicine group on each of the outcomes. The identified covariates included age, sex, education, TTAS level, and primary care physician level. The goodness of fit for the multiple linear regression models was examined by computing the R^2 statistic. Regression diagnostics were used to identify problems in the models or data. The answers to each questionnaire item were analyzed using the Mann-Whitney U test and are presented as mean scores. A two-tailed *P* value ≤.05 was considered to be statistically significant. All statistical analyses were conducted using SAS version 9.4 (SAS Institute).

Results

Characteristics of the Study Participants

We initially enrolled 707 adult ED patients in the study, of whom 203 (28.7%) were excluded from the study because of high TTAS levels (I and II). Before implementing the TIS, 342 patients were interviewed, of whom 237 (69.3%) were not interviewed by the telemedicine team. After the introduction of the TIS, 162 patients were interviewed, including 1 patient who refused the TIS and 68 others who were not interviewed by the telemedicine team. We also excluded all patients who were not interviewed by the telemedicine team and those who refused the TIS. Finally, 93 patients were included in the telemedicine group for analysis, compared with 105 patients in the conventional group (Figure 2).

The clinical characteristics of the patients are presented in Table 1. Compared to the conventional group, the telemedicine group had significantly higher rates of patients with an education level of senior high school or lower (31/93, 33.3%, vs 16/105, 15.2%; *P*=.003), TTAS triage level III (76/93, 81.7%, vs 58/105, 55.2%; *P*<.001), and cardiovascular diseases (8/93, 8.6%, vs 1/105, 1.0%; *P*=.014). The telemedicine group had a lower rate of patients with a travel history than the conventional group (26/93, 28.0%, vs 56/105, 53.3%; *P*<.001). The rate of resident doctors conducting interviews with patients in the telemedicine group was higher than that in the conventional group (39/93, 41.9%, vs 17/105, 16.2%; *P*<.001).

The mean age showed no significant difference between the telemedicine group and the conventional group (mean 39.8 years, SD 17.1, vs mean 38.4 years, SD 25.1; *P*=.65). The two groups did not show any difference in terms of the rate of male patients (41/93, 44.1%, in the telemedicine group vs 44/105, 41.9%, in the conventional group; *P*=.76) or that of married patients (22/93, 23.7%, in the telemedicine group vs 21/105, 20%, in the conventional group; *P*=.53). Regarding comorbidities, the rates of patients with diabetes (8/93, 8.6%, vs 2/105, 1.9%; *P*=.048), chronic renal disease (4/93, 4.3%, vs. 0/105, 0.0%; *P*=.047), and cardiovascular diseases (8/93, 8.6%, vs 1/105, 1.0%; *P*=.014) were significantly higher in the telemedicine group than in the conventional group. Meanwhile, no significant discrepancies were observed in the other rates.

Figure 2. Flowchart of patient disposition. COVID-19: coronavirus disease; ED: emergency department; TTAS: Taiwan Triage and Acuity Scale.

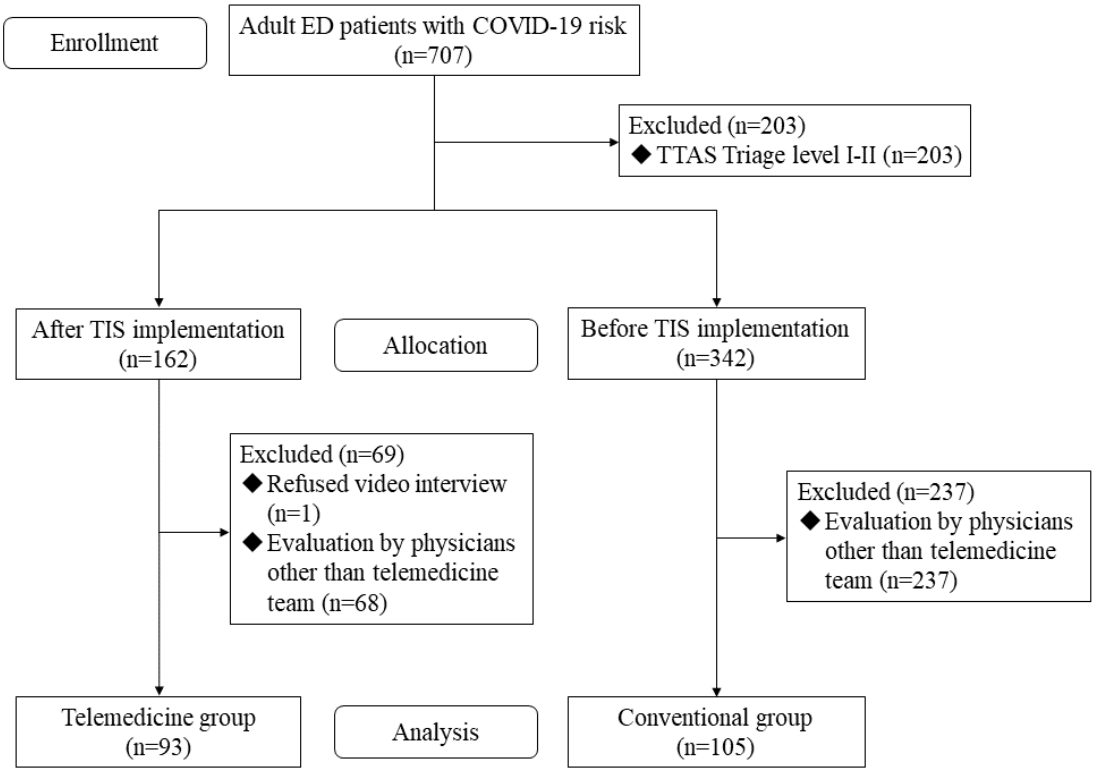


Table 1. Baseline demographic and clinical characteristics of patients in the telemedicine and conventional groups (N=198).

Characteristic	Telemedicine group (n=93)	Conventional group (n=105)	*P* value
Age (years), mean (SD)	39.8 (17.1)	38.4 (25.1)	.65

[d] Hospitalized patients are excluded.

Comparison of the Total Exposure Time, Total Evaluation Time, and 72-Hour Revisit Rate Between the Telemedicine Group and the Conventional Group

The total exposure time and total evaluation time were compared to estimate the benefits of the implementation of the double triage and telemedicine protocol (Figure 3). The total exposure time in the telemedicine group was significantly shorter than that in the conventional group (4.7 minutes, SD 2.4, vs. 8.9 minutes, SD 4.3; *P*<.001). In contrast, the total evaluation time in the telemedicine group was longer than that in the conventional group (12.2 minutes, SD 3.5, vs 8.9 minutes, SD 4.3; *P*<.001). To evaluate the quality of interviews, the two groups were compared in terms of the 72-hour ED revisit rate.

The analysis did not show a statistically significant difference in this rate between the groups (2/93, 2.7%, in the telemedicine group vs 0/105, 0.0%, in the conventional group; *P*=.50) (Table 1). The crude and adjusted mean difference estimates of the total exposure time and total evaluation time between the two groups are shown in Table 2. After adjusting for age, gender, triage level, educational status, and primary care physician level, we found that the total exposure time in the telemedicine group was 4.6 minutes shorter (95% CI −5.7 to −3.5, *P*<.001) than that in the conventional group. However, the total evaluation time in the telemedicine group was 2.8 minutes longer (95% CI −1.6 to −4.0; *P*<.001) than in the conventional group.

Figure 3. Box plot of the differences in the total exposure time and the total evaluation time between the telemedicine and conventional groups.

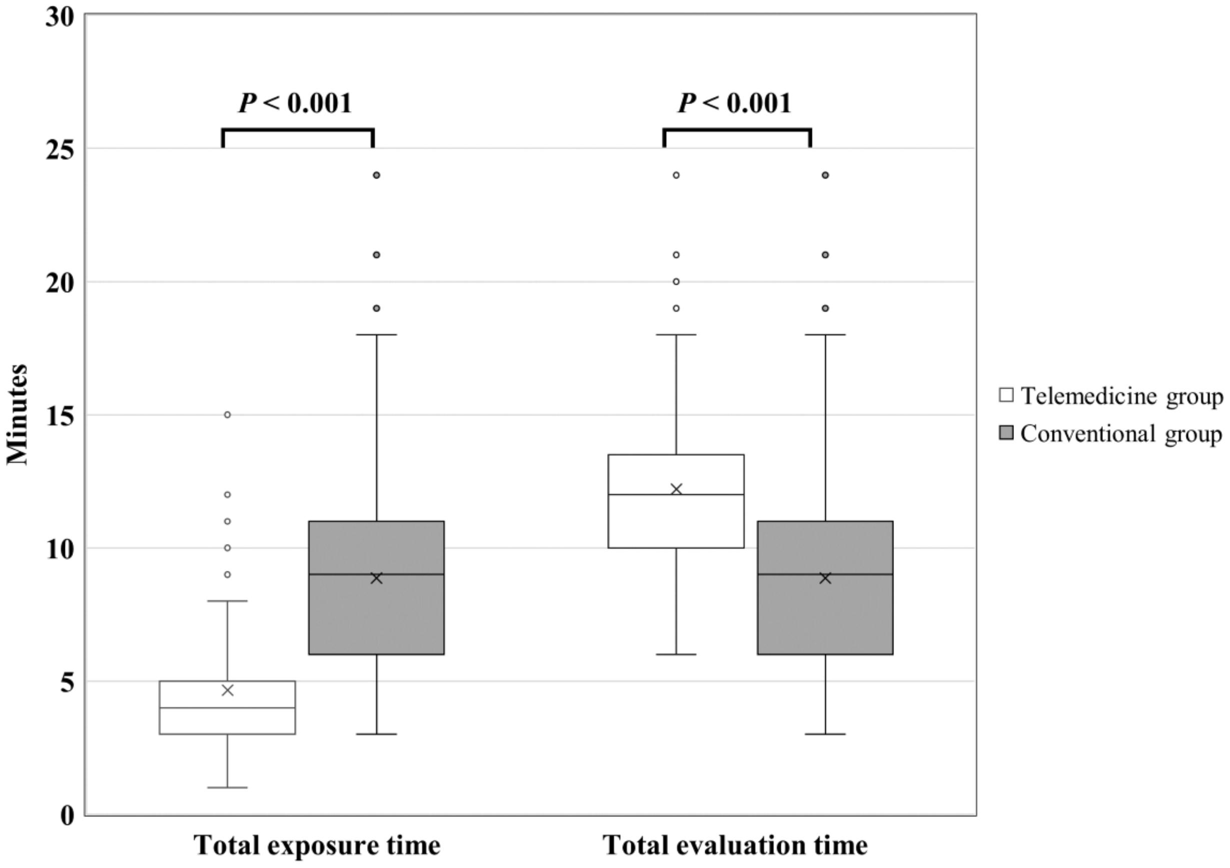

Table 2. Estimates of the crude and adjusted mean differences in the total evaluation time and total exposure time in minutes between the telemedicine and conventional groups.

Outcome	Telemedicine group (n=93), mean (SD)	Conventional group (n=105), mean (SD)	Mean difference estimate[a]		95% CI		*P* value	
			Crude	Adjusted[b]	Crude	Adjusted	Crude	Adjusted
Total exposure time	4.7 (2.4)	8.9 (4.3)	–4.2	–4.6	–5.2 to –3.2	–5.7 to –3.5	<.001	<.001
Total evaluation time	12.2 (3.5)	8.9 (4.3)	3.3	2.8	2.2 to 4.4	1.6 to 4.0	<.001	<.001

[a] The conventional group estimate was subtracted from the telemedicine group estimate.

[b] The model was adjusted for age, gender, triage level, educational status, and primary care physician level.

Comparison of the Mean Scores of the Questionnaire Survey Between the Telemedicine Group and the Conventional Group

Table 3 compares the mean scores of the questionnaire survey between the telemedicine group and the conventional group. Regarding the quality of interpreting imaging and laboratory studies (Question 4), the mean scores for the telemedicine group and the conventional group were 4.7/5 and 4.5/5, respectively (*P*=.07). The scores in relation to acceptance, safety, and satisfaction with the telemedicine protocol were all 4.7/5. The overall patient satisfaction with ED visits did not significantly differ between the two groups (mean score 4.6 vs 4.5, *P*=.33). There were no intergroup differences in the other variables (Table 3).

Table 3. Numbers of respondents by point of the 5-point Likert scale and mean scores of the telemedicine and conventional groups.

Discussion

Principal Results

This study shows that the double triage and telemedicine protocol in the ED could reduce physicians' time of exposure to patients who pose a risk of COVID-19 transmission without compromising patient satisfaction. The time of direct exposure to individual patients in the telemedicine group could be 39% to 64% of that in the conventional group. During the COVID-19 pandemic, our protocol could effectively protect our health care workers from contracting infections in the ED. Moreover, wearing PPE has been shown to constrict mobility and vision and cause heat stress and dehydration, especially in hot weather [33]. This protocol could therefore alleviate the workload and stress of health care workers. However, the total evaluation time in the telemedicine group was longer than that in the conventional group; this may be due to the fact that physicians spent more time communicating with and providing explanations to patients. Our protocol provided a safer and more comfortable interview environment than the conventional method.

Limitations

Our study has some limitations that must be addressed. First, it was a retrospective study using prospectively collected data. Confounding factors during this period, including policy changes, patient characteristics, medical resources, and laboratory examination, may have affected the study results. However, the patients in both the telemedicine group and the conventional group were relatively comparable. The policy in

Taiwan and the criteria of reporting remained roughly unchanged, leading to small confounding effects of time and other policy factors. Second, our patients were relatively young, and telecommunication use was quite common among them; this explains their high familiarity with and acceptance of video interviews. Further studies should therefore investigate the feasibility and benefits of telemedicine among older adults. However, in our COVID-19 emergency clinic, a nurse was assigned to assist patients in receiving video calls if needed, and the patients' families were allowed to accompany them in the clinic and could also help them use the TIS. These mechanisms facilitated the efficient functioning of the system. Third, in our study, 203 patients were excluded due to high TTAS levels. The feasibility of telemedicine for these patients was not investigated. Because these patients are usually in critical condition, face-to-face emergent management may be necessary in clinical scenarios. The possible application of telemedicine with critical patients should be further developed and examined. Fourth, the study was conducted at a single ED in Taiwan. Therefore, the generalizability of the novel model has not been confirmed. Furthermore, the cultural differences between Taiwan and other countries should be considered to ascertain the effectiveness of the proposed model.

Comparison With Prior Work

The double triage method in our protocol facilitated the use of a TIS. The epidemic of an emerging infectious disease may cause a surge of patients in EDs due to clinical symptoms or fear of the disease. This may overwhelm the health care capacity of overcrowded EDs and aggravate the risk of cross infection in hospitals [34]. The CDC has suggested mandatory rapid, safe triage and isolation of patients with symptoms of COVID-19 in EDs for infection control. On admission, all patients should be surveyed about the presence of fever, symptoms of COVID-19, or contact with suspected COVID-19 cases. Patients with symptoms of COVID-19 should be isolated for examination in a separate, well-ventilated space [7]. In Taiwan, we adapted our response to the COVID-19 outbreak based on our experience with SARS in 2003, whereby early identification of patients suspected of having COVID-19 through "triage screening" could help prevent in-hospital transmission [34]. Our ED developed a double triage method to survey suspected patients with COVID-19 and separated them from others. Moreover, this double triage method helped identify patients eligible for telemedicine interviews. For suspected patients with COVID-19 in critical condition, physicians should immediately proceed to face-to-face evaluation and provide them with resuscitation. However, telemedicine interviews could be a safe alternative to face-to-face interviews for patients in stable condition. The protocol described in our study may provide a practical and feasible strategy for other EDs to improve their infection control measures.

Telemedicine has long been used to provide medical care in remote areas and has proved to be beneficial in infection control and management. The published literature demonstrates that telemedicine can increase access to care, with high patient satisfaction, improved outcomes, and reduced costs [35]. Furthermore, the Infectious Diseases Society of America has issued a position statement on telehealth that outlines the various uses of telemedicine and telehealth and supports the appropriate use of telehealth in clinical care, research, and education [36]. Some applications for infection control have been reported in the past decades [19,23], such as telemonitoring of asymptomatic individuals identified as case contacts during the Ebola virus disease outbreak in Africa in 2014. Other applications include caring for symptomatic cases that require isolation (Taiwan during the SARS epidemic in 2003 and the H1N1 influenza pandemic in 2009), tele-expert consultation, and tending patients without access to health care facilities (the MERS epidemic in Korea in 2015). In the current COVID-19 pandemic, many countries are accelerating their transformation to the virtual care interface [37]. Telemedicine, particularly video consultations, has been promoted and scaled up to reduce the risk of transmission. However, almost all existing evidence pertains to highly selected samples of outpatients with chronic, stable conditions. It is largely irrelevant to the current escalating situation that involves patients with an acute and potentially serious illness. Our study showed that telemedicine is feasible and can benefit both infection control and the provision of quality care for suggested COVID-19 patients. Our protocol involves the novel synchronous application of telemedicine for infection control.

The use of video interviews in our TIS had certain advantages over telephonic or conventional methods. Through face-to-face communication, we can directly confirm the identity of patients in routine practice and examine their general appearance and respiratory status. Moreover, the telemedicine system has a share function that can help physicians to simultaneously send high-quality images, laboratory data, and health information to their patients. Notably, our study results showed that the telemedicine group had a more favorable impression of the quality of images and interpretation of laboratory studies than the conventional group, although no statistical significance was observed.

Certain concerns exist about the feasibility and acceptance of telemedicine, especially in the context of the pandemic [24,27]. In this study, we evaluated patients' perception and acceptance of telemedicine, and the results indicated that both groups showed similar overall satisfaction with the quality of interviews. With regard to the perception of stress, discrimination, and privacy, there were no significant differences between the groups. In fact, real-time video interviews may reduce patients' anxiety and physicians' stress.

Conclusions

The implementation of a double triage and telemedicine protocol during the COVID-19 pandemic has high potential to improve infection control. Our study preliminarily validated a promising model in the ED to minimize physicians' direct contact with non-critical suspected COVID-19 patients during evaluation. During the pandemic, this model could help protect critical medical personnel in the health care system from unnecessary exposure and further prevent overwhelming of the health care system.

Authors' Contributions

CHL, WPT, JLW, JT, and MTC conceived and designed the studies. CHL, HNO, HYL, YYC, CHW, and JWC contributed to the acquisition of the data. CHL and WPT contributed to the analysis of the data. The manuscript was drafted by CHL, WPT, CCC, CHH, and SCC. CCC, CHH, and SCC supervised the trial and data collection.

Conflicts of Interest

None declared.

Abstract

Background: During the coronavirus disease (COVID-19) pandemic, patients with cancer in rural settings and distant geographical areas will be affected the most by curfews. Virtual management (telemedicine) has been shown to reduce health costs and improve access to care.

Objective: The aim of this survey is to understand oncologists' awareness of and views on virtual management, challenges, and preferences, as well as their priorities regarding the prescribing of anticancer treatments during the COVID-19 pandemic.

Methods: We created a self-administrated electronic survey about the virtual management of patients with cancer during the COVID-19 pandemic. We evaluated its clinical sensibility and pilot tested the instrument. We surveyed practicing oncologists in Gulf and Arab countries using snowball sampling via emails and social media networks. Reminders were sent 1 and 2 weeks later using SurveyMonkey.

Results: We received 222 responses from validated oncologists from April 2-22, 2020. An awareness of virtual clinics, virtual multidisciplinary teams, and virtual prescriptions was reported by 182 (82%), 175 (79%), and 166 (75%) respondents, respectively. Reported challenges associated with virtual management were the lack of physical exam (n=134, 60%), patients' awareness and access (n=131, 59%), the lack of physical attendance of patients (n=93, 42%), information technology (IT) support (n=82, 37%), and the safety of virtual management (n=78, 35%). Overall, 111 (50%) and 107 (48%) oncologists did not prefer the virtual prescription of chemotherapy and novel immunotherapy, respectively. However, 188 (85%), 165 (74%), and 127 (57%) oncologists preferred the virtual prescription of hormonal therapy, bone modifying agents, and targeted therapy, respectively. In total, 184 (83%), 183 (83%), and 176 (80%) oncologists preferred to continue neoadjuvant, adjuvant, and perioperative treatments, respectively. Overall, 118 (53%) respondents preferred to continue first-line palliative treatment, in contrast to 68 (30%) and 47 (21%) respondents indicating a preference to interrupt second- and third-line palliative treatment, respectively. For administration of virtual prescriptions, all respondents preferred the oral route and 118 (53%) preferred the subcutaneous route. In contrast, 193 (87%) did not prefer the intravenous route for virtual prescriptions. Overall, 102 (46%) oncologists responded that they would “definitely” prefer to manage patients with cancer virtually.

Conclusions: Oncologists have a high level of awareness of virtual management. Although their survey responses indicated that second- and third-line palliative treatments should be interrupted, they stated that neoadjuvant, adjuvant, perioperative, and first-line palliative treatments should continue. Our results confirm that oncologists’ views on the priority of anticancer treatments are consistent with the evolving literature during the COVID-19 pandemic. Challenges to virtual management should be addressed to improve the care of patients with cancer.

KEYWORDS

teleoncology; telemedicine; eHealth; cancer; COVID-19; public health

Introduction

In December 2019, a cluster of patients with severe pneumonia were identified in Wuhan, China, and a novel coronavirus disease (COVID-19) was discovered [1]. This disease can range from asymptomatic infection to severe respiratory distress syndrome and death. The World Health Organization has declared the COVID-19 outbreak a pandemic. As of April 25, 2020, a total of 2,719,897 cases and 187,705 confirmed deaths have been reported across more than 200 countries [2].

This highly contagious virus is characterized by rapid human-to-human transmission [3], and risk factors for mortality include older age and comorbidities [4]. Patients with cancer are susceptible to COVID-19 infections because of the immunosuppressive effect of cancer treatments like chemotherapy or surgery [5], and hence have a poorer prognosis.

Teleoncology is the application of telemedicine to oncology. It has the potential to enhance access to and improve the quality of clinical cancer care [6]. Patients from rural and distant geographical areas will be most affected by curfews. Virtual management (telemedicine) has been shown to reduce health costs and improve access to care. There are examples of successful technology applications for survivorship care, palliative care, symptoms management, and supervision of satellite anticancer infusion suites [7-9]. An updated conceptual framework of telemedicine during the COVID-19 pandemic has been defined and could be applied at larger scale to improve national public health responses [10]. Further reduction of patients’ exposure to infection could be achieved by replacing certain clinic visits with virtual clinics (via videoconference or telephone) to minimize hospital visits. This allows oncologists to defer routine follow-ups, assess patients who can continue certain anticancer treatments (such as chemotherapy, immunotherapy, targeted therapy, or hormonal therapy), and continue cancer care virtually.

Multidisciplinary tumor boards ensure the selection of high priority curative cases and improve outcomes without delays or interruptions of cancer care. This could be continued virtually, depending on availability and the capacity of the health care system.

Virtual prescription and delivery of drugs is an alternative way to manage patients with cancer, especially when delivering drugs to their home via courier services or to health facilities near their home to avoid interruption of treatments, provided that this service is logistically feasible and available.

Oncologists need to weigh the risks and benefits of anticancer treatments during the pandemic. Caring for patients with cancer during this period is challenging. Jeopardizing safety by exposing patients to infection when they leave their home to visit oncology clinics and receive anticancer treatments may lead to greater risks of potential adverse events.

There is a limited number of studies to guide oncologists on how to manage patients with cancer during a pandemic. In this survey, we aim to report the views of oncologists on virtual management (awareness, challenges, and preferences) and their priorities when prescribing anticancer treatments during the COVID-19 pandemic. This could help oncologists conduct future controlled studies or trials, and guide health systems on areas of improvement in supportive infrastructure.

Methods

Study Design

This study presents the findings of a web-based questionnaire submitted to licensed oncologists in the Gulf and Arab regions.

Study Population

We included study subjects who met the following criteria: licensed practicing oncologists in the Gulf or Arab regions who are treating adult or pediatric patients, and involved in the care of patients with cancer using anticancer treatments (eg, chemotherapy, novel immunotherapy, targeted therapy, hormonal therapy, and bone modifying agents). Exclusion criteria were nononcologists and trainees.

Study Procedures

We used a nonprobability snowball sampling [11] design. To identify our target population, we contacted oncologists who are members of established national oncology associations and societies in the region to distribute and participate in the survey. If this was not applicable, we contacted 1 to 2 regional oncologists per area to distribute and participate in the survey. We used email and WhatsApp, the most popular social media network in the region, to reach oncologists.

Development of the Instrument

We generated our survey instrument using rigorous survey development and testing methods [12]. Items were selected based on a literature review, as well as email and telephone correspondence. In total, 5 experts in the field of oncology and hematology from 3 countries extensively discussed the topic and reviewed items until no further questions were missed. Items were nominated and then ranked by expert oncologists to reach a consensus on the selected items. Further review was done by methodology and content experts to eliminate redundant items using binary responses (exclude and include). We aimed to have a survey that is simple, succinct, and easy to understand. During the construction of the survey, we grouped the items into domains we wanted to explore and then refined the questions [13]. The self-administered survey (Multimedia Appendix 1) consisted of 20 items that focused on 4 domains: characteristics of oncologists; COVID-19 pandemic measures; virtual management and oncologists' views on virtual management; and the priority of prescribing anticancer treatments.

The structured response formats used in this survey included binary (yes/no), nominal, and ordinal responses. Other options were also allowed, including "Undetermined," "Other," and any other comments with free text to capture unanticipated responses. Respondents received electronic links accompanied with concise instructions, a cover letter is stating the background, the objectives of the survey, the target population, and a request to participate voluntarily (that stated their answers will be kept anonymously using SurveyMonkey).

Testing of the Instrument

During pretesting and pilot testing, questions were reviewed by 3 colleagues specializing in oncology to check the consistency and appropriateness of the questions designed by investigators [14,15], and were then reviewed by nonexpert colleagues to assess the dynamics, flow, and accessibility. In total, 5 oncology members carried out pilot testing of the instrument with minor modifications. We also conducted a clinical sensibility assessment to evaluate the comprehensiveness, clarity, and face validity of our instrument on a scale of 1 to 5. For this assessment, we invited 5 colleagues with methodologic and oncology expertise. The results of the clinical sensibility assessment, which used the mean scores indicated on a 5-point scale, suggested that the instrument had face validity (4.4), content validity (4.2), clarity (4.6), and discriminability (4.3).

Administration of the Instrument

After the approval of the King Abdullah Medical City Institutional Research Board, we sent the questionnaires electronically to licensed oncologists in the region who treat adult or pediatric patients. Oncologist types included medical oncologists, malignant hematologists, pediatric oncologists, clinical oncologists, and hemato-oncologists.

Study Duration and Timeline

On April 2, 2020, we sent participants an embedded link to the web-based survey on SurveyMonkey (along with an electronic cover letter with instructions to complete the survey) via emails, text messages, and social media such as Facebook, Twitter, and WhatsApp. Primary investigators contacted the oncology members of national associations and societies in the region to participate and create a broad distribution network. Regional oncologists distributed the survey link to their regional members and network; there were no incentives provided. We sent reminders 1 and 2 weeks later, and we closed the survey on April 22.

Statistical Analysis

Descriptive statistics were used to summarize data, and synthesize and report the views of oncologists. Description of the data also included proportions, frequencies, means, and standard deviation for continuous variables when appropriate.

Results

We received 222 completed surveys from 10 different countries in the region (Table 1). Overall, 71% (n=157) of respondents were males. Respondents have been in oncology practice for a median of 10 years. The top respondent specialty was medical oncology (n=97, 44%). Saudi Arabia is the country of current practice for 47% (n=105) of respondents. The remaining respondents practice in Arab countries. In total, 74% (n=163) practice in the public health sector and 97% (n=215) practice in urban locations.

The 222 respondents were asked whether there are any diagnosed COVID-19 cases in their country, city, hospital, and department (Table 2). In total, 97% (n=215), 97% (n=215), and 77% (n=172) of respondents indicated that there were cases in the country, city, and hospital in which they practice, respectively. In total, 18% (n=41) of respondents reported COVID-19 cases among their own patients.

Overall, out of 222 respondents, 91% (n=210) regularly attend multidisciplinary tumor boards with a monthly multidisciplinary tumor board number of 4 or more reported by 56% (n=125). In total, 82% (n=182), 79% (n=175), and 75% (n=166) of respondents were aware of virtual clinics, virtual multidisciplinary tumor boards, and virtual prescription, respectively (Table 3). Additionally, 59% (n=131), 64% (n=142), and 64% (n=143) of respondents have been personally involved in a virtual clinic, virtual multidisciplinary tumor board, and virtual prescription and delivery of drugs, respectively. Challenges faced by respondents regarding virtual management were the lack of physical examination (n=134, 60%), patients' awareness and access (n=131, 59%), the lack of physical attendance of patients (n=93, 42%), information technology (IT) support (n=82, 37%), and safety (n=78, 35%). Overall, 5% (n=10) had other comments such as the lack of a direct doctor-patient encounter, medicolegal aspects, psychological support, and privacy (Figure 1).

Table 1. Characteristics of respondents (N=222).

Characteristics	Respondents
Gender, n (%)	
Male	157 (71)
Female	65 (29)
Years in oncology practice, median	10
Specialty, n (%)	
Medical oncologist	97 (44)
Hematologist	31 (14)
Oncologist and hematologist	29 (13)
Clinical oncologist	28 (13)
Pediatric oncologist	27 (12)
Other	10 (5)
Practicing country, n (%)	
Saudi Arabia	105 (47)
United Arab Emirates	38 (17)
Egypt	18 (8)
Tunisia	13 (6)
Kuwait	10 (5)
Lebanon	8 (4)
Bahrain	7 (3)
Oman	5 (2)
Jordan	4 (2)
Other	12 (5)
Practice setting, n (%)	
Public health care	163 (73)
Private health care	33 (15)

Rural	7 (3)

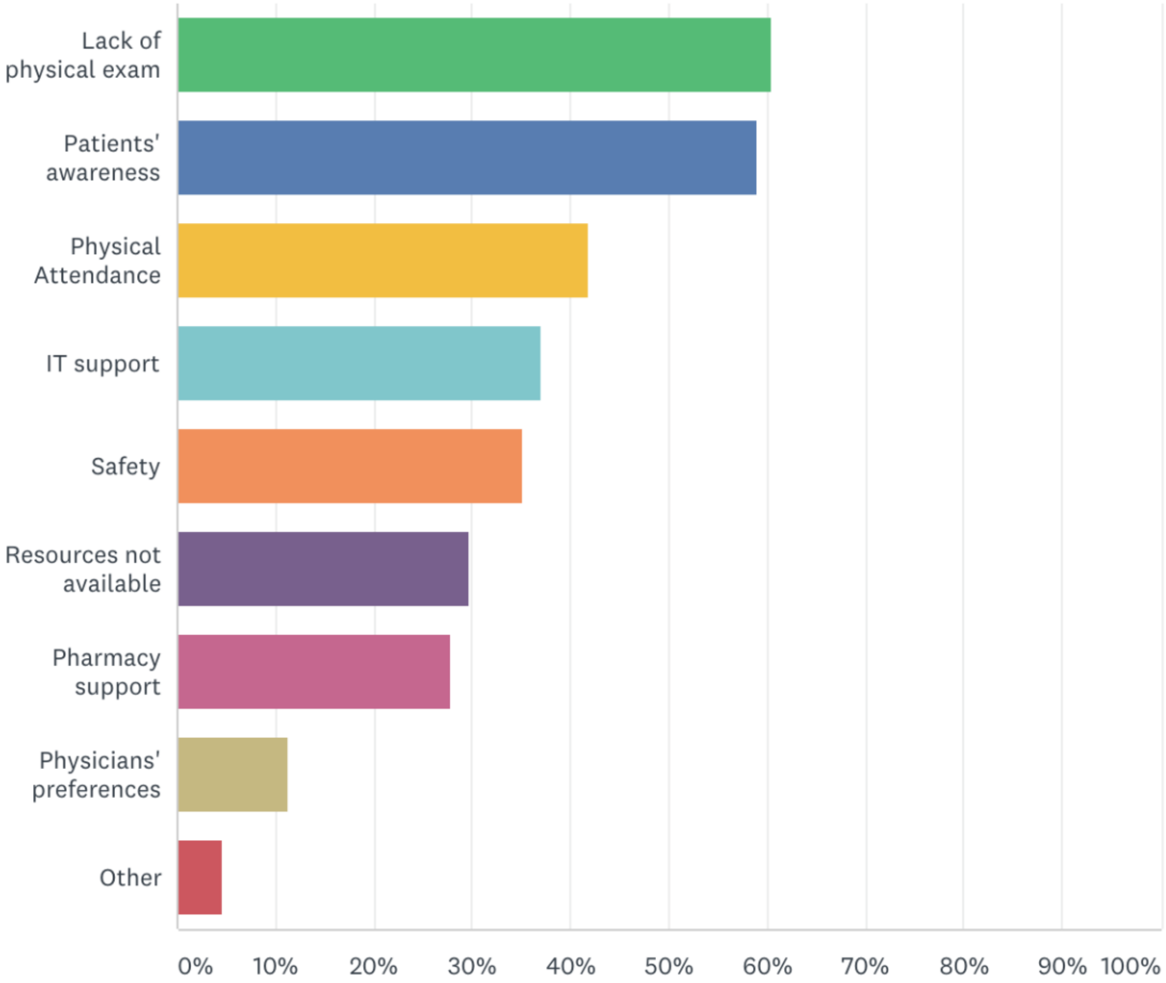
Table 2. Respondents' responses to questions about confirmed coronavirus disease cases.

Questions	Responses		
	Yes, n (%)	No, n (%)	Unknown, n (%)
Are there coronavirus disease cases in the country in which you are practicing?	215 (97)	6 (2.5)	1 (0.5)
Are there coronavirus disease cases in the city in which you are practicing?	215 (97)	6 (2.5)	1 (0.5)
Are there coronavirus disease cases in the hospital in which you are practicing?	172 (77)	41 (18)	9 (4)
Are there coronavirus disease cases in your department?	54 (24)	152 (68)	16 (7)
Are there coronavirus disease cases among your own patients?	41 (18)	165 (74)	16 (7)

Table 3. Respondents' reported awareness about virtual management.

Virtual management type	Awareness	Personally involved
Virtual clinic	182 (82)	131 (59)
Virtual tumor board	175 (79)	142 (64)
Virtual prescription and delivery of drugs	166 (75)	143 (64)

Figure 1. Respondents' reported challenges regarding virtual management. Respondents were requested to select more than one response, if applicable. IT: information technology.



When asked about the priority of prescribing anticancer treatments during the COVID-19 pandemic, 50% (n=111) and 48% (n=107) of the 222 surveyed oncologists indicated they did not prefer the virtual prescription of chemotherapy and novel immunotherapy, respectively (Figure 2). However, 85% (n=188), 74% (n=165), and 57% (n=127) of oncologists preferred the virtual prescription of hormonal therapy, bone modifying agents, and targeted therapy, respectively (Table 4).

When prescribing treatments virtually, all 222 respondents preferred treatments that are administered by the oral route and 53% (n=118) preferred the subcutaneous route. In contrast, 87% (n=193) of oncologists did not prefer the intravenous route for virtual prescriptions (Figure 3).

Of 222 respondents, more than 80% of oncologists preferred to continue neoadjuvant (n=184, 83%), adjuvant (n=183, 83%), and perioperative (n=176, 80%) treatments (Table 5). In addition, 53% (n=118) preferred to continue first-line palliative treatment. In contrast, 30% (n=68) and 21% (n=47) preferred to interrupt second- and third-line palliative treatment, respectively (Figure 4).

When the 222 oncologists were asked if they prefer to manage cases virtually, 46% (n=102) responded "Definitely," 30% (n=67) responded "Probably," 10% (n=22) answered "Neutral," 11% (n=25) said "Probably not," and 3% (n=6) said "Definitely not" (Figure 5). In total, 40% (n=87) of respondents reported that patients were satisfied with virtual management, while 18% (n=40) indicated patients were not satisfied, and 43% (n=95) answered "I don't know." Overall, 36% (n=80) of respondents indicated they are likely to continue virtual management after the pandemic, while 51% (n=112) said they will not, and 14% (n=30) answered "I don't know."

Figure 2. Respondents’ reported anti-cancer treatments that can be prescribed virtually.

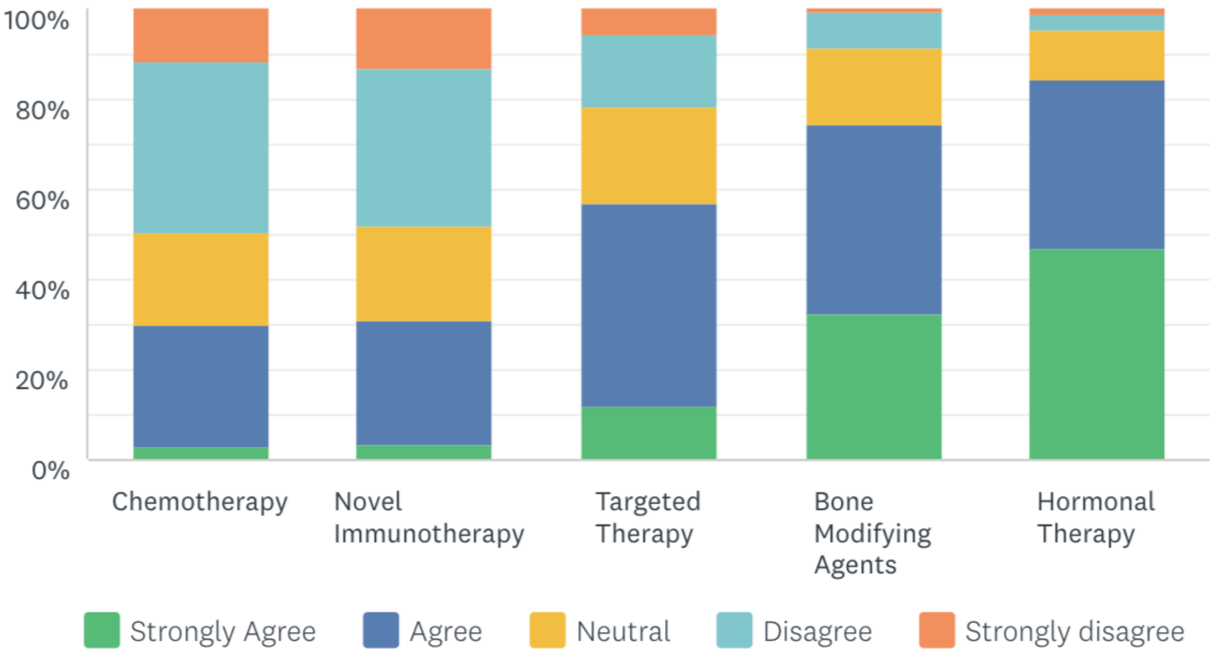


Table 4. Respondents’ reported anticancer treatments that can be prescribed virtually.

Anticancer treatments	Strongly Agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly Disagree, n (%)
Chemotherapy	7 (3)	60 (27)	45 (20)	84 (38)	26 (12)
Novel immunotherapy	8 (4)	61 (27)	46 (21)	78 (35)	29 (13)
Targeted therapy	27 (12)	100 (45)	47 (21)	36 (16)	12 (5)
Hormonal therapy	104 (47)	84 (38)	24 (110)	8 (4)	2 (10)
Bone modifying agents	72 (32)	93 (42)	38 (17)	18 (8)	1 (0.4)

Figure 3. Respondents’ reported anti-cancer treatments that can be prescribed virtually, by route. IV: intravenous. SC: subcutaneous.

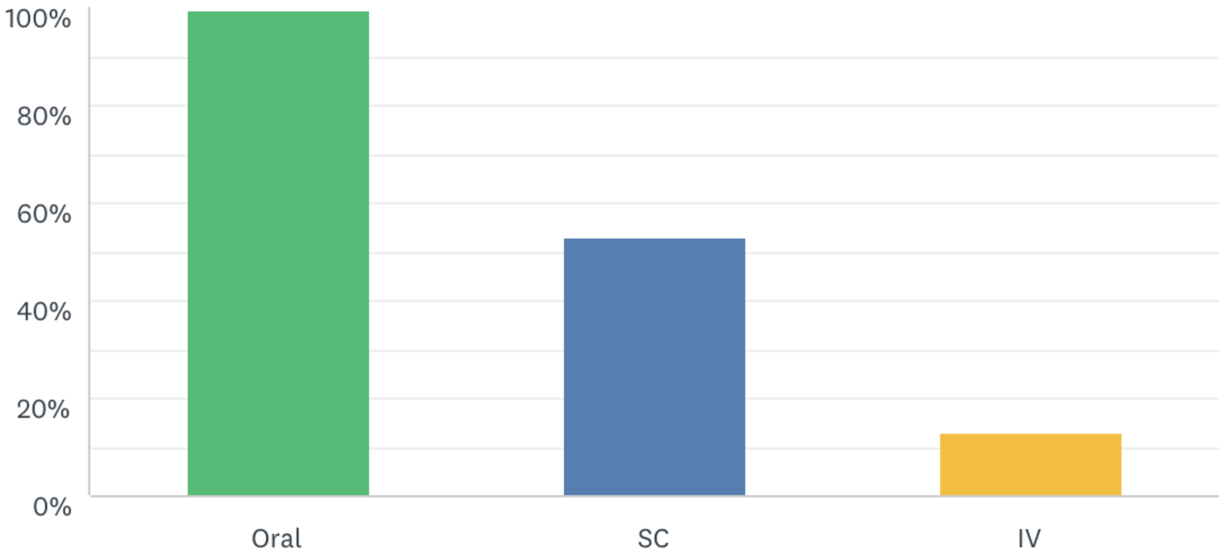

Table 5. Respondents' reported anticancer treatments that should not be interrupted.

Treatments	Strongly Agree, n (%)	Agree, n (%)	Neutral, n (%)	Disagree, n (%)	Strongly Disagree, n (%)
Neoadjuvant	114 (51)	70 (32)	24 (11)	10 (5)	4 (2)
Adjuvant	77 (35)	106 (48)	29 (13)	8 (4)	2 (1)
Perioperative	66 (30)	110 (50)	34 (15)	10 (5)	2 (1)
First-line palliative	25 (11)	93 (42)	75 (34)	27 (12)	2 (1)
Second-line palliative	12 (5)	56 (25)	87 (39)	56 (25)	11 (5)
Third-line palliative	10 (5)	37 (17)	64 (29)	73(33)	38 (17)

Figure 4. Respondents' responses regarding which anti-cancer treatments should not be interrupted.

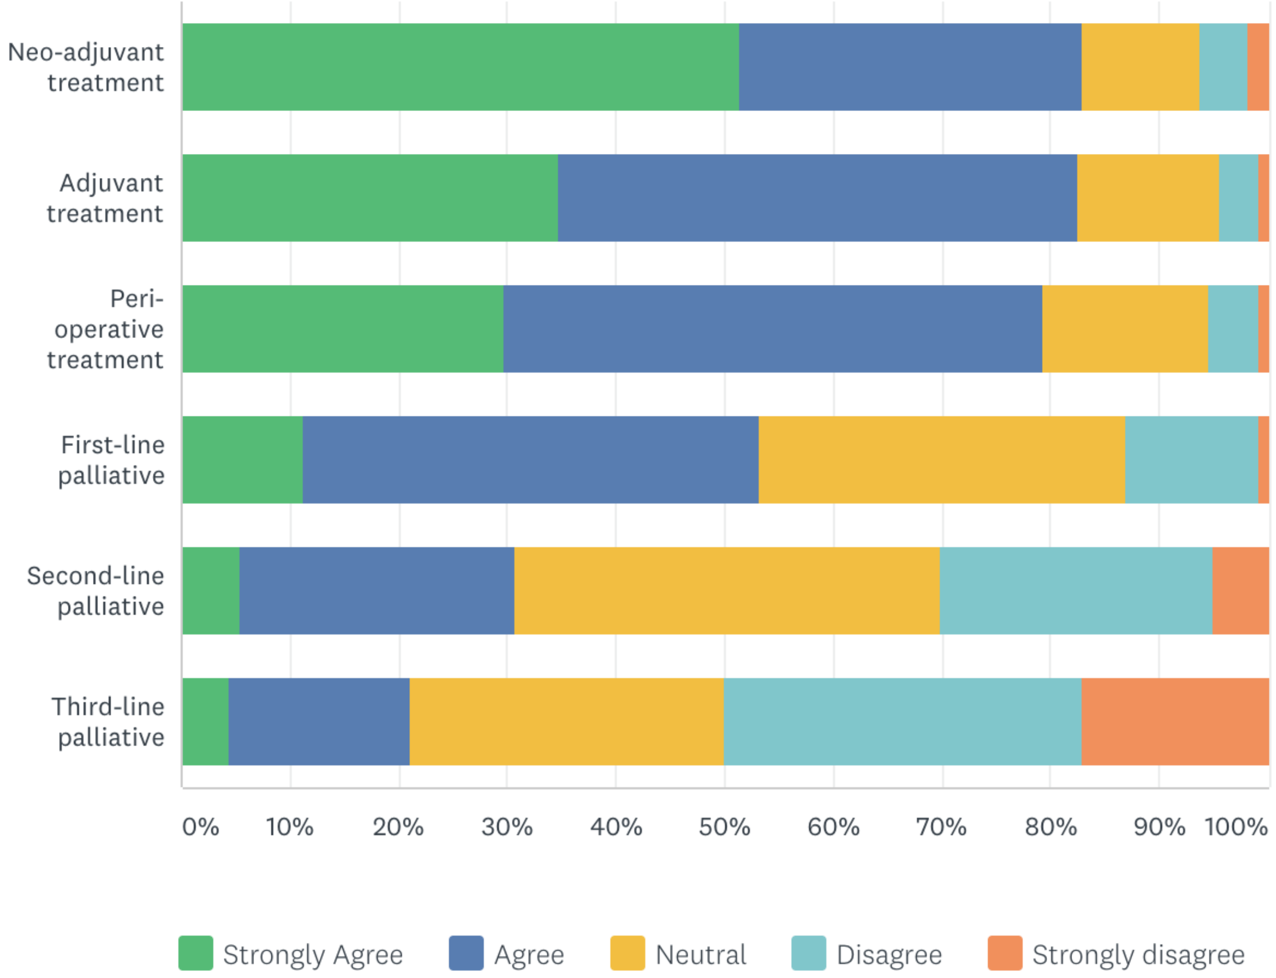

Figure 5. Respondents' responses when asked if they prefer to manage cancer patients virtually.

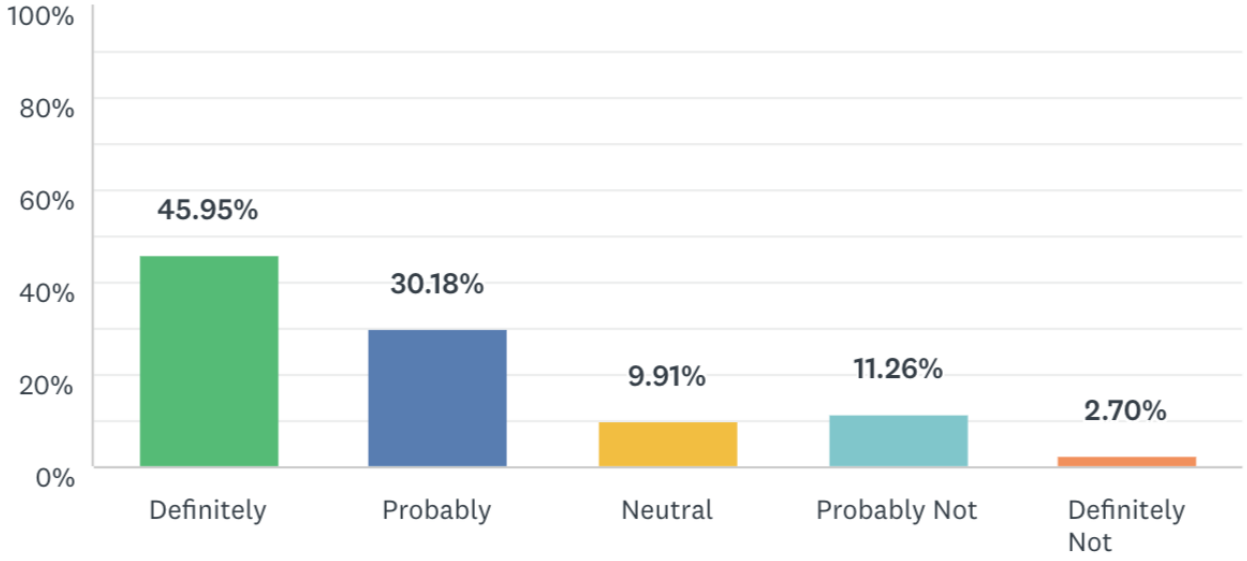

Discussion

Overview

During the COVID-19 curfew, oncologists need to weigh the risks and benefits of anticancer treatments. Patients from distant geographical areas are affected the most. Virtual management (telemedicine) has been shown to reduce health costs and improve access to care. Examples of successful technology applications include symptoms management and supervision of satellite anticancer infusion suites [7]. To our knowledge, oncologists' views about virtual management during the COVID-19 pandemic have not been described previously.

Our work demonstrates that oncologists have a high level of awareness of virtual clinics, virtual multidisciplinary teams, and virtual prescriptions (82%, 79%, and 75%, respectively). However, despite this high level of awareness, oncologists' actual involvement was significantly lower, as shown in Table 3. We presume these differences are related to the major challenges of virtual management faced by respondents, as shown in Figure 1. Challenges mentioned included a lack of physical examination (60%), patient's awareness and access (59%), a lack of physical attendance of patients (42%), IT support (37%), and the safety of virtual management (35%).

Nonetheless, we found that 46% of the surveyed oncologists responded that they "definitely" prefer to manage some cases virtually. However, only 36.0% will continue virtual management after the pandemic; we cannot explain why the proportion is low, although challenges and preferences with virtual management might be potential reasons.

No studies have previously described oncologists' views about the priority of anticancer treatments during the COVID-19 pandemic. The results of our survey demonstrated that more than 80% of oncologists preferred to continue neoadjuvant, adjuvant, and perioperative treatments. Additionally, 53% reported their preference to continue first-line palliative treatment, in contrast to 20% and 30% that preferred to interrupt second- and third-line palliative treatment, respectively. These results are consistent with Hanna et al [16], where the proposed resources utilization, allocation, and prioritization of anticancer treatments indicated a high priority for curative treatments versus a low priority for palliative treatments. Of note, this model has not been tested in clinical studies. Other studies have shown that delaying adjuvant treatments was associated with inferior survival in colon cancer [17] and breast cancer [18].

Changing the drug administration route from intravenous to oral without compromising outcomes has been reported in the literature [19]. In our study, we found that 50% and 48% of oncologists did not prefer the virtual prescription of chemotherapy and novel immunotherapy, respectively; the majority are parenteral drugs. However, 85%, 74%, and 57% of oncologists preferred the virtual prescription of hormonal therapy, bone modifying agents, and targeted therapy, respectively; the majority are oral drugs. All respondents preferred the oral route, in keeping with Hofheinz et al [19], and 53% preferred the subcutaneous route for virtual prescription. In contrast, 87% of oncologists did not prefer the intravenous route for virtual prescription.

This study has several strengths. First, we described the views of oncologists on virtual management and the priority of anticancer treatments during the COVID-19 pandemic, which has not been reported previously. Second, we used a rigorous methodology for our instrument development, validation, and administration, as no appropriate instrument previously existed. Third, we used virtual snowball sampling to identify experts in the field of oncology in the region, as there are no lists or other obvious sources for locating all practicing oncologists who are members of societies or nonmembers. It is difficult to estimate the total size of the sample.

The limitations of our study include that the number of participants in the study was relatively small, and they were mostly from Saudi Arabia. One inherent weakness of this study is its restricted participation to the Arab world, which limits the inferences that can be drawn from the data. Another important limitation is that there were differences in respondent specialties, which included medical oncology, hematology, pediatric oncology; half of the study group specialized in medical oncology. However, we tried to control for this by inviting more respondents to participate. Future research could be done with more specialties and the involvement of oncologists from different geographic regions.

Our study adds to the previous knowledge that oncologists have a high level of awareness about virtual management, although the doctors have lower actual involvement in virtual clinics, virtual multidisciplinary tumor boards, and virtual prescriptions. Our results confirm that oncologists' views on the priority of anticancer treatments are consistent with the evolving literature during the COVID-19 pandemic.

Virtual management could be implemented as an evolving method to manage a selected group of patients with cancer who live in remote locations. Mclean et al [20] showed no differences in outcomes between telehealth and usual care. This would reduce the risk associated with hospital visits and of infection transmisson. Examples of successful implementation include survivorship care, palliative care, symptoms management, and supervision of satellite anticancer infusion suites [7-9]. Similarly, this could be implemented for patients with routine follow-ups who have a low risk of relapse, as well as for patients receiving oral treatment, hormonal treatment, and bone modifying agents.

Challenges to virtual management should be addressed to improve the care of patients with cancer and to enhance oncologists' actual involvement in virtual management. This can be done by improving patients' awareness and access, improving IT support, assessing the safety of virtual management, and finding solutions to the need for physical attendance and physical examination. A number of questions remain unanswered, such as the safety of virtual management. Cancer care is complex and encompasses the need for direct doctor-patient encounters, clinical examination, medicolegal aspects, psychological support, privacy, and adequate infrastructure to support logistics. In addition, virtual management may only be feasible and applicable at some institutions. These are possible avenues for future research and will allow us to understand how these factors translate into the improvement of cancer care.

Taken together, virtual management is an evolving tool for caring for patients with cancer under certain circumstances. If it is implemented in the appropriate venues, it will improve access to care [6] and reduce the health care burden on patients with cancer. Virtual prescription of anticancer treatments during the COVID-19 pandemic has not been addressed before and is worth pursuing in further research.

Conclusions

In this regional survey, we found that oncologists have a high level of awareness about virtual management, with lower actual involvement with virtual clinics, virtual multidisciplinary tumor boards, and virtual prescriptions. Oncologists indicated that second- and third-line palliative treatments should be interrupted, while neoadjuvant, adjuvant, perioperative, and first-line palliative treatments should continue. Our results confirm that oncologists' views on the priority of anticancer treatments are consistent with the evolving literature during the COVID-19 pandemic. Challenges to virtual management should be addressed to improve the care of patients with cancer.

Acknowledgments

The authors wish to thank Roche Products, Saudi Arabia, for supporting the publication fee. We also thank all the oncologists in the MENA (Middle East and North Africa) region who participated in this survey.

Abstract

During the coronavirus disease (COVID-19) pandemic, cardiologists have attempted to minimize risks to their patients by using telehealth to provide continuing care. Rapid implementation of video consultations in outpatient clinics for patients with heart disease can be challenging. We employed a design thinking tool called a customer journey to explore challenges and opportunities when using video communication software in the cardiology department of a regional hospital. Interviews were conducted with 5 patients with implanted devices, a nurse, an information technology manager and two cardiologists. Three lessons were identified based on these challenges and opportunities. Attention should be given to the ease of use of the technology, the meeting features, and the establishment of the connection between the cardiologist and the patient. Further, facilitating the role of an assistant (or virtual assistant) with the video consultation software who can manage the telehealth process may improve the success of video consultations. Employing design thinking to implement video consultations in cardiology and to further implement telehealth is crucial to build a resilient health care system that can address urgent needs beyond the COVID-19 pandemic.

telemedicine; design thinking; cardiology; patient; COVID-19; user experience

Introduction

The coronavirus disease (COVID-19) crisis has challenged health care professionals to rapidly reduce face-to-face consultations. To ensure care continuity, the use of telehealth is recommended [1]. Telehealth refers to the use of electronic services to support a broad range of remote services, such as patient care, education, and monitoring [2]. Many health systems have already invested in telehealth, and some primary care practices in the United States have appeared to adopt telehealth almost instantly [3-5].

In Belgium, cardiologists remotely triaged patients who were originally scheduled for face-to-face consultations; however, many consultations were postponed during the lockdown period. Some patients are afraid to come to the hospital due to the risk of contracting COVID-19. This increases the likelihood that patients will stay at home or postpone consultations despite deteriorating symptoms. In fact, a declining incidence of acute myocardial infarction has been witnessed in the United States during the COVID-19 pandemic [6]. However, early detection of atrial fibrillation is crucial to prevent stroke, which is a leading cause of death globally [7,8]. In addition, early detection of heart failure is necessary to prevent hospitalization and death [9].

Telehealth can help mitigate these risks by enabling continued monitoring of patients. Various telehealth solutions can be leveraged for remote cardiology monitoring [1], such as video communication software and implanted devices. The adoption of these tools is now being facilitated because financial and reimbursement restrictions are being lifted; however, further measures are needed for wider adoption of telehealth [4,10,11].

Given that rapid acceptance of telehealth during COVID-19 is critical, telehealth technologies must be easy to implement and to scale up. To achieve this, we employed design thinking [12,13] to learn from the experiences of a cardiology practice in a regional Belgian hospital where video consultations are rapidly being implemented.

Design Thinking

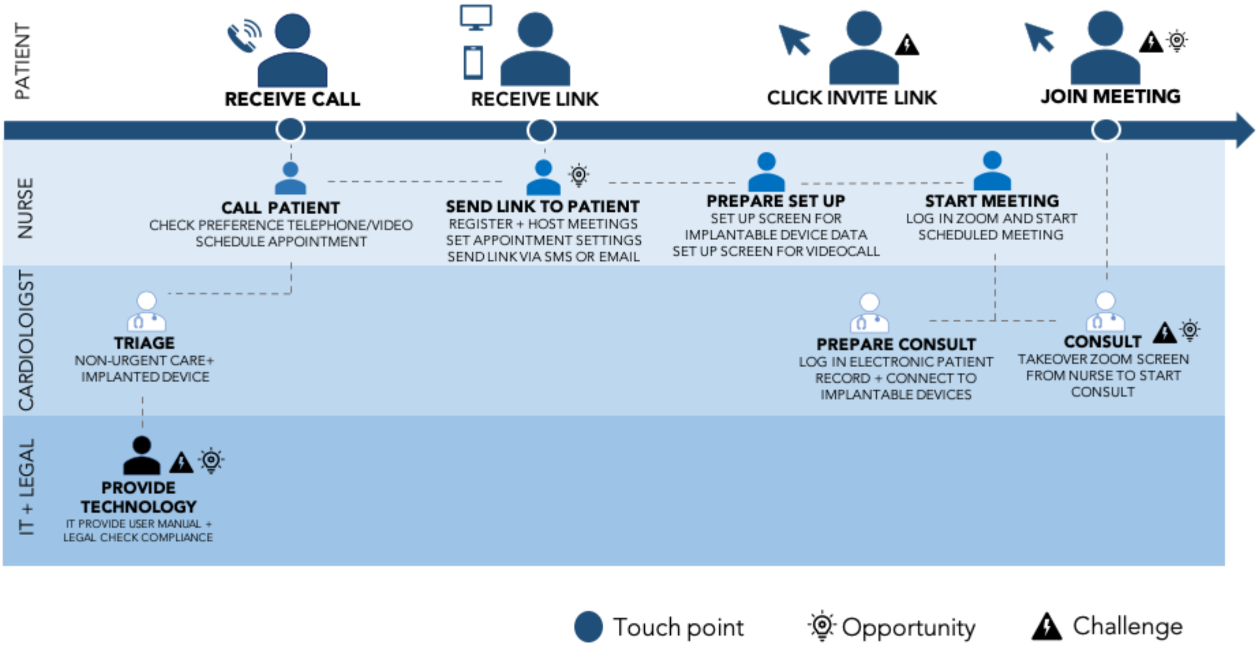
Design thinking aims to identify and solve problems in a systematic and collaborative way [12,13]. Collaborative design methods are widely used to improve electronic health (eHealth) [14], including the development of eHealth to assist heart patients with self-management [15-19]. However, design thinking research focusing on video communication software with heart patients is lacking. We used a design thinking tool called a customer journey to empathize with all stakeholders, identify the challenges facing each stakeholder, and identify opportunities to redesign the service [12]. To develop the customer journey, PV conducted telephone interviews to map the experience of the lead hospital information technology (IT) manager (who liaised with the legal team), a research nurse (KDJ), the treating cardiologist (YV), and the head of the Department of Cardiology (RT). Five patients with an implanted cardioverter-defibrillator device (ICD) were interviewed by a nurse (KDJ) shortly after the end of each video consultation about their experience. The data were analyzed in PowerPoint (Microsoft Corporation).

The treating cardiologist (YV) identified 13 patients with an ICD who were scheduled for face-to-face consultations in the outpatient clinic. The ICD patient population was prioritized because these patients could especially benefit from telehealth due to the opportunity to access their heart monitoring data remotely. These patients did not have any urgent needs, did not require a physical examination with hospital equipment, and had a telephone number on record. Of these 13 patients, 5 (38%, aged 43-64 years) were eligible for a video consultation. Of the 8 patients who were not eligible, 2 (25%) lacked a smartphone or computer, 2 (25%) were not reachable by telephone, 3 (38%) lacked the functionality for remote monitoring, and 1 (13%) had progressed to needing more urgent care.

Challenges and Opportunities for Stakeholders

The customer journey (Figure 1) shows the actions taken by stakeholders in parallel rows and the touch points (blue and white circles) where the patient is in contact with health care professionals. Three areas of challenges (triangles) and opportunities (lightbulbs) are illustrated: the lower left area is related to the provision of technology, the center area is related to inviting the patient to the consultation, and the right area relates to when the patient joins the meeting and the video consultation starts.

Figure 1. Customer journey of a video consultation for a patient with an implanted device. IT: information technology. SMS: short message service.



Video Consultation Technology: Need for Integration, Fewer Steps, and Long-Term Prospects

Available video consultation solutions were explored with the IT and legal teams based on ease of use and suitability for the patient group, short-term implementation for all stakeholders, adaptability, financial constraints, and compliance with the European Union General Data Protection Regulation (GDPR). Skype for Business (Microsoft Corporation) was accessible by all physicians, as it was installed across the hospital on desktop computers. Given its strong security, lack of additional cost, and availability in the hospital, this appeared to be a good option.

However, Skype for Business is a rigid software package that will soon be replaced by Microsoft Teams. Eventually, video communication software will be integrated into the electronic patient record software, as is already the case in larger academic hospitals in Belgium. Therefore, Skype for Business demonstrated little adaptability and no long-term prospects. Given that it would still be necessary to provide training to health care professionals and patients, other software was considered. No solution could be identified that integrated video communication software with ICD monitoring, which would suit the patients best (challenge). However, other video communication software was tested, including Zoom (Basic account, Zoom Video Communications Inc). The cardiologist was given remote training on Zoom by the researchers while they simultaneously tested its functionalities compared to Skype for Business. They considered that Zoom was easier to use, as the patient would not need to install a software package on their computer and would need to complete fewer steps to use the desktop version or smartphone app (opportunity). The IT and legal teams had heavy workloads and were only able to provide limited technical support, such as a user manual.

Receiving the Meeting Invitation: Adapting the Settings

The nurse first called each patient to make an appointment for a consultation by telephone or video. If the patient preferred a video call, they were asked if they would like to receive the call through an app on their smartphone or on a desktop computer. Video consultation appointments were made using Zoom. To reduce the workload for the cardiologist, the nurse was responsible for making appointments and was then made the host of each meeting (opportunity). Here, opportunities were identified to improve safety by changing meeting settings with a password. Other settings were changed to reduce the number of steps the patient was required to take; immediate activation of the camera was enabled when joining a meeting, bypassing the waiting room function. After these steps were completed, a link with the invitation to the video consultation was sent to the patient. Here, another opportunity was identified to circumvent email use if the patient planned to use the app by sending them the link via SMS text message. However, this required the nurse to use an anonymous mobile phone number. Patients using the desktop version of Zoom were sent an invitation link via email.

Joining Meetings: Need for a Virtual Assistant

Before the start of a video consultation, the nurse prepared two screens (opportunity). On one screen, the cardiologist could log in to the patient's device, while the other screen was prepared to show the video communication software. For all the video consultations, a backup plan was established to switch to telephone and continue the consultation on an audio-only basis. The nurse was present throughout the entire VC process to help manage problems with communication connections and record the experiences of the patient and the cardiologist.

In 2 of the 5 video consultations, the patient and the cardiologist were connected with both audio and video via Zoom. In the four cases in which a video connection was established, even without audio (replaced by audio from a telephone), the patients were positive about the experience; however, for the one case in which the video connection could not be established, the patient was disappointed. Key challenges were identified due to failures of the video or audio on either the patient's or the cardiologist's side (3 times): in one case, the cardiologist's computer ran too slowly, in another case, the patient had not signed into the Zoom meeting, and in another case, the patient could not join the Zoom meeting. In addition, the patients were not always immediately in front of their devices at the start of the meeting. The nurse had to attempt to manage these problems in the moment on both the cardiologist and patient sides. However, connections could not always be established or re-established. This reveals the need for more advanced training on the use of video communication software before adopting video consultations, for both patients and health care professionals.

Opportunities were identified to improve the audio and video connections between the patient and the cardiologist. First, the nurse could test the Zoom video and audio links with the cardiologist's and patient's devices before the start of the consultation. This would require the nurse to be the host for all scheduled video consultations before the consultations start. For example, before the first consultation started, the nurse as the host could conduct a test conversation using the cardiologist's device to determine if the audio and video were functional and if the connection with the heart device was functioning. Following this, the cardiologist could take over the account from the nurse to start the consultation. The nurse could then prepare the next scheduled patient for their video consultation by starting the next meeting as the host and checking the audio and video connections between the patient's device and the local device by holding a test conversation.

Currently, there are technical challenges in implementing this workflow, as the meeting host cannot simultaneously start and manage multiple meetings [20]. No other video communication software could be immediately identified that would overcome this obstacle. It may be possible for a chatbot or similar automated diagnostic system to help the patient navigate the steps on their own to test the audio or video connection. All these potential solutions would require additional training for the patients and health care professionals.

Lessons to Improve Video Consultations in Cardiology

We employed a design thinking tool called a customer journey, which revealed several challenges and opportunities for stakeholders in a cardiology practice when testing video consultation software. Three lessons were identified to improve the experience for stakeholders:

Ease of Using the Technology

Attempt to reduce the number of clicks or screens that must be navigated to get to a meeting and preferably avoid downloading or registration of software and activation of a microphone or video camera (these appear to be easier to manage on a smartphone). Ideally, provide the ability to access data on implanted devices and video communication software in one integrated software solution.

Meeting Features

Ensure the video consultations are secure (ie, use a password and data encryption in line with the GDPR) and facilitate the establishment of video and audio connections by automatically starting microphone and video devices for both the health care professional and the patient. Use a convenient method to send information about the meeting to the patient, such as an SMS text message or email, depending on the wishes of the patient.

Management of Video and Audio Connections

Reduce the time spent preparing and managing connectivity. One option would be for a nurse to concurrently host multiple meetings to streamline the process of switching between consultations. If this option is not available or proves to be inadequate, it will be crucial to provide additional training for patients and health care professionals. It is therefore important to select a system that will not require time-consuming training, preferably one with an automated testing system (if available).

Future Considerations

Looking toward the future, the population of heart patients in need of remote care is likely to grow given the prolongation of the COVID-19 pandemic. Using design thinking to improve telehealth for patients who are at risk of acute health problems, such as heart attack and atrial fibrillation, is therefore increasingly urgent. Remote diagnostic tools, such as remote electrocardiogram (ECG) technology, could be integrated into telehealth video communication software, as in smartphones [21]. Although there are some consumer devices on the market with up to six ECG leads [22,23], their use is still limited due to legal obstacles or financial concerns (linked to reimbursement).

Limitations

This short design thinking study was limited due to the physical constraints of COVID-19. The data collection would have benefited from more field observations. In addition, to prevent delays in the implementation process of the video consultation software, the traditional problem exploration process started immediately through testing existing software solutions. Therefore, some problems and solutions for the stakeholders may remain unexplored.

Conclusion

These initial insights highlight that even though financial regulations currently favor the use of video consultations [4,10,11], we identified many practical obstacles from a user perspective that have critical implications. Employing design thinking and involving all relevant stakeholders may help overcome these obstacles and aid further integration of telehealth and other medical device software. This further resonates with the call of the American Heart Association to conduct more human-centered research in this area [24]. In conclusion, employing design thinking to implement video consultations in cardiology and to further implement telehealth is crucial to build a resilient health care system that can address urgent needs beyond the COVID-19 pandemic.

Abstract

Background: An infodemic is an overabundance of information—some accurate and some not—that occurs during an epidemic. In a similar manner to an epidemic, it spreads between humans via digital and physical information systems. It makes it hard for people to find trustworthy sources and reliable guidance when they need it.

Objective: A World Health Organization (WHO) technical consultation on responding to the infodemic related to the coronavirus disease (COVID-19) pandemic was held, entirely online, to crowdsource suggested actions for a framework for infodemic management.

Methods: A group of policy makers, public health professionals, researchers, students, and other concerned stakeholders was joined by representatives of the media, social media platforms, various private sector organizations, and civil society to suggest and discuss actions for all parts of society, and multiple related professional and scientific disciplines, methods, and technologies. A total of 594 ideas for actions were crowdsourced online during the discussions and consolidated into suggestions for an infodemic management framework.

Results: The analysis team distilled the suggestions into a set of 50 proposed actions for a framework for managing infodemics in health emergencies. The consultation revealed six policy implications to consider. First, interventions and messages must be based on science and evidence, and must reach citizens and enable them to make informed decisions on how to protect themselves and their communities in a health emergency. Second, knowledge should be translated into actionable behavior-change messages, presented in ways that are understood by and accessible to all individuals in all parts of all societies. Third, governments should reach out to key communities to ensure their concerns and information needs are understood, tailoring advice and messages to address the audiences they represent. Fourth, to strengthen the analysis and amplification of information impact, strategic partnerships should be formed across all sectors, including but not limited to the social media and technology sectors, academia, and civil society. Fifth, health authorities should ensure that these actions are informed by reliable information that helps them understand the circulating narratives and changes in the flow of information, questions, and misinformation in communities. Sixth, following experiences to date in responding to the COVID-19 infodemic and the lessons from other disease outbreaks, infodemic management approaches should be further developed to support preparedness and response, and to inform risk mitigation, and be enhanced through data science and sociobehavioral and other research.

Conclusions: The first version of this framework proposes five action areas in which WHO Member States and actors within society can apply, according to their mandate, an infodemic management approach adapted to national contexts and practices. Responses to the COVID-19 pandemic and the related infodemic require swift, regular, systematic, and coordinated action from multiple sectors of society and government. It remains crucial that we promote trusted information and fight misinformation, thereby helping save lives.

Introduction

A pneumonia of unknown cause detected in Wuhan, China was first reported to the World Health Organization (WHO) Country Office in China on December 31, 2019. The disease, caused by a novel coronavirus, was subsequently named the coronavirus disease (COVID-19) and declared a Public Health Emergency of International Concern on January 30, 2020. On March 11, 2020, the WHO characterized the outbreak as a pandemic. As of June 2, 2020, more than 6.1 million cases of COVID-19 had been reported in over 200 countries and territories, resulting in more than 373,500 deaths, as reported to the WHO [1].

On February 15, 2020, the WHO Director-General Tedros Adhanom Ghebreyesus raised the concern that the epidemic was accompanied by an infodemic [2]. An infodemic is an overabundance of information—some accurate and some not—that occurs during an epidemic [3]. In a similar manner to an epidemic, it spreads between humans via digital and physical information systems. It makes it hard for people to find trustworthy sources and reliable guidance when they need it [4]. People need accurate information during epidemics to modify their behavior and protect themselves, their families, and their communities against the infection. An infodemic cannot be eliminated, but it can be managed. The management of an infodemic becomes more challenging with social media and the rapid spread of information. Similar to epidemics, the information spreads further and faster, propagated by the interconnected ways in which information is disseminated and consumed through the web, digital and social media, chat apps, TV, radio, and other communication channels.

In the context of the COVID-19 pandemic, the infodemic is exacerbated by the global scale of the emergency. Importantly, even though some misinformation may just be confusing, many false and misleading claims such as those about fake or questionable cures, or incorrect recommendations about prevention or public behavior can be harmful to life and can exacerbate the outbreak. The infodemic can be even more challenging to manage when health information messages and facts are incorporated into political narratives and online commentary that is not grounded in verified facts and evidence.

At the same time, however, with the vast amount of information related to the spread of the virus, online and offline interactions, and public opinions expressed on social media can also be valuable sources of knowledge when analyzing the dynamics of the pandemic. For instance, they can help us gauge public sentiment toward different public health measures, analyze adherence to prevention approaches, develop effective public health campaigns, track and map symptoms, predict outbreaks, and detect and combat misinformation. Big data sources and unstructured text data sets can be used alongside official and established ones for real time analytics and modeling as part of infodemic and pandemic management—although such use cases for data also raise questions related to privacy, security, and the ethics of using public and private data sets.

To counter and understand the rapidly changing landscape of the COVID-19 infodemic and develop effective strategies to mitigate its negative side effects such as the spread of misinformation, on April 7 and 8, 2020, the WHO Information Network for Epidemics (EPI-WIN) organized a 2-day global online consultation on managing the infodemic. The meeting materials, recordings of sessions, and summary illustrations of discussion are available on the WHO website [5]. This paper summarizes the proceedings and outcomes of the consultation and recommendations for further action by the WHO, its Member States, and other stakeholders.

Methods

The aim of this consultation was to crowdsource ideas to form a novel COVID-19 infodemic response framework. A 2-day online consultation with four plenary sessions and a brainstorming session was conducted entirely online using three information and communication platforms: Zoom, Slido, and Twitter. The plenary sessions used the Zoom platform for 19 talks by 21 presenters and 3 discussants. The speakers were identified based on discussion among key staff in the WHO COVID-19 infodemic management response pillar and a search of academic and grey literature for authors in key topics of interest.

Invitations to participate in the consultation were sent out through existing global and regional networks with the aim of bringing together a community of key partners already working to address the infodemic from different perspectives, including but not limited to risk communication, health information systems, research and science, policy analysis, evidence synthesis, digital health, community response, and humanitarian response. All participants were also encouraged to post their thoughts and engage with the wider audience using Twitter and the hashtag #infodemicCOVID19.

The first panel of the meeting consisted of speakers who outlined key perspectives on the infodemic from the points of view of the WHO, national health policy makers, institutes of public health, the news and media, social media platforms, the private sector, publishers of scientific journals, sociobehavioral science, and civil society. The speakers on subsequent panels presented relevant methods, tools, and evidence from past and current experiences dealing with the COVID-19 infodemic. The talks covered a wide range of topics, including risk communication and community engagement in outbreaks; fact-checking practices; identification and response strategies for misinformation; sociobehavioral science research methods; and the use of social listening, artificial intelligence (AI), and computational methods to produce insights for infodemic response decision making. The recommendations from the talks were factored into the subsequent analysis of the actions proposed by the wider group of online participants.

Only panelists and moderators were able to use audio during the Zoom webinar. In parallel, questions were submitted by participants through Slido, a question and answer as well as polling platform. Participants were able to upvote relevant questions and discuss the questions with each other by replying to the questions and comments posted on Slido. Moderators selected the three or four most upvoted questions at the end of each session to pose to panelists. Plenary sessions ran each day from 2 PM to 5 PM Central European Time (CET) to facilitate participation from a wide range of different time zones.

Slido was also used to crowdsource ideas from participants and panelists concerning the elements of a future infodemic management framework. Four breakout topics were established for which ideas could be submitted using Slido from 3 PM CET on April 7, 2020, to 12 PM CET on April 9, 2020. For the final meeting session on April 8, organizers prepared a preliminary narrative analysis of submitted ideas and organized them into subcategories of four thematic areas. For each subcategory, the most frequently named and most innovative ideas were collected for narrative categorization and summary. The selection of ideas was based on the frequency with which an idea was mentioned, the number of likes and replies it generated via Slido, and a qualitative analysis by the WHO analysis team. During the review of the submissions, similar proposals were merged into combined suggestions, and multi-thematic submissions were included in the relevant thematic areas of analysis. Two invited policy makers from the Ministry of Health of Thailand and the Ministry for Health of Malta received the preliminary summary of the narrative 90 minutes before the final session so that they could respond to it with their perspectives and comments. After the submission period for ideas closed on April 9, a final narrative analysis was conducted for all ideas submitted on the platform, including through meeting comments. That summary forms the results of this paper.

After the consultation concluded, the WHO EPI-WIN team conducted an after-action review of the meeting and disseminated lessons from the process of organizing the meeting through the WHO's internal knowledge-sharing networks. A set of follow-up actions and network-building activities was outlined so that the WHO team could engage and foster communities that contribute to the infodemic response.

Results

Meeting Participants and Discussions

A total of 1483 individuals from 111 countries and territories registered for the consultation, with 1375 and 1169 participants joining the consultation on day 1 and day 2, respectively. Registered individuals self-reported as representing the following sectors: academia or research (32%), nongovernmental organizations (21%), the private sector (17%), United Nations or intergovernmental organizations (12%), public health authorities or government (9%), health care professionals (5%), civil society (4%), and students (2%).

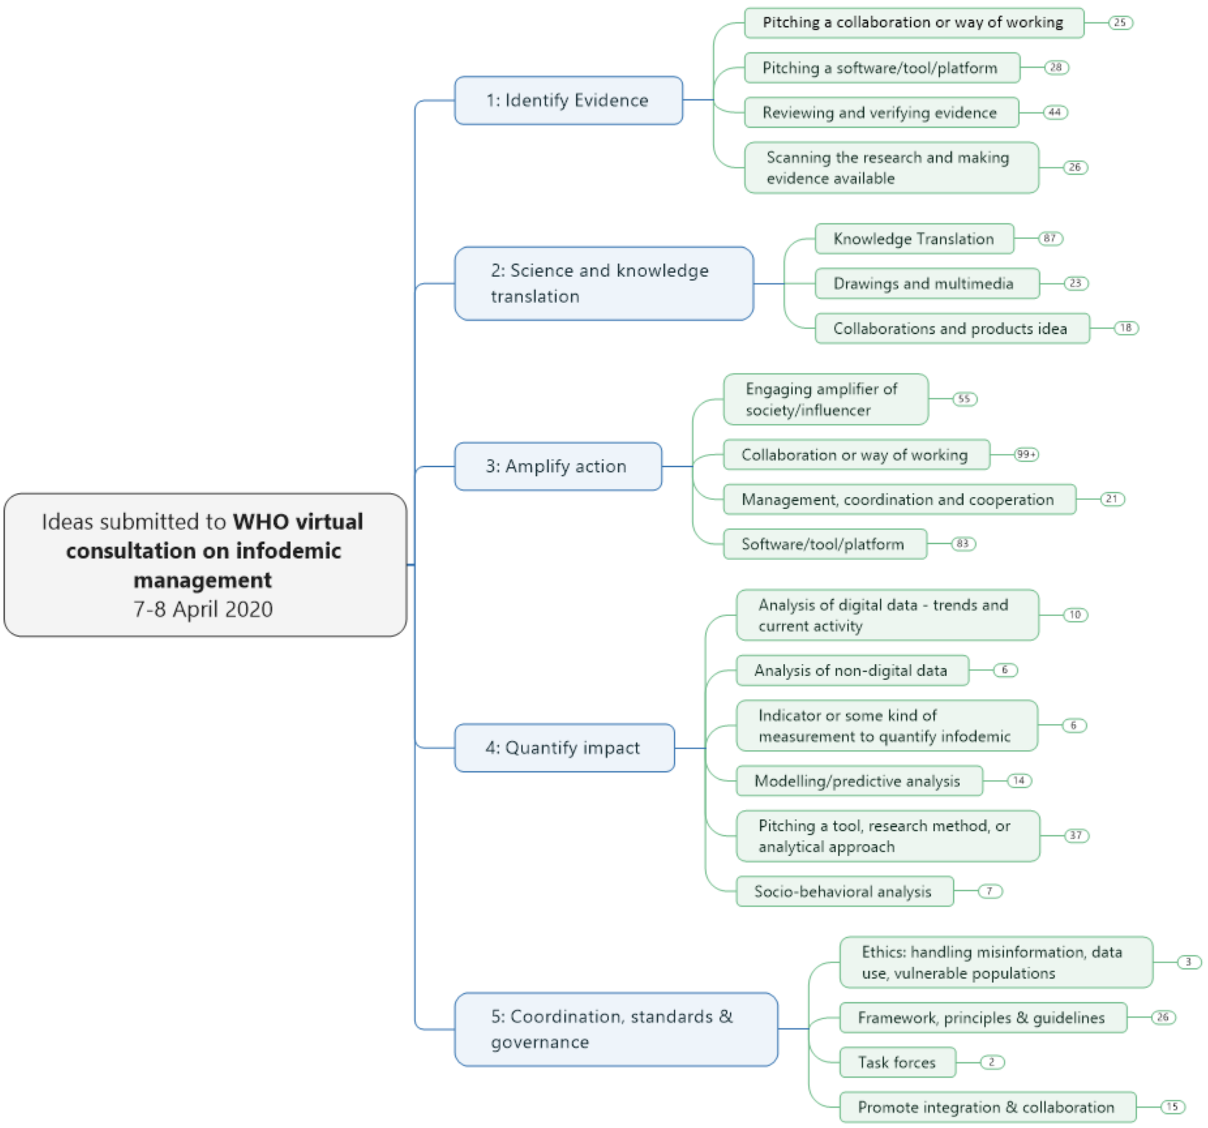
The presenters embodied a diverse, multidisciplinary array of thinking, providing the perspectives of the WHO, the media, government and policy makers, institutes of public health, scientific publishers, social media companies, academia, the private sector, civil society, and the humanitarian sector. They discussed approaches to studying the infodemic using conceptual, web-based, and sociobehavioral approaches, as well as social media analytics, and they demonstrated various tools and techniques designed to check facts and measure and respond to the infodemic. The discussions were grounded in lessons from the speakers' past experiences and research.

Both the presentations and the follow-up emphasized that we are living in an interconnected world, in which the infodemic recognizes no boundaries. Information is transmitted and shared worldwide, traveling fast through social media apps and platforms, online forums, news sites, television, radio, and many other channels. Citizens exchange information more quickly than ever before, collectively experiencing in their own everyday lives the effects and changes brought about by the pandemic and the actions undertaken to respond to it. At the same time, those supporting the response are also experiencing the pandemic and infodemic through their families and communities, as well as in their professional work and networks.

Analysis of Suggested Actions

Using a narrative analysis, we further grouped the submitted ideas into a set of five COVID-19 infodemic management areas: (1) scanning and verifying evidence (18%); (2) explaining the science (20%); (3) amplifying the reach of messages (44%); (4) measuring the infodemic and assessing trends and impacts (12%); and (5) coordination and governance (6%). The 594 collected suggestions were further summarized by theme (Figure 1).

Figure 1. Summary categorization and count of ideas submitted by the end of the consultation period. WHO: World Health Organization.



Almost half of the proposed actions dealt with how to amplify the reach of credible messages. They suggested specific actions that the WHO or Member States could undertake, such as providing coordination and development of guidelines and frameworks; building coalitions with UN agencies, fact-checking organizations, data scientists, the AI community, social media companies, and journalists; and generating specific communication strategies and tools to reach all communities and vulnerable groups. In addition, many called for specific practical actions such as tailoring messages to specific audiences, mindful of context and literacy; developing dashboards to monitor the infodemic; developing and applying research methods to understand the infodemic at the level of information flows, populations, individuals, and communities; and analyzing the adherence to, and impact of, public health measures.

The recommendations and ideas submitted indicate that we lean on existing infodemic experience, knowledge, and tools from a range of sources, including lessons from previous outbreaks such as Zika, severe acute respiratory syndrome, and Ebola; studies on misinformation around vaccine safety and methods for addressing vaccine communication, trust, and misinformation; existing tools for reaching communities with lower internet use or literacy; and experience in community outreach and humanitarian action. At the same time, new tools were suggested to assist the process of reviewing information and taking action, and to simplify the generation and dissemination of information, messages, and materials. It was suggested that we use multidisciplinary approaches in research and analysis, such as AI for natural language processing or treatment of unstructured and text data, as well as sociobehavioral, ethnographic, and medical anthropology research methods. The submissions also called for cooperation and coordination between governments, public health authorities, journalists, fact checkers, communities, social media, the private sector, academia, and others. A detailed mind map of suggestions for action is available in Multimedia Appendix 1.

Policy Implications

The analysis team further distilled the results of the consultation into a set of 50 proposed actions for a framework for managing infodemics in health emergencies (see Multimedia Appendix 2). The consultation revealed six implications for governments and policy makers to consider.

First, interventions and messages must be based on science and evidence, and must reach citizens and enable them to make informed decisions on how to protect themselves and their communities in a health emergency [6,7]. These basic foundations of emergency preparedness and response have been challenged and adapted in the current pandemic context by the rapid exchange of information and consequent shortened time frames for decision making.

To be able to provide policy solutions to the challenges caused by the infodemic, we must acknowledge the challenges that exist in managing the creation and dissemination of trusted information so that it is not excessive, overwhelming, or confusing and deciding when and how to counter misinformation.

- Work is required to slow down and streamline the flow of information of all kinds. This should be guided by a unified strategy for producing and disseminating trusted information, and a constantly updated set of guidelines to counter and correct misinformation using a measured approach firmly grounded in state-of-the-art sociobehavioral research. COVID-19 has resulted in an explosion of evidence generation and synthesis activities—“not only an ‘infodemic on top of the pandemic,’ but also an ‘infodemic on top of the infodemic’” [8]. These activities should be internationally coordinated to avoid duplication while guaranteeing epistemic diversity.
- As the body of evidence grows during an emergency, guidelines and messages may change or be amended. Care needs to be taken to ensure propagation of up-to-date information to communities and individuals through all appropriate channels, including to those communities for which web-based sources are not the primary source of information and those for which information needs to be adapted to local languages, literacy levels, and contexts.
- In parallel, scientific findings must be collated, reviewed, appraised, and assessed for relevance to help form recommendations and policies that have the greatest possible positive impact on the health of individuals and populations [9]. Scientific and public health institutions have central roles to play in this process. Editors of medical journals could also help manage the infodemic problem by, for example, producing plain language summaries for journalists and the public to accompany each article related to COVID-19.
- The capacity must be in place to promote trusted content; check facts; and monitor, verify, report, and respond to misinformation. Work is required to verify and counter the spread of misinformation and introduce effective regulatory approaches to limit its impact. This could be strengthened through partnerships between public health authorities, communities, journalists, fact-checking initiatives, social media platforms, and other communication channels.

Second, knowledge should be translated into actionable behavior-change messages, presented in ways that are understood by and accessible to all individuals in all parts of all societies. Cultural and contextual sensitivity in the platforms and messages used, and translation into local languages are essential. Coordinated work and partnering with a variety of stakeholders, including civil society, is required to ensure the availability of information targeted at vulnerable or hard-to-reach communities via nondigital routes. An on-the-ground network of global field workers could help reach out to highly vulnerable people to ensure they can access reliable information, as many citizens around the world still do not have access to pandemic information on the internet.

Third, governments should reach out to key communities to ensure their concerns and information needs are understood, tailoring advice and messages to address the audiences they represent. Through this process, communities of all kinds, whether neighborhood, religious, professional, or otherwise, should amplify the right public health messages in ways that are user-friendly and can lead to the right changes in behavior. For example, active engagement calls and dialogue could be established between public health authorities and private sector employers, telecom companies, the food and agriculture sector, faith-based organizations, health care and medical professional associations, and the media.

Fourth, to strengthen the analysis and amplification of information impact, strategic partnerships should be formed across all sectors, including but not limited to the social media and technology sectors, academia, and civil society. Through strategic partnerships with health authorities, these platforms can place and prioritize relevant information and advice, ensuring it is seen by citizens, helping to fact-check, measuring and describing the infodemic, tracking trends, and observing and analyzing the impact of messages and interventions on population behavior. There is a wealth of information on these platforms that can help us to understand the sentiments of different populations and guide effective public health measures. Rather than a complement to public health, the infodemic dimension should be considered a pillar of an integrative approach to public health in complex knowledge societies.

Fifth, health authorities should ensure that these actions are informed by reliable information that helps them understand the circulating narratives and changes in the flow of information, questions, and misinformation in communities. Analysis of online conversations; narratives; and TV, radio, and news media could be systematically applied and paired with fact-checking resources. Analysis of circulating narratives, knowledge, risk perceptions, behaviors, and trust at population and community levels could provide rapid snapshots to inform appropriate policy interventions. Mixed-methods research can monitor trends in acceptance of public health measures. Examples of such research methods include sociobehavioral research and sentiment and media analysis of digital information from online conversations; TV, radio, and news media; and community dipstick surveys.

Sixth, following experiences to date in responding to the COVID-19 infodemic and the lessons from other disease outbreaks, infodemic management approaches should be further developed to support preparedness and response, and to inform risk mitigation, and enhanced through data science and sociobehavioral and other research.

Discussion

This WHO technical consultation was entirely held online, with no panelists or participants travelling to the meeting. In terms of the number of participants, it was one of the biggest meetings ever convened by the WHO—comparable to the annual World Health Assembly. It was also the first consultation to address the phenomenon of infodemic management in health emergencies. This online consultation was an effective and cost-efficient way of reaching and interacting with a large and diverse community and producing solid outcomes.

The infodemic impacts citizens in every country, and addressing it is a new and centrally important challenge in responding to the COVID-19 pandemic—and will be so for future pandemics. The consultation discussions and online brainstorming generated clear themes that can inform discussions and actions for effective management of infodemics in all countries. The participants, presenters, and experts collectively agreed that, today more than ever, it is crucially important for authorities, other stakeholders, and the public to have access to the right data and information, at the right time, and in the right formats. The better the data and information available at all levels, the smarter and more effective the response to the pandemic will be [10].

The extraordinary interdependence of the sociobehavioral dimension of the pandemic with individual and public health makes the infodemic a serious threat but is also an opportunity to shape views and behaviors in our societies. The spread of misinformation [11,12] can trigger behavioral responses that, in turn, can further expose individuals and communities to health risks. Although the impact of misinformation on society is still under scrutiny, there is increasingly convincing evidence that deliberate misinformation operations and social manipulation [13] have taken place during major events in the past—including in several high profile political instances [14]—and that they might play an important role during other high profile, strategically important or exceptional events, including the COVID-19 pandemic.

In the study of epidemics, epidemiology experienced a turning point during the 20th century through the application of mathematical and statistical methods to this scientific field. In the study of infodemics, the 21st century will see the development of infodemiology, a novel scientific discipline required to unravel the complex propagation patterns of the infodemic. In practice, infodemiology requires a transdisciplinary approach integrating applied mathematics, social, and behavioral sciences; communication and information science; digital health research; data science; and complexity science. This scientific discipline, as it addresses research priorities driven by health policy-making needs, can generate evidence to inform the development of tools, methods, and infodemic management interventions, and contribute to the monitoring of public health interventions during outbreaks, thus strengthening outbreak preparedness and response in health emergencies.

Responses to the COVID-19 pandemic and the related infodemic require swift, regular, systematic, and coordinated action from multiple sectors of society and government. It remains crucial that we promote trusted information and fight misinformation, thereby contributing to saving lives as the pandemic continues to unfold and run its course. This requires timely translation of evidence into knowledge that people can use, adapted to their local cultures, languages, and contexts. This needs to be supported by facts and analytics, backed up with constant monitoring of the impact of trusted information, and work to counteract misinformation.

We call on citizens from all parts of society to demand reliable, evidence-based information, and to take actions that empower their communities to use trusted information to protect the most vulnerable and themselves.

Acknowledgments

The authors would like to thank all participants for contributing their ideas and opinions during the event, through Twitter, online polls, and chats, and the EPI-WIN team and Olga Fradkina, for contributing to the smooth organization of the event and its accompanying activities. The authors are grateful for the help provided by the reviewers Myrna Marti and Felipe Mejia Medina.

Tim Nguyen, Tina Purnat, Marcelo d'Agostino, Sebastian Garcia-Saiso, Mark Landry, Arash Rashidian, Clayton Hamilton, Abdelhalim AbdAllah, Ioana Ghiga, Alexandra Hill, Daniel Hougendobler, Judith Van Andel, and Sylvie Briand are staff members of the World Health Organization. The authors alone are responsible for the views expressed in this paper and they do not present the views of the organization.

Abstract

Background: Coronavirus disease (COVID-19) has spread explosively worldwide since the beginning of 2020. According to a multinational consensus statement from the Fleischner Society, computed tomography (CT) is a relevant screening tool due to its higher sensitivity for detecting early pneumonic changes. However, physicians are extremely occupied fighting COVID-19 in this era of worldwide crisis. Thus, it is crucial to accelerate the development of an artificial intelligence (AI) diagnostic tool to support physicians.

Objective: We aimed to rapidly develop an AI technique to diagnose COVID-19 pneumonia in CT images and differentiate it from non–COVID-19 pneumonia and nonpneumonia diseases.

Methods: A simple 2D deep learning framework, named the fast-track COVID-19 classification network (FCONet), was developed to diagnose COVID-19 pneumonia based on a single chest CT image. FCONet was developed by transfer learning using one of four state-of-the-art pretrained deep learning models (VGG16, ResNet-50, Inception-v3, or Xception) as a backbone. For training and testing of FCONet, we collected 3993 chest CT images of patients with COVID-19 pneumonia, other pneumonia, and nonpneumonia diseases from Wonkwang University Hospital, Chonnam National University Hospital, and the Italian Society of Medical and Interventional Radiology public database. These CT images were split into a training set and a testing set at a ratio of 8:2. For the testing data set, the diagnostic performance of the four pretrained FCONet models to diagnose COVID-19 pneumonia was compared. In addition, we tested the FCONet models on an external testing data set extracted from embedded low-quality chest CT images of COVID-19 pneumonia in recently published papers.

Results: Among the four pretrained models of FCONet, ResNet-50 showed excellent diagnostic performance (sensitivity 99.58%, specificity 100.00%, and accuracy 99.87%) and outperformed the other three pretrained models in the testing data set. In the additional external testing data set using low-quality CT images, the detection accuracy of the ResNet-50 model was the highest (96.97%), followed by Xception, Inception-v3, and VGG16 (90.71%, 89.38%, and 87.12%, respectively).

Conclusions: FCONet, a simple 2D deep learning framework based on a single chest CT image, provides excellent diagnostic performance in detecting COVID-19 pneumonia. Based on our testing data set, the FCONet model based on ResNet-50 appears to be the best model, as it outperformed other FCONet models based on VGG16, Xception, and Inception-v3.

Introduction

The coronavirus disease (COVID-19) pandemic is currently a global health crisis; more than 1,700,000 cases had been confirmed worldwide and more than 100,000 deaths had occurred at the time of writing this paper [1]. COVID-19, an infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), is highly contagious and has spread rapidly worldwide. In severe cases, COVID-19 can lead to acute respiratory distress, multiple organ failure, and eventually death. Countries are racing to slow the spread of the virus by testing and treating patients in the early stage as well as quarantining people who are at high risk of exposure due to close contact with patients with confirmed infection. In addition, early diagnosis and aggressive treatment are crucial to saving the lives of patients with confirmed infection [2].

COVID-19 is typically confirmed by viral nucleic acid detection using reverse transcription–polymerase chain reaction (RT-PCR) [3]. However, the sensitivity of RT-PCR may not be sufficiently high; it ranges from 37% to 71% according to early reports [4-6]. Thus, RT-PCR can afford a substantial number of false negative results due to inadequate specimen collection, improper extraction of nucleic acid from the specimen, or collection at a too-early stage of infection. A chest computed tomography (CT) scan can be used as an important tool to diagnose COVID-19 in cases with false negative results by RT-PCR [6-9].

Recently, a multinational consensus statement from the Fleischner Society was issued to guide chest imaging during the COVID-19 pandemic in different clinical settings [6]. According to this consensus statement, in a setting such as South Korea, where detecting patients at an early stage and isolating all patients and people with high risk of exposure is essential, CT is a relevant screening tool due to its greater sensitivity for detecting early pneumonic changes. CT can also contribute to the management and triage of the disease by detecting severe cases. In addition, chest CT is noninvasive and is easy to perform in an equipped facility.

However, radiologic diagnostic support is not maintained 24 hours per day in many institutions [10]. In addition, CT may show similar imaging features between COVID-19 and other types of pneumonia, thus hampering correct diagnosis by radiologists. Indeed, in a study that evaluated radiologists' performance in differentiating COVID-19 from other viral pneumonia, the median values and ranges of sensitivity and specificity were 83% (67%-97%) and 96.5% (7%-100%), respectively [11].

The use of artificial intelligence (AI) may help overcome these issues, as AI can help maintain diagnostic radiology support in real time and with increased sensitivity [8,12]. In this era of worldwide crisis, it is crucial to accelerate the development of AI techniques to detect COVID-19 and to differentiate it from non–COVID-19 pneumonia and nonpneumonia diseases in CT images. Therefore, we aimed to rapidly develop an AI technique using all available CT images from our institution as well as publicly available data.

Methods

Data Sets and Imaging Protocol

This study was approved by the institutional review boards of Wonkwang University Hospital (WKUH) and Chonnam National University Hospital (CNUH). Informed consent was waived. Table 1 summarizes the training, testing, and additional validation data sets. In this study, we initially collected data from 3993 chest CT images, which were categorized into COVID-19, other pneumonia, and nonpneumonia disease groups.

For the COVID-19 data group, we used a total of 1194 chest CT images: 673 chest CT images (56.3%, from 13 patients) from CNUH, 421 images (35.3%, from 7 patients) from WKUH, and 100 images (83.8%, 60 patients) from the Italian Society of Medical and Interventional Radiology (SIRM) public database [13]. The 20 patients from CNUH and WKUH included 9 male patients and 11 female patients, with an average age of 59.6 years (SD 17.2). Regarding the COVID-19 data from WKUH and CNUH, all the patients with COVID-19 tested positive for the virus by RT-PCR viral detection, and the CT images were acquired between December 31, 2019 and March 25, 2020. The median period from symptom onset to the first chest CT examination was 8 days (range 2-20 days). The most common symptoms were fever (75%) and myalgia (30%). In addition, according to previous studies related to COVID-19 by Zhao's group [14] from January 19 and March 25, 2020, 264 low-quality chest CT images were used as additional testing data. In summary, 1194 COVID-19 images (80 patients) from WKUH, CNUH, and SRIM were split into the training data set (955 images, 80.0%) and testing data set (239 images, 20.0%). For the additional testing, 264 COVID-19 images (264 patients) from the low-quality image data set were used.

Table 1. Summary of the training, testing, and additional testing data sets (N=4257).

Data type, data source, and data group	Training images, n (%)	Testing images, n (%)
Training and testing data		
WKUH[a]		
COVID-19 pneumonia (n=421)	337 (80.0)	84 (20.0)
Other pneumonia (n=1357)	1086 (80.0)	271 (20.0)
Nonpneumonia and normal lung (n=998)	798 (80.0)	200 (20.0)
Lung cancer (n=444)	355 (80.0)	89 (20.0)
CNUH[b]		
COVID-19 pneumonia (n=673)	538 (80.0)	135 (20.0)
SIRM[c]		
COVID-19 pneumonia (n=100)	80 (80.0)	20 (20.0)
Additional external testing data		
Low-quality CT images from papers		
COVID-19[d] pneumonia (n=264)	0 (0.0)	264 (100.0)

[a] WKUH: Wonkwang University Hospital.

[b] CNUH: Chonnam National University Hospital.

[C] SIRM: Italian Society of Medical and Interventional Radiology.

[d] COVID-19: coronavirus disease.

For the other pneumonia data group, we selected 1357 chest CT images from 100 patients diagnosed with non–COVID-19 pneumonia at WKUH between September 1, 2019, and March 30, 2020. The average age of this group was 62.5 years (SD 17.2), with 68 male and 32 female patients. For the nonpneumonia data group, we also selected 1442 chest CT images from 126 patients who had no lung parenchymal disease or lung cancers at WKUH between January 2009 and December 2014. The average age of these patients was 47 years (SD 17), with 63 male patients (721/1442 images, 50.0%) and 63 female patients (721/1442 images, 50.0%). The patient demographic statistics of the COVID-19 and other pneumonia groups are summarized in Table 2. In this table, other pneumonia (not COVID-19) was categorized into two different types based on clinical characteristics: 68 cases of community-acquired pneumonia (onset 48 hours before hospital admission) and 32 cases of hospital-acquired pneumonia (onset 48-72 hours after hospital admission). Of these other pneumonia patients, 24/100 (24.0%) received laboratory confirmation of the etiology, 21 (21.0%) were confirmed to be bacterial culture positive, 3 (3.0%) were viral influenza positive by RT-PCR, and 76 (76.0%) were negative. Regarding the imaging protocols, each volumetric examination contained approximately 51 to 1094 CT images, with varying slice thicknesses from 0.5 millimeters to 3 mm. The reconstruction matrix was 512×512 pixels, with in-plane pixel spatial resolution from 0.29×0.29 to 0.98×0.98 square millimeters.

The data from WKUH, CNUH, and SIRM were randomly split with a ratio of 8:2 into a training set and a testing set, respectively, in a stratified fashion. In addition, the data for each group (WKUH, CNUH, and SIRM) were spread over different splits with a ratio of 8:2. The training data set was then further separated into sets used for training the model (80% of the training set) and for internal validation (20% of the training set). The testing set was used only for independent testing of the developed models and was never used for training the model or for internal validation. Furthermore, we tested the trained model with the additional external validation data set of low-quality images to evaluate the external generalizability of the model.

Table 2. Demographic data of patients with COVID-19 and other pneumonia.

Characteristic	COVID-19[a] pneumonia (n=20)	Other pneumonia (n=100)	*P* value
Age (years), mean (SD)	59.6 (17.2)	60.1 (17.1)	.91
Male sex, n (%)	9 (45.0)	68 (68.0)	.12
Community-acquired pneumonia, n (%)	20 (100.0)	68 (68.0)	.007
Hospital-acquired pneumonia, n (%)	0 (0.0)	32 (32.0)	
Microbiological study, n (%)			
COVID-19 positive (RT-PCR[b])	20 (100.0)	0 (0.0)	<.001

Preprocessing

For the data acquired from WKUH and CNUH, we converted Digital Imaging and Communications in Medicine (DICOM) images to one-channel grayscale PNG images to standardize the image file format, as the images in the low-quality image data set were in PNG format. To minimize the information loss, we first displayed the DICOM images using a lung window with a 1500 Hounsfield unit window width and a –600 HU window level [15,16] and converted the images to PNG format. Subsequently, we rescaled the images to a size of 256×256 pixels and normalized the pixel values to a range between 0 and 1. All of the converted PNG format images were confirmed by three radiologists to determine any loss of image information related to pulmonary diseases. For the data from SIRM, the original JPEG format was also reformatted to the PNG format, and the images were rescaled and normalized in the same manner. For the low-quality image data set, we also rescaled and normalized the images. In this study, no further preprocessing such as lung segmentation was performed.

Image Augmentation

To reduce overfitting of the training image data, we employed two distinct forms of data augmentation: image rotation and zoom. In the data augmentation method for the rotation, angles of rotation between –10° and 10° were randomly selected. Regarding the zoom, the range was randomly selected between 90% (zoom-in) and 110% (zoom-out). Either rotation or zoom was randomly selected 10 times for each training image. By applying data augmentation, we increased the number of images in the training data set to 31,940. Table 3 shows the number of augmented images for training in each group.

Table 3. Augmented images for training in each group (N=31,940).

Data source and group	Augmented images for training, n (%)
WKUHx[a]	
COVID-19[b] pneumonia	3370 (10.6)
Other pneumonia	10,860 (34.0)
Nonpneumonia and normal lung	7890 (24.7)
Lung cancer	3550 (11.1)
CNUH[c]	
COVID-19 pneumonia	5380 (16.8)
SIRM[d]

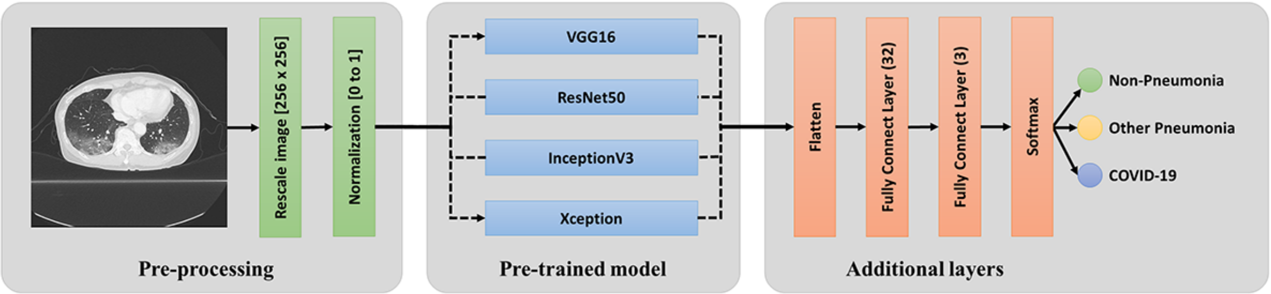
The Fast-Track COVID-19 Classification Network for COVID-19 Classification

We developed a simple 2D deep learning framework based on a single chest CT image for the classification of COVID-19 pneumonia, other pneumonia, and nonpneumonia, named the fast-track COVID-19 classification network (FCONet; Figure 1). FCONet was developed by transfer learning based on one of the following four pretrained convolutional neural network (CNN) models as a backbone: VGG16 [17], ResNet-50 [18], Inception-v3 [19], and Xception [20]. Transfer learning is a popular method in computer vision because it enables an accurate model to be built in a short time [21]. With transfer learning, instead of starting the learning process from an optimal model search, one can start it from patterns that were learned when solving a different problem. To minimize the training time, we initially used the predefined weights for each CNN architecture, which were further updated through the learning process of classification of COVID-19 pneumonia, other pneumonia, and nonpneumonia.

Figure 1. Scheme of FCONet, a 2D deep learning framework based on a single chest CT image for the classification of COVID-19 pneumonia, other pneumonia, and non-pneumonia. COVID-19: coronavirus disease.



Input Layer

After the simple preprocessing stage, in the *input layer*, we arranged three channels (256×256×3 pixels) by copying the one-channel normalized image. The three-channel images were fed into *the pretrained model layers*.

Pretrained Model Layers

A pretrained model is a model that was trained on a large benchmark data set to solve a similar problem to the one we want to solve. In the *pretrained model layers*, we included one of the four pretrained models (VGG16, ResNet-50, Inception-v3, and Xception). Each model comprises two parts: a convolutional base and a classifier. The convolutional base is composed of a stack of convolutional and pooling layers to generate features from the images. The role of the classifier is to categorize the image based on the extracted features. In our pretrained model layers, we retained the convolutional base and removed the classifier, which was replaced by another classifier for COVID-19, other pneumonia, or nonpneumonia.

Additional Layers

The activations from the *pretrained model layers* were fed into the *additional layers*. The layers acted as classifiers for COVID-19 pneumonia, other pneumonia, and nonpneumonia. In the additional layers, we first flattened the activations and connected two fully connected layers; one of the layers consisted of 32 nodes, and the other consisted of three nodes. Subsequently, the three activations from the second fully connected layer were fed into a SoftMax layer, which provided the probability for each of COVID-19, other pneumonia, and nonpneumonia.

Implementation

We implemented FCONet using the TensorFlow package, which provides a Python application programming interface (API) for tensor manipulation. We also used Keras as the official front end of TensorFlow. We trained the models with the Adam optimizer [22] and the categorical cross-entropy cost function with a learning rate of 0.0001 and a batch size of 32 on a GeForce GTX 1080 Ti graphics processing unit (NVIDIA). For the performance evaluation, 5-fold cross-validation was performed to confirm the generalization ability. The training data set (N=31,940) was randomly shuffled and divided into five equal groups in a stratified manner. Subsequently, four groups were selected to train the model, and the remaining group was used for validation. This process was repeated five times by shifting the internal validation group. Next, we averaged the mean validation costs of the five internal validation groups according to each epoch and found the optimal epoch that provides the lowest validation cost. Then, we retrained the model using the entire training data set with the optimal epoch. The testing data set was evaluated only after the model was completely trained using the training data set. This holdout method provides an unbiased evaluation of the final model by avoiding overfitting to the training data set.

Performance Evaluation and Statistical Evaluation

For each of the different four pretrained models (VGG16, ResNet-50, Inception-v3, and Xception) in FCONet, we evaluated the classification performance based on sensitivity, specificity, and accuracy. More specifically, we calculated true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN) based on the groups of COVID-19 pneumonia, other pneumonia, and nonpneumonia. For each group, we expressed measure metrics with the subscripts *covid* for COVID-19, *other* for other pneumonia, and *none* for nonpneumonia, as

where TP_{covid} is the number of COVID-19 testing data correctly classified as COVID-19, TN_{covid} is the number of non–COVID-19 testing data correctly classified as non–COVID-19, FP_{covid} is the number of non–COVID-19 testing data misclassified as COVID-19, and FN_{covid} is the number of COVID testing data misclassified as non–COVID-19. Here, non–COVID-19 testing data include other pneumonia and nonpneumonia. Note that the same calculations were applied to the other pneumonia and nonpneumonia testing data as

We also plotted the receiver operating characteristic (ROC) curve and calculated the area under the curve (AUC) for each of the four different models. Additionally, statistical analysis was performed using MATLAB (R2013b). Analysis of variance (ANOVA) was used to compare differences among COVID-19 pneumonia, non–COVID-19 pneumonia, and nonpneumonia groups. A *P* value less than .001 was considered to indicate statistical significance.

Results

The performance of the FCONet models based on the four pretrained models in the classification of COVID-19 pneumonia, other pneumonia, and nonpneumonia is summarized in Table 4. We compared the metric values of sensitivity (%), specificity (%), and accuracy (%) as well as the AUCs of the four FCONet models based on VGG16, ResNet-50, Inception-v3, and Xception. Based on the testing data, the FCONet models based on ResNet-50, VGG16, and Xception showed excellent classification performance; all these models provided AUC values ranging from 0.99 to 1.00. More specifically, with ResNet-50, the sensitivity, specificity, and accuracy for classifying COVID-19 pneumonia were 99.58%, 100%, and 99.87%, respectively. With VGG16, the sensitivity, specificity, and accuracy for classifying COVID-19 pneumonia were 100%, 99.64%, and 99.75%, respectively. With Xception, the sensitivity, specificity, and accuracy for COVID-19 pneumonia classification were 97.91%, 99.29%, and 98.87%, respectively. For other pneumonia and nonpneumonia, the sensitivity, specificity, and accuracy ranged from 97% to 100% when ResNet-50, VGG16, or Xception was used as the backbone in FCONet. On the other hand, Inception-v3–based FCONet provided relatively low sensitivity, specificity, and accuracy values for all groups of COVID-19 pneumonia, other pneumonia, and nonpneumonia (P<.001).

Table 4. Performance of the FCONet frameworks based on the four pretrained models on the testing data set.

Model and data group	Sensitivity, %	Specificity, %	Accuracy, %	AUC[a]	*P* value
ResNet-50					<.001
COVID-19[b] pneumonia	99.58	100.00	99.87	1.00	
Other pneumonia	97.42	99.81	99.00	0.99	
Nonpneumonia	100.00	98.63	99.12	0.99	
VGG16					<.001
COVID-19 pneumonia	100.00	99.64	99.75	1.00	
Other pneumonia	100.00	99.81	99.87	0.99	
Nonpneumonia	100.00	99.80	99.87	0.99	
Xception					<.001
COVID-19 pneumonia	97.91	99.29	98.87	0.99	
Other pneumonia	98.52	99.05	98.87	0.99	
Nonpneumonia	100.00	100.00	100.00	1.00	
Inception-v3					<.001
COVID-19 pneumonia	88.28	97.68	94.87	0.97	
Other pneumonia	94.10	95.83	95.24	0.98	
Nonpneumonia	98.27	97.25	97.62	0.99	

[a] AUC: area under the curve.

[b] COVID-19: coronavirus disease.

The confusion matrices and ROC curves for the pretrained models on the testing data set are presented in Figures 2-5. More specifically, ResNet-50 exhibited TP_{covid}, TP_{other}, and TP_{none} of 238/239, 268/271, and 289/289, respectively (Figure 2). VGG16 exhibited TP_{covid}, TP_{other}, and TP_{none} of 234/239, 269/271, and 289/289, respectively (Figure 3). Xception exhibited TP_{covid}, TP_{other}, and TP_{none} of 188/239, 257/271, and 289/289, respectively (Figure 4). Inception-v3 exhibited TP_{covid}, TP_{other}, and TP_{none} of 211/239, 255/271, and 284/289, respectively (Figure 5). For the three models of ResNet-50, VGG16, and Xception, the values of AUC were very close to 1 because the predicted probability values were provided as values close to 1 for correct labeling and values close to 0 for incorrect labeling.

On the additional external validation data set, which comprised low-quality CT images of COVID-19 pneumonia embedded in recently published papers, the detection accuracy of ResNet-50 was the highest with 96.97%, followed by Xception (90.71%), Inception-v3 (89.38%), and VGG16 (87.12%) (Table 5).

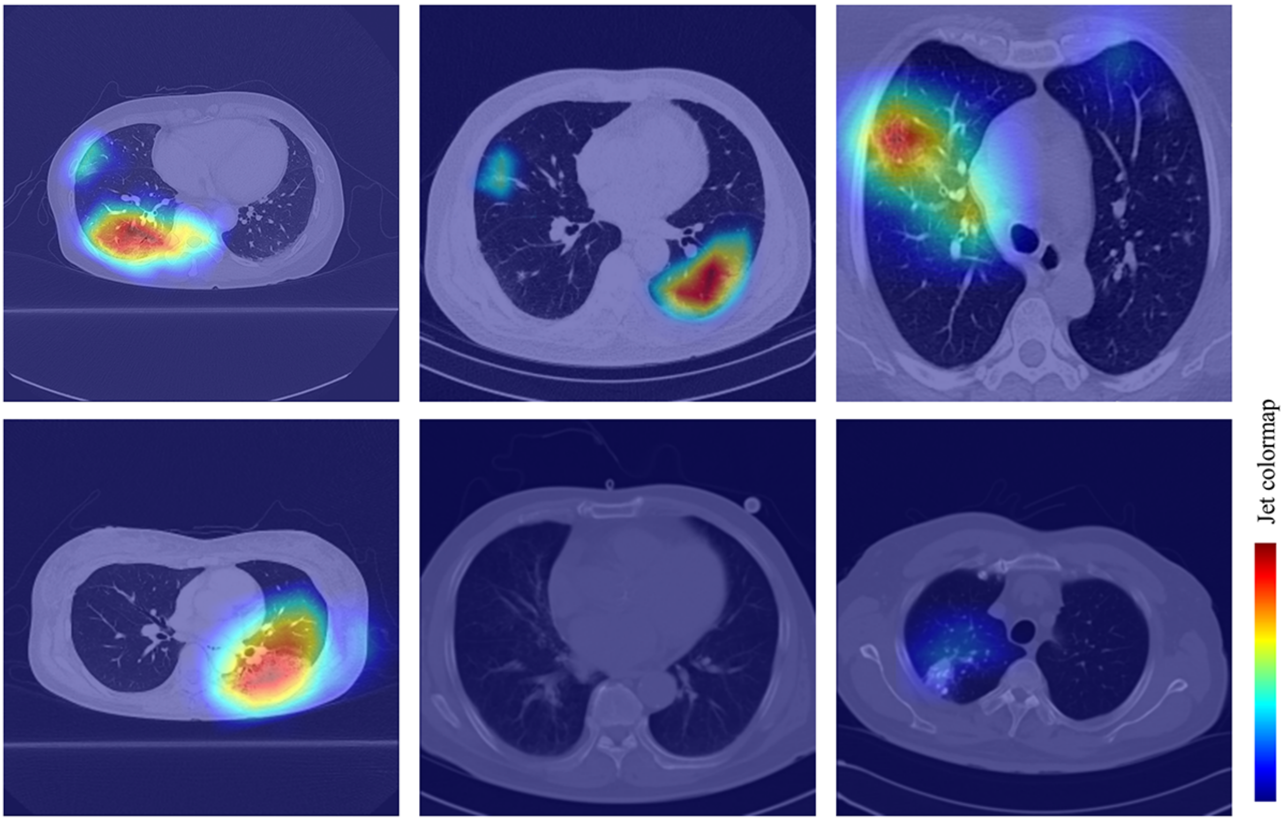
Table 5. Performance of each deep learning model on the additional external validation data set of COVID-19 pneumonia images.

Model	Detection accuracy, %
ResNet-50	96.97
VGG16	87.12
Xception	90.71
Inception-v3	89.38

To improve the interpretability of our model, we used the gradient-weighted class activation mapping (Grad-CAM) method [23] to visualize the important regions leading to the decision of FCONet. The model fully generates this localization map without the mapping annotation. The heatmaps (Figure 6) show the suspected regions for the examples of COVID-19, other pneumonia, and nonpneumonia. The heatmaps are standard jet colormaps and are overlapped on the original image, where red color highlights the activation region associated with the predicted class. More specifically, for the COVID-19 image group, the heatmap strongly indicated the suspected regions, as shown in examples from WKUH (Figure 6, top left), CNUH (Figure 6, top middle) and SIRM (Figure 6, top right). For the other pneumonia image groups, the heatmap demonstrated some suspected regions inside the lung area; the intensity was lower than that of the regions in the COVID-19 image group (Figure 6, bottom left). For the healthy image group, there was no heatmap corresponding to the suspected regions (Figure 6, bottom middle). For the lung cancer images, the heatmap indicated some suspected regions inside the lung area; however, the intensity was also lower than that of the regions in the COVID-19 pneumonia group (Figure 6, bottom right).

Figure 6. Confusion matrice and ROC curve in FCONet using VGG16; COVID-19: coronavirus disease; ROC: receiver operating characteristic.



To test the generalizability of our proposed framework, we also trained and tested the models based on institutional data split for COVID-19 data: training data from CNUH and SIRM and tested data from WKUH. Because the COVID-19 data were split with a ratio of 65:35 (773 training data and 421 testing data for COVID-19), the other non–COVID-19 data were randomly split with the same ratio in a stratified fashion. Table 6 summarizes the performance of the FCONet framework. With ResNet-50, the sensitivity, specificity and accuracy for classifying COVID-19 pneumonia were 97.39%, 99.64% and 98.67%, respectively ($P<.001$). With VGG16, the sensitivity, specificity, and accuracy for classifying COVID-19 pneumonia were 97.15%, 99.64% and 98.57%, respectively ($P<.001$). With Xception, the sensitivity, specificity, and accuracy for classifying COVID-19 pneumonia were 90.50%, 94.82% and 92.97%, respectively ($P<.001$). With Inception-v3, the sensitivity, specificity, and accuracy for classifying COVID-19 pneumonia were 74.58%, 99.46% and 88.79%, respectively ($P<.001$). These results show that the FCONet framework can classify COVID-19 regardless of the data split approach.

Table 6. Performance of the FCONet framework based on institutional data split for COVID-19 data.

Model and data group	Sensitivity, %	Specificity, %	Accuracy, %	AUC[a]	*P* value

Discussion

Principal Findings

We were able to develop the FCONet deep learning models to diagnose COVID-19 pneumonia in a few weeks using transfer learning based on pretrained models. The FCONet based on ResNet-50 showed excellent diagnostic performance to detect COVID-19 pneumonia. Although the diagnostic accuracy of the FCONet models based on VGG16, ResNet-50, and Xception was excellent in the testing data set (sensitivity, 97.91%, 100%, and 97.91%, respectively; specificity, 100%, 99.64% and 99.29%, respectively), external validation using the low-quality image data set demonstrated that detection accuracy was the highest with ResNet-50 (96.97%), followed by Xception (90.71%), Inception-v3 (89.38%), and VGG16 (87.12%).

To collect as many images as possible within a limited time, we collected readily available chest CT images of COVID-19 patients from institutions in our region (WKUH and CNUH) and a public COVID-19 database established by SIRM. We also systematically searched for chest CT images of COVID-19 embedded in recent papers published between January 19 and March 25, 2020. As these CT images in the published paper were of low quality, we used them only in an additional external validation data set.

During a national crisis such as the COVID-19 pandemic, when the number of infected patients is precipitously increasing and physicians are occupied combating the disease, rapid development of AI methods to detect COVID-19 in CT is crucial to alleviate the clinical burden of physicians and to increase the efficiency of the patient management process [8]. However, significant challenges remain when developing such AI techniques within a limited time to collect CT data and train AI models.

To save time for AI training, we used the chest CT images directly without preprocessing of the lung segmentation. In general, lung segmentation preprocessing is regarded to improve the accuracy of AI training [24-27]; we believe that this improvement can be traded off in exchange for saving time. For AI training, we chose the transfer learning algorithms. Transfer learning enabled us to save time by using pretrained CNN models in the ImageNet data sets, including VGG16, ResNet-50, Inception-v3, and Xception [28]. In our study, FCONet based on ResNet-50 showed excellent results and outperformed the FCONet models based on the other three pretrained models in both our testing data set and the additional external validation data set. The VGG model is regarded as a traditional sequential network architecture and may be hampered by slow training and a large model size [17]. The ResNet-50 model is characterized by network-in-network architectures, which have much deeper layers than those of VGG models, enabling reduction of the model size [18]. Our results suggest that transfer learning for a 2D deep learning framework can be robustly applied to deep learning models and that the ResNet-50 model provides the best accuracy.

We adopted AI training based on a 2D image framework rather than a 3D framework because 3D deep learning requires significantly higher computation power than sequential 2D image analyses [29]. In our emergent clinical setting to fight COVID-19, a simple and rapid model may be preferable to a complex and slow model. In addition, training a 2D image framework saves time for AI development.

Despite limited resources and time, we were able to generate a deep learning model to detect COVID-19 from chest CT with excellent diagnostic accuracy. To date, a few papers have been published on AI models for detecting COVID-19 in chest CT images [6]. An AI model named COVNet was trained using 4356 CT images from six hospitals in China. It showed 90% sensitivity (95% CI 83%-94%) and 96% specificity (95% CI 93%-98%) in detecting COVID-19, which is comparable with our results. However, we cannot compare our FCONet to COVNet because the training and testing data sets are different.

Although chest radiography is the most commonly used imaging tool to detect COVID-19, its sensitivity is lower than that of CT [30]. However, in this pandemic period, clinicians may hesitate to perform chest CT due to limited resources such as CT scanners and radiologists as well as contamination of CT scanners [31]. In our hospitals (WKUH and CNUH), we recently dedicated a mobile CT scanner exclusively to COVID-19 patients to alleviate the physical and mental stress of medical staff. We believe that incorporating an AI model to detect suspicious lesions of COVID-19 pneumonia can improve the workflow by providing rapid diagnostic support.

Limitations and Future Work

Our study has several limitations. Firstly, our AI models were validated mainly using a split testing data set. Thus, the testing data set was obtained from the same sources as the training data set. This may raise issues of generalizability and overfitting of our models [32,33]. Indeed, the detection accuracy of our model decreased slightly for the external validation data set using chest CT images from published papers. However, the initial goal was to incorporate a deep learning model in our emergent clinical setting as a supporting tool. In the near future, we will train our model using CT images from various institutions and countries. Secondly, we used a relatively small amount of data to train the deep learning models. Thus, we will establish a sustainable AI training system that can continue to train our model using prospectively collected CT images.

Conclusions

We described FCONet, a simple 2D deep learning framework based on a single chest CT image, as a diagnostic aid that provides excellent diagnostic performance to diagnose COVID-19 pneumonia. The FCONet model based on ResNet-50 appears to be the best model, outperforming other models based on VGG16, Xception, and Inception-v3.

Abstract

Background: The coronavirus disease (COVID-19) has become an urgent and serious global public health crisis. Community engagement is the first line of defense in the fight against infectious diseases, and general practitioners (GPs) play an important role in it. GPs are facing unique challenges from disasters and pandemics in delivering health care. However, there is still no suitable mobile management system that can help GPs collect data, dynamically assess risks, and effectively triage or follow-up with patients with COVID-19.

Objective: The aim of this study is to design, develop, and deploy a mobile-based decision support system for COVID-19 (DDC19) to assist GPs in collecting data, assessing risk, triaging, managing, and following up with patients during the COVID-19 outbreak.

Methods: Based on the actual scenarios and the process of patients using health care, we analyzed the key issues that need to be solved and designed the main business flowchart of DDC19. We then constructed a COVID-19 dynamic risk stratification model with high recall and clinical interpretability, which was based on a multiclass logistic regression algorithm. Finally, through a 10-fold cross-validation to quantitatively evaluate the risk stratification ability of the model, a total of 2243 clinical data consisting of 36 dimension clinical features from fever clinics were used for training and evaluation of the model.

Results: DDC19 is composed of three parts: mobile terminal apps for the patient-end and GP-end, and the database system. All mobile terminal devices were wirelessly connected to the back end data center to implement request sending and data transmission. We used low risk, moderate risk, and high risk as labels, and adopted a 10-fold cross-validation method to evaluate and test the COVID-19 dynamic risk stratification model in different scenarios (different dimensions of personal clinical data accessible at an earlier stage). The data set dimensions were (2243, 15) when only using the data of patients' demographic information, clinical symptoms, and contact history; (2243, 35) when the results of blood tests were added; and (2243, 36) after obtaining the computed tomography imaging results of the patient. The average value of the three classification results of the macro–area under the curve were all above 0.71 in each scenario.

Conclusions: DCC19 is a mobile decision support system designed and developed to assist GPs in providing dynamic risk assessments for patients with suspected COVID-19 during the outbreak, and the model had a good ability to predict risk levels in any scenario it covered.

Introduction

Background

In December 2019, cases of pneumonia with unknown cause, which was designated the coronavirus disease (COVID-19) in February by the World Health Organization (WHO), were reported in Wuhan, Hubei Province, China [1]. The number of cases of COVID-19 increased rapidly worldwide over the next few months, and the WHO announced a pandemic on March 11, 2020 [2]. As of April 29, 2020, 2,995,758 cases of infection and 204,987 deaths were reported worldwide [3]. COVID-19 has become an urgent and serious global public health crisis.

As a new infectious disease in humans caused by severe acute respiratory syndrome coronavirus 2 (SARS-COV-2), COVID-19 is characterized by respiratory symptoms and human-to-human transmission [4]. Rapid asymptomatic transmission of COVID-19 and high mortality in susceptible, elderly, and immunocompromised people make it necessary to identify and control positive patients quickly [5]. However, some characteristics of SARS-COV-2 have further increased the difficulty of early identification and isolation of patients. Wu et al's [6] research showed that the mean basic reproduction number of SARS-CoV-2 is 2.68 (95% credible interval [CrI] 2.47-2.86) and that the epidemic doubling time is 6.4 days (95% CrI 5.8-7.1 days). Viral RNAs can be found in nasal discharge, sputum, and sometimes in blood or feces [7]. As described in past studies, similar to the other respiratory viral infections, the most common symptoms at the onset of COVID-19 were fever, cough, and fatigue [4,7], which increased difficulties in early identification of patients who were infected. Meanwhile, with the development of the epidemic, people's panic and the shortage of medical resources has greatly hindered the prevention and control of the disease. In addition, research by Ji et al [8] revealed that the current mortality of COVID-19 is significantly positively related to the burden of health care. Therefore, how to evaluate patients with COVID-19, suspected cases, and other patients with similar symptoms, and effectively triage under the condition of medical resource shortages is of great significance to protect the susceptible population, reduce hospital cross infection, and decrease the burden on medical resources.

Challenges to General Practitioners in the COVID-19 Outbreak

Community engagement is the first line of defense for effective prevention and control of infectious diseases [9]. In addition, in China, general practitioners (GPs) in primary care institutions play an important role in this battle. GPs are engaged in blocking the viral transmission by monitoring people at designated checkpoints, treating patients, and providing medical surveillance in the community. In addition, they detect, diagnose, and treat patients at different levels of fever clinics, providing continuous care for patients who are discharged and are chronically ill [9].

Disasters and pandemics pose unique challenges to health care delivery [10]. There are a lot of challenges for GPs and other health professionals to maintain their work and meet the increasing need for digital health care. First, the most serious problem is that they are at risk of getting infected; therefore, in-person visits need to be reduced to a minimum level. Second, many health service centers have experienced a rush of people who are worried or infected, and patients with chronic diseases who are undergoing treatment or observation are also at risk of being infected when they visit the outpatient clinics. Finally, medical information systems are generally interrupted and discontinuous; data still needs to be manually recorded or repeatedly registered by health professionals, which increases the workload of health professionals and makes it impossible to manage the dynamic information of patients in a timely and comprehensive manner.

The Role of Telemedicine in the Era of COVID-19

Telemedicine has a critical role in emergency responses and is an ideal model for managing infectious diseases [10,11]. In addition, the key factor that slows the spread of the virus is the "social distance," which can directly reduce person-to-person contact [11]. Telemedicine can also deploy large numbers of health care providers rapidly to facilitate triaging without in-person visits, provide clinical services when local medical resources are unable to meet the demand, and reduce the risk of nosocomial infection.

Until now, researchers have developed many different forms of telemedicine systems to meet the needs of fighting against the epidemic. Jin et al [12] built and deployed an artificial intelligence (AI)–assisted system for automatic computed tomography (CT) image analysis and recognition of COVID-19 within 4 weeks, which has been applied in many hospitals, greatly reducing the pressure of radiologists. Du et al [13] proposed a hybrid AI model for COVID-19 prediction that fully considered the effects of prevention and control measures, and the improvement of public prevention awareness, and has been applied in a number of Chinese cities. Moreover, Reeves et al [14] built a series of standardized tools based on the existing electronic health record (EHR) system for the COVID-19 epidemic to support outbreak management, including scripted triaging, electronic check-in, standard ordering and documentation, secure messaging, real time data analytics, and telemedicine capabilities.

These models and systems have considered the main problems from different perspectives during the COVID-19 epidemic and have been deployed and published in a short time, which has played a significant role in fighting the epidemic. However, to the best of our knowledge, there is still no suitable mobile management system that can help GPs realize the automatic collection of data, dynamic risk assessment, and effective triaging and follow-ups with patients with COVID-19, as well as the effective reduction of the pressure on large designated general hospitals.

Study Aims

In this study, by integrating doctor experience, clinical guidelines, and retrospective data, we designed and developed a dynamic risk assessment decision support system for COVID-19 (DDC19) to assist GPs in data collection, dynamic risk assessment, triage management, and follow-ups during the outbreak of COVID-19. The DDC19 is designed to build a free mobile app that can cover all the different situations encountered by residents and GPs, and GPs can use it for dynamic continuity management. We describe our experiences, lessons learned, and recommendations for the design and implementation of telemedicine tools in future health emergencies.

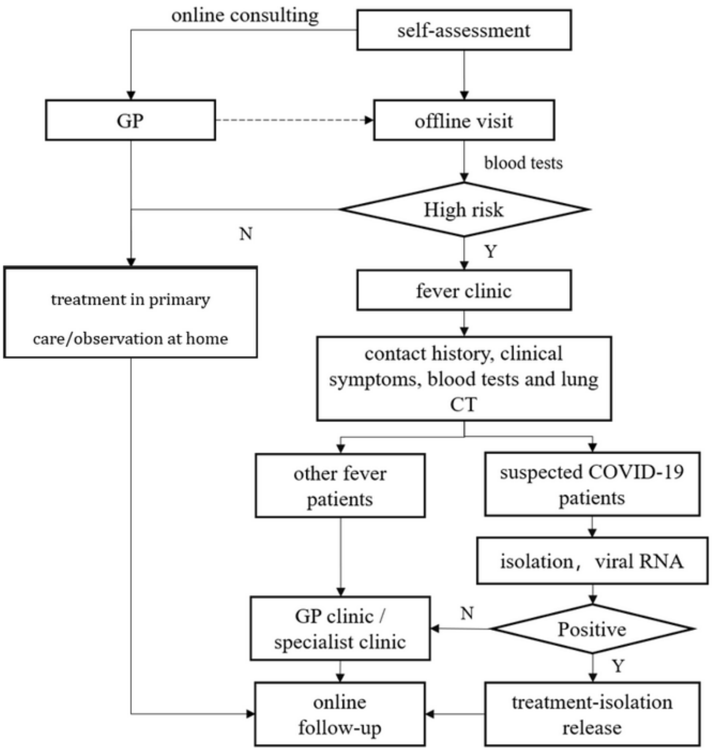
Methods

The Covering Scenes of DDC19

To achieve the early assessment and triage of patients with COVID-19 and ease the pressure of shortages in medical resources, the following key issues need to be resolved: how to fully grasp and effectively manage the residents' status in real time without increasing the GP's working burden and, without omitting potential patients with COVID-19, how to effectively use medical knowledge and risk stratification models to achieve effective evaluation and classification, as well as the patients' scientific stratification.

Accordingly, based on the principle of the four early approaches (early detection, early reporting, early isolation, and early treatment) and the actual scenes and process of patients using health care, DDC19 was designed to help GPs manage their patients who had a fever or respiratory symptoms, or suspected infection with SARS-CoV-2 during the outbreak of COVID-19. Several scenarios were involved and are demonstrated in Figure 1. First, patients should fill in the self-assessment questionnaire in the system. After that, according to the risk level assessed by the system and the diagnosis and treatment suggestions given, patients can choose to contact the GPs online for consultations or directly go to the primary care center for further examination and treatment. Second, when patients choose to visit in-person, those who are at low- and moderate-risk may receive blood tests and have their risks reassessed based on actual clinical symptoms and blood test results. After reassessment, if patients are still at low- and moderate-risk, GPs will give them some necessary treatment and follow-up online. For patients who are high risk, they should be transferred to a fever clinic as soon as possible. Third, patients at high risk who are transferred to the fever clinic will receive a lung CT scan and viral RNA test. If the lung CT shows a clinical manifestation of COVID-19 or the viral RNA test is positive, they will be isolated and treated. Otherwise, they will be transferred to the GP or specialist that is needed. Finally, the cured patients will return to the community, GPs will continue monitoring their conditions and dynamically assess risk online, as well as follow-up with them offline if needed.

Figure 1. The covering scenes of patients using health care during the outbreak of COVID-19. COVID-19: coronavirus disease; CT: computed tomography; GP: general practitioner.



The Design of Main Functions and Business Process of DDC19

To make full use of the previously mentioned online-offline combined triage mode during the COVID-19 outbreak, we deeply integrated GP's experience and suggestions, and designed the business process of the DDC19 system in detail. In the first step, we reviewed the COVID-19 guidelines [15] and fully integrated the actual clinical experience of GPs on the frontline of COVID-19 prevention and control to determine the main functions of the system and the content of the questionnaire. In the second step, based on the content of the questionnaire, the main data elements of the risk stratification model were determined, and, further considering the variability of the amount of the available questionnaire content data, a dynamic risk stratification model was constructed. In the third step, we validated and adjusted the model with retrospective clinical data. Therefore, the functions and business processes of the system were gradually completed according to the changes of clinical requirements.

As shown in Figure 2, the system mainly includes the patient-end and the doctor-end. Its main functions, including online patient clinical data collection, dynamic risk assessment, online classification, and appointment, can be achieved through the interaction between two mobile terminals. For the online collection module of the patient's clinical data, it was completed by the structured questionnaires and uploading of examination report pictures. The questionnaire content related to the early assessment of COVID-19 will be gradually adjusted according to the experience of GPs and clinical guidelines [15]. The detailed information of the health questionnaire is shown in Multimedia Appendix 1. To ensure that patients with COVID-19 were not omitted and that enough attention was given to the patients with low risk and moderate risk, and to improve the reliability of risk assessment, a dynamic risk assessment module was designed based on the current clinical practice experience and expert recommendations, and the risk assessment level of COVID-19 was divided into low risk, moderate risk, and high risk. In addition, to ensure the patients' risk level can be provided in real time and to consider the different dimensions of clinical data that patients uploaded, the dynamic risk stratification model, based on machine learning, was trained by the retrospective data (see details in the next section).

The Construction of the COVID-19 Dynamic Risk Stratification Model

Considering the characteristics of COVID-19 such as unobvious symptom specificity and long incubation period, we constructed a COVID-19 dynamic risk stratification model with high recall and clinical interpretability. Based on a multiclass logistic regression algorithm, it integrates the retrospective clinical data analysis results of patients, doctors' experiences, and clinical guidelines.

To meet the risk assessment requirements of COVID-19 at the system level for multiple levels and multiple scenarios, this model was based on patients' data from the fever clinic during the COVID-19 epidemic period and patients' risk levels provided by GPs according to COVID-19 diagnosis and treatment guidelines [15]. Currently, for patients who visit the fever clinic of designated hospitals during the epidemic, GPs will provide the COVID-19 risk assessment to them based on epidemiological history and clinical manifestations (symptoms, blood tests, and lung CT scan). The detailed content and process of evaluation are shown in Textbox 1. According to the different levels of health information submitted by patients in the system, the research team used the patient's risk level (assessed by GPs according to clinical guidelines as patient's label), demographic data, epidemiological history, clinical symptoms, data of laboratory tests, and lung CT imaging as the characteristics of the patient to construct a dynamic risk stratification model. The detailed model construction process is shown in Figure 3.

Compared with the fixed-risk assessment method, which required all the information of patient's medical history, laboratory examination, and the result of the lung CT, this model can not only provide COVID-19 risk stratification for new patients but also provide a dynamic risk level assessment and medical advice based on the clinical data submitted in the system by the patient at the different stages.

Textbox 1. The content and standards of coronavirus disease risk assessment.

Epidemiological history

- Within 14 days before the onset of the disease, the patient has a travel or residence history in the high-risk regions or countries.
- Within 14 days before the onset of the disease, the patient has a history of contact with those infected with severe acute respiratory syndrome coronavirus 2 (those with a positive nucleic acid testing result).
- Within 14 days before the onset of the disease, the patient had direct contact with patients with fever or respiratory symptoms in high-risk regions or countries.
- Disease clustering (2 or more cases with fever or respiratory symptoms occur at such places as homes, offices, and school classrooms, within 2 weeks)

Clinical manifestations

- Fever or respiratory symptoms
- The white blood cell counts in the early stage of the disease is normal or decreased, or the lymphocyte count decreases over time.
- Computed tomography imaging features of the coronavirus disease

Figure 3. The construction process of the dynamic risk stratification model.

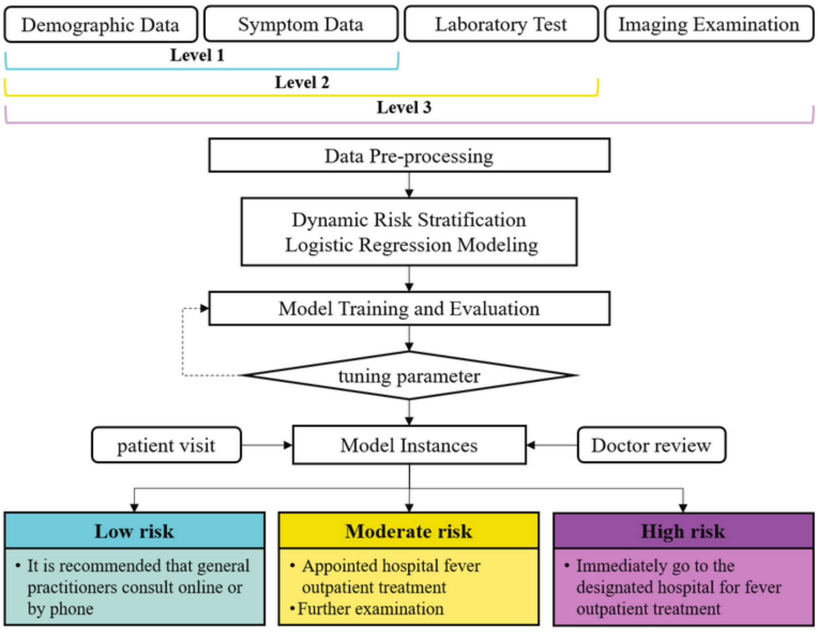

Table 1 shows the data elements used in the dynamic risk stratification model and their corresponding detailed descriptions. Data elements mainly include four categories: demographic data, epidemiological history, clinical symptoms (eg, fever, cough), the data of laboratory tests (eg, blood routine test and C-reactive protein [CRP] test), and lung CT imaging data. According to several studies [16-19], these data elements include the early clinical symptoms of COVID-19 and the easily accessible data of clinical examination, which plays an important role in early assessment.

Table 1. The data elements in the dynamic risk stratification model.

Main category, data element	Description
Patient demographic information	
Patient ID	Unique patient identifier
Gender	Patient’s gender identity
Age	Patient’s age
Clinical symptoms	
Fever	Normal: temprature≤37.2˚C; low fever: temperature between 37.2˚C and 38.5˚C; High fever: temperature≥38.5˚C
Cough	Cough or dry cough
Sputum production	N/A[a]
Fatigue	N/A
Breathing	Shortness of breath, anhelation, polypnea, etc
Chest uncomfortable	Chest pain or chest distress
Pharyngalgia	Pharyngalgia
Headache	Headache or dizziness
Chills	Fear of cold
Soreness	Body aches, joint pain, myalgia
Stuffy nose	Stuffy nose or runny nose
Gastrointestinal reactions	Feeling sick, vomiting, abdominal pain, diarrhea, etc
Epidemiology history	
Contact history	Have a COVID-19[b] contact history
Imaging examination	
CT[c]	Lung CT shows viral pneumonia
Blood routine examination	
WBC[d]	White blood cell count (10E9/L)
GRAN[e]	Neutrophil count (10E9/L)
LYM[f]	Lymphocyte count (10E9/L)
RBC[g]	Red blood cell count (10E12/L)
HGB[h]	Hemoglobin concentration (g/L)
HCT[i]	Hematocrit (%)
MCV[j]	Mean corpuscular volume (fl)
MCH[k]	Mean hemoglobin content (pg)
MCHC[l]	Mean corpuscular hemoglobin concentration (g/L)
RDW[m]	Red blood cell distribution width (%)
PLT[n]	Blood platelet count (10E9/L)
MPV[o]	Mean platelet volume (fl)
PCT[p]	Platelet hematocrit (%)
PDW[q]	Platelet distribution width (10 [GSD[r]])
MO[s]	Mononuclear cell count (10E9/L)
EO[t]	Eosinophil count (10E9/L)

Main category, data element	Description
BA[u]	Basophil count (10E9/L)
NRBC[v]	Percentage of nucleated red blood cells
IG[w]	Immature granulocyte percentage (%)
CRPH[x]	C-reactive protein (mg/L)

[a] Not applicable.
[b] COVID-19: coronavirus disease.
[c] CT: computed tomography.
[d] WBC: white blood cell.
[e] GRAN: granulocytes.
[f] LYM: lymphocyte.
[g] RBC: red blood cell.
[h] HGB: hemoglobin.
[i] HCT: hematocrit.
[j] MCV: mean corpuscular volume.
[k] MHC: mean hemoglobin content.
[l] MCHC: mean corpuscular hemoglobin concentration.
[m] RDW: red blood cell distribution width.
[n] PLT: platelet.
[o] MPV: mean platelet volume.
[p] PCT: platelet hematocrit.
[q] PDW: platelet distribution width.
[r] GSD: geometric standard deviation.
[s] MO: mononuclear.
[t] EO: eosinophil.
[u] BA: basophil.
[v] NRBC: nucleated red blood cells.
[w] IG: immature granulocyte.
[x] CRPH: C-reactive protein.

After the optical character recognition (OCR) module and natural language processing (NLP) module recognize and preprocess the image and text data, the structured patient data is extracted from the app back end database to the data preprocessing module for subsequent data analysis; the detailed data elements are shown in Table 1. The system established a multiclass logistic regression model to dynamically predict and stratify the risk of COVID-19 infection based on the input of different levels of patient clinical data. Logistic regression has good classification ability and interpretability, which has been widely used in the field of machine learning. The hypothetical function is:

In this formula, x is the model input, and θ is the main parameter of the model. This parameter is obtained mainly by fitting the observed data features and corresponding labels. For the case of linear boundaries, $\theta^T x$ can be explained as follows:

The output $h_\theta(X) \in (0,1)$ represents the probability that the result is 1. Therefore, for the binary classification problem, the probability that the result of the input $x$classification is category 1 and category 0 is:

$$P(y = 1 \mid x; \theta) = h_\theta(x)$$

$$P(y = 0 \mid x; \theta) = 1 - h\theta(x)$$

To measure the difference between the model prediction classification result $h_\theta(X)$ and the true value y, the corresponding loss function is defined as:

For m training samples, the loss function is expressed as follows:

Based on the retrospective data of m patients, by minimizing the loss function $J(\theta)$, the parameter θ makes the predicted classification category closest to the patient's true risk level obtainable. However, to balance the distribution of medical resources as much as possible and allow more patients to get enough medical attention, the risk stratification is set to three categories: low risk, moderate risk, and high risk. Therefore, in terms of model construction, to adapt to the above multiclassification situation, the training set data is divided into two different categories to train multiple classifiers. Assuming that n represents the number of categories in the training set, then classifiers need to be trained for prediction; the function is expressed as:

Where i is the i-th category. For the input data of the newly visited patient, classifiers will be used to predict the risk level, and the classification result with the highest output probability is taken as the risk level of the patient. The function is expressed as:

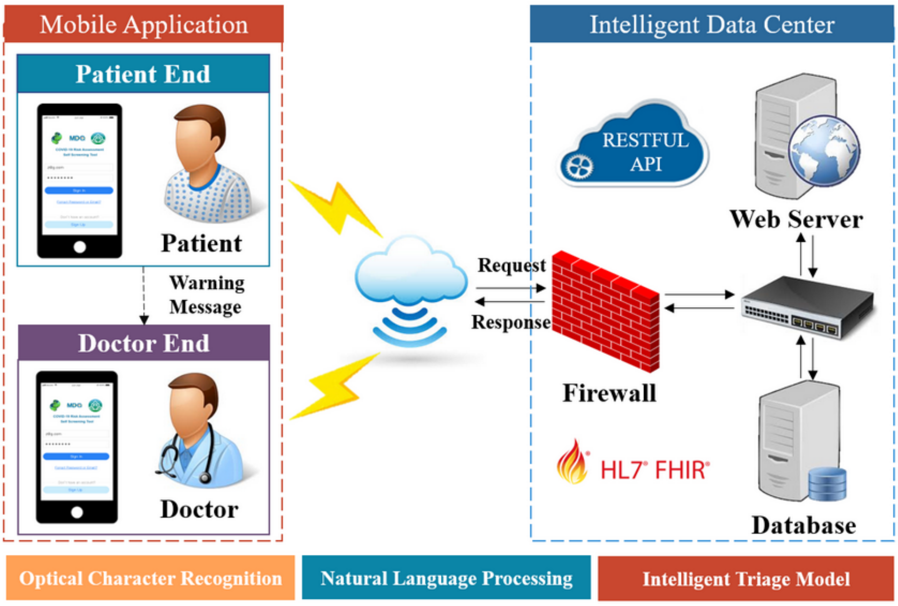
Results

The Architecture and Prototype of DDC19

To prove the effectiveness of the previously mentioned COVID-19 dynamic risk stratification model, as well as the feasibility and practicability of the early assessment and triage system, the research team developed the system prototype and put it into practical operation and application.

As shown in Figure 4, the DDC19 is mainly composed of three parts: two main mobile terminal apps (patient-end and GP-end), and the database system with its related components and underlying related support model. All mobile terminal devices connect to the back end data center wirelessly to achieve request sending and data transmission. In this section, the main architecture and functions of each part will be described in detail.

Figure 4. System architecture diagram. API: application programming interface; FHIR: Fast Healthcare Interoperability Resources; HL7: Health Level 7; RESTFUL: representational state transfer.



The mobile app end builds user interface based on the progressive Vue framework. The server end implements data and service interaction with the front end by the representational state transfer application programming interface specification. It is more concise and lighter, both for the processing of uniform resource locators and the encoding of the payload [20]. The server end builds a JavaScript scripting environment by Node.js; improves the system performance using event-driven, nonblocking, and asynchronous input and output models; and optimizes the transmission volume and scale of the app. The data storage adopts the MongoDB open-source database system, which has the characteristics of open-source, cross-platform, and powerful expansion capabilities. To achieve the storage and exchange of patient's clinical data, structured processing data of the laboratory test, and image reports, the system adopts the standard framework of Fast Healthcare Interoperability Resources to ensure the accuracy of clinical data storage and expression. To make full use of the data in the form of pictures contained in the laboratory test and image reports, the system integrates the mature OCR module and NLP module to complete the identification and extraction of relevant clinical information in the picture.

For the patient-end (Figure 5A), the app assists patients in collecting, recording, and transferring their health data. There are two forms of recording health data for patients, including filling in a structured questionnaire by themselves and uploading pictures (Figure 5B and C). The range of health data includes the patient's basic information, a health questionnaire related to COVID-19 early assessment, and clinical test results. In addition, the content of the health questionnaire will be gradually adjusted according to the relevant authoritative guidelines (see details in Multimedia Appendix 1) [15]. In addition, the data of clinical examination, including laboratory test reports such as blood routine test and CRP, and image examination reports such as lung CT reports can be uploaded as pictures directly by the camera of the mobile device. The mobile app communicates with the back end server through a message transmission mechanism. This mechanism establishes a balance between real time data transmission and system availability, which can completely meet the requirements of medical data transmission. After being analyzed by the back end database risk stratification model and related algorithms, the evaluation report will be returned to the patient app, mainly including results and evidence of the risk level evaluation and the corresponding detailed medical advice (Figure 5C). Patients can also update their symptoms and clinical data in real time on the app. The app will give new evaluation results and medical advice immediately. In addition, the patient app supports online patient appointments and provides a list of GPs working in the primary care clinics or fever clinics in designated hospitals (Figure 5D).

For the GP-end (Figure 6A), the app mainly assists GPs in managing their patients, including checking the information of their patients in the system, the results, and the basis of the automatic risk assessment, and giving recommendations based on the assessment results. First, it supports GPs to check their patients according to their risk level or appointment date and searches their patients by their name or mobile phone number (Figure 6B). Second, for the patient who has completed an in-person visit, it supports GPs in uploading the patient’s laboratory test results, image examination reports, and other data to the back end database to which the patient belongs, and they will obtain an update on the patient's risk assessment report. In addition, it also supports GPs in checking the details of their risk assessment results and the previous evaluation records, which helps GPs to grasp the patient's dynamic condition completely and in a timely manner. For a patient who is high risk that did not go to the designated hospital for further investigation timely, the system would send a reminder message for GPs to deal with it as soon as possible. At the same time, GPs can also give recommendations for the patient who applies for offline consultation based on their personal information and submitted clinical data (Figure 6C). GPs can grasp the status of all the residents they managed by these functions of the app. Third, to help GPs in different health institutions grasp the latest prevention and control knowledge of COVID-19 in real time, the GP-end has also developed the function of online training for GPs (Figure 6D).

Case Studies and Data Validation

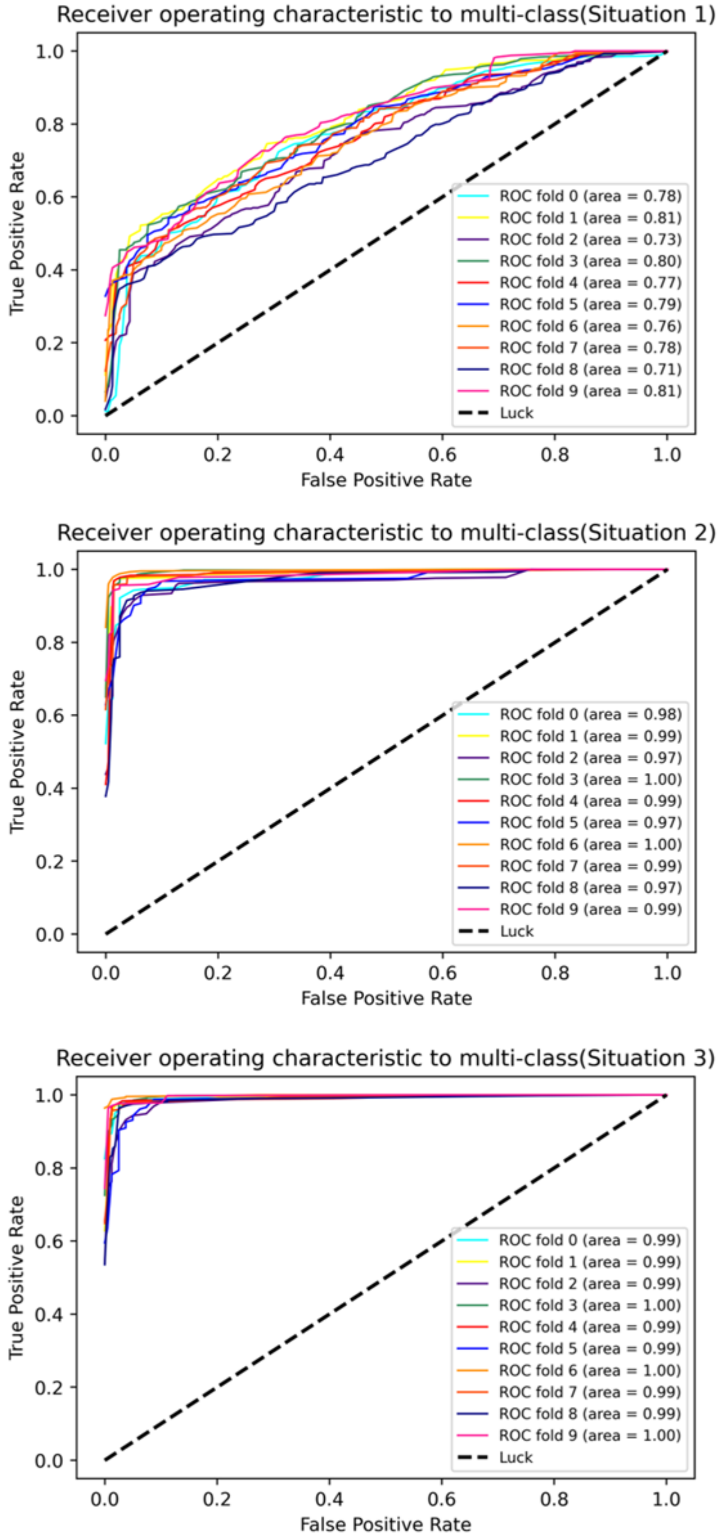
For the purpose of testing and verifying the dynamic risk stratification model of DDC19, 2243 patients’ information were collected from the fever clinic of the first affiliated hospital of Zhejiang University from January 19 to March 11, 2020. The data includes the patients’ basic information (gender and age), chief complaint, medical history, physical examination, laboratory tests, and the lung CT image examination reports. The first affiliated hospital of Zhejiang University is a class A hospital with 2500 beds. In 2019, the number of outpatient and emergency services reached 5 million and 243,300 were discharged.

The patient's medical record number is used as the unique identifier, and the data corresponding to the earliest outpatient visit record of each patient within the range from January 19, 2020, to March 11, 2020, is taken. In terms of data preprocessing, except for age, which is used as a continuous variable, the other data are classified as categorical variables. The imaging examination results were divided into clearly marked “viral pneumonia,” other lung function categories, and no abnormalities. According to the first hospital’s reference threshold, the results of laboratory tests were classified as “lower/normal/higher” or “normal/higher.” Age was standardized, and other missing elements were filled with 0.

In our study, according to the risk assessment model, patients were divided into three groups: high-risk group, moderate-risk group, and low-risk group. Out of the 2243 patients, 628 (28.00%) were in the low-risk group, 1447 (64.51%) were in the moderate-risk group, and 168 (7.49%) were in the high-risk group. Among them, 17 patients were clinically diagnosed with COVID-19; 16 patients were in the high-risk group, and 1 patient was in the moderate-risk group (see details in Multimedia Appendix 2).

To ensure the accuracy of risk stratification and to avoid the model overfitting, we used the three categories of low risk, moderate risk, and high risk as labels, and adopted a 10-fold cross-validation method to evaluate and test the model in different scenarios (different dimensions of personal clinical data accessible at the early stage). When we only used the data of patients’ demographic information, clinical symptoms, and contact history, the data set dimensions were (2243, 15). When the results of blood tests were added, the data set dimensions were (2243, 35). After obtaining the CT imaging results of the patient, the data set dimensions were (2243, 36; see details in Multimedia Appendix 2). Figure 7 demonstrates the training set based on the data set in the previously mentioned three scenarios, labels based on the patient's risk level, the receiver operating characteristic (ROC) curve, and its corresponding area under the curve (AUC) value after 10 cross-validation model test results.

Figure 7. The ROC curve of the dynamic risk stratification model. ROC: receiver operating characteristic.



As can be seen from the ROC curve and its corresponding AUC value, even if only the information of the patient's epidemiology contact history and clinical symptoms were used, the average value of the three classification results of macro-AUC were all above 0.71. When the data of laboratory tests and imaging were added, the macro-AUC increased to above 0.97. Therefore, the model has a good prediction ability for the above three scenarios. The detailed evaluation indicators of the model are shown in Table 2. All indicators were averaged after 10-fold cross-validation, and Class 1, Class 2, and Class 3 refer to low risk, moderate risk, and high risk, respectively.

Table 2. The indicators of the model.

Variables	Situation 1			Situation 2			Situation 3		
	Precision	Recall	F1 score	Precision	Recall	F1 score	Precision	Recall	F1 score
Class 1	0.380	0.576	0.456	0.947	0.956	0.951	0.949	0.956	0.952
Class 2	0.750	0.552	0.634	0.976	0.956	0.966	0.980	0.957	0.968
Class 3	0.750	0.947	0.831	0.841	0.941	0.885	0.850	0.982	0.909
Accuracy	0.588	0.588	0.588	0.955	0.955	0.955	0.959	0.959	0.959
Macroaverage	0.627	0.692	0.640	0.921	0.951	0.934	0.926	0.965	0.943
Weighted average	0.646	0.588	0.599	0.958	0.955	0.956	0.961	0.959	0.959

Discussion

Principal Findings

This paper describes a dynamic risk assessment decision support system, which has been used by many Chinese GPs in Zhejiang Province during the COVID-19 outbreak. The DDC19 was designed for GPs working in different situations such as online consultation, assessment evaluation, and triaging in different offline scenarios (community, airport, train station, fever clinic, etc) and following up with suspected patients and discharged patients. It fills in the gap of traditional health care and helps GPs effectively manage residents with different statuses. For patients in DDC19, they can use it to record health data, obtain real time results of risk assessment, and communicate with their GPs without in-person visits; for GPs, they can intuitively grasp their patients' conditions and provide online advice and interventions in real time. DDC19 contributes to the effective triaging of patients, relieves the pressure of offline clinics of designated hospitals to a certain extent, and reduces cross-infection in the hospital during the COVID-19 outbreak.

With the worldwide spread of COVID-19 and the shortage of medical resources, achieving scientific assessment and effectively triaging the patients in different states is the key to control it. Under the actual clinical condition, GPs need to comprehensively evaluate patients offline without specific symptoms based on their epidemiological contact history, symptoms, laboratory, and imaging findings, and advise in conjunction with the guideline's recommendations. Although it can assess patients, distinguish them with different risk levels, and find patients who are at high risk, it has a number of inherent defects that cannot meet the need for efficient prevention and control of COVID-19. At present, there is a lack of mobile medical information systems to meet the needs of patient classification, and it is infeasible to truly complete the triage of patients who are potentially infected with SARS-CoV-2 and other patients with similar symptoms before the outpatient clinic of the designated hospital. Researchers at the University of California, San Diego built a number of COVID-19–related tools to support physician's work based on the EHR system [14]. Although it is beneficial for docking with the process of the original standardized system in the hospital, it cannot directly obtain the data of patients at an early stage and grasp the dynamic conditions of patients. Nowadays, the implementation of early assessment and triage of COVID-19 relies on GP's knowledge and experience. GPs cannot make a dynamic risk assessment for their patients because they cannot completely grasp the condition of patients at each period in a timely manner. In addition, the problem of a large number of panicked patients with mild symptoms or no risk of COVID-19 going to the designated hospitals during the epidemic has not been resolved.

In the traditional model, clinicians need to obtain patient's clinical information within a short time by in-person visits. Due to the limitations of time and environment, it may be arduous to assess the patients' risk for clinicians. In our study, DDC19 can dynamically obtain patients' clinical information by self-report or upload health information, assess their risk level by the dynamic risk stratification logistic regression model, and assist GPs to diagnose and provide recommendations. Therefore, DDC19 helps GPs with online triaging, reduces the pressure of offline clinic, and lowers the risk of cross-infection in the hospital. On the coverage of patient clinical information, our system has been further expanded through questionnaires and inspection reports. The multiclass logistic regression model constructed by the retrospective data (Figure 7 and Table 2) shows that the average recall rate for patients who are high risk reached 0.947, even if the overall accuracy is 0.588 when we only have patients' contact history and clinical symptoms. As we added the results of blood cell counts and CRP, the accuracy rate of the average classification of the model in different risks reached 0.955, and it is close to 0.959 when considering the results of the lung's CT. Therefore, our results proved that the dynamic risk stratification model in DDC19 can accurately identify patients who are high risk by their basic health information (epidemiological history, clinical symptoms, and blood tests). DDC19 can help GPs dynamically manage each patient and expand the scope of COVID-19 risk assessment from traditional outpatient clinics to a new type of continuous health care. In addition, the model proves that only considering the contact history data, clinical symptoms, and blood test data available can achieve the risk stratification effect that combines the results of lung CT. It will reduce the burden of the radiologist and unnecessary waste of health resources.

DDC19 is also a new method for using clinical data, which can respond to emergencies conveniently and quickly. The existing COVID-19–related clinical analysis methods focus on establishing new hypotheses or searching for new research evidence. It is difficult to translate into a direct impact on accurate control and rapid response to the epidemic in a short time. Therefore, we built a complete mobile information system that integrates the workflow in the health care system. On the other hand, although there is a lot of research on informationization and AI-related to COVID-19 at the moment [21-24], most of the reported AI-driven tools are still limited to proof-of-concept models. To the best of our knowledge, there is currently only one article about risk assessment and prehospital triaging of patients with suspected COVID-19 [25], but the tools designed by this study are embedded in EHR systems to provide self-triaging and self-scheduling for patients, so doctor-patient interaction and posthospital follow-ups are not supported. In contrast, the mobile information system we designed fits well with the actual triage practice in business processes and supports GPs' real time grasp and assessment of the patient's health status with better flexibility.

Limitations

This study has some limitations that must be addressed in the next steps of development. First, the complete clinical situation should be considered during the establishment of the dynamic risk assessment model, including the severity of symptoms and history of underlying chronic diseases, but the early retrospective data of fever clinics do not contain these data elements. With further accumulation of relevant clinical data, our system can attempt earlier assessment and triage support methods, and we can also discuss and explore the impact of dynamic changes in patients' clinical information on their COVID-19 risk stratification. Second, as the system is still in the deployment and app stage, the relevant data of patients in the system and in-hospital visits cannot be obtained in a timely manner, so the clinical effects produced by the actual app of the system cannot be evaluated in a timely manner.

Conclusions

DCC19 is a mobile decision support system designed and developed to assist GPs in providing dynamic risk assessments for potential patients during the COVID-19 outbreak. It collects potential patients’ health information by mobile apps and data transmission mechanisms in different situations, assesses their risk levels through a dynamic risk stratification logistic regression model, and helps GPs manage patients and make further clinical decisions.

Abstract

Background: The outbreak of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes coronavirus disease (COVID-19), has been declared a global pandemic. Identifying individuals whose infection can potentially become severe is critical to control the case fatality rate of COVID-19. However, knowledge of symptoms that are prognostic of COVID-19 severity is lacking.

Objective: The objective of our study was to identify symptoms prognostic of COVID-19 infection severity.

Methods: We analyzed documented symptoms, including fever, cough, fatigue, expectoration, sore throat, chest distress, headache, diarrhea, rhinorrhea, stuffed nose, nausea, vomiting, muscle or joint ache, shortness of breath, and their associations with disease severity using a case series, including 655 confirmed cases from January 23 to February 5, 2020 in Henan Province, China. We also analyzed the influence of individual characteristics, including age, gender, and comorbidities, on symptoms with prognostic value.

Results: Fatigue (95% CI 0.141 to 0.334, *P*<.001), expectoration (95% CI 0.107 to 0.305, *P*<.001) and stuffed nose (95% CI –0.499 to –0.082, *P*=.006) were identified as the prognostic symptoms of COVID-19 patients from the multivariate analysis. Fever occurred in 603/655 (92.1%) of the patients but was not associated with disease severity. Fatigue accounted for 184/655 (28.1%) of the patients and was linearly associated with infection severity with statistical significance. Expectoration occurred in 169/655 (25.8%) patients in the cohort and was the sole prognostic factor for patients with cardiovascular complications, including hypertension. Shortness of breath, chest distress, muscle or joint ache, and dry cough, which occurred in 33 (5%), 83 (12.7%), 78 (11.9%), and 276 (42.1%) of the 655 patients, respectively, were significantly enriched among patients classified as severe. Stuffed nose and nausea were associated with favorable disease severity, especially among male patients. More female than male patients were documented as having muscle or joint ache. Headache was most enriched in patents aged 15 to 39 years, followed by those aged 40 to 64 years, with statistical significance.

Conclusions: Fatigue and expectoration are signs of severe COVID-19 infection. Shortness of breath, chest distress, muscle or joint ache, and dry cough are prevalent in severe patients. Expectoration is commonly present in older individuals and patients with cardiovascular disorders, including hypertension. Shortness of breath is prognostic of severe infection in male patients. Stuffed nose and nausea are favorable prognostic factors of severe infection, especially among male patients.

Introduction

In early December 2019, a pneumonia of unknown etiology emerged in Wuhan, a city in China with 11 million permanent residents and 5 million recurrent residents. On December 29, 2019, the first four cases of this pneumonia were reported, all of which were linked to the Huanan Seafood Wholesale Market in Wuhan. On January 7, 2020, a novel coronavirus was identified from the bronchoalveolar lavage fluid of a patient [1] and was named severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) by the World Health Organization (WHO) [2]. SARS-CoV-2 is the seventh enveloped RNA coronavirus to be identified [3]; it is transmittable via humans and has a 3-day median incubation time [4]. This virus has rapidly spread worldwide and has become a global health threat [5]. The high binding affinity of SARS-CoV-2 to angiotensin-converting enzyme 2 enables its rapid transmission [6]. Approximately 8 million individuals were infected and over 0.4 million deaths were reported worldwide as of June 2020 [7]. The death rate varies among countries and reached as high as 27.1% in Yemen [7].

Suspected cases were identified as having “fever or respiratory symptoms” and “traveling history or contact with confirmed infections within 2 weeks” [8]. Unlike the symptoms of severe acute respiratory syndrome (SARS), where fever was the symptom in approximately 100% of infected individuals [9], fever is only observed in 87.9% of patients with COVID-19 on admission [4]; other symptoms, such as cough (67.7%) and fatigue (38.1%), also frequently occur in SARS-CoV-2–infected individuals. Despite the many reports on symptoms associated with COVID-19, little effort has been devoted to the identification of symptoms associated with its severity. This study aims to identify symptoms with prognostic value on disease severity and their correlations with individual characteristics such as age, gender, and comorbidities to aid the prognosis of COVID-19 severity.

Methods

Data Source

This case series was collected by the Center for Disease Control and Prevention of Henan Province (Henan CDC) from 279 hospitals in the province. It includes 655 confirmed patients with COVID-19 who showed symptoms on admission and were admitted to hospitals from January 23, 2020, to February 5, 2020, with February 5 being the last follow-up date. Oral consent was obtained from the patients. All enrolled patients were diagnosed according to the WHO interim guidance [10].

Epidemic, clinical, and severity data were obtained with data collection forms from electronic medical records as part of standard care. The information recorded included demographic data, comorbidities, symptoms, and chest computed tomography (CT) scans. The date of disease onset was defined as the day when the symptom was noted. This study was approved by the ethics commissions of the Henan CDC with a waiver of informed consent. Cardiovascular disease (CVD) is a group of disorders of the heart and blood vessels, including cerebrovascular disease, coronary heart disease, cerebrovascular disease, peripheral arterial disease, and rheumatic heart disease.

We stratified severity into three groups: light, normal, and severe. According to the Novel Coronavirus Diagnostic and Therapeutic Plan (Seventh Edition) [11], COVID-19 severity was initially divided into four types: light, normal, severe, and terminal. We merged severe and terminal patients into one group, named the severe group. The clinical symptoms of patients in the light group were mild, with no pneumonia found in imaging. Patients in the normal group had fever, respiratory tract infection, and other symptoms, with manifestation of pneumonia observable in imaging. In adults, if one of the following three conditions was satisfied, the patient was classified as severe: 1) shortness of breath, respiratory rate ≥30 times per minute; oxygen saturation ≤93% in the resting state; arterial blood sample partial pressure (PaO_2)/oxygen concentration (FiO_2) ≤300 millimeters of mercury. Among children, if any of the following criteria were met, the child was classified as severe: shortness of breath (≤2 months of age, respiratory rate ≥60 times/min; 2 to 12 months of age, respiratory rate ≥50 times/min; 1-5 years of age, respiratory rate ≥40 times/min; >5 years of age, respiratory rate ≥30 times/min), excluding the effects of fever and crying; oxygen saturation in the resting state is ≤92%; assisted respiration (moaning, alar fluttering, three-concave sign); cyanosis; intermittent apnea; drowsiness; convulsion; refusing to eat or difficulty in feeding; and signs of dehydration. Patients with critically severe cases satisfied the following criteria: respiratory failure that requires mechanical ventilation; shock; other organ failure that requires intensive care unit monitoring and treatment.

Laboratory Testing

Throat or nose swab samples were collected from patients suspected of having SARS-CoV-2 infection for total RNA extraction using the respiratory sample RNA isolation kit (Shanghai BioGerm Medical Technology Co Ltd, Catalog No. ZC-HX-201-2), followed by real time reverse transcription–polymerase chain reaction (RT-PCR) using a SARS-CoV-2 nucleic acid detection kit (Shanghai BioGerm Medical Technology Co Ltd) in the biosafety level 2 lab at Henan CDC. Targeting the open reading frame (ORF1a/b), the primers and sequences were forward primer CCCTGTGGGTTTTACACTTAA, reverse primer ACGATTGTGCATCAGCTGA, and probe 5'-FAM-CCGTCTGCGGTATGTGGAAAGGTTATGG-BHQ1-3'. Targeting nucleocapsid protein, the primers and sequences were forward primer GGGGAACTTCTCCTGCTAGAAT, reverse primer CAGACATTTTGCTCTCAAGCTG, and probe 5'-FAM-TTGCTGCTGCTTGACAGATT-TAMRA-3'. Conditions for the amplifications were 50 °C for 10 minutes and 95 °C for 5 minutes, followed by 40 cycles of 95 °C for 10 seconds and 55 °C for 40 seconds. Following recommendations by the Chinese National Institute for Viral Disease Control and Prevention [12], positive and negative tests were defined as cycle threshold (C_t) values <37 and ≥40, respectively; samples with C_t values between these thresholds were subjected to retesting. A case was confirmed if two targets (ORF1a or 1b, nucleocapsid protein) tested positive by real-time RT-PCR in the initial test or both tests (when a retest was needed).

Statistical Analysis

Continuous variables were described using mean, SD, median, interquartile range (IQR), and range, and categorical variables were described by frequency and percentage. Means for continuous variables were compared using independent group tests when the data were normally distributed (Shapiro-Wilk test); otherwise, the Kruskal-Wallis H test was used (adjusted by Bonferroni correction). Proportions for categorical variables were compared using the chi-square test or Fisher exact test. The correlation of two variables was compared using Spearman rank correlation. The influencing variables for the severity of COVID-19 were analyzed using a linear regression model (forward method). All statistical analyses were performed using SPSS version 23.0 (IBM Corp). A 2-sided α less than .05 was considered statistically significant.

IT Infrastructure

We implemented the new Public Health Emergency Management Information System of Henan Province and extracted data from the system to analyze the epidemiological characteristics of COVID-19 patients in Henan Province and develop a COVID-19 cluster statistical information template. In addition, the hospital information system, dashboards, electronic prescription system, and cloud-based medical image sharing system were used to facilitate the analysis of the clinical data of COVID-19 patients.

Results

In this case series including 655 COVID-19 patients, regarding disease severity, 163 (24.9%) patients were classified as light, 420 (64.1%) as normal, and 72 (11%) as severe (Table 1). Of the infected individuals, 12/655 (1.8%) were less than 15 years of age, 265 (40.5%) were between 15 and 39 years of age, 322 (49.2%) were between 40 and 64 years of age, and 71 (8.5%) were aged 65 years or older (Table 1). Most patients were male (367/655, 56.0%). Of the 150/655 patients (22.9%) who had coexisting medical disorders, 89 (59.3%) had CVD. Given the high percentage of CVD comorbidities in this dataset, we analyzed symptoms prognostic of COVID-19 severity separately among patients with CVD, patients without CVD, and patients without comorbidities. The average number of days from illness onset to diagnosis was 5.66 (SD 3.64, range 0-32). Among the 655 patients included in this case series, 634 (96.8%) had chest CT scans, and 535 (84.4%) showed typical pneumonia features (bilateral ground glass opacities, Figure 1).

Among all documented symptoms in this case series, fever and dry cough were prevalent in all patient cohorts as stratified by COVID-19 severity. Fatigue and expectoration were enriched symptoms in the severe and normal groups (Figure 2A).

The symptom of fever occurred in 603/655 (92.1%) of the patients (Table 1) but was not associated with disease severity. A higher “highest temperature of fever” was typically associated with more severe SARS-CoV-2 infection; however, it is difficult to precisely define high and low highest temperatures of fever given the high dependence of this parameter on the time slot when it was measured and high individual heterogeneity among patients. The mean highest temperature in the light group was 38.0ºC (range 37.6-38.5ºC), that in the normal group was 38.0ºC (range 37.8-38.5ºC), and that in the severe group was 38.4ºC (range 38.0-38.9ºC) (χ^2_2=15.5, P<.001).

Other symptoms, including dry cough, fatigue, expectoration, chest distress, muscle or joint ache, shortness of breath, and multiple symptoms, all convey significant prognostic value on disease severity. Fatigue was the most prevalent symptom (184/655, 28.1%) among patients (Table 1) and could significantly (χ^2_2=20.8, P<.001) stratify and linearize patients into light, normal, and severe groups regarding clinical severity (Table 2, Figure 2A). Expectoration was observed in 169/655 (25.8%) of the patients, with significant (χ^2_2=14.5, P=.001) prognostic value on disease severity (Table 1, Table 2). Expectoration significantly (χ^2_2=6.6, P=.04) differed among patients with CVD and patients with complications other than CVD as well as patients without coexisting disorders (Multimedia Appendix 1), and it was the sole explanatory symptom included in the linear regression among CVD patients (β=0.310, 95% CI 0.042-0.579, P=.02, Table 3). Shortness of breath was significantly (χ^2_2=18.3, P<.001) enriched in the severe group (Table 2) and was observed in 33/655 (5.0%) of the patients infected with COVID-19 (Table 1). Chest distress occurred in 12.7% of this cohort (Table 1), and the sample group was significantly enriched with severely infected patients (χ^2_2=11.367, P=.003, Table 2). Muscle or joint ache was documented in 78/655 (11.9%) of the patients and was significantly enriched in severe patients (χ^2_2=7.7, P=.02, Table 2) and female patients (χ^2_1=4.5, P=.03, Multimedia Appendix 1). Dry cough, although it could stratify patients according to COVID-19 severity with statistical significance (χ^2_2=7.4, P=.03, Table 2), did not show good discrimination power (Figure 2B); this may be due to the high prevalence of dry cough among patients (276/655, 42.1%, Table 1). Headache was enriched in the 15 to 39 years age group, followed by the 40 to 64 years age group, with statistical significance (χ^2_3=11.6, P=.009, Multimedia Appendix 1); however, headache could not differentiate disease severity. The majority of the patients (501/655, 76.5%) reported multiple symptoms (Table 1).

Table 1. Documented symptoms and general clinical characteristics of 655 patients with COVID-19 (N=655).

Characteristic	n (%)
Disease severity

[a] Pairwise significance.

[b] Calculated with the R by C chi-square test.

[c] Significant compared with the other two groups.

Linear models were established to explain disease severity by including all patients or cohort groups stratified by age, gender, and coexisting disorder. All models constructed were significant (Table 3). Fatigue was the most frequently present symptom in these equations, followed by expectoration, and the coefficients of both symptoms were positive (Table 3). While expectoration was the sole symptom associated with patients with CVD, fatigue was linked to patients with coexisting disorders other than CVD (Table 3). Excluding patients with comorbidities did not change the variables included in the model except for slight variations in the coefficients. Stuffed nose was a negative explanatory variable in the models including all patients, individuals without comorbidities, and male patients only (Table 3). Nausea was a negative explanatory variable and played a dominant role in the equation established for male patients (Table 3).

The symptoms of highest temperature of fever (correlation 0.166, 95% CI 0.082-0.251, *P*<.001), expectoration (correlation 0.104, 95% CI 0.022-0.184, *P*=.012) and shortness of breath (correlation 0.125, 95% CI 0.001-0.041, *P*=.002) were significantly correlated with days from illness onset to diagnosis (Table 4).

Table 3. Linear models of clinical severity as explained by symptoms.

Stratification factor	Parameter from stepwise modeling	Regression coefficient	95% CI	*P* value	Model[a]
All	Constant	1.755	1.697 to 1.812	<.001	Y=0.237*F+0.206*E-0.291*S+1.755

Discussion

Principal Findings

The main findings of this study were that fatigue and expectoration are signs of severe COVID-19 infection and that stuffed nose and nausea are favorable prognostic factors of disease severity.

Two symptoms, fatigue and expectoration, showed linear associations with COVID-19 severity (Figure 2B). Four symptoms, namely shortness of breath, chest distress, muscle or joint ache, and dry cough, were more commonly present in severe patients. Thus, if more patients are documented with these symptoms, more resources for intensive medical care should be administrated.

These prognostic symptoms were interconnected with gender, CVD, and age. The enrichment of shortness of breath in severe patients was the most evident, especially among male patients; this suggests its feasibility as a sign (with relatively low type I error) for intensive care among confirmed cases. Stuffed nose and nausea were associated with less severe COVID-19, especially among male patients. Expectoration was significantly associated with CVD complications, suggesting a correlation between CVD and lower respiratory tract infection. An age of 40 years was shown to be a breakpoint for symptoms prognostic of disease severity. While fatigue conveyed prognostic value for all age groups, expectoration showed significance when the patients' age exceeded 40 years and dominated the model when their age exceeded 65 years. This may be due to the increased likelihood of developing CVD with increasing age and explainable by the strong association between expectoration and CVD comorbidity. As a clinical suggestion, individuals concomitantly having these characteristics and symptoms should be suspected for infection and given immediate quarantine and potential intensive medical care during the COVID-19 epidemic.

It is known that immune response to virus infection plays a vital role in the inflammation involved in heart diseases such as myocarditis, atherosclerosis, and cardiac insufficiency, and it constitutes the pathogenesis of cardiac disorder in humans [13]. Shortness of breath is a typical sign of heart and lung conditions, and fever is a symptom of stimulated immune response to infection. It was observed from our study that expectoration was associated with CVD and male gender; expectoration, shortness of breath, and fever were significantly correlated with days from illness onset to diagnosis. Therefore, we expect that patients with comorbidities, especially CVD, would experience exacerbated COVID-19 severity.

It is worth mentioning that symptoms prognostic of COVID-19 severity differ from symptoms for early COVID-19 diagnosis. While fever and dry cough were the most prevalent symptoms among infected individuals, fatigue, expectoration, and chest distress conveyed prognostic value on disease severity. This can be explained by the small percentage of patients represented in the whole case series (72, 11%) who could not be predicted from prevalent symptoms.

Although many case series including higher numbers of cases than that in this study have been reported [4,14-16], given the rapid changing global situation of COVID-19 and the sharp rise in the number of infected cases during the past few months, relatively little research has been devoted to studying the prognostic value of symptoms on severity. The sole relevant study was reported by Dong et al [17], who analyzed data from 663 patients. Compared with Dong's study, which analyzed two symptoms (expectoration and muscle ache), one laboratory test index (albumin), and one patient characteristic (gender), our study concentrates on a more focused and complete list or characteristics that encompasses 14 symptoms. However, this study is limited by its high dependence on the accuracy and completeness of the symptoms recorded for each patient.

Conclusions

Our study provides a statistical analysis of documented symptoms of 655 confirmed COVID-19 patients from Henan Province to aid SARS-CoV-2 diagnosis and prognosis. We conclude that fatigue and expectoration are the most important symptoms prognostic of severe COVID-19, and gender, age, and CVD comorbidity are factors associated with these symptoms; muscle or joint ache commonly occurs in female patients, and younger patients are likely to develop headache; and high temperature in fever, expectoration, and shortness of breath are typically associated with delayed diagnosis.

Abstract

Background: The population of Europe is aging rapidly. Most community-dwelling older adults (CDOAs) want to remain in their homes, particularly those experiencing functional decline. Politicians and academics repeatedly praise technological instruments for being the preferred solution for helping older adults with deteriorating health to remain at home.

Objective: This study aimed to understand the perceptions of CDOAs and their informal caregivers (ICs) and professional caregivers (PCs) about technologies that can help keep older adults at home.

Methods: This qualitative study used personal interviews, focus groups, and photo-elicitation interviews to better understand the perceptions of a convenience sample of 68 CDOAs, 21 ICs, and 32 PCs.

Results: A fraction of CDOAs did not perceive technological instruments to be a very useful means of helping them remain at home. However, the ICs and PCs were more positive. The CDOAs preferred and were more willing to adopt technologies related to their mobility and safety and those that would help slow down their cognitive decline. The ICs preferred technological aids that assist in the activities of daily living as well as safety-related technologies for detecting falls and helping to locate disoriented older adults. The PCs preferred integrated communication and information systems to improve collaboration between all stakeholders, housing equipped with technologies to manage complex care, high-performance ancillary equipment to transfer people with reduced mobility, and surveillance systems to ensure safety at home.

Conclusions: Although our study reports that CDOAs have limited interest in innovative technologies to help them remain at home, their technological skills will undoubtedly improve in the future, as will those of ICs and PCs. Technological tools will play an increasingly important role in home health care.

Introduction

Background

The population of Europe is aging rapidly [1]. Most countries will have to cope with increasing numbers of frail, community-dwelling older adults (CDOAs) who are losing their autonomy and becoming dependent on assistance [1]. Despite their disabilities, 9 out of 10 CDOAs want to remain at home, even those experiencing significant functional decline and loss of autonomy [2]. In this context, caring for CDOAs has become a major health care, social, economic, and political issue [3]. Demographic transition results in an aging society, with fewer young adults available to support the needs of a dramatically rising number of dependent older adults [4]. The costs of specialist home care and social care to support CDOAs will increase exponentially. Innovation in the management of person-centered care is unavoidable, and it must consider medical history, life expectancy, economic constraints, and society's expectations for optimal autonomy and mobility [5,6]. Technology can provide proactive solutions for some of the main health and societal problems encountered during aging, such as loss of independence, chronic diseases, psychopathological disorders, and falls at home [6,7]. Despite the omnipresence of technology in modern society, research into its use for improving the daily lives of frail, cognitively impaired CDOAs is limited in naturalistic settings. Technologies can offer innovative ways of improving the health and quality of life of frail CDOAs—or other people losing their autonomy—and help them to remain at home [6].

Technology aimed at older adults is usually termed gerontechnology (which this paper will use as a synonym of technology). It is destined to have an important future role in providing support and solutions, monitoring health status to optimize autonomy, and improving the quality of life of CDOAs, regardless of their level of dependency [8,9]. Gerontechnologies usually have two main, and in most cases, complementary purposes: (1) strengthening the (objective) monitoring of older adults by remotely collecting large amounts of data to alert their informal caregivers (ICs) or professional caregivers (PCs) about health decompensation, so that they can anticipate and implement appropriate intervention strategies, and (2) remotely intervening with CDOAs for the first interaction (using voice or images) [10].

Cornet and Carre [11] mentioned that certain technologies could help maintain levels of autonomy despite debilitating age-related diseases, improve social cohesion, reduce loneliness, compensate for declining capacities, help both ICs and PCs, and, finally, reduce some of the effects of pathological aging. Science and technology will also serve CDOAs by ensuring safer environments, promoting and strengthening their independence and quality of life, and supporting both their ICs and PCs [11-13]. New devices should make it possible to alert ICs and PCs about the risks of health decompensation so that they can anticipate and implement appropriate intervention strategies or even intervene remotely, thus reducing the burden on both groups of caregivers [14]. Several studies have shown that telehealth (ie, technological solutions that enable remote monitoring of health status) is effective in improving the well-being and quality of life of CDOAs [15-17]. Technological instruments also allow users to participate actively in their health care and treatment follow-up [18,19]. Despite this potential, the perceptions of CDOAs and their ICs and PCs about the usefulness of technologies in maintaining their health status and helping them to age well at home have only rarely been examined. Previous studies have demonstrated that gerontechnologies are seldom used actively by older adults themselves, and indeed, the vast majority were unaware of their existence [20,21]. However, in recent years, there has been a resurgence of creativity in this field, involving academic researchers, private companies, and public health care services. Questioning the utility of new technologies, their potential uses, and their acceptance and limitations remains relevant [22].

How are technologies that help them remain at home perceived by CDOAs, their ICs, and PCs? More specifically, how do they rate their actual and potential utility?

Objectives

This study, overall, aimed to examine and understand the perceptions and utility of these technologies among physically and cognitively dependent CDOAs, their ICs, and PCs.

Theoretical Framework

This study was guided by the theoretical framework developed by Peek et al [23] and is thus based on the basic components of accepting technology as stated in the results and finding it useful. This framework integrates several factors: (1) utility and ease of use; (2) covering basic needs with technologies; (3) the sense, meaning, acceptance, and value of these technologies; and (4) technologies that help regain or maintain autonomy. According to Peek et al [24], technology can play a role in helping CDOAs remain independent, active, and healthy for as long as possible. Previous studies indicate that the current models of technology acceptance lacked essential predictors, specifically for older adults [25,26].

Methods

Design

This international multicenter study used a qualitative design to collect data on the perceptions of CDOAs, their ICs, and PCs using one-to-one interviews, focus groups (FGs), and photo-elicitation interviews (PEIs). Reporting on the study was based on the checklist for the explicit and comprehensive reporting of qualitative studies [27].

Population and Settings

The study population included CDOA men and women, aged ≥65 years, living in the French department of Haute-Savoie or the French-speaking part of Switzerland's canton Valais, and with a medical prescription or indication for home care. The reason for examining perspectives in 2 countries was not to compare their populations but rather to explore a common issue together (especially in a border area) and codevelop implementable recommendations for clinical practice and technology companies. ICs and PCs involved in clinical practice and employed in 1 of the 5 different community health care centers (2 in France and 3 in Switzerland) were also questioned.

Participant Recruitment

A similar sampling strategy was applied to CDOAs in both countries. On the basis of the comprehensive geriatric assessment database in the Autonomy Scale of Gerontology and Iso-Resource Groups (AGGIR) [28], researchers categorized the functional state of potential participants into 1 of the 3 relevant categories: (1) independent CDOA sustained with meals and cleaning services, (2) mainly physically impaired CDOA, or (3) mainly mild-to-moderately cognitively impaired CDOA.

CDOAs who were unable to understand and speak French or who lacked the capacity for discernment to consent were excluded.

The AGGIR scale includes 2 types of variables: discriminative and illustrative. Discriminative variables evaluate coherence, orientation, washing, dressing, feeding, excretion, transfers, moving indoors, moving outdoors, and remote communication. These elements are assessed via a clinical evaluation carried out in the home of the CDOA by a nurse, who chooses from among 3 criteria for each variable: (1) the person can complete the activity alone, (2) the person can complete the activity partially, or (3) the person cannot complete the activity. Each criterion is also evaluated based on whether the person carries out the activity spontaneously, totally, usually, and correctly.

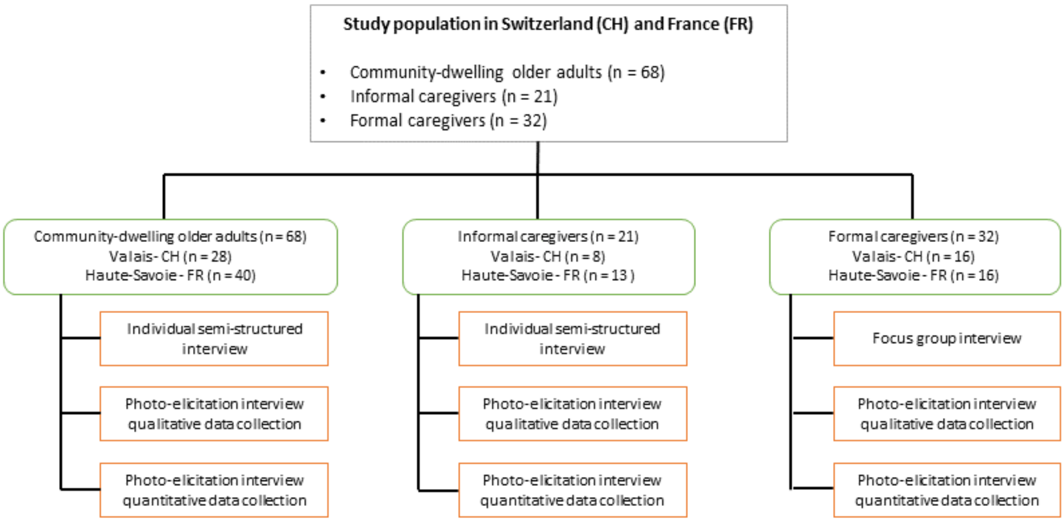
The AGGIR scale is the official national tool in France for comprehensive geriatric assessment under home health care settings. It classifies the geriatric profiles of home-dwelling adults into 6 categories (Groupes Iso-ressources; GIRs). GIRs 5 and 6 designate independent CDOAs who only receive minimal home help, such as meals, cleaning, and shopping. GIRs 3 and 4 designate CDOAs with mostly physical impairments, and GIRs 1 and 2 designate CDOAs with mostly cognitive impairments but also some physical impairments. The AGGIR tool uses clinical observations and questions ICs and older adults themselves on their need for assistance in the essential activities of daily living (ADL). Indeed, AGGIR is based on the topics in the Katz ADL scale, which also classifies CDOAs as independent or physically and/or cognitively impaired. Our study did not use the mini-mental state examination. The research team's geriatrician (NV) clinically judged the participants' physical and mental health statuses. In agreement with the ethical committee's expectations concerning the use of existing clinical data, psychiatric diagnoses were not explored prospectively, as this was beyond the aim of this study. A detailed explanation of the tool is provided in Multimedia Appendix 1.

All 5 centers used randomized sampling to select CDOAs in their respective AGGIR categories (independent, physically impaired CDOAs, and cognitively impaired CDOAs). Multimedia Appendix 1 presents detailed information on categorization using the AGGIR tool. In addition, significant ICs, designated by their CDOAs, were asked to participate in a personal interview and a PEI. The number of ICs recruited was proportional to the CDOA dependency classifications. In collaboration with their supervisors at the 5 community health care centers, purposive samples of PCs involved in direct daily care were invited to participate in 1 of 4 FGs.

Data Collection Procedure

This study was approved by the Human Research Ethics Committee of the Canton Vaud (CER-VD – 2017/000789), Switzerland, and the French Data Protection Authority. Data collection took place from September 2017 to June 2018. After the CDOAs, their ICs, and PCs had given their written informed consent to participate, the study nurse collected the participants' sociodemographic, professional, and health status data (only for the CDOAs) and conducted the scheduled interviews (Figure 1).

Figure 1. Data collection procedure among the community-dwelling older adults, informal caregivers, and formal caregivers.



Community-Dwelling Older Adults

A randomized sample of CDOAs was selected from the 3 categories defined using the AGGIR tool (ie, independent, physically impaired CDOAs, or cognitively impaired CDOAs).

Thus, CDOAs with no limitations according to the AGGIR tool were placed in the independent group, those with physical limitations (eg, traveling and dressing) were categorized in the physically impaired group, and those with cognitive limitations (eg, communication and orientation) joined the cognitively impaired group. Older adults with cognitive and physical limitations were included in the group corresponding to their most pronounced limitation.

Candidates were contacted by telephone and invited to participate. Potential participants received written information about the study before any data were collected. After 48 hours to reflect, a research assistant contacted the potential participants by telephone to address any queries they may have and to obtain their verbal consent to participate in the study. On their acceptance, the assistant made an appointment with the CDOAs for providing more information about the study and to collect the signed consent to participate in the study, before the interview stage. On the day of the interview, the interviewer verified that the participants understood all the information and the implications of participation. Data collection used 10 photographs of relevant technologies and an interview guide developed from a literature review [29]. Audio recordings of the interviews were made.

Informal Caregivers

The CDOAs identified their significant ICs. Theoretical samples of 3 to 4 ICs per type of CDOA (independent, physically impaired, or cognitively impaired) were selected by each of the 5 community health care centers, and they were invited to participate in a personal interview and a PEI. Those without the capacity for discernment were excluded. Audio recordings of the interviews were made.

Professional Caregivers

In collaboration with the supervisors at the 5 community health care centers, 4 FGs were organized (2 in France and 2 in Switzerland), each with 7 to 8 PCs. The research team proposed meeting dates and times for the FGs. The PCs who were willing to participate signed the consent form beforehand, and audio recordings of the FG discussions were made.

Data Collection Instruments

The research team developed and tested guides for the one-to-one interviews and PEIs for the CDOAs and ICs and for the FGs. The interview guides encouraged the participants to discuss relevant research issues by asking open-ended questions. The interviewer could reformulate, reorganize, or clarify questions to gain a deeper understanding of the participant's answers. The guides also helped the participants to better identify practical technologies that might improve health care [30,31]. Data collection using PEIs involved including photographs of relevant technologies into the interview [32,33]. The PEI guide contained 10 photographs, selected using the research team's empirical expertise (Multimedia Appendix 2), from a recent classification of gerontechnologies [29]. The PEI guide was used at the end of the personal interviews and FG discussions. Each participant was asked to select one or more technologies that they thought would be useful to the 3 separate groups of participants (CDOAs, ICs, and PCs). Each photograph was presented in turn with information on the respective technology. The CDOAs were asked, "What do you think of this technology? What could you use it for?" When all the photographs were laid out on the table, they were asked to choose the technology that seemed the most useful or acceptable in their daily life. The ICs were asked, "What do you think about this technology? How could it be useful to you as an informal caregiver? Among all these photographs, could you choose the one that seems the most useful in your daily life?" The PCs were asked, "What do you think when you see this technology? How could you use it? Which of these technologies would you retain, whether for the help it could provide you or for the help it could provide the clients you work with?" Multimedia Appendix 2 presents the technologies included in the PEI.

Data Analysis

Descriptive statistics were compiled to describe the participants' sociodemographic, health, and professional characteristics as well as the technologies selected. Statistical analyses were performed using the IBM Statistical Package for the Social Sciences 25.0 [34]. Personal interviews, PEIs, and FG discussions were transcribed and analyzed using a qualitative content analysis approach [35,36] using NVivo 12 (Qualitative Software International) software [37]. The PEIs were analyzed in parallel using a transversal iterative process and by developing emerging themes. We adopted the approach described by Graneheim and Lundman [35] to ensure the reliability of the results. The interview transcripts were read several times to obtain a sense of the whole. Given the context, units of meaning were condensed into descriptions close to those of the transcripts' contents and, as far as possible, to an interpretation of their underlying meaning (the latent content). Data were condensed for analysis and examination of their content based on the one-to-one interview guide. Once condensed, the units of meaning were considered as a whole and were abstracted into themes. An 8-hour process of reflection and discussion by the research team resulted in an agreed set of themes. The results were presented in the light of the categories taken from the condensed interviews, and the occurrences selected were illustrated with significant examples, including transcriptions from the interviews. For reasons of confidentiality, reporting considered the CDOAs, ICs, and PCs as 3 groups, without distinguishing health care centers or nationalities.

Results

Samples

The study sample was composed of 68 CDOAs, 21 ICs, and 32 PCs. The distribution between the French and Swiss centers was 40 and 28 CDOAs, 13 and 9 ICs, and 16 and 16 PCs, respectively.

Sociodemographic Data

Community-Dwelling Older Adults

Of the 68 CDOAs, almost three-quarters were women (50/68, 74%), with an average age of 82.3 years (SD 7.2; median 82); approximately two-thirds (41/68, 60%) lived in urban areas. Table 1 presents their sociodemographic data and dependency categorization based on the AGGIR scale (Multimedia Appendix 1).

Informal Caregivers

The average age of the 21 ICs was 68.4 years (SD 13.8; median 68), with 16 women and 5 men. Most were retired (n=13), lived in urban settings (n=13), and took care of a loved one with a cognitive impairment (n=12) who required partial assistance with the ADL (n=6; Table 2).

Formal Professional Caregivers

A total of 4 FGs of 8 participants each brought together 32 PCs, all employed at community health care centers. Their average age was 46.7 years (SD 9.4; median 47) and most were female. Their varied professional roles included physicians, nurses, social workers, nursing assistants, care assistants, and occupational therapists (Table 3).

Table 1. The sociodemographic characteristics and functional status of community-dwelling older adults (N=68).

Sociodemographic characteristics and functional status	Values
Age (years)	
Mean (SD)	82.34 (7.2)
Range	64-95
Sex, n (%)	
Male	18 (26)
Female	50 (74)
Place of residence, n (%)	
Rural	27 (40)
Urban	41 (60)
Level of independence, n (%)	
Independent	24 (35)
Physically impaired	23 (34)
Cognitively impaired	21 (31)

Table 2. The sociodemographic characteristics of informal caregivers (N=21).

Sociodemographic characteristics	Value
Age (years)	
Mean (SD)	68.4 (13.4)
Range	43-88
Sex, n (%)	
Male	5 (24)
Female	16 (76)
Loved one’s level of independence, n (%)	
Independent loved one	3 (14)
Physically impaired loved one	6 (29)
Cognitively impaired loved one	12 (57)
Relationship with loved one, n (%)	
Spouse	9 (43)
Daughter/son	9 (43)
Brother	1 (5)
Friend	2 (9)

Occupational therapists	1 (3)
Physicians	3 (10)
Care assistants	10 (31)
Nursing assistants	3 (10)
Supervisors	2 (6)

Findings

We recorded a total of 40 hours and 53 min of personal interviews and PEIs with CDOAs (mean 36 min, SD 13 min; median 35 min; minimum 16 min and maximum 76 min) and 12 hours and 25 min with their ICs (mean 35 min, SD 13 min; median 34 min; minimum 13 and maximum 65 min). We recorded a further 4 hours and 50 min of interviews with the 4 FGs (mean 75 min, SD 6 min; median 72 min; minimum 71 min and maximum 85 min).

In light of the theoretical framework adopted [24], we applied our deductive content analysis along three thematic axes: (1) usefulness and meaning of technology to support the needs of CDOAs, (2) strategies to increase (ease of) technology use among direct and supporting stakeholders, and (3) acceptability of using technology to remain at home among direct and indirect users.

Usefulness and Meaning of Technology to Support the Needs of Community-Dwelling Older Adults

Community-Dwelling Older Adults

CDOAs perceived technology as something that could be useful, especially for other older adults with health problems, but they rarely saw any sense in using them themselves, except when they had significant difficulties with their ADLs. CDOA 6 said that technology was:

> *For people who can't get anything done alone.*

CDOA 63 thought it might be needed in future:

> *Not for the moment, anyway. Maybe in a few years, yes, let's say, if I have problems in a few years, because I have...well, because of my age!"*

CDOA 53 had negative perceptions:

> *Because all these...these modern techniques, and everything, don't interest me much. Because it doesn't match my past life at all.*

CDOA 73, however, held an opposing view:

> *But if something can make life easier, why not? At my age, now's the time to try.*

The concept of technology, in general, was often misunderstood. CDOA 75 exemplified this:

> *Technologies? What do you mean by technology?*

Some CDOAs stated that technology could be useful but not in their current situation. CDOA 9 stated that they did not see any need for it in their current situation:

> *It works automatically, huh? Of course, but for the moment, it's not for me.*

CDOA 13 thought that some devices might be useful to them if they had more severe health problems:

> *I think that I'd have to be really bad, huh, to put this thing on.*

The (positive or negative) interest in technologies was also often stated by this group. CDOA 9's positive perceptions of technology were typical:

> *Well, I think it's...it's 2017; I think it's a necessity, isn't it?*

CDOA 85 spoke out against technology:

> *And then, it's no good at all. Sometimes it's completely harmful, like when things are made available to people, like me, who aren't always able to understand.*

Among CDOAs with mainly cognitive impairments, the word *technology*, without context, was not really understood. As CDOA 82 said:

> *I don't know what that means.*

The relatively *independent* group mainly spoke about how technology could be useful for others. CDOA 7 gave their opinion:

> *Well, it's good for people who don't have many visitors or people who don't get any help from their families. And I'm not one of them. So then, no.*

Misunderstandings about the term and the meaning of *technology* itself, as in the other groups, came up regularly. CDOA 10 expressed this as a lack of knowledge:

> *I don't know which technologies, that's the problem. That's because I don't understand everything...I don't get it...because, well, I know there are a lot of things now, but I don't know everything about them.*

Positive and negative assumptions appeared in similar proportions among the independent group, as they did for the other 2 groups. For example, CDOA 72 gave their opinion on the internet:

> *Today, what I don't agree with is the internet. It's going to destroy the planet. That's it, one way or another because it is so dangerous, especially because of those who know it very well, they could flatten the whole world. So, I'm really not interested in the internet; so I'm not interested in computers either.*

CDOA 83 shared their positive perception:

> *If it's easier for us, if it can help us out, why not, eh?*

Informal Caregivers

Some ICs considered technologies potentially useful in helping CDOAs remain at home, whereas others considered them as indispensable. Their perceptions on the usefulness of a technology seemed to depend mainly on their current state of health, their own openness to technologies, and the costs involved. Different ICs expressed these aspects as follows:

> *The thing that might encourage me is if it, err, her case worsened.* [IC 38]
>
> *She has already been offered them, but she doesn't want them.* [IC 56]
>
> *Yes, change. I think if we change things, I think it would be complicated for her.* [IC 38]
>
> *Oh, well, that must be very expensive.* [IC 43]

Professional Caregivers

PCs perceived technology as useful, but they specified that there was the risk of creating distance in their relationship with the persons in their care and that technology must complete and complement a PC's work, not replace it:

> *It can only be complementary. At some point, it makes sense if a real person has to be involved.* [FG 2]

Moreover, the indication chosen for the use of a specific technology should not only reassure ICs:

> *What worries me is situations like this, where the children have even put cameras in the bedroom, not to monitor their parents, but rather to reassure themselves.* [FG 2]

Technologies that could be introduced to enhance the daily lives of CDOAs include furniture with home automation technologies, suitably adapted public transport, and an elderly friendly urban architecture in environments that facilitate transport mobility:

> *We often have patients who have to take taxis or be driven to hospital or to a medical consultation in town...It's a real transportation problem.* [FG 2]
>
> *Fifteen years ago, they were all at home, they didn't move. Now you see some, I don't know how many, in the city center, using their rollators. It's pretty impressive. Soon, they'll invent rollator parking lots.* [FG 1]

Urban living could also be rethought, perhaps by setting up social centers for CDOAs, on the same principle as youth centers:

> *Architecturally, it would have to be equipped with ramps for the handicapped, for the rooms where they can meet up. As we do for youth centers, why not build a place for older people with physical difficulties?* [FG 1]

PCs highlighted their lack of knowledge about the technological devices available on the market and their lack of training on how to pass on skills to CDOAs and ICs:

> *I don't have much knowledge about this. It's true and it makes sense that some training on this wouldn't be bad.* [FG 2]

Strategies to Increase Ease of Technology Use Among Direct Users and Supporting Stakeholders

Community-Dwelling Older Adults

Encouragement from children and grandchildren, financial help for purchasing technology, and increasing feelings of safety were the main strategies identified by CDOAs themselves for improving the ease of use among their peers. For the groups with mainly *physical* and *cognitive impairments*, encouragement to use technology by *children and grandchildren* was mentioned as an important strategy. Family members often gift devices that they no longer use to their older adult relatives. Children choosing devices, such as remote alarms, was also a facilitator of technology use. CDOAs mentioned that receiving financial aid for the acquisition of a device was a facilitator, as was receiving recommendations from PCs. CDOA 35 exemplified the assistance received from PCs:

> *There is a home for the blind; they proposed it to me. And they sold me the [talking] watch.*

CDOA 76 stated:

> *Yeah, that's right. So, my granddaughter has a tablet, and my son put my number into it.*

Several facilitators to improve beliefs about and attitudes toward technology emerged during the interviews, one being that a device can improve feelings of safety. Financial assistance can be considered a facilitator because it influences people's willingness to acquire a device. Indeed, for the group of *independent* CDOAs, *financial support* for buying a device and receiving help on usage were the main facilitators of their use. CDOA 84 explained their situation:

> *Listen, my son gave me this mobile; I didn't want it. And he said to me, "It'll be easy." Anyway, there you go.*

CDOA 83 said:

> *Someone should come and explain and turn it on and say "You have to do this and do that."*

Again, with regard to beliefs and attitudes, a technology that made participants *feel safer* was the main facilitator of use among this group. CDOA 84 explained this in relation to their personal situation:

> *And then I was unsure, and I was thinking about it, but as I said, I was putting it off and putting it off. And then there's the personal side, you see? I have great neighbors, but the young ones work, and the old ones are no stronger than me, right? So, I said, "Oh, well!" and then it's a bit of a safety thing, even though, as I said, I hope I'll never need it.*

Devices' properties, such as ease of use, also influenced CDOAs. CDOA 10 described using a stair-lift:

> *Yes, usage. You press a button; there's nothing complicated, eh? There are knobs, one at the top, one at the bottom, so it depends on where you are. Well, you grab the knob. And then, if you go up the stairs, you use the stair-lift device.*

Informal Caregivers

Some ICs supported the use of technologies if they found them useful and easy to use. As IC 43 said:

> *If it is a technology that can help me, I will accept it. If it can lighten the burden of helping her.*

Surprisingly, other ICs would only introduce certain technologies if the CDOA's state of health deteriorated. Nevertheless, ICs often felt that they lacked the knowledge to use technologies properly. As IC 71 said:

> *I like the technological side, but I just have one problem with it. It's clear that people who weren't born in the technological age, or who haven't got themselves up to date by 50 or thereabouts (are going to have trouble). I even find that I'm often overwhelmed.*

ICs also noted their relatives' lack of motivation about the introduction of new technologies:

> *Ah, well, it's certainly a very good thing, but she still has to want to do it. She's not on board with all that's modern. So, she'll say no to that* [IC 43]

The ease of use of technologies was overrided, as perceived by the ICs, by the fear of making mistakes when using them or of infringing on the CDOA's privacy and autonomy.

Professional Caregivers

PCs mentioned that the context of technology implementation was important in its ease of use:

> *Older adults just need to be interested in new technologies. They are pushed towards it by their children—by their grandchildren, especially.* [FG 2]

> *Sometimes a neighbor will say, "You know, I've got a rollator, and it goes great," and that's it. It's not some young woman who comes in and says, "This is what you need."* [FG 1]

Indeed, technologies were accepted more readily if relatives and ICs were involved:

> *Sometimes they actually need their family's support in order to be reassured.* [FG 1]

Ease of use also seemed important:

> *There are some things that could improve autonomy as long as they remain simple and easy for people to use.* [FG 2]

According to PCs, the CDOAs who had either found a technology useful or had used technology in their working lives were more willing to use the proposed technologies:

> *Some CDOAs are familiar with Skype, for example, using it with grandchildren abroad or even in another city.* [FG 3]

> *The elderly population that needs these aids now, is often a population that is unaware of the digital revolution.* [FG 4]

Although the point of view of individuals and the context in which technologies are implemented tend to be the factors that promote technology use among CDOAs, the cost involved in acquiring different technologies and the different steps required to obtain them can be seen as barriers:

> *And I find that they're always scared that "It's going to be expensive; I can't." Sometimes they don't realize the means they still have, whether financial or not.* [FG 4]

The emotions associated with technology use can also be a barrier when they generate stress and fear:

> *The more things or equipment involved, the greater the source of stress, for the patient and the family.* [FG 4]

> *You get to a certain point in the aging process where people are not necessarily very accepting of their loss of autonomy. And consequently, in accepting any assistance that might be provided to them.* [FG 4]

Acceptability of Using Technology to Remain at Home Among Direct and Indirect Users

Community-Dwelling Older Adults

For all groups of CDOAs, the acceptability of using technologies was influenced by the self-developed strategy for achieving this purpose, difficulties in using the device, and the technology's cost. As an example of avoiding technology use, several CDOAs said that a simple bedside lamp gave out sufficient light to get to the toilet. The CDOAs found no reason, for example, to replace the home helps who came to clean their home with a robot vacuum cleaner. Help provided directly by humans was the preferred option for many CDOAs. CDOA 13's thoughts on electronic pill dispensers began with a deep breath:

> *I'm telling you, I don't feel the need for one. Oh! If I have something special, my daughter still comes, three times a week, and she is a nurse.*

The CDOAs with mainly *physical impairments* did not find some device properties to be user-friendly, and multiple participants considered this to be the main obstacle. CDOA 35 complained about their tablet:

> *Because handling this device is very complicated for me, you see? I have to turn it all over the place to find out what is going on...No, I'm just not interested.*

Another barrier was the cost of acquiring a new technology, as explained by CDOA 6:

> *Oh, yes, because I can't say I'm going to buy anything, in addition to what we have to buy every day, because we can't afford it.*

For the CDOA group with mainly *cognitive impairments*, the main barrier was the difficulty in using technologies. This was reflected by CDOA 20:

> *So, to start with, I don't want a computer. That's out of the question; I don't want a computer. Well because I wouldn't know how to use it. That's why.*

In several interviews, the group members were found to prefer human contact over technological assistance. CDOA 76 expressed doubts about robots:

Because there's a person, the nurse, working; a robot isn't human, whereas a nurse can talk, say something nice, give you a little smile. But a robot's just "Crash! Bang!"'

Financial hardship was also consistently mentioned as a barrier to technology use. CDOA 76 said:

> *Yeah, robots. Yeah, but you need the means to buy one.*

For the *independent* CDOA group, financial and usage difficulties were also the most frequently mentioned obstacles. Regarding financial aspects, CDOA 10 said:

> *Well, let's say, it's a good thing. It's good, but it must have a cost. Well, yes because...I still have to pay for the nursing home; don't forget that. My husband's pension, unfortunately, only pays for half of it.*

Regarding usage difficulties, CDOA 10 described their tablet:

> *Right now, I do not know how to use it. My daughter, she's got one. My grandsons have one each, but so far I'm not interested.*

Technologies designed to promote older adults' home support, such as fall detectors, GPS, and brain training, are the ones that are most frequently accepted by CDOAs. CDOA 73 explained their acceptance:

> *But we don't know if I'll ever be able to...it's because I'm a little scared, that's why I don't go out alone. I'm a little scared to cross the street. So that's why it's really the fall detector that would suit me best.*

Regarding brain training, CDOA 63 explained:

> *Well, because by...improving your powers of concentration, developing your vocabulary, anyway because of the propositions that are there, I think it's good. That's why.*

Informal Caregivers

Perceptions about the acceptability of technology use were significantly influenced by safety, ease of use, keeping CDOAs autonomous, and the costs of devices.

ICs explained how the acceptability of technologies was related to the safety of their loved ones. This result can be explained by the fact that of the 21 ICs interviewed, 12 were relatives of CDOAs with mainly cognitive impairments. Thus, the technologies chosen by the ICs were very similar to those chosen by the group of mainly cognitively impaired older adults. Opinions of the ICs regarding the acceptability of the technologies presented during the PEI interviews are as follows. For the light path selected by several ICs, the caregivers said:

> *Yes, I think that is really good. Well because my mum gets up at night, she can't find the light.* [IC 42]
>
> *That's right, because I see he gets lost going to the toilet.* [IC 44]

Concerning the fall detector, accepted by about one-third of the ICs, they said:

> *Yes, that could be the most useful there. [...] in the future there could be others [devices].* [IC 43]
>
> *Maybe rather the fall detector, I'd say.* [IC 55]

The ICs were more reluctant about the electronic pill dispenser:

> *Ah, well [...], it could be useful because I want him to have a pillbox; the nurses come to put the pills in. But if he doesn't think about it—if I don't think about it, he doesn't think about it—then it's not much use.* [IC 29]
>
> *Yeah, it's not bad, but I think it's pretty expensive for how much we use it. As long as we're here, well, they're taken at mealtimes, so I'm here [laughs].* [IC 40]
>
> *[…] In my mother's case [...] she'd be unable to take her medication alone.* [IC 42]

The ICs had diverse opinions about robot vacuum cleaners:

> *For me, these robots are good. You shouldn't have anything on the ground [laughs] [...] You shouldn't; it doesn't go in corners, it's round [laughs].* [IC 29]
>
> *Well, it depends on how much it costs, huh?* [IC 38]
>
> *Not essential, in my opinion.* [IC 40]
>
> *[….] I think not. No, it might be more dangerous than useful.* [IC 42]

As for the opinions on the service robot, the ICs said:

> *Yes, listen, yes, it's good, but in the end, a human being is still better.* [IC 23]
>
> *[…] I find it rather stressful.* [IC 29]

Opinions on the usefulness of a GPS bracelet could be summed up by this statement:

> *That, I, I'm for that. If she ever decided to go somewhere, it would let her know where she was...it would let us know where she was.* [IC 38]

Only a fraction of the ICs found the touchpad to be an interesting technology. There were different opinions on this:

> *No, so my mom, my mom... she's not interested.* [IC 23]
>
> *It might make things easier for him, but since he was not very enthusiastic, he quickly lost patience.* [IC 29]
>
> *Uh, no [laughs], there. Uh, I think it's impossible. Because even a mobile phone would be complicated to use, so...He still manages to work the TV, but that's all.* [IC 55]

Among the ICs interviewed, the idea of a social network for ICs raised little interest:

> *I think it's good… For the moment, I don't need it, because...Well, I have a good rapport with the home help; it's going well.* [IC 23]
>
> *I'm not…I've never been a person like that, not very communicative and that...So, everyone has to say what they do, what they've got...It's not...No, not for me. But I'm not saying that it might not be a help to a lot of people.* [IC 29]
>
> *Oh! It's not bad. It could...for someone who is alone, be a help, yes.* [IC 40]

Brain training technology was selected by only one IC, but the quoted text below illustrates the difficulties in using this technology:

> *She can't do it alone either. Well, memory exercises would be great, but maybe someone would have to help because of her not being able to use a tablet.* [IC 42]

To the ICs, activity sensors were not a promising technology to strengthen home support:

> *Ah! Well, for people who live alone, that's very good.* [IC 23]
>
> *Oh, yeah, sometimes he hasn't closed [the fridge door] properly. It's happened sometimes, when it didn't shut properly.* [IC 29]
>
> *[…] she'll say to me: "You don't think I'm crazy yet, do you?" All this scares me.* [IC 38]
>
> *Yes. Yes, well that could be, err, that could be good, indeed. Yeah because in half an hour anything can happen, eh?* [IC 42]
>
> *[…] I wouldn't even trust the sensor [...].* [IC 44]
>
> *[…] it's true that these are technologies that are great for those who are not safe, but who are in their right mind, and everything, who don't have all their heads and bodies; and who may be putting themselves in danger, uh, about that.* [IC 55]

Professional Caregivers

Among PCs, perceptions about the acceptability of technology differed according to the constraints that technologies impose on the CDOAs. The more technologies focus on monitoring a CDOA's behavior, the more ethical questions they raise. On the contrary, the more they increase a CDOA's autonomy and safety and decrease the burden on ICs, the more the PCs promoted them. Opinions on the acceptability of some of the technologies proposed during the PEIs were as follows. The light path technology was broadly well-received by the PCs, and the following statement illustrates their favorable opinion of this technology:

> *A technology that should be introduced and available for all older people.* [FG 1]

Technologies that increase safety, such as the fall detector, were mostly preferred by the PCs:

> *[…] if it's good, it can be very useful.* [FG 2]

The PCs showed little interest in the robot vacuum cleaner and the service robot:

> *[…] There's a risk of falling over the vacuum cleaner when it's running...* [FG 4]
>
> *[…] It's interesting if it assists caregivers [gives them time to do another activity while the robot is working].* [FG 1]
>
> *There's a risk of replacing humans […].* [FG 3]

Several PCs had questions regarding the GPS bracelet technology:

> *[…] it's not relevant if its only purpose is to calm the family […]* . [FG 3]
>
> *[…] there are ethical problems if it's used as a means to monitor the person […].* [FG 3]

The touch tablet and brain training technologies were rarely chosen by the PCs. Their reluctance was expressed as follows:

> *You have to accompany the arrival of the tablet in the person's environment and ensure that the person is interested in using it….* [FG 4]
>
> *It might be interesting to couple a tablet to the remote alarm [to enable visualizing the person's condition if they can't or can no longer express themselves because of cognitive disorders]...* [FG 4]
>
> *[…] difficult to offer if the person does not know how to use a tablet…* [FG 4]
>
> *...can be a prevention tool…* [FG 3]

Although some PCs selected the social network and activity sensor technologies, there were mixed opinions:

> *[Social networking] technology is not necessarily appropriate if the caregiver does not understand those technologies; it's rather aimed at young caregivers [...].* [FG 2]
>
> *[…] it can make caregivers feel supported [...].* [FG 2]

Concerning activity sensors, this response was obtained:

> *[...] Pose an ethical dilemma [...]; [...] culture can be an obstacle to the use of this technology; [...] interesting technology, and install the sensors only as needed [to see if the fridge is opening in case of a heatwave; to see that people are getting out of bed]. It can be a complementary tool in food monitoring if this problem has been previously identified [...]* [FG 2]

When choosing the most useful technology overall, the PCs differed according to their profession. Physicians, nurses, and occupational therapists chose the fall detector, whereas nursing assistants, social workers, and direct community health providers chose social network. Table 4 presents a summary of the main topics covered.

Multimedia Appendix 3 provides detailed data on the technologies preferred by CDOAs, ICs, and PCs. Multimedia Appendix 4 presents a detailed overview of the perceived barriers to technology use among CDOAs, as well as the photographs selected during their PEIs. Multimedia Appendix 5 provides a detailed overview of CDOAs' perceptions of technology and its facilitators.

Table 4. Themes and subthemes highlighted by the thematic content analysis.

Themes	Subthemes		
	CDOAs[a]	ICs[b]	PCs[c]
Usefulness and meaning of technology to support the needs of CDOAs	• Useful for others in my peer group • Useful later in my life • Lack of meaning • Technology often misunderstood	• Useful depending on the CDOA's state of health • The CDOA's openness to using technologies • Technology costs	• Useful to sustain the ADL[d] • Risk of creating distance in relationships with patients • Fear of being replaced by technology
Strategies to increase ease of technology use among direct users and supporting stakeholders	• Encouragement from children/grandchildren • Financial support • Increase feeling of safety	• Easing the daily strain for ICs and PCs • Lightening the burden of helping • Fear of mistakes	• Appropriate technology implementation strategy • Involving relatives • Increasing the autonomy of CDOAs
Acceptability of using technology to remain at home among direct and indirect users	• Influenced by having a self-developed strategy to achieve purposes • Difficulties using devices • The cost of devices • Increasing the ability to remain at home	• Safety first • Ease of use • Staying autonomous • The cost of devices	• Constraints that technologies impose • Ethical questions if the focus is on monitoring behavior • Increasing the CDOA's autonomy and safety • Lessing the burden on ICs

[a] CDOA: community-dwelling older adults.

[b] IC: informal caregiver.

[c] PC: professional caregiver.

[d] ADL: activities of daily living.

Discussion

Principal Findings and Comparison With Previous Work

To the best of our knowledge, this is the first research in the field to have combined personal interviews, FGs, and PEIs in the same study. Our results show that technologies are not yet well integrated into the daily care of frail or cognitively impaired CDOAs. Although technology can certainly offer solutions to some of the specific impairments typical among CDOAs, ICs and PCs still have little knowledge about their existence and how they should use them in everyday practice. The heterogeneity of participants' profiles made it difficult to compare this study with others involving more homogeneous samples [38,39].

Our results indicate that most participants had both positive and negative attitudes toward technology. Positive attitudes were most often related to technologies that ensured continued mobility at a lower cost and with advanced functions (a GPS bracelet). Negative attitudes of CDOAs were often associated with the risks of becoming technology–dependent and the risk of fewer or poorer interactions with ICs and PCs, the realization that they were no longer able to stay at home, potential social problems (disturbing ICs and PCs with alarms), and the financial costs of technology use. Furthermore, the findings suggest that ICs had more positive attitudes toward assisting technology and an increased acceptance of technology than the CDOAs themselves. This could be explained by the fact that the average participating IC was 14 years younger than their CDOA and thus had more contact with technology in their daily life [40]. Nevertheless, some ICs evoked their feelings of being overwhelmed by technology. An analysis of their sociodemographic profiles shows that these ICs were generally older relatives, which is in line with the hypothesis that younger ICs are more open to using technologies. Another possible explanation is related to the feeling of being burdened, which urges ICs to seek technological support to alleviate their problems [41].

Technology use was often conditioned by the multiple expected outcomes CDOAs had with regard to remaining at home, risk control by ICs and PCs, and trying to avoid hospitalization or institutionalization. In contrast, the nonuse of technology was linked to the participants' use of their personal and individual capacities, their health, their physical and intellectual functional capacities, and the environmental barriers they encountered (eg, risk of falling). To encourage the participants to adopt technology, our findings suggest that the potential barriers to this should first be removed at the individual level (each situation is unique, including costs), then at the technological level (technological flexibility adaptable to the situation), and finally at the environmental level (life context). These results were consistent with the research conducted by Chen and Chan [30].

Results from the PC FGs revealed that they had mixed attitudes toward technology, although most were interested in specific technologies for everyday use. They highlighted that each care situation was unique, uncertain, and often complex. They were particularly interested in the development of new technologies to help with the ADL. Finally, barriers to the use of technology by PCs themselves included lack of interest, a need for training, the architectural inadequacies of house design, cost issues, and their fears of being replaced by that technology and of the risks of dehumanizing care relationships with CDOAs. Our results highlight the need to pay more attention to adapting technology to users' personal preferences, while focusing on technologies that provide solutions to individual problems. However, to date, there is little evidence to evaluate the usefulness or effectiveness of certain technologies in home care and notably to avoid hospitalization [42]. Causal intervention research expects a coconstruction between users, inventors, researchers, and manufacturers. This would make it possible to develop technologies that meet users' needs (eg, a device that detects falls and sends an alert) and to fulfill the commercial requirements for making those technologies accessible to large numbers of CDOAs [43]. Our findings suggest that most devices will not require significant technological breakthroughs but rather careful adaptations to the specificities of end users. Many technologies will still require an assessment of user needs and their real potential for use. Technology development must consider the somatic and psychopathological states of health of CDOAs, as mentioned in Cohen-Mansfield's work [33]. Our findings suggest that it is important to go beyond the myth that technology will replace ICs and PCs. Indeed, integrating technologies into the home care activities of PCs should be promoted, as this would give them the time to do other things [44,45]. Technologies for care practices are promoted as facilitating safety and independent living as well as avoiding or delaying institutionalization. However, there is still a gap between these goals and the complex realities in which technologies are used [46].

Technologies in home health care settings must also be adapted to the needs and concerns of PCs [44]. In line with previous research, complex surveillance technologies (eg, cameras and motion detectors) were perceived to be intrusive and as posing a high risk to privacy; they were widely rejected by home health care stakeholders [47]. PCs raised concerns that the data collected might be stored for a long time and be accessible and misused by other actors (eg, insurance companies) [13]. The complex context surrounding care for frail CDOAs is unique, uncertain, and constantly changing [48]. This study showed that ICs were often involved in the daily care of a loved one, but that they rarely used technologies. Slowly introducing effective technologies into the everyday care they give would be a way to make their support more effective, either for monitoring care or in maintaining their relationship with the CDOA. This would help to maintain the health of both CDOAs and their ICs, who often become overwhelmed by their care responsibilities, leading to stress and physical and mental exhaustion.

The development of technologies to strengthen home support and prevent the loss of autonomy is a demographic, human, social, and economic imperative; it must be accompanied by the development of multidisciplinary skills [49]. Academic institutions should supervise this development, particularly by proposing critical reflection. It should also be noted that the realities of life will force both researchers in innovative technologies and prescribers to accept that the effectiveness of a technological tool should be based primarily on pragmatic approaches that lack the scientific rigor of causality [50].

Strengths and Limitations

The significant sample of CDOAs, ICs, and PCs involved in this study suggests that our results may be transferable to other regions of Western Europe. The PEIs made it possible to clarify perceptions and specify acceptable technologies. Another strength of this study was its use of a novel combination of methodological approaches, via one-to-one interviews, FGs, and PEIs. This approach illustrated which technologies might be acceptable and useful to CDOAs, ICs, and PCs in the context of home care support. Our research population's heterogeneity did not permit a thorough comparison with other studies in the literature as they involved more homogeneous samples [18-20]. In addition, to the best of our knowledge, this is the first paper in the field to combine one-to-one interviews, FGs, and PEIs, which enriches the value of our results but complicates their comparison with previous studies. One limitation of this study concerns the AGGIR tool's subjectivity when used as an overall clinical classification system of impairment among CDOAs. In contrast, other tools are more oriented toward disease and physiopathological classification (Resident Assessment Instrument-Home care). Finally, this study had some methodological limitations concerning the choices of the images shown in the PEIs. These could not always best present the different gerontechnologies to the heterogeneous research participants (CDOAs, ICs, and PCs).

Conclusions

Despite the omnipresence of technology in modern society, research into perceptions about it and its use to improve the daily lives of frail and cognitively impaired CDOAs is poor compared with research into its impact on younger populations. Despite some evidence that technologies promote independence among CDOAs, they are often underused in daily home health care. With this in mind, this study explored the perceptions about technology's place in home health care among CDOAs, ICs, and PCs. Our findings showed that although many technologies were available to support independent living for CDOAs, they were significantly underused. Our results also affirmed that efforts should be made to adapt technologies to the needs of CDOAs, their ICs, and PCs. It seems important to continue searching for empirical evidence of the relevance and effectiveness of new technologies. This will help to specify the most important areas requiring intervention and indications for technology use among different profiles of CDOAs, their ICs, and PCs. Technology will also help to optimize the management of CDOAs' health problems and slow their loss of autonomy, both of which will strengthen home health care. Progress toward this goal will only be achieved through close cooperation between technical experts, home health care experts, and the end users—CDOAs, ICs, and PCs—who need the appropriate technological tools to meet their needs and expectations. Finally, as the mean age of the population is rising, the proportion of older adults with an interest in technology and with technological skills will increase. The findings in this study will enable future CDOAs to clearly express the advantages and limitations of the technologies in their lives. The current situation is therefore very fluid, and research will have to adjust to this dynamic process. Although there is no doubt that technologies will play an increasingly important role in health care services for CDOAs and in the work of their ICs and PCs, it is more difficult to predict which types of interventions may develop. Establishing convincing results based on robust scientific evidence will be difficult, but clinical research will play a key role.

Acknowledgments

The authors wish to thank Christelle Mercier, Françoise Martinet, and Dominique German for their contributions to data collection and their suggestions during the writing of the manuscript. This work was supported by the European cross-border cooperation program Interregion France-Switzerland V 2014-2020, whose total budget is EUR 1,394,247.16 (US $1,401,080.54). The French side of the project received EUR 701,895.75 (US $705,336.42) from the European Regional Development Fund. The Swiss side of the project was supported by CHF 187,503.34 (US $183,826.80) of federal funds from INTERREG Switzerland and by CHF 75,000 (US $73,529.41) and CHF 50,000 (US $49,019.61) of cantonal funds from Vaud and Valais, respectively.
