Principal-component factors analysis only highlighted 1 factor with an 89.9% proportion of explained variability, while the Horn parallel analysis identified 2 factors with eigenvalues of >1.0 and a 49.8% and 10.3% proportion of explained variability, respectively.

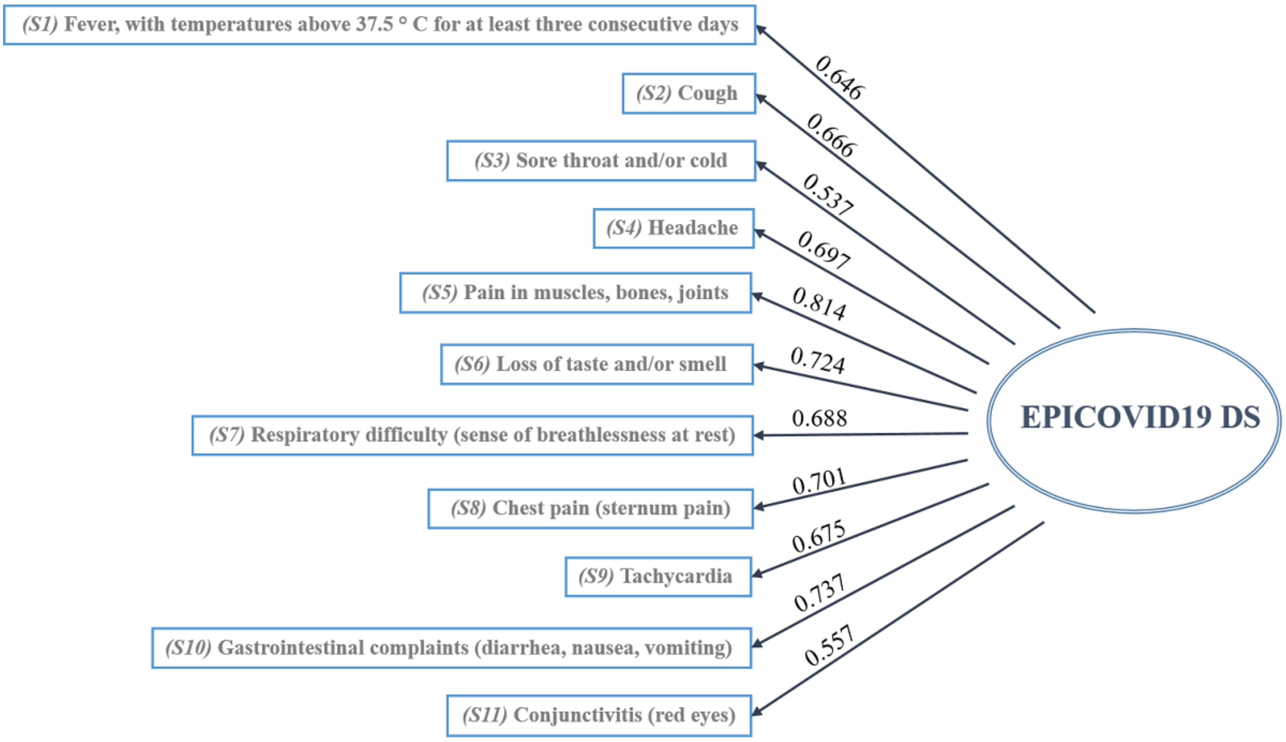
Table 2. Descriptive and goodness-of-fit dimensionality indices from the exploratory factor analysis of the 11 EPICOVID19 symptoms reported by 2703 subjects, based on the principal-component factors and Horn parallel analysis methods with an eigenvalue of >1.

Factor	Exploratory factor analysis					
	Principal-component factors analysis			Horn parallel analysis		
	Eigenvalue	Proportion of explained variability	Cumulative explained variability	Eigenvalue	Proportion of explained variability	Cumulative explained variability
1	5.00	89.9%	89.9%	5.48	49.8	49.8%
2	N/A[a]	N/A	N/A	1.14	10.3	60.1%

[a] N/A: not applicable.

Based on a priori determined cutoff value, a factor loading of >0.35 was maintained. The factor loading rule of the 1-factor solution extracted from the principal-component factors analysis is available in page 13 in Multimedia Appendix 1. The dimensionality indices of the 1-factor solution, which had a high cumulative and proportion of explained variability (89.9%), confirmed the presence of 1 latent variable underlying COVID-19 symptom items. Therefore, we defined the 1-factor solution as the EPICOVID19 diagnostic scale (EPICOVID19 DS). Based on our CFA results, we confirmed that the latent construct was unidimensional and determined how the variables contributed to the EPICOVID19 DS. Figure 2 shows the values of the standardized factor loadings for the 1-factor model. The magnitude of each factor loading value was >0.4, which indicated the importance of the corresponding item to the EPICOVID19 DS. For example, pain in muscles, bones, and joints was the most important variable, with a factor loading value of 0.814. The other variables with an optimal specific validity index were respiratory difficulty (sense of breathlessness at rest: 0.688; loss of taste and smell: 0.724) and gastrointestinal complaints, with item-factor correlations of 0.737. The lowest values were observed for the sore throat and cold and conjunctivitis items, which had a specific validity index of 0.537 and 0.557, respectively. The goodness of fit (ie, SMSR and RMSEA) of the EPICOVID19 DS was acceptable, because 2 indices were <0.10 (SMSR 0.072; RMSEA 0.052; CFI 0.977; TLI 0.971). We computed CFA indices to measure the internal validity of the model (page 14 in Multimedia Appendix 1).

Figure 2. Standardized factor loading values of the 1-factor model, EPICVOID19 DS. The goodness-of-fit indices are as follows: a standardized root mean square residual of 0.072, root mean square error of approximation of 0.052, comparative fit index of 0.977, and Tucker-Lewis index of 0.971. EPICOVID19 DS: EPICOVID19 diagnostic scale.



Given the successful unidimensionality testing of the EPICOVID19 DS, optimal scaling was performed. The proposed optimal score was extracted from the HOMALS procedure (ie, single-factor measurement), and for each subject, the computed optimal score was obtained by summing the category quantifications of the screening questionnaire item responses. Cronbach (α=0.88) and Greenacre (statistic=78%) indices confirmed the unidimensionality found in the EFA and CFA. The HOMALS optimal category quantifications of the EPICOVID19 symptom variables are summarized in Table 3, which has columns for the binary options (ie, Yes/No) and rows for the different symptoms. The HOMALS category quantifications were scaled so that the score obtained from the sum of responses would range from 0 (ie, if a subject answered “No” to all the symptoms) to 10 (ie, if a subject answered “Yes” to all the symptoms). These values are shown in the last column of Table 3. An example of a resulting score calculation is as follows: if the subject response pattern with respect to symptoms is “Yes, No, Yes, No, No, Yes, Yes, No, No, No, Yes,” the corresponding recoded response pattern is 0.80, 0, 0.64, 0, 0, 0.97, 1.03, 0, 0, 0, 0.88, and the subject’s optimal score would be calculated as 0.8 + 0 + 0.64 + 0 + 0 + 0.97 + 1.03 + 0 + 0 + 0 + 0.88 = 4.2.

Table 3. Multiple correspondence analysis optimal weights for the recoding of the EPICOVID19 diagnostic scale.

Symptoms	HOMALS[a] category quantifications		Recoded HOMALS category quantifications	
	No	Yes	No	Yes
Fever with a temperature of >37.5°C for at least 3 consecutive days	−0.362	0.8421	0	0.80
Cough	−0.426	0.810	0	0.81
Sore throat and/or cold	−0.358	0.622	0	0.64
Headache	−0.470	0.780	0	0.83
Pain in muscles, bones, and joints	−0.505	0.959	0	0.97
Loss of taste and/or smell	−0.326	1.133	0	0.97
Respiratory difficulty (ie, sense of breathlessness at rest)	−0.246	1.305	0	1.03
Chest pain (ie, sternum pain)	−0.232	1.388	0	1.07
Tachycardia (ie, heart palpitations)	−0.209	1.374	0	1.05
Gastrointestinal complaints (ie, diarrhea, nausea, and vomiting)	−0.393	1.042	0	0.95
Conjunctivitis (ie, red eyes)	−0.164	1.170	0	0.88

[a] HOMALS: homogeneity analysis by means of alternating least squares.

There was no significant difference in the mean EPICOVID19 DS score between men (mean 2.34, SD 2.2) and women (mean 2.49, SD 2.4) (*P*=.14). A low negative correlation between the scores and ages of the participants was found (ρ=−0.126; *P*<.001). Of the 2703 subjects, 1738 (64.3%) reported no preexisting diseases, 684 (25.3%) only had 1 chronic condition, while the remaining 281 (10.4%) declared ≥2 conditions. Significant differences in the mean EPICOVID19 DS score were observed between participants who did not report any disease (mean 2.26, SD 2.3) and those with at least 1 preexisting condition (mean 2.75, SD 2.4) (*P*<.001). Based on our analysis of the mean EPICOVID19 DS score among healthy subjects and subjects with 1 chronic condition, we observed significant differences between healthy subjects and subjects with lung diseases (healthy subjects: mean 2.40, SD 2.3; subjects with lung diseases: mean 3.10, SD 2.5; *P*<.001), healthy subjects and subjects with immune system diseases (healthy subjects: mean 2.39, SD 2.3; subjects with immune system diseases: mean 2.91, SD 2.4; *P*<.001), and healthy subjects and subjects with depression and anxiety diseases (healthy subjects: mean 2.42, SD 2.4; subjects with depression and anxiety: mean 2.79, SD 2.6; *P*=.036). For the other chronic conditions (ie, heart disease: *P*=.22; hypertension: *P*=.59; kidney disease: *P*=.45; tumor: *P*=.13; metabolic disease: *P*=.52; liver disease: *P*=.64), no significant differences in mean EPICOVID19 DS score were found.

The screening properties of the EPICOVID19 DS were compared to those of COVID-19–positive molecular and serological tests. These are shown in Table 4. The best Youden index value was observed for EPICOVID19 DS, with respect to subjects diagnosed with COVID-19 via NPS testing. A good trade-off between sensitivity and specificity was observed (sensitivity: 76.56%; specificity: 68.24%; AUC 77.5, 95% CI 75.6-79.4). The cutoff score obtained was 2.56. The sensitivity and specificity of the EPICOVID19 DS improved when compared to those of COVID-19–positive IgG antibody test (sensitivity: 80.37%; specificity: 80.17%; AUC 86.0, 95% CI 82.3-89.5). The cutoff value obtained (2.59) was similar to that of the NPS-positive test. The positive and negative predictive values for the IgG-positive serological test (positive predictive value [PPV]: 54.43%; negative predictive value [NPV]: 93.27%) were higher than those of the NPS test (PPV: 42.26%; NPV: 90.55%). We observed a poor performance with regard to IgM test results, so these are not presented in Table 4.

Table 4. Sensitivity and specificity of the EPICOVID19 diagnostic scale compared to those of positive COVID-19 molecular and serological diagnoses (ie, for subjects aged 18-84 years).

Statistic	SARS-CoV-2 tests	
	Nasopharyngeal swab test (n=2703), value (95% CI)[a,b]	Immunoglobulin G antibody test (n=472), value (95% CI)[c,d]
Sensitivity, %	76.56 (72.99-79.87)	80.37 (71.58-87.42)
Specificity, %	68.24 (66.16-70.28)	80.17 (75.69-84.14)
Positive likelihood ratio	2.41 (2.23-2.61)	4.05 (3.23-5.08)
Negative likelihood ratio	0.34 (0.30-0.40)	0.24 (0.17-0.36)
COVID-19–positive tests, %	23.29 (21.68-24.96)	22.77 (19.05-26.83)
Positive predictive value, %	42.26 (40.38-44.17)	54.43 (48.77-59.98)
Negative predictive value, %	90.55 (89.23-91.74)	93.27 (90.40-95.33)
Accuracy, %	70.18 (68.39-71.93)	80.21 (76.32-83.72)

[a] There were 694 NPS-positive subjects.

[b] The cutoff value for the nasopharyngeal swab test was 2.59.

[c] There were 108 immunoglobulin G-positive patients.

[d] The cutoff value for the immunoglobulin G antibody test was 2.56.

When the EPICOVID19 DS scoring algorithm was applied to specific age groups, the sensitivity and specificity of the IgG-positive antibody test (sensitivity: 88.00%; specificity: 89.58%; AUC 93.10, 95% CI 86.0-99.5) improved greatly among subjects aged ≥60 years, and the obtained cutoff value (1.28) was lower than the cutoff value for the subjects aged <60 years (2.71; sensitivity: 88.00%; specificity: 89.58%; AUC 93.10, 95% CI 86.0-99.5). The PPV and NPV of the IgG test were higher for subjects aged ≥60 years (PPV: 81.48%; NPV: 93.48%) than those for subjects aged <60 years (PPV: 51.52%; NPV: 94.38%). Furthermore, we observed the same performance in the NPS test between the specific age groups (ie, aged ≥60 years and aged <60 years), with respect to the overall sample (ie, aged 18-84 years). The details of the screening properties of the EPICOVID19 DS compared to those of COVID-19–positive molecular and serological tests for specific age groups are reported in page 16 in Multimedia Appendix 1.

Discussion

Our focus was on developing a tool composed of simple questions related to COVID-19 symptomatology for the identification of subjects who are more likely to be infected with SARS-CoV-2 in the general population. We validated the EPICOVID19 DS with a sample of voluntary subjects based on serological and molecular clinical diagnoses. The optimal score, which was computed for 2703 adults aged 18-84 years, discriminated symptomatic individuals. Before calculating the score, we performed both exploratory and confirmatory factor analyses to determine the number of factors/dimensions underlying the questionnaire. The results of these analyses supported the 1-factor model and the unidimensionality of the EPICOVID19 questionnaire. The magnitude of all factor loading values was satisfactory, and the highest factor loading values were observed for respiratory difficulty, chest pain, tachycardia (ie, heart palpitations), and loss of taste and smell. Furthermore, gastrointestinal complaint items appeared to be the most essential features of the EPICOVID19 DS. The high value for chest pain can also be explained by the fact that several patients reported it, possibly because of tracheal pain caused by pneumonia [12,13]. Several clinical studies on hospitalized patients have shown that, at the onset of COVID-19, patients frequently show typical symptoms of viral pneumonia [3]. Symptoms that are less common, but still reported by a substantial number of patients, are nasal congestion, sore throat, gastrointestinal complaints, and olfactory and taste disorders [14-16]. Subjects have often reported gastrointestinal complaints as concurrent symptoms instead of isolated symptoms of SARS-CoV-2 infection [17]. The lowest factor loading values were observed for sore throat and cold and conjunctivitis. These lower values may be related to the fact that conjunctivitis and cold are not the most frequent symptoms of COVID-19 [18]. In line with other recent studies [19,20], the features we encountered in this study showed various aspects of the definition for COVID-19 diagnosis. Cough, loss of taste and smell, and respiratory difficulty are among the most reported symptoms in previous studies, and they corresponded to the items that were the most important to our score [12,16,21,22].

The clinical presentation of COVID-19 varies, and discrepancies may exist between symptoms and the disease. A recent meta-analysis of the symptoms of 50,000 patients with COVID-19 found that fever and cough were the most common symptoms (incidence: 89.1% and 72.2%, respectively) [23], and a separate study on hospitalized subjects has suggested that respiratory distress has been reported in the most critical cases of COVID-19 [24]. With the aim of supporting medical decision making, predicted models have been developed for detecting people in the general population who are at risk of being admitted to hospital and diagnosing COVID-19 in patients with related symptoms. However, the results presented in a recent systematic review on such models describe poor research performance and a high risk of bias [25].

Based on our HOMALS, we proposed a scoring methodology for developing an improved scale. Therefore, we provided a numerical weight value (ie, optimal quantification) that represents the importance of the binary response categories (ie, Yes/No) for each question in the EPICOVID19 DS. As a result, the various binary items of the 11 questions in the EPICOVID19 DS contributed to the overall score, albeit with different weights. This produced an improved scale (ie, 0-10) that reflects the importance of each symptom. Thus, respiratory problems and chest pain were the most important symptoms, with a score of 1.03 and 1.07, respectively. The other symptoms that had an important contribution to the total score were gastrointestinal complaints (0.95), loss of taste and smell (0.97), and tachycardia (ie, heart palpitations) (1.05). Subsequently, we computed the sensitivity and specificity of EPICOVID19 DS compared to those of COVID-19–positive serological and molecular tests. For NPS-positive subjects, the cutoff score was 2.56, with a sensitivity of 76.56% and specificity of 68.24%. For IgG-positive subjects, the cutoff score was 2.59, and sensitivity, specificity, PPV, and NPV with respect to NPS-positive tests substantially improved (sensitivity: 80.37%; specificity: 80.17%; PPV: 54.43%; NPV: 93.27%). When the EPICOVID19 DS scoring algorithm was tested on subjects aged ≥60 years, the accuracy of IgG-positive antibody tests improved (sensitivity 88.00%; specificity 89.58%; AUC 93.10, 95% CI 86.0-99.5; PPV: 81.48%; NPV IgG 93.48%), and the threshold of detection (1.28) was lower than that of subjects aged <60 years.

Our data are consistent with the findings reported in previous studies. In mid-May 2020, the European all-cause mortality monitoring system showed that all-cause mortality was above the expected rate in several European countries (ie, Belgium, France, Malta, and Spain), including Italy [26], mainly for people aged ≥60 years. People aged ≥60 years are more vulnerable to SARS-CoV-2 infection, and those with preexisting medical conditions are particularly at risk. Several best practices for older people and their families have been recommended by the World Health Organization, Centers for Disease Control and Prevention, geriatricians, and infectious diseases specialists [27]. The sensitivity and specificity of serological and molecular diagnostic tests for COVID-19 have not been fully elucidated, but several studies have suggested that sensitivity could be as low as 80% [28,29]. This raises concerns of high false-negative rates, which could result in an increase in infection spread among the community. There is no absolute answer for the sensitivity and specificity of COVID-19 diagnostic tests, because to determine their accuracy, they must be compared with a gold-standard test, which does not currently exist. By considering estimates for sensitivity and specificity, PPVs and NPVs can be calculated based on disease prevalence and the rate of illness in the population. However, there is considerable uncertainty with regard to the prevalence of COVID-19 [30]. Statistically, it has been assumed that PPVs vary widely and range between 30-50% in areas with a low COVID-19 prevalence, as stated in a recent US study on COVID-19 [31].

Early recognition screening and rapid diagnosis are essential for preventing transmission and providing supportive care in a timely manner. Nevertheless, screening is different from further, more detailed diagnostic test assessments. This is of particular relevance, as resources for full testing remain limited, and optimizing the use of such resources is critical. The EPICOVID19 DS can be used as a preliminary assessment that attempts to detect subjects with symptoms that are potentially associated with COVID-19 among a wide population. The EPICOVID19 DS does not enable clinical interviews for determining complete symptomatic profiles and needs, but it does identify those who may warrant further assessment. Therefore, it would be advantageous to use the EPICOVID19 DS for screening in primary care settings, so that general practitioners can avoid people with suspected COVID-19 in primary care offices whenever possible [32]. The EPICOVID19 DS can also be used as an initial screening tool before patients are managed remotely via telephone or video consultations [33]. Additionally, the EPICOVID19 DS can be applied to the general population. Once a score is assigned to each symptom, the EPICOVID19 DS can allow for different cutoff values to be set, based on the subjects involved and the gold standards used (ie, NPS tests, serological tests, clinical evaluation by clinicians, etc).

It should be noted that since it is plausible to expect a lower prevalence rate in the general population than the 22.77% in this study, the probability of NPVs would increase beyond the current 93.27%. Consequently, the probability of progressing to COVID-19 for subjects who test negative (ie, 1 − NPV) would be less than the current 6.7%. Furthermore, although the identified symptoms in this study are not specific to COVID-19, they have been reported as valid references for a population setting, because they are frequently reported by patients with COVID-19. In a nonpandemic scenario, it is likely that these symptoms could be assessed with different weights because of their aspecificity, which would configure the EPICOVID19 DS as a valid diagnostic support tool for pandemic situations. Moreover, health authorities are still unable to use classic tests to monitor the spread of SARS-CoV-2 infection, and allowing the circulation of unsuspecting individuals with COVID-19 could represent a risk for the spread of the infection. The validation of an instrument that can easily identify a suspected COVID-19 case by attributing a score to each symptom related to COVID-19 can be of great importance in facilitating the containment of the epidemic. Our proposed cutoff score seems worthy of validation for use in broader populations to confirm its clinimetric properties. In the event of its validation, our cutoff score might be useful in selecting people who require serological and molecular diagnostic tests for COVID-19.

The availability and accessibility of diagnostic tests for the SARS-CoV-2 coronavirus have proven to be key in containing the COVID-19 pandemic. The early identification of subjects who test positive for COVID-19 (ie, via molecular and serological tests) among people with specific symptoms or people who are at risk is crucial for limiting the spread of the infection. The tool we validated responds to the need for readily identifying a suspected COVID-19 case, by attributing a score to each symptom related to COVID-19. Although our validation was satisfactory, our proposed cutoff score seems worthy of further testing in larger populations in order to confirm its clinimetric properties and usefulness in selecting people who require serological and molecular diagnostic tests for COVID-19.

Although the EPICOVID19 DS tool can be used as a public health prevention instrument, directing subjects to a self-assessment tool without warning may trigger panic, alarm, and concern among the screened population. Furthermore, the limitations of our study must be considered. First, participation in this study was voluntary, and the sample was not representative of the general population. This means that potential selection biases must be taken into consideration. Second, data were collected from a highly educated, young-adult convenience population sample with low multimorbidity. This was a result of the phase I EPICOVID19 study [10], and such a sample is expected in studies that involve a web-based questionnaire that is promoted via email invitation. Third, in the context of a pandemic, our survey might have interested people who had no opportunity to report symptoms to clinicians. Moreover, the effect of recall bias cannot be excluded among the participants who tested positive for COVID-19 or presented with symptoms related to SARS-COV2 infection. The fourth limitation of our study is the small sample size in the analysis of the 2 age groups (ie, subjects aged <60 and ≥60 years). Given these limitations, the adoption of the EPICOVID19 DS should be considered with caution. The procedures outlined for the development of the EPICOVID19 DS can be applied iteratively as new data is collected, to continue the refinement of this potentially valuable clinical decision support tool.

In conclusion, the proposed EPICOVID19 DS seems worthy of further testing in different scenarios and populations to achieve a comprehensive understanding of its clinimetric properties for both low-prevalence and high-prevalence COVID-19 settings, and its aptitude for capturing disease severity data. This will allow us to define the boundaries of its use and identify optimal indicators to assist clinicians with the early recognition of COVID-19.

Acknowledgments

We would like to thank Professor Mario Grassi of the University of Pavia for his suggestions regarding statistical analysis and Dr Michael N Liebman for his support in the final revision of the manuscript contents. We would also like to thank them both for their English language support. The authors would like to thank all the participants who took part in this study and made this study possible.

Authors' Contributions

SM, LB, FA, and FP were responsible for the study concept and design. LB, LF, and SP were responsible for the literature search. FA, LF, and SP were responsible for the acquisition of data. LB, FA, FB, FP, and SM were responsible for the analysis and interpretation of data. LB, LF, SM, SP, and FB were responsible for drafting the manuscript. MG, AG, RAI, CP, MA, and GP were responsible for critically revising the manuscript for important intellectual content. LB and SM were responsible for statistical analysis. GP, SM, CT, MN, NJ, AS, CP, and MA critically revised the manuscript for important intellectual content. All authors participated in data interpretation. All authors read and approved the final version of the manuscript. The corresponding author, SM, attests that all listed authors meet authorship criteria and that no others who meet the criteria have been omitted.

Conflicts of Interest

AG received consultancy fees from Mylan and educational support from Gilead.

Abstract

Background: Effectively identifying patients with COVID-19 using nonpolymerase chain reaction biomedical data is critical for achieving optimal clinical outcomes. Currently, there is a lack of comprehensive understanding in various biomedical features and appropriate analytical approaches for enabling the early detection and effective diagnosis of patients with COVID-19.

Objective: We aimed to combine low-dimensional clinical and lab testing data, as well as high-dimensional computed tomography (CT) imaging data, to accurately differentiate between healthy individuals, patients with COVID-19, and patients with non-COVID viral pneumonia, especially at the early stage of infection.

Methods: In this study, we recruited 214 patients with nonsevere COVID-19, 148 patients with severe COVID-19, 198 noninfected healthy participants, and 129 patients with non-COVID viral pneumonia. The participants' clinical information (ie, 23 features), lab testing results (ie, 10 features), and CT scans upon admission were acquired and used as 3 input feature modalities. To enable the late fusion of multimodal features, we constructed a deep learning model to extract a 10-feature high-level representation of

CT scans. We then developed 3 machine learning models (ie, k-nearest neighbor, random forest, and support vector machine models) based on the combined 43 features from all 3 modalities to differentiate between the following 4 classes: nonsevere, severe, healthy, and viral pneumonia.

Results: Multimodal features provided substantial performance gain from the use of any single feature modality. All 3 machine learning models had high overall prediction accuracy (95.4%-97.7%) and high class-specific prediction accuracy (90.6%-99.9%).

Conclusions: Compared to the existing binary classification benchmarks that are often focused on single-feature modality, this study's hybrid deep learning-machine learning framework provided a novel and effective breakthrough for clinical applications. Our findings, which come from a relatively large sample size, and analytical workflow will supplement and assist with clinical decision support for current COVID-19 diagnostic methods and other clinical applications with high-dimensional multimodal biomedical features.

Introduction

COVID-19 is an emerging major biomedical challenge for the entire health care system [1]. Compared to severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS), COVID-19 has much higher infectivity. COVID-19 has also spread much faster across the globe than other coronavirus diseases. Although COVID-19 has a relatively lower case fatality rate than SARS and MERS, the overwhelmingly large number of diagnosed COVID-19 cases, as well as the many more undiagnosed COVID-19 cases, has endangered health care systems and vulnerable populations during the COVID-19 pandemic. Therefore, the early and accurate detection and intervention of COVID-19 are key in effectively treating patients, protecting vulnerable populations, and containing the pandemic at large.

Currently, the gold standard for the confirmatory diagnosis of COVID-19 is based on molecular quantitative real-time polymerase chain reaction (qRT-PCR) and antigen testing for the disease-causing SARS-CoV-2 virus [2-4]. Although these tests are the gold standard for COVID-19 diagnosis, they suffer from various practical issues, including reliability, resource adequacy, reporting lag, and testing capacity across time and space [5]. To help frontline clinicians diagnose COVID-19 more effectively and efficiently, other diagnostic methods have also been explored and used, including medical imaging (eg, X-ray scans and computed tomography [CT] scans [6]), lab testing (eg, various blood biochemistry analyses [7-10]), and identifying common clinical symptoms [11]. However, these methods do not directly detect the disease-causing SARS-CoV-2 virus or the SARS-CoV-2 antigen. Therefore, these methods do not have the same conclusive power that confirmatory molecular diagnostic methods have. Nevertheless, these alternative methods help clinicians with inadequate resources detect COVID-19, differentiate patients with COVID-19 from patients without COVID-19 and noninfected individuals, and triage patients to optimize health care system resources [12,13]. When applied appropriately, these supplementary methods, which are based on alternative biomedical evidence, can help mitigate the COVID-19 pandemic by accurately identifying patients with COVID-19 as early as possible.

Currently, CT scans can be analyzed to differentiate patients with COVID-19, especially those in a severe clinical state, from healthy people or patients with non-COVID infections. Patients with COVID-19 usually present the typical ground-glass opacity (GGO) characteristic on CT images of the thoracic region. A recent study has reported a 98% COVID-19 detection rate based on a 51-patient sample without a comparison group [14]. Detection rates that ranged between 60% and 93% were also reported in another study on 1014 participants with a comparison group [15]. Furthermore, the recent advances in data-driven deep learning (DL) methods, such as convolutional neural networks (CNNs), have demonstrated the ability to detect COVID-19 in patients. On February 2020, Hubei, China adopted CT scans as the official clinical COVID-19 diagnostic method in addition to molecular confirmatory diagnostic methods for COVID-19, in accordance with the nation's diagnosis and treatment guidance [2]. However, the effectiveness of using DL methods to further differentiate SARS-CoV-2 infection from clinically similar non-COVID viral infections still needs to be explored and evaluated.

With regard to places where molecular confirmatory diagnoses are not immediately available, symptoms are often used for quickly evaluating presumed patients' conditions and supporting triage [13,16,17]. Checklists have been developed for self-evaluating the risk of developing COVID-19. These checklists are based on clinical information, including symptoms, preexisting comorbidities, and various demographic, behavioral, and epidemiological factors. However, these clinical data are generally used for qualitative purposes (eg, initial assessment) by both the public and clinicians [18]. Their effectiveness in providing accurate diagnostic decision support is largely underexplored and unknown.

In addition to biomedical imaging and clinical information, recent studies on COVID-19 have shown that laboratory testing, such as various blood biochemistry analyses, is also a feasible method for detecting COVID-19 in patients, with reasonably high accuracy [19,20]. The rationale is that the human body is a unity. When people are infected with SARS-CoV-2, the clinical consequences can be observed not only from apparent symptoms, but also from hematological biochemistry changes. Due to the challenge of asymptomatic SARS-CoV-2 infection, other types of biomedical information, such as lab testing results, can be used to provide alternative and complementary diagnostic decision support evidence. It is possible that our current definition and understanding of asymptomatic infection can be extended with more intrinsic, quantitative, and subtle medical features, such as blood biochemistry characteristics [21,22].

Despite the tremendous advances in obtaining alternative and complementary diagnostic evidence for COVID-19 (eg, CT scans, chest X-rays, clinical information, and various blood biochemistry characteristics), there are still substantial clinical knowledge gaps and technical challenges that hinder our efforts in harnessing the power of various biomedical data. First, most recent studies have usually focused on one of the multiple modalities of diagnostic data, and these studies have not considered the potential interactions between and added interpretability of these modalities. For example, can we use both CT scan and clinical information to develop a more accurate COVID-19 decision support system [23]? As stated earlier, the human body acts as a unity against SARS-CoV-2 infection. Biomedical imaging and clinical approaches can be used to evaluate different aspects of the clinical consequences of COVID-19. By combining the different modalities of biomedical information, a more comprehensive characterization of COVID-19 can be achieved. This is referred to as multimodal biomedical information research.

Second, while there are ample accurate DL algorithms/models/tools, especially in biomedical imaging, most of them focus on differentiating patients with COVID-19 from noninfected healthy individuals. A moderately trained radiologist can differentiate CT scans of patients with COVID-19 from those of healthy individuals with high accuracy, making current efforts in developing supplicated DL algorithms not clinically useful for solving the binary classification problem [14]. The more critical and urgent clinical issue is not only being able to differentiate patients with COVID-19 from noninfected healthy individuals, but also being able to differentiate SARS-CoV-2 infection from non-COVID viral infections [24,25]. Patients with non-COVID viral infection present with GGO in their CT scans of the thoracic region as well. Therefore, the specificity of GGO as a diagnostic criterion of COVID-19 is low [15]. In addition, patients with nonsevere COVID-19 and patients with non-COVID viral infection share several common symptoms, which are easy to confuse [26]. Therefore, for frontline clinicians, effectively differentiating nonsevere COVID-19 from non-COVID viral infection is a challenging task without readily available and reliable confirmatory molecular tests at admission. Incorrectly diagnosing severe COVID-19 as nonsevere COVID-19 may result in missing the critical window of intervention. Similarly, differentiating asymptomatic and presymptomatic patients, including those with nonsevere COVID-19, from noninfected healthy individuals is another major clinical challenge [27]. Incorrectly diagnosing patients without COVID-19 or healthy individuals and treating them alongside patients with COVID-19 will substantially increase their risk of exposure to the virus and result in health care–associated infections. There is an urgent need for a multinomial classification system that can detect patients with COVID-19, including patients with asymptomatic COVID-19, patients with non-COVID viral infection, and healthy individuals, all at once, rather than a system that analyzes several independent binary classifiers in parallel [28].

The third major challenge addresses the computational aspect of harnessing the power of various biomedical data. Due to the novelty of the COVID-19 pandemic, human clinicians have varying degrees of understanding and experience with regard to COVID-19, which can lead to inconsistencies in clinical decision making. Harnessing the power of multimodal biomedical information from combined imaging, clinical, and lab testing data can be the basis of a more objective, data-driven, analytical framework. In theory, such a framework can provide a more comprehensive understanding of COVID-19 and a more accurate decision support system that can differentiate between patients with severe or nonsevere COVID-19, patients with non-COVID viral infection, and healthy individuals all at once. However, biomedical imaging data, such as CT data, with a high-dimensional feature space do not integrate well with low-dimensional clinical and lab testing data. Current studies have usually only described the association between biomedical imaging and clinical features [15,29-33], and the potential power of an accurate decision support tool has not been reported. Technically, CT scans are usually processed with DL methods, including the CNN method, independently from other types of biomedical data processing methods. Low-dimensional clinical and lab testing data are usually analyzed with traditional hypothesis-driven methods (eg, binary logistic regression or multinomial classification) or other non-DL machine learning (ML) methods, such as the random forest (RF), support vector machine (SVM), and k-nearest neighbor (kNN) methods. The huge discrepancy of feature space dimensionality between CT scan and clinical/lab testing data makes multimodal fusion (ie, the direct combination of the different aspects of biomedical information) especially challenging [34].

To fill these knowledge gaps and overcome the technical challenge of effectively analyzing multimodal biomedical information, we propose the following study objective: we aimed to clinically and accurately differentiate between patients with nonsevere COVID-19, patients with severe COVID-19, patients with non-COVID viral pneumonia, and healthy individuals all at once. To successfully fulfill this much-demanded clinical objective, we developed a novel hybrid DL-ML framework that harnesses the power of a wide array of complex multimodal data via feature late fusion. The clinical objective and technical approach of this study synergistically complement each other to form the basis of an accurate COVID-19 diagnostic decision support system.

Methods

Participant Recruitment

We recruited a total of 362 patients with confirmed COVID-19 from Wuhan Union Hospital between January 2020 and March 2020 in Wuhan, Hubei Province, China. COVID-19 was confirmed based on 2 independent qRT-PCR tests. For this study, we did not aggregate patients with COVID-19 under the same class because the clinical characteristics of nonsevere and severe COVID-19 were distinct. Patients' COVID-19 status was confirmed upon admission. The recruited patients were further categorized as being in severe (n=148) or nonsevere (n=214) clinical states based on their prognosis at 7-14 days after initial admission. This step ensured the development of an early detection system for when the initial conditions of patients with COVID-19 were not severe upon admission. Patients in the severe state group were identified by having 1 of the following 3 clinical features: (1) respiratory rate>30 breaths per minute, (2) oxygen saturation<93% at rest, and (3) arterial oxygen partial pressure/fraction of inspired oxygen<300 mmHg (ie, 40 kPa). These clinical features are based on the official COVID-19 Diagnosis and Treatment Plan from the National Health Commission of China [2], as well as guidelines from the American Thoracic Society [35]. The noninfected group included 198 healthy individuals without any infections. These participants were from the 2019 Hubei Provincial Centers for Disease Control and Prevention regular annual physical examination cohort. This group represented a baseline healthy group, and they were mainly used as a comparison group for patients with nonsevere COVID-19, especially those who presented with inconspicuous clinical symptoms.

In order to differentiate patients with COVID-19, especially those with nonsevere COVID-19, from patients with clinically similar non-COVID viral infection, we also included another group of 129 patients diagnosed with non-COVID viral pneumonia in this study. It should be noted that the term “viral pneumonia” was an umbrella term that included diseases caused by more than 1 type of virus, such as the influenza virus and adenovirus. However, in clinical practice, it would be adequate to detect and differentiate between SARS-CoV-2 infection and non-COVID viral infections for initial triaging. Therefore, we recruited 129 participants with confirmed non-COVID viral infection from Kunshan Hospital, Suzhou, China. The reality was that most health care resources were optimized for COVID-19, and some patients who presented with COVID-19–like symptoms or GGOs were clinically diagnosed with COVID-19 without the use of confirmatory qRT-PCR tests in Hubei, especially during February 2020. Therefore, it was not possible to recruit participants with non-COVID viral infection in Hubei during the same period that we recruited patients with COVID-19.

In summary, the entire study sample was comprised of the following 4 mutually exclusive multinomial participant classes: severe COVID-19 (n=148), nonsevere COVID-19 (n=214), non-COVID viral infection (n=129), and noninfected healthy (n=198). This study was conducted in full compliance with the Declaration of Helsinki. This study was rigorously evaluated and approved by the institutional review board committees of Jiangsu Provincial Center for Disease Control and Prevention (approval number JSJK2020-8003-01). All participants were comprehensively told about the details of the study. All participants signed a written informed consent form before being admitted.

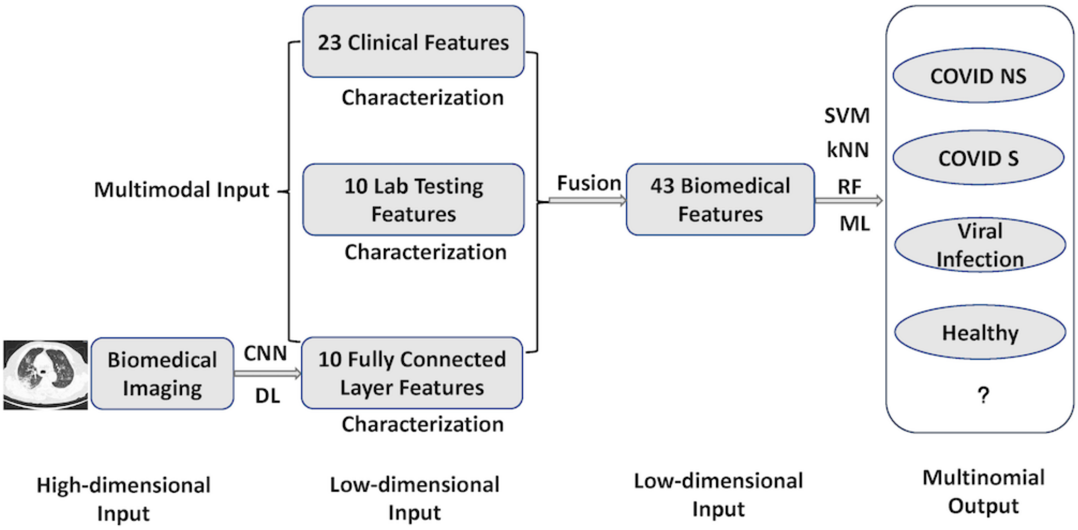
Medical Feature Selection and Description

Patient participants, including those in the severe COVID-19, nonsevere COVID-19, and non-COVID viral infection classes, were screened upon initial admission into hospitals. Their clinical information, including preexisting comorbidities, symptoms, demographic characteristics, epidemiological characteristics, and other clinical data, were recorded. For the noninfected healthy class, participants’ clinical data were extracted from the Hubei Provincial Centers for Disease Control and Prevention physical examination record system. Patient-level sensitive information, including name and exact residency, were completely deidentified. After comparing the different classes, the following 23 clinical features were selected for this study: smoking history, hypertension, type-2 diabetes, cardiovascular disease (ie, any type), chronic obstructive pulmonary disease, fever, low fever, medium fever, high fever, sore throat, coughing, phlegm production, headache, feeling chill, muscle ache, feelings of fatigue, chest congestion, diarrhea, loss of appetite, vomiting, old age (ie, >50 years; dichotomized and encoded as old), and gender. These clinical data were dichotomized as either having the condition (score=1) or not having the condition (score=0) (Figure 1). It should be noted that several clinical features, especially symptoms, were self-reported by the patients. A more comprehensive definition and description of clinical features are provided in Multimedia Appendix 1. The prevalence (ie, the number of participants that have a given feature over the total number of participants in the class) of each clinical feature was computed across the 4 classes. For the 0-1 binary clinical features, a pairwise z-test was applied to detect any substantial differences in the prevalence (ie, proportion) of these features between classes.

The lab testing features were extracted from participants’ electronic health records (Figure 1). Only the features from lab tests that were performed at the time of admission were included. Noninfected healthy participants’ blood samples were taken during their annual physical examination. We selected lab testing features that were present in at least 90% of participants in any of the 4 classes (ie, severe COVID-19, nonsevere COVID-19, non-COVID viral infection, and noninfected healthy). After screening, the following 10 features were included: white blood cell count, hemoglobin level, platelet count, neutrophil count, neutrophil percent, lymphocyte count, lymphocyte percent, C-reactive protein level, total bilirubin level, and creatine level. Features in the lab testing modality all had continuous numeric values, which were different from the 0-1 binary values in the clinical feature modality. The distributions of these lab testing features were compared across the 4 classes by using a 2-sided Kolmogorov-Smirnov test. In addition, we also applied the Kruskal-Wallis test for multiple comparisons across the 4 classes for the top 3 most differentiating features, which were identified later by an ML workflow. The Kolmogorov-Smirnov test was applied during initial screening to investigate whether the values of the same biomedical feature were distributed differently between 2 classes. The nonparametric Kruskal-Wallis test was chosen because it could rigorously compare classes and provide robust results for nonnormal data. The test was able to accommodate more than 2 classes (ie, multinomial classes) in this study.

Each participant underwent CT scans of the thoracic region in the radiology department. Toshiba Activion 16 multislice CT scanners were used to perform CT scanning at around 120 kVp with a tube current of 50 mA. We obtained 50 CT images per scan, and each image had the following characteristics: slice thickness=2 mm, voxel size=1.5 mm, and image resolution=512×512 pixels. Each participant underwent an average of 50 CT scans. The total number of CT images obtained in this study was over 30,000. CT images were archived and presented as DICOM (Digital Imaging and Communications in Medicine) images for DL.

Figure 1. Multimodal feature late fusion and multinomial classification workflow. A deep learning convolutional neural network was applied to computed tomography images for representation learning and extracting 10 features from a customized fully connected layer. These 10 features were merged with other modality data through feature late fusion. In the machine learning stage of the workflow, each of the 3 machine learning models (ie, the support vector machine, k-nearest neighbor, and random forest models) worked independently to provide their respective outputs. kNN: k-nearest neighbor; ML: machine learning; RF: random forest; SVM; support vector machine.



The Multinomial Classification Objective

The main research goal of this study was to accurately differentiate between patients with severe COVID-19, patients with nonsevere COVID-19, patients with non-COVID viral infection, and noninfected healthy individuals from a total of N participants all at once. Therefore, a formula was developed to address the multinomial output classification problem. The following equation uses 1 of the 4 mutually exclusive output classes (ie, H=noninfected healthy, V=non-COVID viral pneumonia, NS=nonsevere COVID-19, and S=severe COVID-19) of an individual (ie, i), as follows:

$$f(X_c,X_l,X_m)_i = \{H,V,NS,S\},\ i = 1...N \quad \textbf{(1)}$$

In this equation, the inputs were individuals' (ie, i) multimodal features of binary clinical information (ie, X_c), continuous lab test results (ie, X_l), and CT imaging (ie, X_m). The major advantage of our study was that we were able to classify 4 classes all at once, instead of developing several binary classifiers in parallel.

The Hybrid DL-ML Approach: Feature Late Fusion

As stated earlier, the voxel level of CT imaging data does not integrate well with low-dimensional clinical and lab testing features. In this study, we proposed a feature late fusion approach via the use of hybrid DL and ML models. Technically, DL is a type of ML that uses deep neural networks (eg, CNNs are a type of deep neural network). In this study, we colloquially used the term “machine learning” to refer to more traditional, non-DL types of ML (eg, RF ML), in contrast with DL that focuses on deep neural networks. An important consideration in the successful late fusion of multimodality features is the representation learning of the high-dimensional CT features.

For each CT scan of each participant, we constructed a customized residual neural network (ResNet) [36-39], which is a specific architecture for DL CNNs. A ResNet is considered a mature CNN architecture with relatively high performance across different tasks. Although other CNN architectures exist (eg, EfficientNet, VGG-16, etc), the focus of this study was not to compare different architectures. Instead, we wanted to deliver the best performance possible with a commonly used CNN architecture (ie, ResNet) for image analysis.

By constructing a ResNet, we were able to transform the voxel-level imaging data into a high-level representation with significantly fewer features. After several convolution and max pooling layers, the ResNet reached a fully connected (FC; ie, FC1 layer) layer before the final output layer, thereby enabling the delivery of actual classifications. In the commonly used ResNet architecture, the FC layer is a 1×512 vector, which is relatively closer in dimensionality to clinical information (ie, 1×23 vector) and lab testing (ie, 1×10 vector) feature modalities. However, the original FC layer from the ResNet was still much larger than the other 2 modalities. Therefore, we added another

FC layer (ie, FC2 layer) after the FC1 layer, but before the final output layer. In this study, the FC2 layer was set to have a 1×10 vector dimension (ie, 10 elements in the vector) to match the dimensionality of the other 2 feature modalities. Computationally, the FC2 layer served as the low-dimensional, high-level representation of the original CT scan data. The distributions of the 10 features extracted from the ResNet in the FC2 layer were compared across the 4 classes with the Kolmogorov-Smirnov test. The technical details of this customized ResNet architecture are provided in Multimedia Appendix 2.

Once low-dimensional high-level features were extracted from CT data via the ResNet CNN, we performed multimodal feature fusion. The clinical information, lab testing, and FC2 layer features of each participant (ie, i) were combined into a single 1× 43 (ie, 1×[23+10+10]) row vector. The true values of the output were the true observed classes of the participants. Technically, the model would try to predict the outcome as accurately as it could, based on the observed classes.

The Hybrid DL-ML Approach: Modeling

After deriving the feature matrix, we applied ML models for the multinomial classification task. In this study, 3 different types of commonly used ML models were considered, as follows: the RF, SVM, and kNN models. An RF model is a decision-tree–based ML model, and the number of tree hyperparameters was set at 10, which is a relatively small number compared to the number of input features needed to avoid potential model overfitting. Other RF hyperparameters in this study included the Gini impurity score to determine tree split, at least 2 samples to split an internal tree, and at least 1 sample at a leaf node. All default hyperparameter settings, including those of the SVM and RF models, were based on the scikit-learn library in Python. An SVM model is a model of maximum hyperplane and L-2 penalty; radial basis function kernels and a gamma value of 1/43 (ie, the inverse of the total number of features) were used as hyperparameter values in this study. kNN is a nonparametric instance-based model; the following hyperparameter values were used in this study: k=5, uniform weights, tree leaf size=30, and p=2. These 3 models are technically distinct types of ML models. We aimed to investigate whether specific types of ML models and multimodal feature fusion would contribute to developing an accurate COVID-19 classifier for clinical decision support.

We evaluated each respective ML model with 100 independent runs. Each run used a different randomly selected dataset comprised of 80% of the original data for training, and the remaining 20% of data were used to test and validate the model. Performing multiple runs instead of a single run revealed how robust the model was, despite system stochasticity. The 80%-20% split of the original data for separate training and testing sets also ensured that potential model overfitting and increased model generalizability could be avoided. In addition, RF models use bagging for internal validation based on out-of-bag errors (ie, how the "tree" would split out in the "forest" model).

After each run, important ML performance metrics, including accuracy, sensitivity, precision, and F1 score, were computed for the test set. We reported the overall performance of the ML models first. These different metrics evaluated ML models based on different aspects. In this study, we also considered 3 different approaches for calculating the overall performance of multinomial outputs, as follows: a micro approach (ie, the one-vs-all approach), a macro approach (ie, unweighted averages; each of the 4 classes were given the same 25% weights), and a weighted average approach based on the percentage of each class in the entire sample.

In addition, because the output in this study was multinomial instead of binary, each class had its own performance metrics. We aggregated these performance metrics across 100 independent runs, determined each metric's distribution, and evaluated model robustness based on these distributions. If ML performance metrics in the testing set had a small variation (ie, small standard errors), then the model was considered robust against model input changes, thereby allowing it to reveal the intrinsic pattern of the data. This was because in each run, a different randomly selected dataset (ie, 80% of the original data) was selected to train the model.

An advantage that the RF model had over SVM and kNN models was that it had relatively clearer interpretability, especially when interpreting feature importance. After developing the RF model based on the training set, we were able to rank the importance of input features based on their corresponding Gini impurity score from the RF model [40,41]. It should be noted that only the training set was used to compute Gini impurity, not the test set. We then assessed the top contributing features' clinical relevance to COVID-19.

We also developed and evaluated the performance of single-modality (ie, using clinical information, lab testing, and CT features individually) ML models. The performance results were used as baseline conditions. The models' performance results were then compared to the multimodal classifications to demonstrate the potential performance gain of the feature fusion of different feature modalities. In this study, each individual ML model (ie, the RF, SVM, and kNN models) was independently evaluated, and the respective results were reported, without combining the prediction of the final output class.

The deep learning CNN and late fusion machine learning codes were developed in Python with various supporting packages, such as scikit-learn.

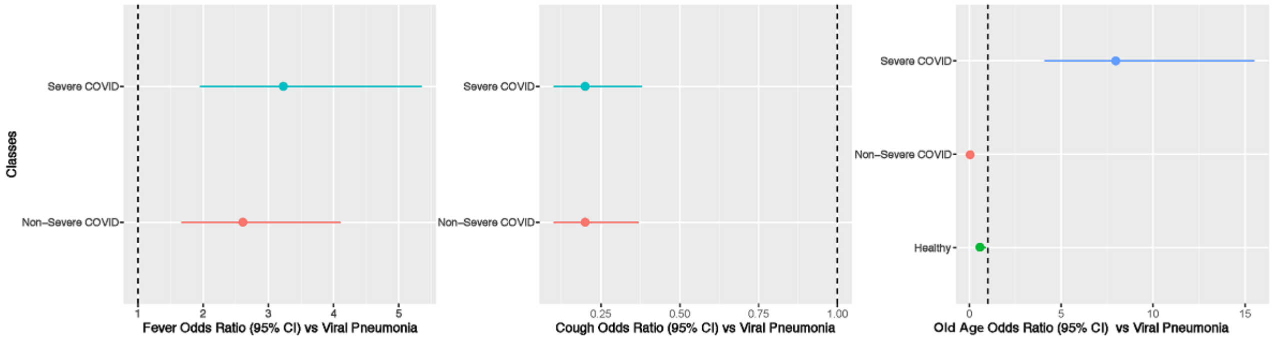
Results

Clinical Characterization of the 4 Classes

Detailed demographic, clinical, and lab testing results among four classes were provided in supplementary Table S1. We compared clinical features across the 4 classes. The prevalence of each feature in all 4 classes is shown in Multimedia Appendix 3. In general, most clinical features varied substantially between the nonsevere COVID-19, severe COVID-19, and non-COVID viral pneumonia classes. It should be noted that all symptom feature values, except gender and age group (ie, >50 years) values, in the noninfected healthy class were set to 0, so that they could be used as a reference. Based on the 2-sample z-test of proportions, the nonsevere COVID-19 and severe COVID-19 classes differed significantly (*P*<.05) in 10 out of 22 symptom features, including comorbidities such as hypertension (*P*<.001), diabetes (*P*<.001), cardiovascular diseases (*P*<.001), and chronic obstructive pulmonary disease (*P*=.005). The nonsevere COVID-19 and non-COVID viral infection classes differed significantly in 12 features, including smoking habit (*P*<.001), fever (*P*<.001), and sore throat (*P*=.002). However, the nonsevere COVID-19 and non-COVID viral infection classes did not differ significantly in terms of comorbidities. The severe COVID-19 and non-COVID viral infection classes differed significantly in 16 out of 22 features, making these 2 classes the most distinct in terms of symptoms. These results showed that the prevalence of clinical features differed substantially between the classes. The complete z-test results for each clinical feature in each pair of classes are provided in Multimedia Appendix 1.

In addition, based on the ML RF analysis, the top 3 differentiating clinical features were fever, coughing, and old age (ie, >50 years). For fever and coughing, we used the non-COVID viral infection class as the reference and constructed 2×2 contingency tables for the nonsevere COVID-19 and non-COVID viral infection classes, and the severe COVID-19 and non-COVID viral infection classes. The odds ratios and 95% confidence intervals for the forest plot are shown in Figure 2. Compared to patients in the non-COVID viral infection class, patients in both the nonsevere and severe COVID-19 classes were more likely to develop fever (ie, >37°C). In addition, based on the forest plot, patients with severe COVID-19 also experienced more fevers than patients with nonsevere COVID-19. Therefore, fever was one of the major determining factors of differentiating between multiple classes. Furthermore, patients with nonsevere COVID-19 (*P*<.001) and patients with severe COVID-19 (*P*<.001) reported significantly less coughing than the patients with non-COVID viral infection (Figure 2). There were no statistically significant differences between the nonsevere and severe COVID-19 classes in terms of clinical features. With regard to the old age feature, we included the severe COVID-19, nonsevere COVID-19, and noninfected healthy classes in the analysis because the prevalence of old age in the noninfected healthy class was not 0. The forest plot for this analysis is shown in Figure 2. Patients with severe COVID-19 were significantly older than patients with non-COVID viral infection, while patients with nonsevere COVID-19 and noninfected healthy individuals were younger than patients with non-COVID viral infection. These differences in clinical features between the 4 classes could pave the way toward a data-driven ML model.

Figure 2. Forest plot of the top 3 differentiating clinical features. Viral pneumonia was used as the reference class during comparisons and the calculation of odds ratios. The noninfected healthy class had no individuals with fevers or coughs. Therefore, these individuals were not included in the first 2 graphs (ie, the left and middle graphs). The error bars represent variation in estimated odds ratios, not the original feature variations.

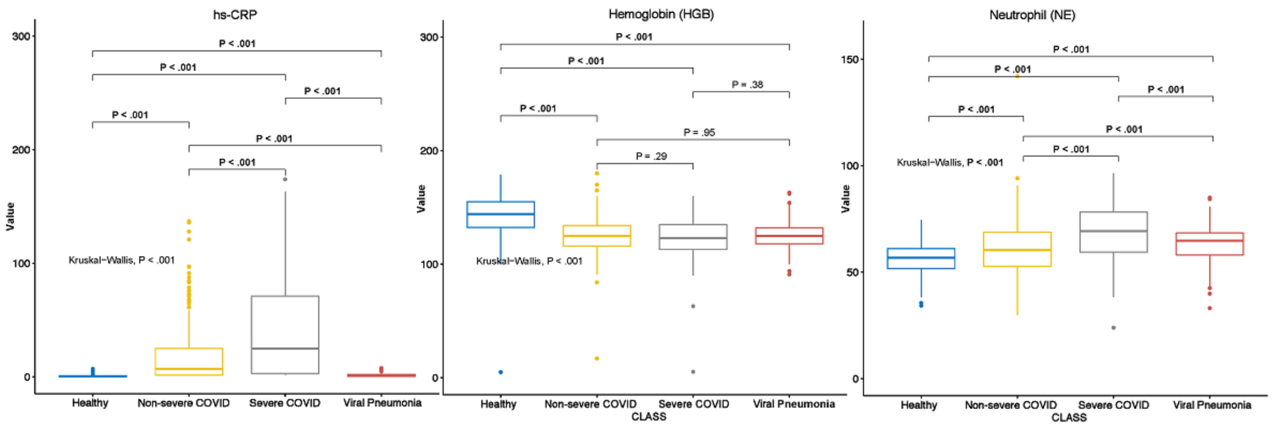


Differences in Lab Testing Features Between the 4 Classes

With regard to the continuous lab testing features, we calculated and compared the exact distributions among the 4 classes. The boxplots for each lab testing feature across the 4 classes are provided in Multimedia Appendix 4. In general, the 4 classes differed substantially across many lab testing features. Based on the 2-sided Kolmogorov-Smirnov test results, the nonsevere and severe COVID-19 classes were only similar in hemoglobin level (HGB *P*=.74) and platelet count (PLT *P*=.61). These 2 classes differed significantly in the remaining 8 lab testing features (WBC *P*=.02; NE% *P*<.001; NE *P*<.001; LY% *P*<.001; LY *P*=.002; CRP *P*<.001; TBIL *P*=.001; CREA *P*<.001;) . In other words, the lab testing features of patients with severe or nonsevere COVID-19 had distinct distributions. Similarly, the nonsevere COVID-19 and noninfected healthy classes were only similar in creatine level; the nonsevere COVID-19 and non-COVID viral infection classes were only similar in hemoglobin level (*P*=.65), platelet count (*P*=.14), and total bilirubin level (*P*=.09); the severe COVID-19 and noninfected healthy classes were only similar in total bilirubin level (*P*=.24); the severe COVID-19 and non-COVID viral infection classes were only similar in hemoglobin level (*P*=.11) and neutrophil count (*P*=.08); and the non-COVID viral infection and noninfected healthy classes were only similar in white blood cell count (*P*=.70). The complete Kolmogorov-Smirnov test results for each lab testing feature in each pair of classes are provided in Multimedia Appendix 1.

Based on the RF model, the 3 most influential differentiating features were C-reactive protein level, hemoglobin level, and neutrophil count. The distribution of C-reactive protein level among the 4 classes are provided in the boxplot in Figure 3. In addition to the Kolmogorov-Smirnov test, which did not account for multiple comparisons between classes, further pairwise comparisons were performed with the nonparametric Kruskal-Wallis H test. Each of the 6 pairs used in the Kruskal-Wallis H test, as well as the overall Kruskal-Wallis test, showed significant differences between each class. The distribution of hemoglobin levels is shown in Figure 3. Although the noninfected healthy class differed significantly from the nonsevere COVID-19, severe COVID-19, and non-COVID viral infection class in terms of hemoglobin level, the other 3 pairs did not show statistically significant differences in lab testing features. The distribution of neutrophil count is shown in Figure 3. All pairwise comparisons and the overall Kruskal-Wallis test showed significant differences between classes in terms of lab testing features.

Figure 3. Multiple comparisons of the top differentiating lab testing features. hs-CRP: high-sensitivity C-reactive protein.



CT Differences Between the 4 Classes Based on High-Level CNN Features

We analyzed the FC2 layer features from the ResNet CNN in relation to the 4 classes. The corresponding boxplot is shown in Multimedia Appendix 5. The 2-sided Kolmogorov-Smirnov tests showed significant differences between every pair of classes in almost all 10 CT features in the FC2 layer. The only exceptions were feature 6 (ie, CNN6) between the severe COVID-19 and non-COVID viral infection classes and features 1, 4, and 5 between the noninfected healthy and non-COVID viral infection classes (Multimedia Appendix 6). Based on the RF model results, features 1, 6, and 10 were the 3 most critical features in the FC2 layer with regard to multinomial classification. Further Kruskal-Wallis tests were performed for these 3 features, and the results are shown in Figure 4. These results showed that developing an accurate classifier based on the CNN representation of high-level features is possible.

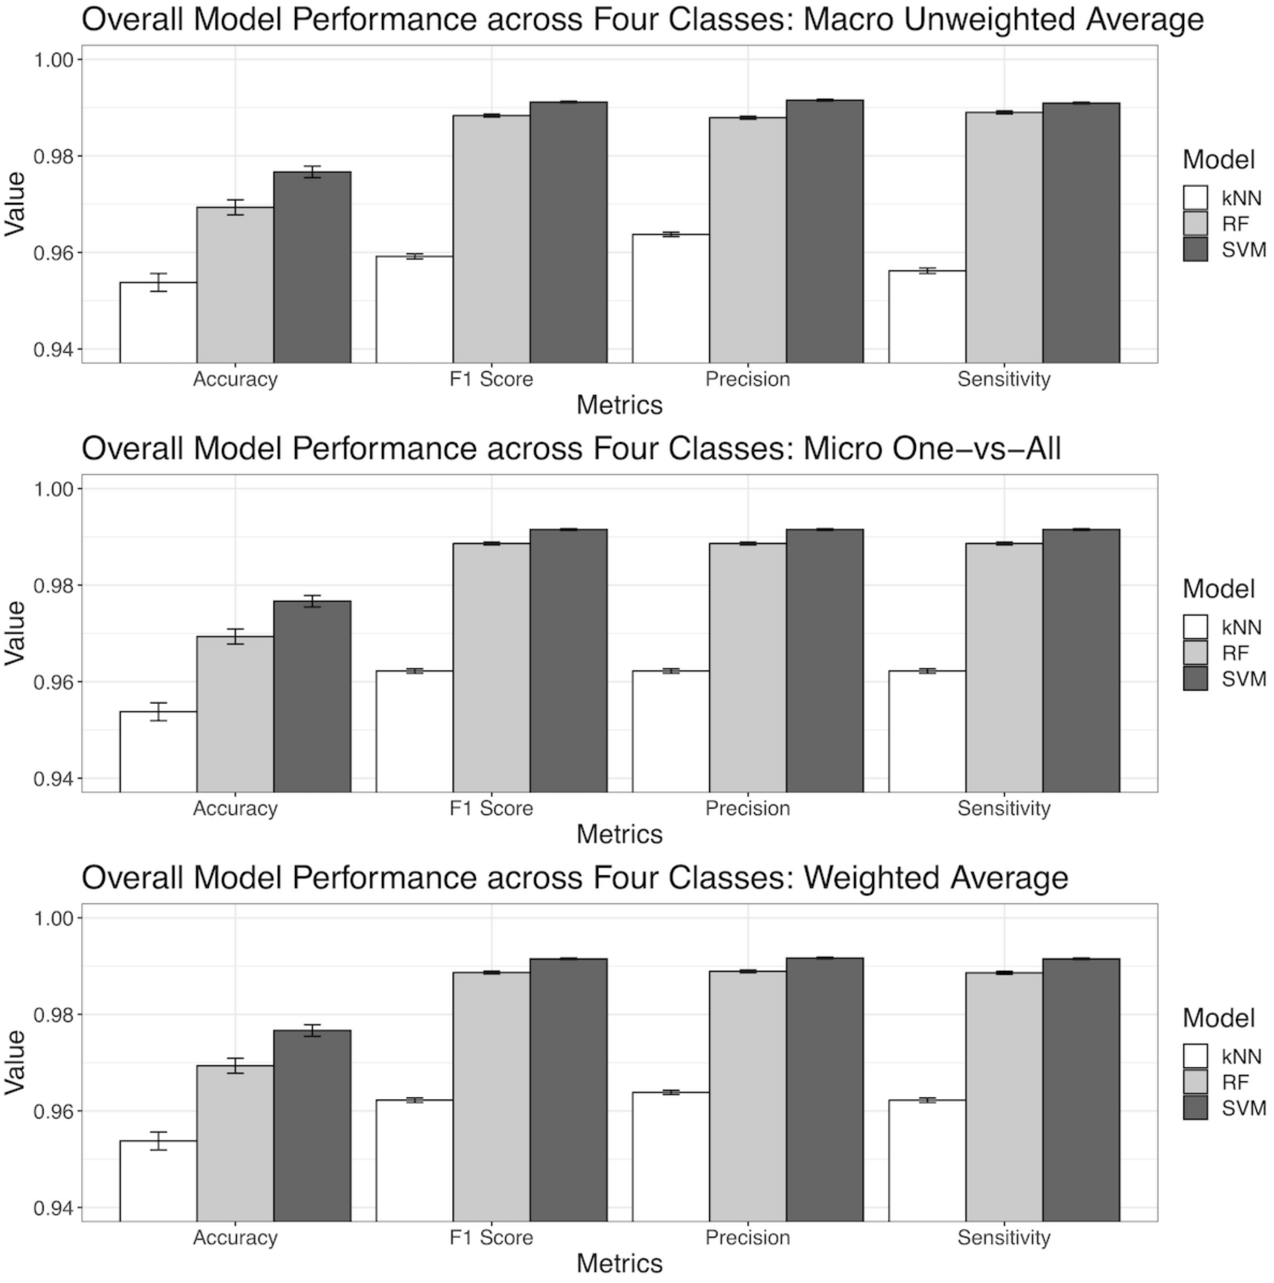
Accurate Multimodal Model for COVID-19 Multinomial Classification

We developed and validated 3 different types of ML models, as follows: the kNN, RF, and SVM models. With regard to training data, the average overall multimodal classification accuracy of the kNN, RF, and SVM models was 96.2% (SE 0.5%), 99.8% (SE 0.3%), and 99.2% (SE 0.2%), respectively. With regard to test data, the average overall multimodal classification accuracy of the 3 models was 95.4% (SE 0.2%), 96.9% (SE 0.2%), and 97.7% (SE 0.1%), respectively (Figure 5). These 3 models also achieved consistent and high performance across all 4 classes based on the different approaches for calculating the overall performance, including the micro approach (ie, the one-vs-all approach), macro approach (ie, unweighted averages across all 4 classes), and weighted average approach (ie, based on percentage of each class in the entire sample). It should be noted that overall accuracy did not depend on sample size, so there was only 1 approach for calculating accuracy. The F1 score, sensitivity, and precision were quantified via each approach (ie, the micro, macro, and weighted average approaches). The F1 scores that were calculated using the macro approach were 95.9% (SE 0.1%), 98.8% (SE<0.1%), and 99.1% (SE<0.1%) for the kNN, RF, and SVM models, respectively. The F1 scores that were calculated using the micro approach was 96.2% (SE<0.1%), 98.8% (SE<0.1%), and 99.2% (SE<0.1%) for the kNN, RF, and SVM models, respectively. The F1 scores calculated using the weighted average approach was 96.2% (SE<0.1%), 98.9% (SE<0.1%), and 99.2% (SE<0.1%) for the kNN, RF, and SVM models, respectively. The differences in F1 scores based on the different approaches (ie, the micro, macro, and weighted average approaches) were minimal (Figure 5). In addition, the differences in F1 scores across the different ML models (Figure 5) were also not significant. Similarly, model sensitivity and precision were all >95% for all ML model types and all approaches for calculating the performance metric. The complete overall performance metrics for the 3 different evaluation approaches and 3 ML models are presented in Multimedia Appendix 7.

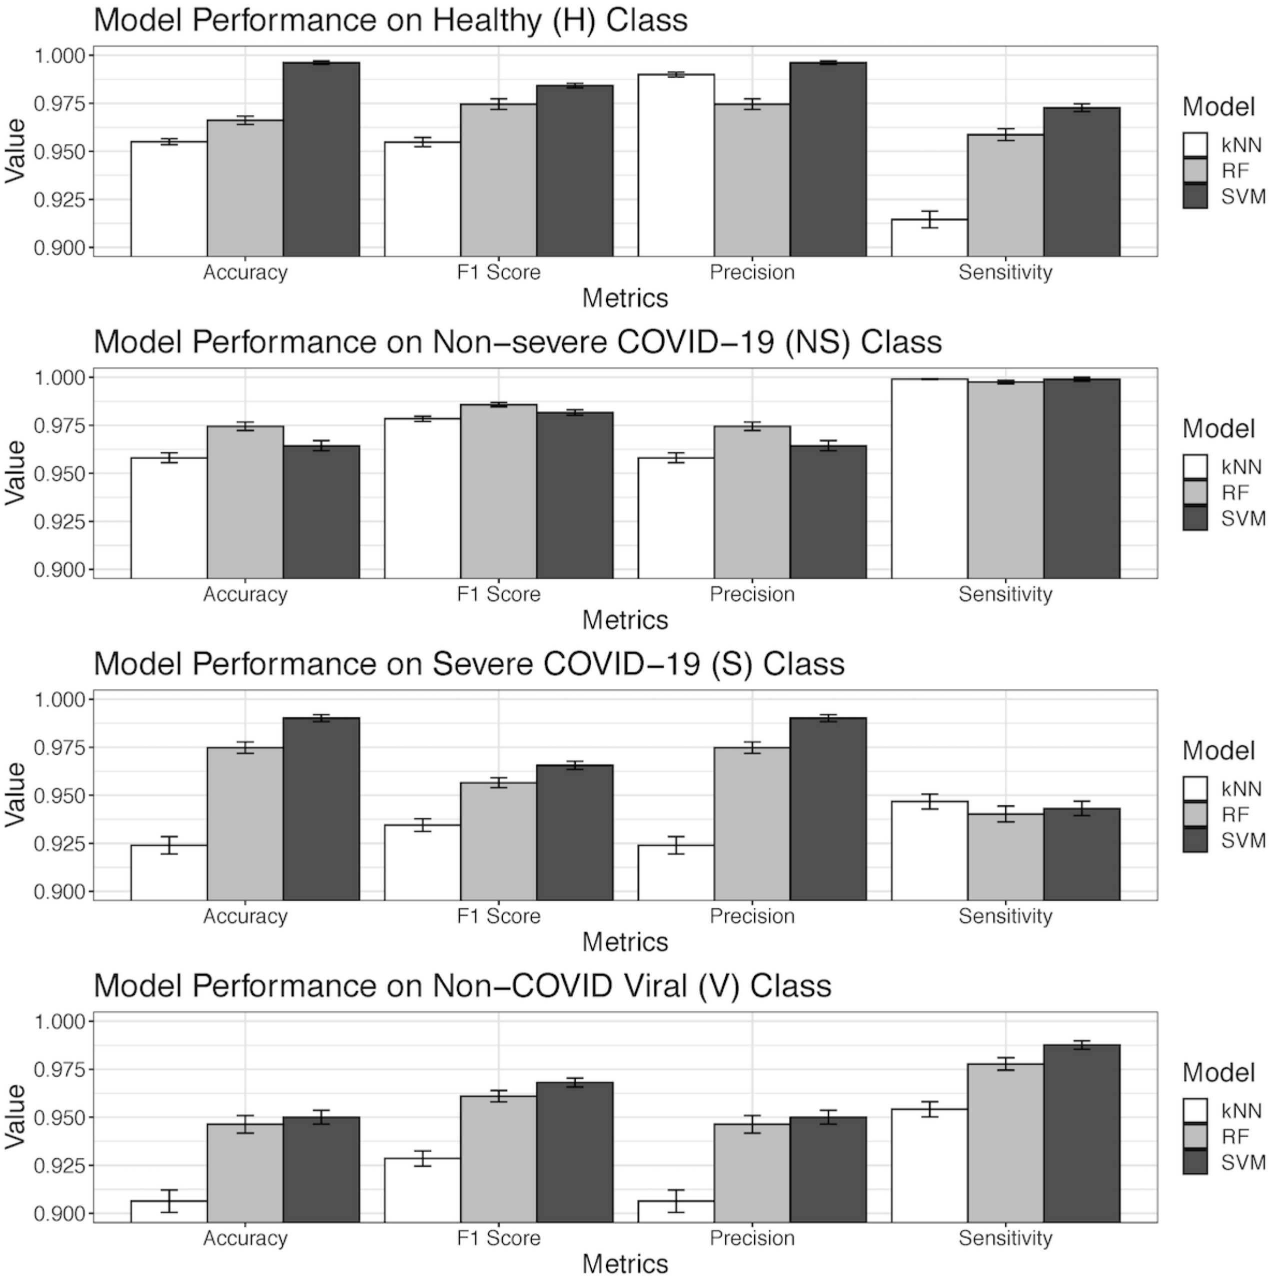
Figure 5. The overall performance of machine learning models across the 4 classes. Model performance was based on the prediction of unseen testing data (ie, the 20% of the original data), not on the 80% of the original data that were used to develop the model. kNN: k nearest neighbor; RF: random forest; SVM: support vector machine.



After examining the performance metrics across the 3 different types of ML models, it was clear that the SVM model consistently had the best performance with regard to all metrics, followed by the RF model, though the difference was almost indistinguishable. The kNN model had about a 1%-3% deficiency in performance compared to the other 2 models. It should be noted that the kNN model also had an accuracy, F1 score, sensitivity, and precision of at least 95%. Therefore, the kNN model was only bested by 2 even more competitive models. Furthermore, the relatively small standard errors demonstrated that the ML models were robust against different randomly sampled inputs (Multimedia Appendix 7).

With regard to each individual class, the noninfected healthy class had a 95.2%-99.9% prediction accuracy, 95.5%-98.4% F1 score, 91.4%-97.3% sensitivity, and 97.5%-99.9% precision in the testing set, depending on the specific ML model used. It should be noted these are ranges, not standard errors, as shown in Figure 6. The approach to computing class-specific model performance was the one-vs-all approach. With regard to the nonsevere COVID-19 class, ML models achieved a 95.8%-97.4% accuracy, 97.8%-98.6% F1 score, 99.8%-99.9% sensitivity, and 95.8%-97.4% precision. With regard to the severe COVID-19 class, ML models achieved a 92.4%-99.0% accuracy, 93.4%-96.6% F1 score, 94.3%-94.7% sensitivity, and 92.4%-99.0% precision. With regard to the non-COVID viral pneumonia infection class, ML models achieved a 90.6%-95.0% accuracy, 92.9%-96.8% F1 score, 95.4%-98.8% sensitivity, and 90.6%-95.0% precision. The non-COVID viral infection class was relatively more challenging to differentiate from the other 3 classes, but the difference was not substantial. Therefore, the potential clinical use of the ML models is still justified. Similar to the results of overall model performance (Figure 5), class-specific performance metrics also had relatively small standard errors, indicating that the training of models was consistent and robust against randomly selected inputs. Except for a few classes and model performance metrics, the SVM model performed slightly better than the RF and kNN models. The complete class-specific results are shown in Figure 6. The complete class-specific performance metrics across the 3 ML models are shown in Multimedia Appendix 8.

Figure 6. Class-specific performance of machine learning models. kNN: k nearest neighbor; RF: random forest; SVM: support vector machine.



All 3 ML multinomial classification models, which were based on different computational techniques, had consistently high overall performance (Figure 5, Table S3) and high performance for each specific class (Figure 6, Multimedia Appendix 8). Of

the 3 types of ML models developed and evaluated, the SVM model was marginally better than the RF and kNN models. As a result, the ML multinomial classification models were able to accurately differentiate between the 4 classes all at once, provide accurate and detailed class-specific predictions, and act as reliable decision-making tools for clinical diagnostic support and the triaging of patients with suspected COVID-19, who might or might not be infected with a clinically similar type of virus other than SARS-CoV-2.

In addition to the multimodal classification that incorporated all 3 different feature sets (ie, binary clinical, continuous lab testing, and CT features in the ResNet CNN; Figure 1), we also tested how each specific feature modality performed without feature fusion (ie, unimodality). By using each of the 23 symptom features alone, the RF, kNN, and SVM models achieved an average accuracy of 74.5% (SE 0.3%), 73.3% (SE 0.3%), and 75.5% (SE 0.3%) with the testing set, respectively. By using each of the 10 lab testing features alone, the RF, kNN, and SVM models achieved an average accuracy of 67.7% (SE 0.4%), 56.2% (SE 0.4%), and 59.5% (SE 0.3%) with the testing set, respectively.

The overall accuracy of the CNN with CT scan data alone was 90.8% (SE 0.3%) across the 4 classes. With regard to each pair of classes, the CNN was able to accurately differentiate between the severe COVID-19 and noninfected healthy classes with 99.9% (SE<0.1%) accuracy, the non-COVID viral infection and noninfected healthy classes with 99.2% (SE 0.1%) accuracy, the severe COVID-19 and nonsevere COVID-19 classes with 95.4% (SE 0.1%) accuracy, and the non-severe COVID-19 and noninfected healthy classes with 90.3% (SE 0.2%) accuracy. However, by using CT features alone (ie, without feature late fusion), the CNN could only differentiate between the non-COVID viral infection and nonsevere COVID-19 classes with 84.9% (SE 0.2%) accuracy, and the non-COVID viral infection and severe COVID-19 with 74.2% (SE 0.2%) accuracy in the testing set.

Substantial performance boosts were gained by combining input features from the different feature modalities and performing multimodal classification, instead of using a single-feature modality alone. A 15%-42% increase in prediction accuracy with the testing set was achieved compared to the single-modality models. It should be noted that the RF, SVM, and kNN models were technically distinct ML models. However, the performance differences between these 3 distinct ML models were marginal, based on the multimodal features. Therefore, we concluded that the high performance in COVID-19 classification in this study (Figures 5 and 6) was largely due to multimodal feature late fusion, not due to the specific type of ML model.

Gini impurity scores derived from the RF model identified major contributing factors that differentiated the 4 classes. With regard to clinical feature modality, the top 3 most influential features were fever, coughing, and old age (ie, >50 years). The forest plots of odds ratios for these features are provided in Figure 2, which shows the exact influence that these features had across classes. With regard to lab testing features, the top 3 most influential features, in descending order, were high-sensitivity C-reactive protein level, hemoglobin level, and absolute neutrophil count. The distribution of these 3 features across the 4 classes and the results of multiple comparisons are shown in Figure 3. Although high-sensitivity C-reactive protein level is a known factor for COVID-19 severity and prognosis [42], we showed that it could also differentiate patients with COVID-19 from patients with non-COVID viral pneumonia and healthy individuals. In addition, we learned that different hemoglobin and neutrophil levels were novel features for accurately distinguishing between patients with clinical COVID-19, patients with non-COVID viral pneumonia, and healthy individuals. These results shed light on which set of clinical and lab testing features are the most critical in identifying COVID-19, which will help guide clinical practice. With regard to the CT features extracted from the CNN, the RF models identified the top 3 influential features, which were CT features 6, 10, and 1 in the 10-element FC2 layer (Figure 4). Although the actual clinical interpretation of CT features was not clear at the time of this study due to the nature of DL models, including the ResNet CNN applied in this study, these features showed promise in accurately differentiating between multinomial classes all at once via CT scans, instead of training several CNNs for binary classifications between each class pair. Future research might reveal the clinical relevance of these features in a more interpretable way with COVID-19 pathology data.

Discussion

Principal Findings

In this study, we provided a more holistic perspective to characterizing COVID-19 and accurately differentiating COVID-19, especially nonsevere COVID-19, from other clinically similar viral pneumonias and noninfections. The human body is an integrated and systemic entity. When the body is infected by pathogens, clinical consequences can be detected not only with biomedical imaging features (eg, CT scan features), but also with other features, such as lab testing results for blood biochemistry [20,43]. A single-feature modality might not reveal the full clinical consequences and provide the best predictive power for COVID-19 detection and classification, but the synergy of multiple modalities exceeds the power of any single modality. Currently, multimodality medical data can be effectively stored, transferred, and exchanged with electronic health record systems. The economic cost of acquiring clinical and lab testing modality data are lower than the economic cost of acquiring current confirmatory qRT-PCR data. Availability and readiness are also advantages that these modalities have over qRT-PCR, which currently has a long turnaround time. This study harnessed the power of multimodality medical information for an emerging pandemic, for which confirmatory molecular tests have reliability and availability issues across time and space. This study's novel analytical framework can be used to prepare for incoming waves of disease epidemics in the future, when clinicians' experience and understanding with the disease may vary substantially.

Upon the further examination of comprehensive patient symptom data, we believed that our current understanding and definition of asymptomatic COVID-19 would be inadequate.

Of the 214 patients with nonsevere COVID-19, 60 (28%) had no fever (ie, <37°C), 78 (36.4%) did not experience coughing, 141 (65.9%) did not feel chest congestion and pain, and 172 (80.4%) did not report having a sore throat upon admission. Additionally, there were 10 (4.7%) patients with confirmed COVID-19 in the nonsevere COVID-19 class who did not present with any of these common symptoms and could be considered patients with asymptomatic COVID-19. Even after considering headache, muscle pain, and fatigue, there were still 4 (1.9%) patients who did not show symptoms related to typical respiratory diseases. Of these 4 patients, 1 (25%) had diarrhea upon admission. Therefore, using symptom features alone is not sufficient for detecting and differentiating patients with asymptomatic COVID-19. Nevertheless, all asymptomatic patients were successfully detected via our model, and no false negatives were observed. This finding shows the incompleteness of the current definition and understanding of asymptomatic COVID-19, and the potential power that nontraditional analytical tools have for identifying these patients.

Based on this perspective, we developed a comprehensive end-to-end analytical framework that integrated both high-dimensional biomedical imaging data and low-dimensional clinical and lab testing data. CT scans were first processed with DL CNNs. We developed a customized ResNet CNN architecture with 2 FC layers before the final output layer. We then used the second FC layer as the low-dimensional representation of the original high-dimensional CT data. In other words, a CNN was applied first for dimensional reduction. The feature fusion of CT (ie, represented by the FC layers), clinical, and lab testing feature modalities demonstrated feasibility and high accuracy in differentiating between the nonsevere COVID-19, severe COVID-19, non-COVID viral pneumonia, and noninfected healthy classes all at once. The consistent high performance across the 3 different types of ML models (ie, the RF, SVM, and kNN models), as well as the substantial performance boost from using a single modality, further unleashed the hidden power of feature fusion for different biomedical feature modalities. Compared to the accuracy of using any single-feature modality alone (60%-80%), the feature fusion of multimodal biomedical data substantially boosted prediction accuracy (>97%) in the testing set.

We compared the performance of our model, which was based on the multimodal biomedical data of 683 participants, against the performance of state-of-the-art benchmarks in COVID-19 classification studies. A DL study that involved thoracic CT scans for 87 participants claimed to have >99% accuracy [37], and another study with 200 participants claimed to have 86%-99% accuracy in differentiating between individuals with and without COVID-19 [36]. Another study reported a 95% area under the curve for differentiating between COVID-19 and other community-acquired pneumonia diseases in 3322 participants [39]. Furthermore, a 92% area under the curve was achieved in a study of 905 participants with and without COVID-19 by using multimodal CT, clinical, and lab testing information [44]. A study that used CT scans to differentiate between 3 multinomial classes (ie, the COVID [no clinical state information], non-COVID viral pneumonia, and healthy classes) achieved an 89%-96% accuracy based on a total of 230 participants [38]. In addition, professionally trained human radiologists have achieved a 60%-83% accuracy in differentiating COVID-19 from other types of community-acquired pneumonia diseases [45]. Therefore, the performance of our model is on par with, or superior to, the performance of these benchmark models and exceeds the performance of human radiologists. Moreover, previous studies have generally focused on differentiating patients with COVID-19 from individuals without COVID-19 or patients with other types of pneumonia. In other words, the current COVID-19 classification models are mostly binary classifiers. Our study not only detected COVID-19 in healthy individuals, but also addressed the more important clinical issue of differentiating COVID-19 from other viral infections. Our study also distinguished between different COVID-19 clinical states (ie, severe vs nonsevere). Therefore, our study provides a novel and effective breakthrough for clinical applications, not just incremental improvements for existing ML models.

The success of this study sheds light on many other disease systems that use multimodal biomedical data inputs. Specifically, the feature fusion of high- and low-dimensional biomedical data modalities can be applied to more feature modalities, such as individual-level high-dimensional "-omics" data. Currently, a study on the genome-wide association between individual single nucleotide polymorphisms and COVID-19 susceptibility has revealed several target loci that are involved in COVID-19 pathology. Following a similar approach, we may also conduct another study, in which we first carry out the dimensional reduction of "-omics" data, and then perform data fusion with other low-dimensional modalities [46-48].

With regard to classification, this study adopts a hybrid of DL (ie, CNN) and ML (ie, RF, SVM, and kNN ML) models via feature late fusion. By using various data-driven methods, we avoided the potential cause-effect pitfall and focused directly on the more important clinical question. For instance, many comorbidities, such as diabetes [49,50] and cardiovascular diseases [51,52], are strongly associated with the occurrence of severe COVID-19. It is still unclear whether diabetes or reduced kidney function causes severe COVID-19, whether SARS-CoV-2 infection worsens existing diabetes, or whether diabetes and COVID-19 actually mutually influence each other and result in undesirable clinical prognoses. Future studies can use data-driven methods to further investigate the causality of comorbidities and COVID-19.

There are some limitations in this study and potential improvements for future research. For instance, to perform multinomial classification across the 4 classes, we had to discard a lot of features, especially those in the lab testing modality. The non-COVID viral pneumonia class used a different electronic health record system that collected different lab testing features from participants in Wuhan (ie, participants in the severe COVID-19, nonsevere COVID-19, and noninfected healthy classes). Many lab testing features were able to accurately differentiate between severe and nonsevere COVID-19 in our preliminary study, such as high-sensitivity Troponin I level, D-dimer level, and lactate dehydrogenase level. However, these features were not present, or largely missing, in the non-COVID viral infection class. Eventually, only 10 lab testing features were included, which is small compared to the average of 20-30 features that are usually available in different electronic health record systems. This is probably the reason why the lab testing feature modality alone was not able to provide accurate classifications (ie, the highest accuracy achieved was 67.7% with the RF model) across all 4 classes in this study. In addition, although we had a reasonably large participant pool of 638 individuals, more participants are needed to further validate the findings of this study.

Another potential practical pitfall was that not all feature modalities were readily available at the same time for feature fusion and multimodal classification. With regard to single-modality features, CT had the best performance in generating accurate predictions. However, CT is usually performed in the radiology department. Lab testing may be outsourced, and obtaining lab test results takes time. Consequently, there might be lags in data availability among different feature modalities. We believe that when multimodal features are not available all at once, single-modality features can be used to perform first-round triaging. Multimodal features are needed when accuracy is a must.

It should be noted that although the participants in this study came from different health care facilities, the majority of them were of Chinese Han ethnicity. The biomedical features among the different COVID-19 and non-COVID classes may be different in people of other races and ethnicities, or people with other confounding factors. The cross-validation of the findings in this study based on other ethnicity groups and larger sample sizes is needed for future research.

This study used a common CNN architecture (ie, a ResNet). The 10 CT features extracted from the FC2 layer of the ResNet were used to match the dimensionality of the other 2 low-dimensional feature modalities. Future research on different disease systems can explore and compare other architectures that use different biomedical imaging data (eg, CT, X-ray, and histology data). The actual dimensionality of the FC2 layer can also be optimized to deliver better performance. Finally, this study presented the results of individual classification models. To achieve even higher performance, the combination of multiple models can be explored in future studies.

Conclusion

In summary, different biomedical information across different modalities, such as clinical information, lab testing results, and CT scans, work synergistically to reveal the multifaceted nature of COVID-19 pathology. Our ML and DL models provided a feasible technical method for working directly with multimodal biomedical data and differentiating between patients with severe COVID-19, patients with nonsevere COVID-19, patients with non-COVID viral infection, and noninfected healthy individuals at the same time, with >97% accuracy.

Acknowledgments

This study is dedicated to the frontline clinicians and other supporting personnel who have fought against COVID-19 worldwide. This study is supported by the National Science Foundation for Young Scientists of China (81703201, 81602431, and 81871544), the North Carolina Biotechnology Center Flash Grant on COVID-19 Clinical Research (2020-FLG-3898), the Natural Science Foundation for Young Scientists of Jiangsu Province (BK20171076, BK20181488, BK20181493, and BK20201485), the Jiangsu Provincial Medical Innovation Team (CXTDA2017029), the Jiangsu Provincial Medical Youth Talent program (QNRC2016548 and QNRC2016536), the Jiangsu Preventive Medicine Association program (Y2018086 and Y2018075), the Lifting Program of Jiangsu Provincial Scientific and Technological Association, and the Jiangsu Government Scholarship for Overseas Studies.

Abstract

Background: The COVID-19 infodemic, a surge of information and misinformation, has sparked worry about the public's perception of the coronavirus pandemic. Excessive information and misinformation can lead to belief in false information as well as reduce the accurate interpretation of true information. Such incorrect beliefs about the COVID-19 pandemic might lead to behavior that puts people at risk of both contracting and spreading the virus.

Objective: The objective of this study was two-fold. First, we attempted to gain insight into public beliefs about the novel coronavirus and COVID-19 in one of the worst hit countries: the United States. Second, we aimed to test whether a short intervention could improve people's belief accuracy by empowering them to consider scientific consensus when evaluating claims related to the pandemic.

Methods: We conducted a 4-week longitudinal study among US citizens, starting on April 27, 2020, just after daily COVID-19 deaths in the United States had peaked. Each week, we measured participants' belief accuracy related to the coronavirus and COVID-19 by asking them to indicate to what extent they believed a number of true and false statements (split 50/50). Furthermore, each new survey wave included both the original statements and four new statements: two false and two true statements. Half of the participants were exposed to an intervention aimed at increasing belief accuracy. The intervention consisted of a short infographic that set out three steps to verify information by searching for and verifying a scientific consensus.

Results: A total of 1202 US citizens, balanced regarding age, gender, and ethnicity to approximate the US general public, completed the baseline (T0) wave survey. Retention rate for the follow-up waves— first follow-up wave (T1), second follow-up wave (T2), and final wave (T3)—was high (≥85%). Mean scores of belief accuracy were high for all waves, with scores reflecting low belief in false statements and high belief in true statements; the belief accuracy scale ranged from –1, indicating completely inaccurate beliefs, to 1, indicating completely accurate beliefs (T0 mean 0.75, T1 mean 0.78, T2 mean 0.77, and T3 mean 0.75). Accurate beliefs were correlated with self-reported behavior aimed at preventing the coronavirus from spreading (eg, social distancing) (r at all waves was between 0.26 and 0.29 and all P values were less than .001) and were associated with trust in scientists (ie, higher trust was associated with more accurate beliefs), political orientation (ie, liberal, Democratic participants held more accurate beliefs than conservative, Republican participants), and the primary news source (ie, participants reporting CNN or Fox News as the main news source held less accurate beliefs than others). The intervention did not significantly improve belief accuracy.

Conclusions: The supposed infodemic was not reflected in US citizens' beliefs about the COVID-19 pandemic. Most people were quite able to figure out the facts in these relatively early days of the crisis, calling into question the prevalence of misinformation and the public's susceptibility to misinformation.

Introduction

Public health crises tend to go hand in hand with information crises. The COVID-19 pandemic, which is taking many lives and is hospitalizing hundreds of thousands of people globally, is no exception. In the wake of the COVID-19 pandemic, we are seeing signs of a misinformation pandemic. Around the first peak of the coronavirus outbreak in the United States, the country with the highest COVID-19 death toll [1], about two-thirds of Americans said they had been exposed to at least some made-up news and information related to the virus [2]. Misinformation about the pandemic seems to have proliferated quickly, especially on social media [3]. The World Health Organization (WHO) has labelled this surge of information and misinformation about the COVID-19 pandemic an *infodemic* [4].

Countries and social media platforms are trying to tackle this infodemic in a number of ways. Several social media platforms, including Facebook and Twitter, have implemented new procedures to remove or label false and misleading content [5,6]. However, with the vast number of posts made to these platforms every day and the platforms' fear of infringing on free speech, the success of these procedures is limited (eg, [7]). A second strategy consists of surfacing trusted content, for instance, by referring people with questions to the WHO or to national health agencies, such as the Centers for Disease Control and Prevention in the United States and the National Epidemiology Center in Brazil. This approach might be hindered by government officials, including US president Donald Trump and Brazilian president Jair Bolsonaro, actually contributing to the spread of misinformation (eg, [8,9]). Considering this apparent infodemic, are people able to distinguish facts from fiction? And what correlates might enable or disable them in forming accurate beliefs?

One promising approach to limiting the effects of misinformation was already on the rise before the COVID-19 pandemic: increasing misinformation resistance through educational interventions. A substantial number of countries have implemented educational interventions, primarily focused on *media literacy* [10], which can be understood as the ability to access, analyze, evaluate, and communicate messages in a variety of forms [11]. The Swedish Civil Contingencies Agency, for instance, has included a section about misinformation in its public emergency preparedness brochure, advising Swedes to be aware of the aim of information and to check the source of information, among others [12]. Similarly, Facebook tries to help its users recognize misinformation by providing 10 tips [13]. One advantage of such a focus on media literacy is that it can help prevent problems with misinformation, instead of having to correct false beliefs after they have taken hold. Previous media literacy research, with interventions focusing on identification of misinformation, has yielded promising results indicating that some interventions can reduce the perceived accuracy of misinformation [14,15]. Other research highlights the difficulties in crafting media literacy interventions [16]. Can these types of interventions, focusing on empowerment of media consumers, help individuals deal with the supposed COVID-19 infodemic?

Our approach focuses on helping individuals figure out what is true and what is false, considering false such beliefs about factual matters that are not supported by clear evidence and expert opinion [17]. We test an intervention that empowers people to search for and identify scientific consensus. Communicating scientific consensus (ie, a high degree of agreement between scientists) is effective in eliciting scientifically accurate beliefs [18]. This effectiveness is described in the gateway belief model, which states that people's perceived scientific consensus functions as a gateway to their personal factual beliefs [19,20]. Here, we focus on empowering individuals to search for and identify scientific consensus, because this approach is more flexible than communicating a scientific consensus on every single issue.

The current strategy is considered a *boosting* approach. Boosting encompasses interventions targeting competence rather than immediate behavior [21]. In line with this, our intervention focuses on improving people's skills to form accurate beliefs, instead of altering the external context within which people form beliefs. In addition, our boosting approach can be considered an educational intervention, just like media literacy interventions. However, compared to media literacy interventions that target the identification of misinformation, boosting *consensus reasoning* is not dependent on being exposed to misinformation. One can investigate any claim, true or false, from any source.

This study had two main goals. One involved an exploratory, not preregistered, investigation to gain insight into the effects of the supposed infodemic on individuals' belief accuracy in times of crisis, and to investigate potential correlates of belief accuracy. The second goal was a preregistered test of the boosting intervention aimed at increasing belief accuracy. Accordingly, we hypothesized that our intervention would lead to more accurate beliefs about the COVID-19 pandemic than the control condition; the complete preregistration can be found on the Open Science Framework (OSF) [22]. The research was conducted online, and a balanced sample of the US population was recruited. We decided to focus on the United States, because this is arguably the country worst hit by the COVID-19 pandemic. Using a longitudinal design, measuring beliefs about the pandemic over 4 weeks just after daily confirmed COVID-19 deaths had peaked at over 4000, allowed us to investigate belief formation in the relatively early days of the pandemic. All data and material are available on the project page on the OSF [23].

Methods

Recruitment

We used Prolific, a UK-based online crowdsourcing platform that connects researchers to participants, to collect data from US citizens over a 4-week period. Prolific has been demonstrated to yield high-quality data and more diverse participants than student samples or other major crowdsourcing platforms [24]. In addition, it allowed for recruitment that balanced age, gender, and ethnicity to approximate the US general public, via stratification using US census data [25]. Recruitment for the initial baseline wave started on April 27, 2020.

A total of 1212 individuals participated in the study at baseline (T0), for which they received £0.45 (~US $0.56). A total of 1089 individuals participated in the first follow-up wave (T1), 1070 individuals participated in the second follow-up wave (T2), and 1028 individuals participated in the final wave (T3); see Table 1 for total sample size, exclusions, and final sample size per wave. Participants received £0.33 (~US $0.41) for participation per follow-up survey. Each of the waves was separated by approximately one week (mean$_{\text{T0-T1}}$ 6.98 days, SD $_{\text{T0-T1}}$ 14.92 hours; mean$_{\text{T1-T2}}$ 7.01 days, SD $_{\text{T1-T2}}$ 12.72 hours; mean$_{\text{T2-T3}}$ 7.06 days, SD $_{\text{T2-T3}}$ 13.18 hours). The sample size was determined by the available resources. This study is part of a research project that was reviewed and approved by the Ethics Committee Social Science at Radboud University (reference No. ECSW-2018-056).

Table 1. Total sample size, exclusions, and final sample size per wave.

Wave and sample	Value, n (%)	Retention rate, %[a]
T0 (baseline): April 27-29, 2020		
Total sample	1212 (100)	N/A[b]
Excluded[c]	10 (0.8)	N/A
Final sample	1202 (99.2)	N/A
T1 (first follow-up wave): May 4-7, 2020		
Total sample	1089 (100)	N/A
Excluded[c]	11 (1.0)	N/A
Final sample	1078 (99.0)	89.7
T2 (second follow-up wave): May 11-14, 2020		
Total sample	1070 (100)	N/A
Excluded[c]	3 (0.3)	N/A
Final sample	1067 (99.7)	88.8
T3 (final wave): May 18-21, 2020		
Total sample	1028 (100)	N/A
Excluded[c]	6 (0.6)	N/A
Final sample	1022 (99.4)	85.0

[a] The retention rate is based on the final sample sizes of T0 and the respective wave. Total sample sizes of follow-up waves were counted, excluding 2 participants who should have been excluded but had been allowed to participate in the follow-up waves due to a technical error.

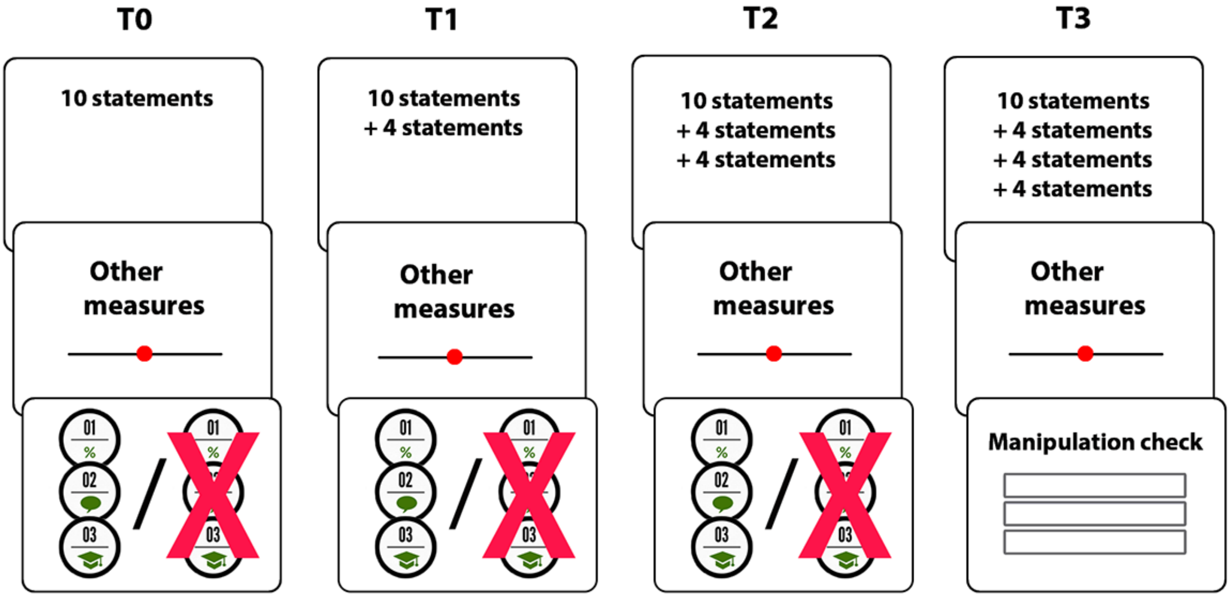
[b] N/A: not applicable; retention rates were calculated using final sample sizes of T0 and the follow-up waves.

[c] More details on exclusions can be found in the Statistical Analysis, Data Exclusion section.

Procedure

Participants were randomly assigned to either receive the intervention (ie, the boost condition) or no intervention (ie, the control condition). All surveys started with the measure of belief accuracy, for which participants were presented with 10 (T0), 14 (T1), 18 (T2), or 22 (T3) statements about the coronavirus and COVID-19 (see Figure 1). Participants indicated to what extent they believed each statement to be true. An attention check was included among these statements (see Multimedia Appendix 1). Subsequently, participants reported their behavior aimed at preventing the spread of the coronavirus and completed the other measures. The boosting intervention, an infographic presenting three steps that can be used to evaluate a claim, was included at the end of T0, T1, and T2. Only participants in the boost condition were presented with the infographic, allowing them to apply their boosted consensus reasoning skill in the week leading up to the next wave. At T3, all participants completed a manipulation check. At the end of T0, all participants entered demographic information and completed a seriousness check (see Multimedia Appendix 1). All surveys took about 3 to 6 minutes.

Figure 1. Flowchart of the main elements of the procedure per wave. Participants first completed the measure of belief accuracy, then completed other measures, and, finally, were exposed to the intervention or not. At T3, participants completed a manipulation check. The bottom panels of the first three columns display the intervention condition (left; infographic) and the control condition (right; no intervention). T0: baseline; T1: first follow-up wave; T2: second follow-up wave; T3: final wave.



Materials and Measures

Belief Accuracy

The key dependent variable was the accuracy of participants' beliefs related to the COVID-19 pandemic. This variable consisted of responses to a number of statements about the pandemic, which were sourced from preprints of early research on public perceptions of COVID-19 (eg, [26]), public health agencies and medical institutes (eg, the WHO), media tracking organizations (eg, NewsGuard), and expert reports in established media (eg, CNBC); a comprehensive list of these resources is available in Multimedia Appendix 2. Only statements based on scientific claims were included in order to make sure that there was compelling evidence that the claims were either true or false.

At T0, participants were exposed to 10 statements, of which five were scientifically accurate (eg, "Fever is one of the symptoms of COVID-19") and five were at odds with the best available evidence (eg, "Radiation from 5G cell towers is helping spread the coronavirus"). Participants responded by indicating the accuracy of a statement as follows: *false*, *probably false*, *don't know*, *probably true*, or *true*. In each subsequent wave, four new statements were added to the list of statements: two accurate ones and two inaccurate ones. This allowed us to keep the belief accuracy measure current, reflecting contemporary insights and discussion points. The order of the statements was randomized per participant and varied per wave.

A belief accuracy score was calculated by converting the response to each statement to a number reflecting how accurate the response was; a correct judgment was counted as 1 and an incorrect judgment was counted as –1. A less certain but correct *probably true* or *probably false* counted as 0.5 and an incorrect one as –0.5. Finally, a *don't know* response was counted as 0. Average scores were calculated per wave per participant, resulting in a repeated measure of belief accuracy. Internal consistency was acceptable to good across the four waves; the McDonald ω_t was between 0.75 and 0.87 in all waves.

Coronavirus-Related Behavior

Coronavirus-related behavior aimed at preventing the coronavirus from spreading was measured by asking participants to indicate their agreement with three statements. The statements were "To prevent the coronavirus from spreading..." (1) "I wash my hands frequently," (2) "I try to stay at home/limit the times I go out," and (3) "I practice social distancing (also referred to as 'physical distancing') in case I go out"; agreement was measured on a scale from 1 (strongly disagree) to 7 (strongly agree). Scores were averaged per wave per participant. Internal consistency was acceptable to good across the four waves; the McDonald ω_t was between 0.77 and 0.83 in all waves.

Additional Measures

Trust in scientists was measured in all four waves with responses to the statement "I trust scientists as a source of information about the coronavirus." Participants responded on a 7-point scale ranging from 1 (strongly disagree) to 7 (strongly agree).

Participants' primary news source for information about the COVID-19 pandemic was identified by asking them at T0 what their main source of news about the coronavirus was. Participants could choose one option from a list of 11 news sources, based on data from the Pew Research Center on Americans' news habits [27].

Finally, we included a manipulation check at T3. This consisted of asking participants how they evaluated the truthfulness of the statements about the coronavirus and coronavirus disease in the study over the past weeks. We asked them to name the steps that they took to evaluate the claims in three open text boxes, of which at least one had to be used. These answers were coded by the first author to indicate whether they mention consensus—or something similar—or not. A second coder coded a random subset of 120 answers, with Krippendorff α indicating good (α=.85) interrater reliability. Therefore, the complete coding from the first author was used in the analyses.

Not all measures included in the study are listed here, because not all measures are relevant here. Please see the material on the project page on the OSF for the remaining measures [23].

Intervention

The boosting intervention that was included at the end of T0, T1, and T2 consisted of a short infographic that was aimed at empowering participants to use scientific consensus when evaluating claims related to the COVID-19 pandemic. The infographic set out three steps that can be used to evaluate a claim: (1) searching for a statement indicating consensus among scientists, (2) checking the source of this consensus statement, and (3) evaluating the expertise of the consensus. The infographic can be found in Multimedia Appendix 3. Participants in the control condition were not exposed to the infographic.

Demographics

Demographics including political orientation, age, gender, ethnicity, and education were asked about at T0. Political orientation was measured by combining political identity (ie, strong Democrat, Democrat, independent lean Democrat, independent, independent lean Republican, Republican, or strong Republican) and political ideology (ie, very liberal, liberal, moderate, conservative, or very conservative) into one numeric, standardized measure centered on 0 (ie, moderate, independent), based on Kahan [28].

Statistical Analysis

Data Exclusion

First, we removed one of two duplicate responses at T1 and excluded all responses from one participant with three varying responses at T3.

As preregistered, participants who failed the attention check at T0 were excluded and replaced (n=8; including 2 who had been allowed to participate in the follow-up waves due to a technical error). If a participant failed one of the attention checks in the subsequent waves, data from that wave was not included in the analyses (n_{T1}=5, n_{T2}=2, n_{T3}=5), but other surveys in which the attention check was passed were retained. Participants who indicated at the T0 seriousness check that their data should not be used were excluded from further participation and their data were not used, but they were not replaced (n=2). No participants completed T0 in less than 1 minute, but if a participant completed a subsequent wave in less than 1 minute, data from that survey were not included in the analyses (n_{T1}=6, n_{T2}=1, n_{T3}=0). Other waves in which the 1-minute threshold was passed were retained.

Exploratory Analyses

General increase in belief accuracy over time was explored using linear mixed modeling for each set of statements, with wave as predictor, controlling for political orientation and including a random intercept per participant. The relationship between belief accuracy and coronavirus-related behavior was explored with correlations for each wave. The relationship of belief accuracy with trust in scientists at T0, political orientation, and primary news source was explored using mixed modeling, controlling for wave, age, gender, education, and ethnicity. The interaction term between trust and political orientation was included in the model. The five most chosen news sources (ie, CNN, Fox News, NPR, social media sites, and The New York Times, excluding the option *Other sources*) were included as dummy-coded variables. Finally, we included a random intercept and a random slope for wave per participant. Mixed modeling was performed with the lme4 package [29] in R (The R Foundation) [30]. The models were examined using likelihood ratio tests, using the R package lmerTest [31].

Preregistered Analysis

The hypothesis that our intervention would lead to more accurate beliefs than would the control condition was also tested using linear mixed modeling. The condition (ie, intervention vs control) and wave, and the interaction between condition and wave, were included as predictors in the model. Political orientation was included as a covariate, because beliefs about the COVID-19 pandemic are related to political ideology [32], and a random intercept and a random slope for wave were included per participant. The hypothesis was tested by comparing the full model, with the interaction between condition and wave, to a model without this interaction effect. We used the PBmodcomp function from the R package pbkrtest [33] for parametric bootstrapping (10,000 simulations).

Results

Participants

The final sample roughly reflects US census data [25] on gender, age, and ethnicity, indicating that the balanced sampling worked well. See Table 2 for more details.

Table 2. Participant characteristics.

Demographic characteristic	Sample value (N=1202), n (%)[a]	Census value, %[b]
Gender		
Female	604 (50.2)	51.3
Male	587 (48.8)	48.7
Other	11 (0.9)	N/A[c]
Age in years		
18-24	164 (13.6)	11.9
25-34	243 (20.2)	17.9
35-44	209 (17.4)	16.4
45-54	199 (16.6)	16.0
55-64	232 (19.3)	16.6
65-74	139 (11.6)	12.4
≥75	16 (1.3)	8.8
Ethnicity		
White	918 (76.4)	73.6
Black	158 (13.1)	12.5
Asian	79 (6.6)	5.9
Mixed	30 (2.5)	2.5
Other	17 (1.4)	5.5

[a] Due to rounding, percentages may not add up to 100% exactly.

[b] The percentages in the census data reflect the population aged 18 years and over.

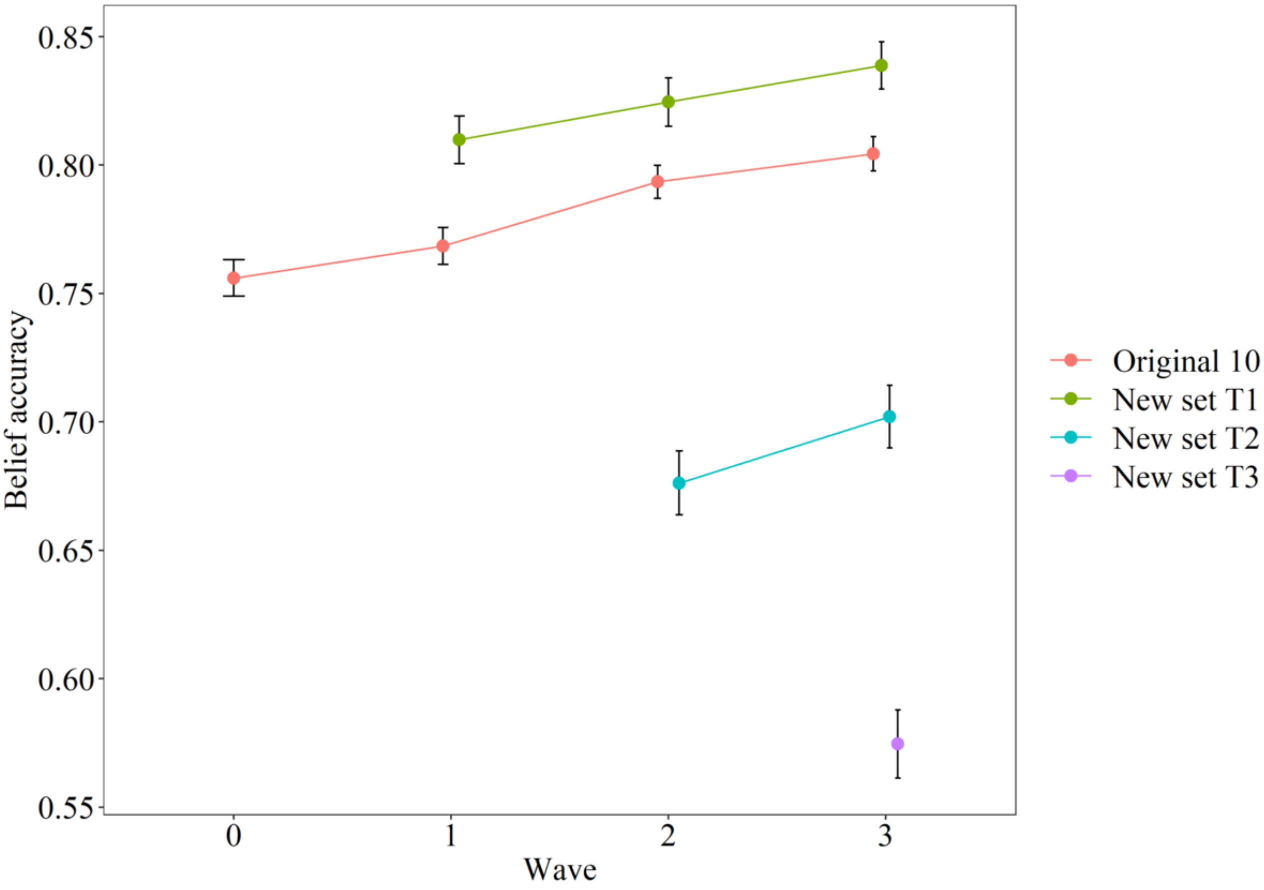
[c] N/A: not applicable.

Belief Accuracy

Mean scores of belief accuracy were very high for all waves, with scores reflecting low belief in false statements and high belief in true statements. There was substantial variation in the accuracy of responses between statements, although none of the statements was ever interpreted with less than 0.25 accuracy, on average; see Multimedia Appendix 4 for a complete overview of scores per statement per wave.

There was a modest increase in belief accuracy over time, looking at each set of statements separately (first 10: estimate=0.02, SE<0.01; $t_{3202.59}$=13.82, *P*<.001; T1 set: estimate=0.01, SE<0.01; $t_{2041.94}$=4.80, *P*<.001; T2 set: estimate=0.02, SE<0.01; $t_{1003.22}$=3.40, *P*<.001). This increase was positive for all three sets of statements that were asked more than once (see Figure 2 [34,35]), indicating that participants became more accurate in their interpretation of the statements over time.

Figure 2. Belief accuracy per set of statements over time. The new set at T3 was included for completeness. Focusing on within-subject change, dots represent normed means and error bars indicate 95% CIs of the within-subject SE [34], calculated using the summarySEwithin function from the Rmisc package [35]. The belief accuracy scale ranged from –1, indicating completely inaccurate beliefs, to 1, indicating completely accurate beliefs. T1: first follow-up wave; T2: second follow-up wave; T3: final wave.



Coronavirus-Related Behavior

Accurate beliefs were correlated with self-reported behavior aimed at preventing the coronavirus from spreading; *r* at all waves was between 0.26 and 0.29 and all *P* values were less than .001. This small but robust correlation suggests that accurate beliefs could be important for coronavirus-related behavior. We explored potential evidence of any causal effects in the data using a random-intercept cross-lagged panel model. This yielded a tentative indication that accurate beliefs might be predictive of behavior, with belief accuracy at T2 predicting coronavirus-related behavior at T3. However, with all other paths showing no sign of significant predictive effects, the results regarding causality are largely inconclusive (see Multimedia Appendix 5).

Associations With Belief Accuracy

We explored the relationship of trust in scientists at T0, political orientation, and the primary news source with belief accuracy. The mixed model yielded a significant positive relationship between belief accuracy and trust (estimate=0.07, SE<0.01; $t_{1200.23}$=16.44, *P*<.001) and a significant negative correlation with political orientation (estimate=–0.02, SE<0.01; $t_{1199.62}$=–6.78, *P*<.001). These main effects indicated that participants with higher trust in scientists scored higher on the measure of belief accuracy and that liberal, Democratic participants held more accurate beliefs than conservative, Republican participants. Moreover, these main effects were partially qualified by an interaction effect among trust and political orientation (estimate=–0.01, SE<0.01; $t_{1195.05}$=–3.62, *P*<.001). Plotting of this interaction effect demonstrated that trust in scientists had a stronger relationship with belief accuracy for liberal, Democratic participants than it had for conservative, Republican participants (see Figure 3).

Two of the five most chosen primary news sources were associated with a worse understanding of the facts regarding the COVID-19 pandemic than others (see Figure 4). Participants who reported CNN (estimate=–0.03, SE=0.01; $t_{1194.49}$=–2.33, *P*=.02) or Fox News (estimate=–0.05, SE=0.02; $t_{1202.49}$=–3.05, *P*=.002) as their main news source scored below average on belief accuracy.

Figure 3. Linear relationship between belief accuracy (averaged over wave for plotting) and trust in scientists at T0 (baseline), split by political orientation (dichotomized for plotting). The grey area represents the 95% CI. The belief accuracy scale ranged from –1, indicating completely inaccurate beliefs, to 1, indicating completely accurate beliefs. Trust in scientists was measured with responses to the statement “I trust scientists as a source of information about the coronavirus.” Participants responded on a 7-point scale ranging from 1 (strongly disagree) to 7 (strongly agree).

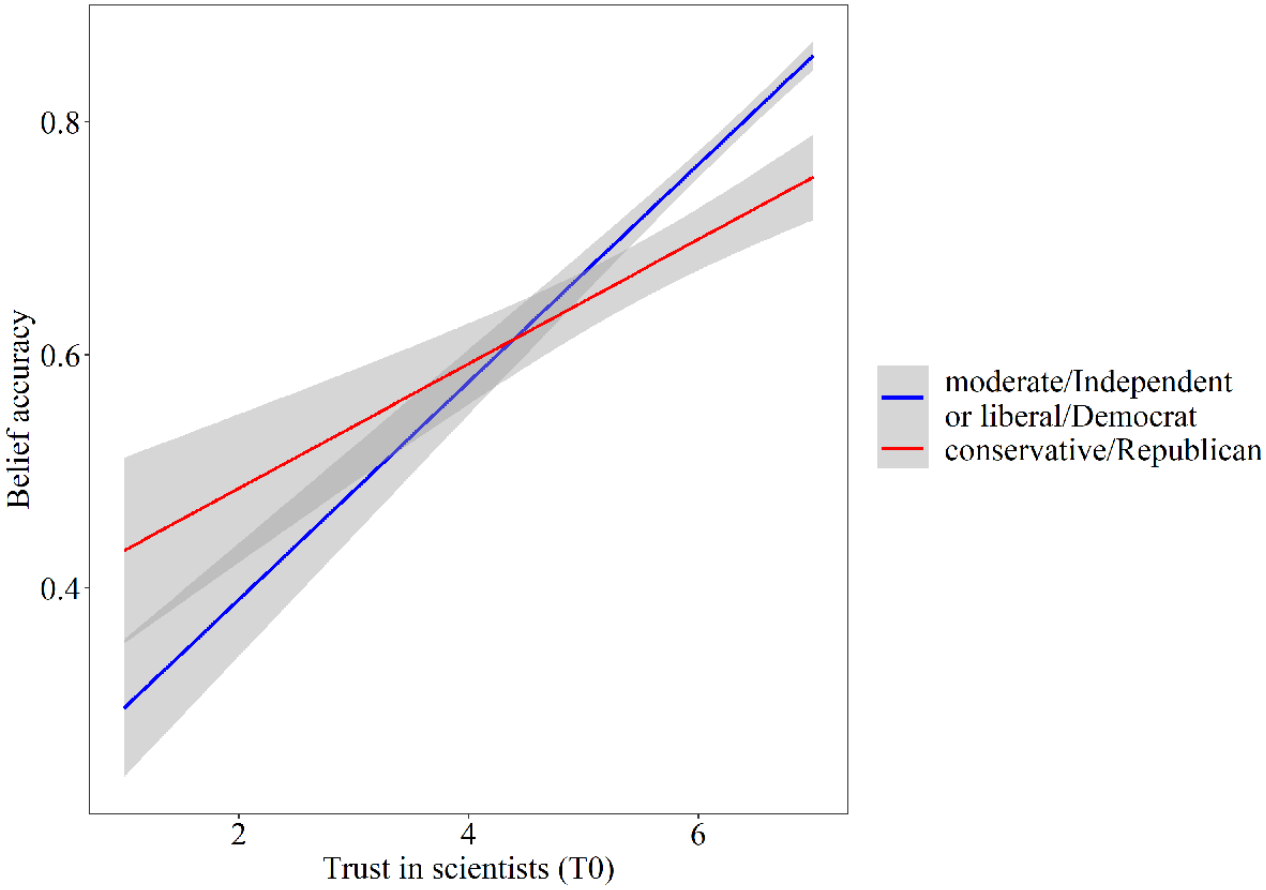


Figure 4. Box plot of raw (unadjusted) scores of belief accuracy (averaged over wave for plotting) by main news source. The belief accuracy scale ranged from –1, indicating completely inaccurate beliefs, to 1, indicating completely accurate beliefs.

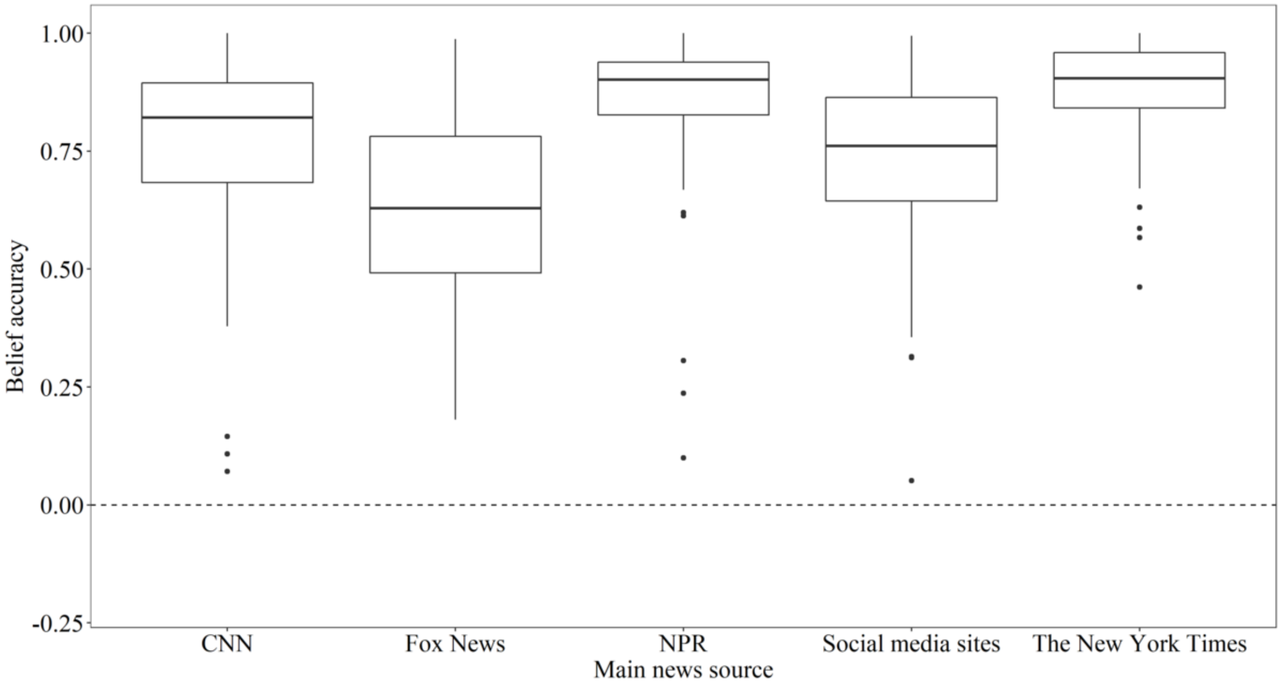
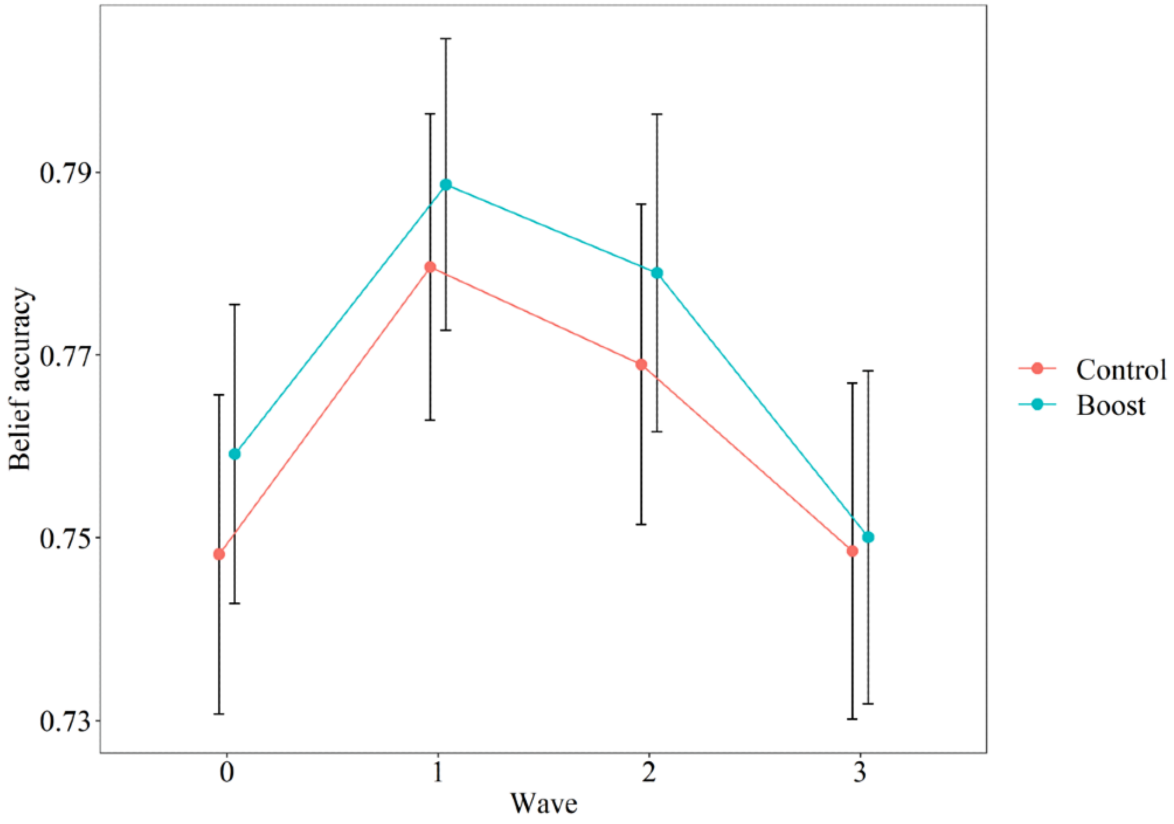


Intervention

We conducted a manipulation check and, as expected, when asked how they evaluated claims, participants in the boost condition (136/600, 22.7%) mentioned consensus, or something similar, more often than participants in the control condition (26/602, 4.3%; χ^2_1=85.2, *P*<.001, N=1202).

We hypothesized that our boosting intervention would lead to more accurate beliefs about the COVID-19 pandemic than would the control condition. However, the interaction effect between condition and wave on belief accuracy was not significant (estimate<0.01, SE<0.01; $t_{1074.36}$=0.22, *P*=.83). This means that the boosting intervention did not significantly alter belief accuracy of participants over time, compared to the control condition (see Figure 5). This was also the case when we explored effects of the intervention on inaccurate statements only (*P*=.48), accurate statements only (*P*=.49), only the original 10 statements that were included in all waves (*P*=.61), and only included participants who scored relatively low on belief accuracy at T0 (belief accuracy_{T0}<0.76; *P*=.32).

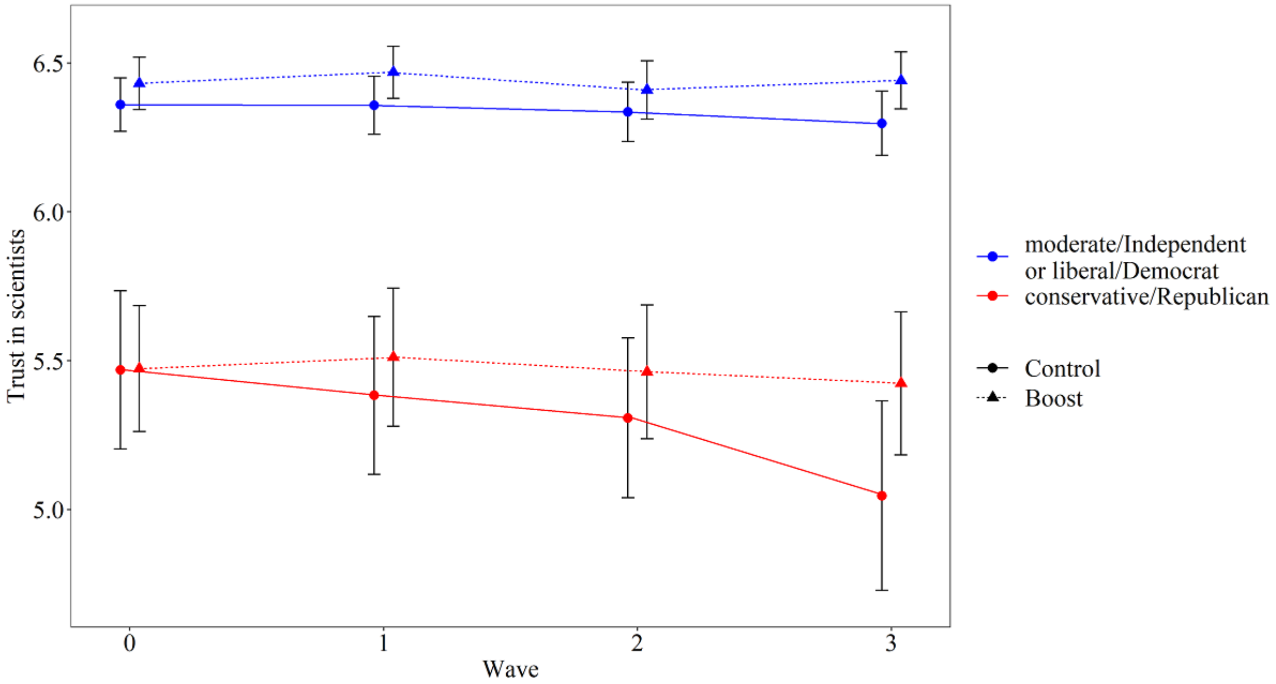
Figure 5. Belief accuracy per condition over time. Error bars indicate 95% CI focusing on the comparison between experimental conditions, not adjusted for within-subject variability. The belief accuracy scale ranged from –1, indicating completely inaccurate beliefs, to 1, indicating completely accurate beliefs.



When the subsample of participants in the boost condition who mentioned consensus, or similar, in the manipulation check was compared to participants in the control condition, we again found that the intervention did not increase belief accuracy (*P*=.21). However, there was a main effect of condition (estimate=0.06, SE=0.02; $t_{725.66}$=3.50, *P*=.001), indicating that participants in the boost condition who did use consensus while evaluating claims scored higher on belief accuracy than participants in the control condition. This difference was already present at T0, so was not caused by the intervention.

We explored the effect of the boosting intervention on trust in scientists as a source of information about the coronavirus. The mixed-effects model, similar to the hypothesis test but with the repeated measure of trust as the dependent variable and including the interaction term between condition, wave, and political orientation, yielded a significant three-way interaction effect between condition, wave, and political orientation (estimate=0.02, SE=0.01; $t_{1088.42}$=2.39, *P*=.02). Trust in scientists was very high in all four waves (means between 6.11 and 6.19), but investigation of the two-way interaction effects per condition indicated a significant interaction effect among wave and political orientation in the control condition (estimate=–0.02, SE=0.01; $t_{562.01}$=–3.24, *P*=.001), while there was no such significant interaction effect in the boost condition (*P*=.90). As illustrated by Figure 6, there was a clear overall difference in trust in scientists between participants related to their political orientation. More interestingly, trust remained stable for all participants in the boost condition, but decreased slightly for conservative, Republican participants in the control condition. This could indicate that the boosting intervention inhibited a decline of trust in scientists as a source of information about the coronavirus among more conservative, Republican participants.

Figure 6. Trust in scientists as a source of information about the coronavirus per condition and political orientation (dichotomized for plotting) over time. Error bars indicate 95% CI focusing on the comparison between experimental conditions, not adjusted for within-subject variability. Trust in scientists was measured with responses to the statement "I trust scientists as a source of information about the coronavirus." Participants responded on a 7-point scale ranging from 1 (strongly disagree) to 7 (strongly agree).



Discussion

Principal Findings

The aims of this study were to gain insight into the beliefs of the US public about the COVID-19 pandemic and to investigate whether a boosting intervention could improve people's belief accuracy. Interestingly, the average scores on belief accuracy over the surveyed 4-week period were high, indicating low belief in false statements and high belief in true statements. Looking at each set of statements, we found a small but significant increase in belief accuracy over time. This indicates that the general public is quite able to figure out what is true and what is not in times of crisis. Moreover, a small but robust correlation suggests that accurate beliefs about the pandemic might be important for coronavirus-related behavior. Associations with belief accuracy suggest that the processes of belief formation and correction might be affected by individuals' trust in scientists and political orientation, as well as their news habits. Finally, the boosting intervention yielded no significant increase in belief accuracy over the control condition, demonstrating that the boosting infographic was not successful in helping people figure out what is true and what is false. Exploratory analyses suggested that the intervention did, however, inhibit a decline in trust in scientists as a source of information about the coronavirus among more conservative, Republican participants.

Comparison With Prior Work

There is a great deal of worry about the prevalence of misinformation during the current pandemic, which is reflected in popular media (eg, [36,37]), as well as among scientists (eg, [38,39]) and public health agencies (eg, [4,40]). The supposed COVID-19 infodemic is not reflected in US citizens' beliefs. The finding that most Americans hold quite accurate beliefs about the COVID-19 pandemic is in line with emerging work on perceptions of the pandemic that shows that belief in COVID-19 misperceptions and conspiracy theories is quite low [41-44]. Consequently, this calls into question the prevalence of misinformation or the public's susceptibility to misinformation.

A convincing body of empirical work on the prevalence of misinformation surrounding the COVID-19 pandemic is not yet available. Research from before the COVID-19 pandemic indicates that the prevalence of misinformation might be lower than many believe [45-47]. Still, it is possible that the current pandemic has led to an increase in misinformation compared to the information landscape from before the pandemic. However, when looking for potential explanations of this study's findings, we should consider the possibility that COVID-19 misinformation is not as prevalent as expected. Perhaps misinformation makes up only a small portion of the average US citizen's media diet.

The second possibility is that we are indeed facing a COVID-19 infodemic, but that the public is not very susceptible to it. Misinformation campaigns regarding other topics, such as climate change and the health effects of tobacco [18,48], have demonstrated that misinformation can contribute to misperceptions about important matters. In these cases, however, misinformation campaigns have been carefully organized and executed, continually misinforming the public for decades. In contrast, the COVID-19 pandemic is a novel issue and, at least in the relatively early months that we investigated, did not yield many such coordinated misinformation campaigns. Moreover, the COVID-19 pandemic originated in a very different media landscape than the climate change and tobacco misinformation campaigns. Fake news, misinformation, and disinformation have been discussed widely and frequently in popular media since the 2016 US presidential election and the 2016 United Kingdom European Union membership referendum. This might have resulted in the public being more aware of misinformation campaigns targeting them. Perhaps the widespread discussion of misinformation in popular media has worked as a large-scale media literacy intervention, putting people *on guard* against false information. In support of this idea, recent research has demonstrated that simply asking one to consider the accuracy of a claim improved subsequent choices about what COVID-19 news to share on social media [49].

A third possibility that should be considered is that the public is more careful in forming beliefs in times of crisis, especially in the relatively early days of a crisis, making a well-informed public not unique to the COVID-19 pandemic. In times of crisis, people are likely to increase news consumption (eg, [50]). This was also the case in the United States during the first months of the COVID-19 pandemic, with people reporting increased news consumption [51]. Although we found that those who reported CNN or Fox News as their main news source scored below average on belief accuracy, the general increase in news consumption may lead to a better understanding of the crisis situation, including more accurate beliefs.

Turning to the finding that political orientation is associated with individuals' belief accuracy, we see that this is in line with other emerging work [41]. There is likely a multitude of explanations for this evolving partisan divide [52] regarding perceptions about the pandemic, such as political party cues in the news affecting opinion formation [53], the difficulty of correcting false beliefs for the ideological group most likely to hold those misperceptions [17], as well as the differences in news consumption that are reflected in this study. A second variable that is even more strongly related to belief accuracy is trust in scientists as a source of information about the coronavirus, demonstrating that higher trust is related to more accurate beliefs. Interestingly, the associations of political orientation and trust with accurate beliefs were partially explained by an interaction effect among political orientation and trust. The stronger association of trust with belief accuracy for more liberal, Democratic individuals might mean that they rely more on scientists' perceptions in forming beliefs, while relatively more conservative, Republican individuals might rely more on other cues. Relatedly, the inhibited decline in trust in scientists among conservative, Republican participants in the boost condition could indicate that information about the scientific process might resonate more with them than just hearing the results of this process. Though this exploratory finding should be replicated, it could provide a fruitful avenue for further research on trust in scientists and political orientation.

In addition, this study demonstrates that some news sources might be doing a worse job of informing their consumers about the COVID-19 pandemic than others, or perhaps that better-informed news consumers turn to different news sources than less well-informed consumers, again in line with other emerging work [41]. Most likely, a combination of both selection and influence (eg, [54]) explain the differences in belief accuracy found in this study. Interestingly, considering the role of social media in the spread of misinformation (eg, [55]), with about 26% to 42% of tweets in the data collection period containing unreliable facts [56], participants who reported social media sites as their main source of news about the coronavirus did not display significantly worse belief accuracy than others. However, it is possible that participants who reported social media sites as their main source followed major news outlets via the social media site, thereby being exposed to similar news content as the other participants.

Finally, this study demonstrates the difficulty of crafting interventions aimed at increasing belief accuracy. Recent work demonstrates that simple, short media literacy interventions can work [14,15], while other work highlights the difficulties of crafting these interventions [16]. We argue that the divergent findings can be explained by the fact that in the former work the interventions were paired with corrections, while in this study participants had to put their new skill to use outside of the study context. Considering that cues signaling the existence of consensus in relevant news content are very rare [57], participants likely had to search for information about scientific consensus themselves. The results from the manipulation check indicated that only a relatively small portion of participants actually applied this strategy. However, those individuals who indicated that they did apply a strategy related to consensus reasoning scored higher on belief accuracy than the control group. This difference highlights the potential of the intervention in situations where individuals can be empowered to actually apply it.

Limitations

There are two notable limitations to this study. First, our belief accuracy measure consisted only of science-based statements. We incorporated only science-based claims in our study to ensure that there was sufficient empirical evidence stating that a claim was either true or false. However, this decision did exclude some coronavirus-related claims that were not based on science (eg, "Bill Gates patented the coronavirus") or were unresolved at the time (eg, "A vaccine will be available before the end of the year"). It should have been harder for participants to figure out whether such unresolved issues were true or not, yielding different responses from participants for a measure reflecting non-science-based, unresolved issues about the pandemic.

A second limitation is the fact that the recruitment platform that we used, Prolific, is known as a platform for research. Although participants on the platform receive financial incentives for completing studies, they might be more interested in scientific research than the average US citizen. This could lead to them also having a higher trust in science than the general population, even though our sample was balanced regarding age, gender, and ethnicity. As trust in science was highly related to belief accuracy, it could be possible that this led to an inflated belief accuracy score. Future research should attempt to replicate this study with a sample that represents the US population better than our balanced sample.

Conclusions

Our work demonstrates that most people are quite able to figure out the facts in this time of crisis, but also that it is difficult to craft an intervention targeting these beliefs. However, in cases where people do not immediately have a clear understanding of the facts, they are capable of figuring them out over time. There are some factors that might make it easier or harder for one to figure out the facts. We found that the accuracy of participants' beliefs was related to political orientation, as well as their primary news source. This suggests that, even in the relatively early days of the pandemic, political polarization and media diet had a grip on US citizens' factual beliefs, leading to polarization along party lines. Another factor strongly related to accurate beliefs about the pandemic was trust in scientists. It is unclear whether an already-high trust led to accurate beliefs or whether being able to figure out the facts increased trust in scientists, but the importance of expert communication is underlined by these findings.

Although a small but robust correlation suggests that accurate beliefs about the pandemic might be important for coronavirus-related behavior, the role of misinformation in the pandemic seems to be relatively small, either because it is rare or because it is unable to persuade. However, we note that even if misinformation is not prevalent and only accepted by a small portion of the receivers, it can still be dangerous. To illustrate, we found that almost all participants in this study disregarded the statement that injecting or ingesting bleach is a safe way to kill the coronavirus, but this false claim is reported to have cost at least one life [58]. Additionally, with the antivaccine community launching coordinated misinformation campaigns against potential coronavirus vaccines [59] and politicization of the pandemic looming, the infodemic might become a much bigger threat.

Acknowledgments

The research was funded solely by the first author's research institute and supported by Prolific's generous decision to waive service fees on COVID-19-related research.

Authors' Contributions

AvS designed the experiments, conducted the experiments, and analyzed the data. GS, HV, and MB advised on the design of the experiments and analyses. All authors contributed to writing the manuscript.

Abstract

Background: Digital communication technologies are playing an important role in the health communication strategies of governments and public health authorities during the COVID-19 pandemic. The internet and social media have become important sources of health-related information on COVID-19 and on protective behaviors. In addition, the COVID-19 infodemic is spreading faster than the coronavirus itself, which interferes with governmental health-related communication efforts. This jeopardizes national public health containment strategies. Therefore, digital health literacy is a key competence to navigate web-based COVID-19–related information and service environments.

Objective: This study aimed to investigate university students' digital health literacy and web-based information-seeking behaviors during the early stages of the COVID-19 pandemic in Germany.

Methods: A cross-sectional study among 14,916 university students aged ≥18 years from 130 universities across all 16 federal states of Germany was conducted using a web-based survey. Along with sociodemographic characteristics (sex, age, subjective social status), the measures included five subscales from the Digital Health Literacy Instrument (DHLI), which was adapted to the specific context of the COVID-19 pandemic. Web-based information-seeking behavior was investigated by examining the web-based sources used by university students and the topics that the students searched for in connection with COVID-19. Data were analyzed using univariate and bivariate analyses.

Results: Across digital health literacy dimensions, the greatest difficulties could be found for assessing the reliability of health-related information (5964/14,103, 42.3%) and the ability to determine whether the information was written with a commercial interest (5489/14,097, 38.9%). Moreover, the respondents indicated that they most frequently have problems finding the information they are looking for (4282/14,098, 30.4%). When stratified according to sociodemographic characteristics, significant differences were found, with female university students reporting a lower DHLI for the dimensions of "information searching" and "evaluating reliability." Search engines, news portals, and websites of public bodies were most often used by the respondents as sources to search for information on COVID-19 and related issues. Female students were found to use social media and health portals more frequently, while male students used Wikipedia and other web-based encyclopedias as well as YouTube more often. The use of social media was associated with a low ability to critically evaluate information, while the opposite was observed for the use of public websites.

Conclusions: Although digital health literacy is well developed in university students, a significant proportion of students still face difficulties with certain abilities to evaluate information. There is a need to strengthen the digital health literacy capacities of university students using tailored interventions. Improving the quality of health-related information on the internet is also key.

Introduction

Shortly after the outbreak of SARS-CoV-2 and the associated disease, COVID-19, were first reported [1], it was declared a pandemic [2,3] by the World Health Organization. When the first case of COVID-19 was reported in Germany on January 27, 2020, the government responded immediately by launching an unprecedented nationwide emergency response plan that focused on four pillars: prevention, detection, containment, and treatment [4]. In addition to the National Pandemic Plan [5] and to health care and medical interventions [4], the government endorsed a public health communication strategy that was supported by all health agencies and public health bodies on national and local levels [6-9]. This communication strategy involved public broadcasting agencies, which launched web-based media campaigns, including daily nationwide podcasts. The underlying objective of this approach was to provide citizens with the necessary information on COVID-19 and how it affected people's health [4,10-13]. Within a short period of time, a massive amount of web-based health-related information on COVID-19 became available on issues such as protective behaviors, preventive measures, treatment options, dashboard statistics, the latest scientific insights, and various safety recommendations [14-16]. It has now become clear that this pandemic has been accompanied by an "infodemic"—an overabundance of valid and invalid health information on COVID-19 [17,18]. By means of digital communication technologies, especially the internet and social media, the COVID-19 infodemic is spreading faster than the coronavirus itself, which interferes with governmental health communication efforts and jeopardizes national public health containment strategies.

Altogether, this situation creates a complex information environment that requires people to be able to access, navigate, understand, use, and critically evaluate information and services in ways that support healthy and protective behaviors in the time of the COVID-19 pandemic. Therefore, health literacy, which is the ability to find, understand, and evaluate health information and apply it in daily decision-making and health behavior [19], is of utmost importance during the current pandemic [14]. Digital health literacy applies this understanding of health literacy to digital contexts and environments [20], and it has become a core competence and necessity for navigating web-based information and health service environments within the realm of the COVID-19 pandemic and the associated infodemic [21]. However, in Germany, it has been shown that more than half of the population has limited health literacy; therefore, people report difficulties in dealing with health-related information [22]. A recent study conducted in Germany on health literacy in relation to information regarding COVID-19 resulted in similar findings [23]. People particularly have difficulty assessing the trustworthiness of media information on COVID-19 and its associated health problems. In addition, people with limited health literacy are more likely to be confused due to the massive amounts of information available in the media and on the internet [23]. Information is a carrier of important health knowledge to contain the virus and empower citizens to demonstrate health literacy [16,24]; the pandemic has placed increased demand on the general population to find information relevant to them and critically reflect on this information, as well as to transfer information into their everyday life and practices.

This issue is particularly critical for university students, who consist of a significant proportion of young adults in Germany. University students comprise the population that primarily uses digital technologies and web-based health information [25,26]. Although it can be noted that students have not been the primary focus of research since the beginning of the pandemic, a recent study with over 5400 medical students from Vietnam revealed that higher levels of health literacy were associated with less fear of COVID-19 [27]. Therefore, health literacy is a critical intervention target, especially since fear is one of the toxic outcomes that result from an infodemic [17,28]. The aim of this study is to investigate the digital health literacy and web-based information-seeking behaviors among university students in Germany during the first wave of the COVID-19 pandemic, particularly during university closures. This study is informed by the conceptual model of health literacy as presented by Sørensen and colleagues [19] and the model of digital health literacy as proposed by van der Vaart and Drossaert [20]. The assumptions in both models are that personal and environmental determinants influence an individual's capacity regarding various dimensions of personal information management, which include informing health decisions and behaviors that are beneficial for health. Our study focuses on personal and environmental determinants, personal information management, and behavioral aspects. In this context, the following research questions were addressed:

- What are the levels of COVID-19–related digital health literacy in German university students stratified by social, economic, and geographical indicators?

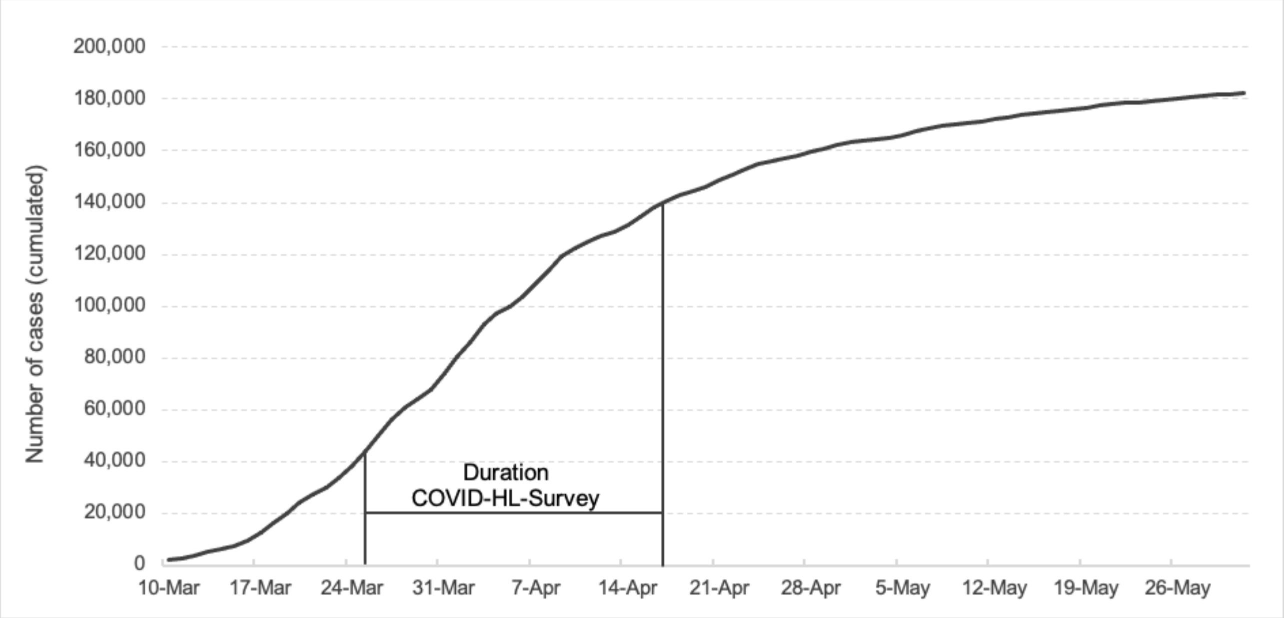
- Which sources of web-based information are used and which topics are searched for in the context of COVID-19 by German university students?
- Can differences be identified between students with regard to health literacy, the sources used for information searching, and the topics addressed in relation to COVID-19?

Methods

Study Design and Participants

A national cross-sectional web-based survey was conducted including a nonrandomized sample (convenience sample) of German university students. To address as many university students as possible, all private and state universities (ie, 392 universities containing 2.9 million students [29]) were invited to participate in the study by email. A reminder was sent two weeks after the survey started. The presidencies of all the universities and the deaneries of all faculties were contacted and asked to forward an invitation letter to their students. University students enrolled at a private or state university were eligible to participate in this study. To increase the homogeneity of the sample, respondents were initially asked to indicate their current status. Those who indicated that they were not currently enrolled as students at a German university were excluded from the data set (n=245). The duration of the study was 3 weeks, and it took place from March 25 to April 17, 2020. Within the 3 weeks during which the survey was implemented, the number of confirmed COVID-19 cases in Germany increased from 44,175 to 141,016 (Figure 1 [30]). The survey was administered electronically using the Enterprise Feedback Suite survey tool (Questback) [31]. Participation was voluntary, and anonymity was ensured. Upon entering the web-based survey site, participants were presented with information regarding the background and the aims of the study. After checking a consent box at the bottom of the page, participants were directed to the questionnaire. Our study was approved by the Bielefeld University ethics committee (No. EUB 2020-053).

Figure 1. Confirmed cumulative cases of COVID-19 in Germany from March to May 2020 (source: RKI COVID-19 Dashboard [30]).



Measures

Sociodemographic information included sex (male, female, diverse), age, study course (bachelor's degree, master's degree, other), and subjective social status (SSS). Age was measured in absolute numbers, and based on an analysis of the distribution, four categories were created (≤20 years, 21-23 years, 24-26 years, and ≥27 years). Social status was assessed using the German version of the MacArthur Scale, which includes a ladder with 10 steps [32]. Respondents were asked to position themselves at the step that best reflected their status in the social hierarchy, with higher values indicating a higher social status. According to previous studies, respondents were categorized into three groups: low SSS (1-4), medium SSS (5-7), and high SSS (8-10) [33].

Digital health literacy was evaluated using five of the seven subscales from the validated Digital Health Literacy Instrument (DHLI) [20], each including three items to be answered on a 4-point scale (eg, 1, very difficult; 4, very easy). The DHLI was adapted to the context of the COVID-19 pandemic (eg, "When you search the Internet for information on the coronavirus or related topics, how easy or difficult is it for you to…"). The five subscales include (1) searching the web for information on COVID-19, (2) adding self-generated content on COVID-19, (3) evaluating the reliability of COVID-19–related information, (4) determining personal relevance of COVID-19–related information, and (5) protecting privacy on the internet. The internal consistency (Cronbach α) of the first four subscales was acceptable to good ($.70<\alpha<.83$). Due to low reliability ($\alpha=.46$), scaling was omitted for the protecting privacy subscale.

The section about web-based information-seeking behaviors focused on the sources that were used to receive web-based health information about COVID-19 and related topics. The respondents were presented with a 10-item list of different web-based sources (eg, search engines, websites of public health bodies, government agencies, and social media providers), in which the frequency of their use could be rated on a 5-point scale (0, don't know; 4, often) [34]. Students were also asked to indicate the specific topics they searched for in the context of COVID-19. The assessment was based on a self-developed list of 9 topics (eg, current spread of COVID-19, symptoms of COVID-19, measures to protect against infection, dealing with psychological stress caused by the COVID-19 pandemic), using yes or no answers.

An overview of all items and scales used for this paper can be found in Multimedia Appendix 1. The entire questionnaire is available on request from the first authors.

Statistical Analysis

To control for the selection bias caused by a convenience sampling procedure, we used weighting to adjust the sample distribution to the characteristics of the general population of German university students. Based on the data provided by the Federal Statistical Office via the GENESIS database [35], the data could be weighted for gender and desired study degree. In the first step, all data on digital health literacy and information-seeking behavior were analyzed descriptively. Subsequently, bivariate analyses were conducted by cross-tabulating the two levels of digital health literacy (limited vs sufficient) with sociodemographic characteristics using chi-square tests. For this purpose, all DHLI subscales (except “protecting privacy”) were dichotomized using median splits. Due to the low internal consistency for the dimension “protecting privacy” and the fact that two subscales from the original DHLI instrument were not used, we also refrained from calculating an overall mean value, as done by Van der Vaart and Drossaert [20]. For all analyses, *P* values <.05 were considered statistically significant. However, due to the large sample size, the strength of the association was determined using the Cramer index (Cramer V). The Cramer V is a normalized version of the chi square statistic test for nominal scaled variables. According to Cohen [36], the strength of each association was interpreted as an effect size measure using the following conventions: ≥0.1 (small), ≥0.3 (medium), ≥0.5 (large). In further analyses, chi-square tests were also performed for the levels of digital health literacy and the topics searched for with regard to COVID-19. Finally, to analyze differences between the levels of digital health literacy and the sources used to search for COVID-19–related information, *t* tests for independent samples were conducted. Cohen *d* was used as an effect size measure by applying the following conventions: ≥0.2 (small), ≥0.5 (medium), ≥0.8 (large) [36].

Results

After further plausibility checks and adjustment for incorrect data, the data set contained complete questionnaires from 14,916 participants aged between 18 and 72 years (mean age: 24.3). Students from 130 universities and all 16 federal states participated (see Table 1). In terms of geographical coverage (see Figure 2), most respondents were from the west of Germany (6355/14,833, 42.8%), followed by students from the south (3694/14,833, 24.9), and almost equally from the north (2307/14,833, 15.6%) and the east (2476/14,833, 16.7%).

Table 1. Characteristics of the study participants (N=14,916; values are weighted).

Characteristic	Value, n (%)		
	Total	Male (n=7687, 51.5%)	Female (n=7229, 48.5%)
Age (years; n=14,897)			
≤20	2640 (17.7)	1342 (17.5)	1298 (18.0)
21-23	5495 (36.9)	2586 (33.7)	2909 (40.3)
24-26	3567 (23.9)	1923 (25.0)	1643 (22.8)
≥27	3195 (21.4)	1827 (23.8)	1369 (19.0)
Study course (n=14,916)			
Bachelor’s degree	10,351 (69.4)	5463 (71.1)	4887 (67.6)
Master’s degree	2796 (18.7)	1460 (19.0)	1337 (18.5)
Other (eg, PhD)	1769 (11.9)	764 (9.9)	1005 (13.9)
Subjective social status (n=14,913)			
Low	2575 (17.3)	1408 (18.3)	1168 (16.2)
Middle	10,090 (67.7)	4974 (64.7)	5116 (70.8)
High	2247 (15.1)	1303 (17.0)	945 (13.1)

Figure 2. Geographical distribution of the study sample (N=14,916). BB: Brandenburg; BE: Berlin; BW: Baden-Wuerttemberg, BY: Bavaria; HB: Bremen; HE: Hesse; HH: Hamburg; MV: Mecklenburg-Western Pomerania; NI: Lower Saxony; NW: North Rhine-Westphalia; RP: Rhineland-Palatinate; SH: Schleswig-Holstein; SL=Saarland; SN: Saxony; ST: Saxony Anhalt; TH: Thuringia.

In comparison with the whole population of German university students via the GENESIS database, some deviations could be observed. While students from Baden-Wuerttemberg (12.7% vs 4.5%) and North Rhine-Westphalia (27.5% vs 12.4%) were underrepresented in our study, our sample includes significantly more students from Bavaria (14.0% vs 20.4%) and Hesse (9.4% vs 21.7%). The gender distribution was almost balanced, with 51.5% male university students (7687/14,916) and 48.5% female students (7229/14,913). Regarding SSS, more than two-thirds of respondents reported a middle SSS (10,090/14,913, 67.7%), while 17.3% (2575/14,916) reported a low SSS and 15.1% (2247/14,913) reported a high SSS (mean SSS 6.0, SD 1.54).

Figures 3 to 7 show the different dimensions of digital health literacy and the percentages of student scoring. Within the "information search" subscale, university students indicated that they most frequently had problems finding the information they were looking for (4282/14,098, 30.4%), while the use of suitable words and search queries caused less difficulty (1644/14,101, 11.7%). Regarding the dimension of "adding self-generated content," respondents reported the most difficulties in expressing their own opinion, in expressing thoughts or feelings in writing (3975/13,754, 28.9%), and in writing a message in a way that is understandable for others (4661/13,752, 33.9%). Across all dimensions, the greatest difficulties could be found in assessing the reliability of health-related information (5964/14,103, 42.3%) and the ability to determine whether the information was written with commercial interest (5489/14,097, 38.9%). The use of the found information for one's own health-related decisions (eg, regarding protective measures, 2443/14,079, 14.4%) and the application of this information in daily life caused difficulties for approximately one-fifth of the respondents (2812/14,067, 20.0%). Finally, some heterogeneity could also be found in the items relating to the dimension of "protecting privacy." Although approximately 35% of the respondents experienced difficulties to judge who could read messages posted on the web (4768/13,589, 35.1%), only 6.7% stated that they sometimes or often shared private information on the web (914/13,715).

Figure 3. Responses to questions in the Digital Health Literacy Instrument subscale “information search” (n=14,098 to n=14,110), %.

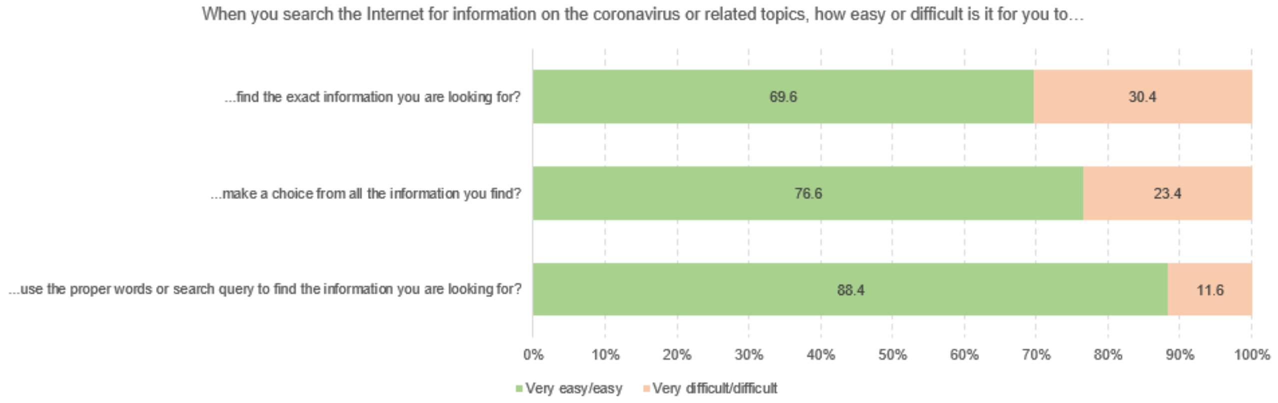


Figure 4. Responses to questions in the Digital Health Literacy Instrument subscale “adding self-generated content” (n=13,721 to n=13,754), %.

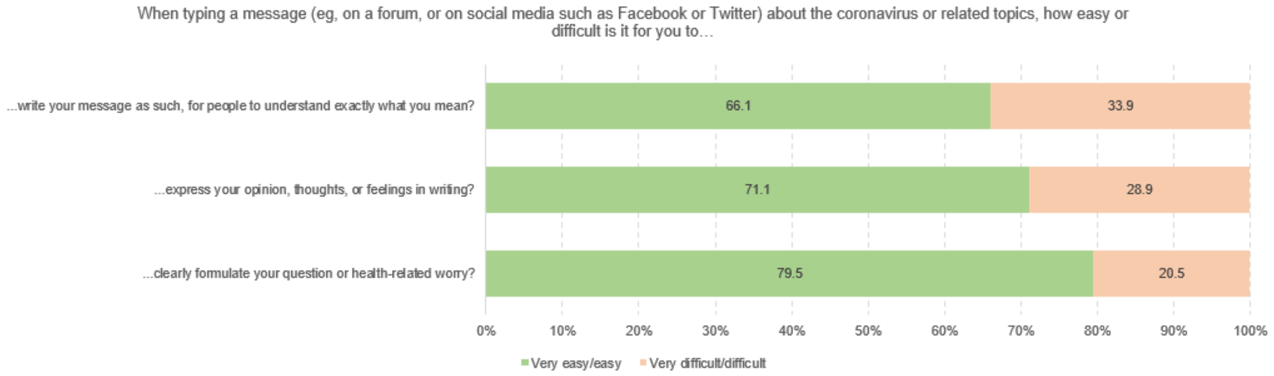

Figure 5. Responses to questions in the Digital Health Literacy Instrument subscale “evaluating reliability” (n=14,081 to n=14,103), %.

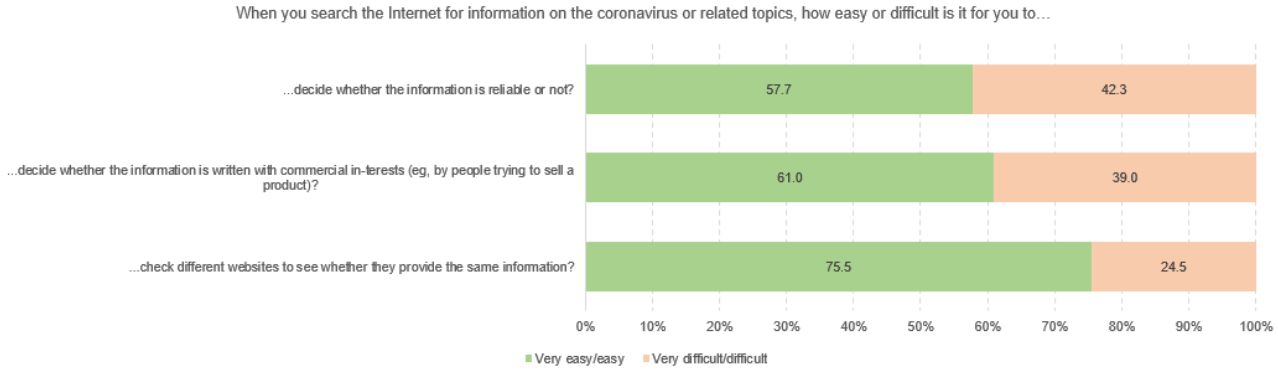

Figure 6. Responses to questions in the Digital Health Literacy Instrument subscale “determining relevance” (n=14,076 to n=14,092), %.

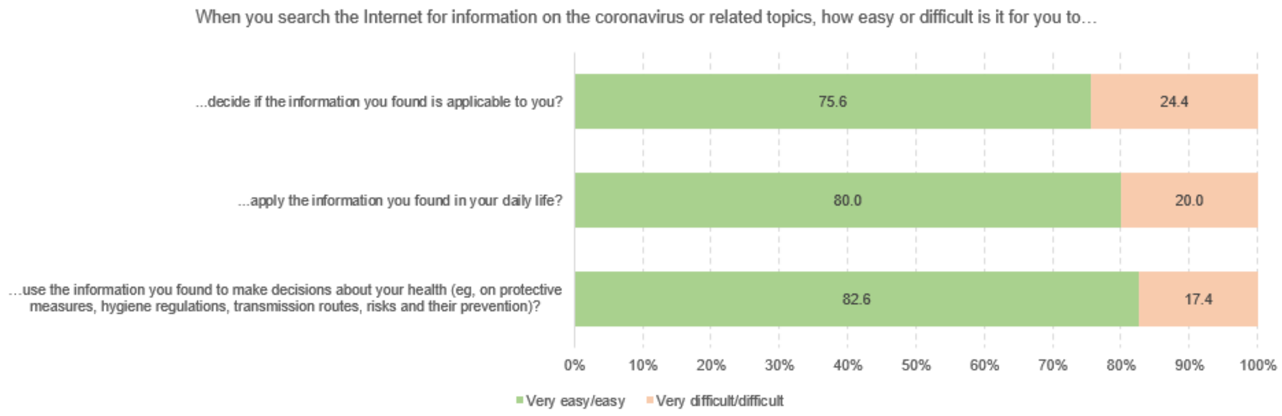

Figure 7. Responses to questions in the Digital Health Literacy Instrument subscale “protecting privacy” (n=13,589 to n=13,715), %.

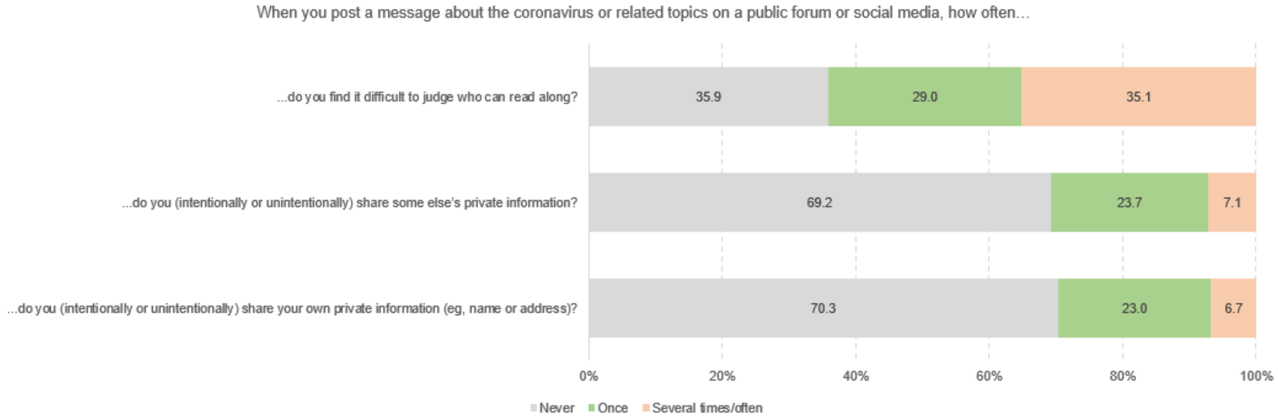

Table 2 and Table 3 show the digital health literacy levels of the respondents, stratified by sociodemographic and geographic characteristics. Concerning gender, significant differences were found, with female university students showing lower digital health literacy across all subscales. However, taking the strength of the association (*V*) into account, small effect sizes could be identified only for the dimensions “information searching” (male: 2087/7219, 28.9%, female: 2711/6865, 39.5%, χ^2_1=175.37, *P*<.001, *V*=0.11) and “evaluating reliability” (male: 2156/5994, 36.0%, female: 2660/5630, 47.2%, χ^2_1=152.16, *P*<.001, *V*=0.11). All other differences were below the threshold for small effects and were hence considered trivial. When considering differentiation by age group, in all subscales, a slight tendency of increasing level of digital health literacy with increasing age was observed. However, these significant differences proved to be trivial when calculating effect sizes. The same was observed for study course, SSS, and geographical distribution. Slight differences between the groups were observed; however, the differences remained below the threshold for small effects.

Table 2. Digital health literacy levels of university students for the subscales of "information search" and "adding self-generated content" according to their sociodemographic and geographic characteristics.

Characteristic	Information search					Adding self-generated content				
	Limited, n (%)	Sufficient, n (%)	χ^2 (*df*)	*P*	V	Limited, n (%)	Sufficient, n (%)	χ^2 (*df*)	*P*	V
Gender			175.37 (1)	<.001	0.11			29.77 (1)	<.001	0.05

Total	4816 (41.4)	6808 (58.6)				5004 (35.7)	9032 (64.3)			

Search engines, news portals, and websites of public bodies were most often used by the respondents as sources to search for and find information on COVID-19 and related issues (see Figure 8 and Figure 9). These sources were followed by social media platforms such as Facebook, Instagram, and Twitter, or video portals such as YouTube, with 37.6% of respondents (5302/14,092) stating that they used these media sometimes or frequently. In contrast, health-related blogs or web-based guides were used much less frequently. When stratified by sociodemographic characteristics, relevant differences could only be observed for gender. Female students were found to use social media ($t_{13,921}$=–19.09, *P*<.001, *d*=–0.32) and health portals ($t_{13,463}$=–14.42, *P*<.001, *d*=–0.24) more frequently than male students. In contrast, Wikipedia and other web-based encyclopedias ($t_{14,051}$=19.19, *P*<.001, *d*=0.32), as well as YouTube ($t_{14,054}$=18.13, *P*<.001, *d*=0.30), were more often used by male students. Regarding the topics, respondents stated that they most frequently searched for information on the current spread of SARS-CoV-2 (12,648/14,114, 89.6%) and associated restrictions (12,126/14,114, 85.9%), recommendations and assessments regarding the situation (10,975/14,114, 77.8%), and the symptoms of COVID-19 (10,089/14,114, 71.5%). Although significantly less often, one-fifth of the university students stated that they looked for information on how to cope with psychological stress caused by the COVID-19 situation (2921/14,114, 20.7%). When differentiated by sociodemographic variables, gender differences could be found, as male students searched significantly more often for information on economic and social consequences of the COVID-19 pandemic (male: 4943/7237, 68.3%, female: 3817/6878, 55.5%, χ^2_1=245.62, *P*<.001, *V*=.13).

Figure 8. Internet search queries related to COVID-19 (n=14,111), %.

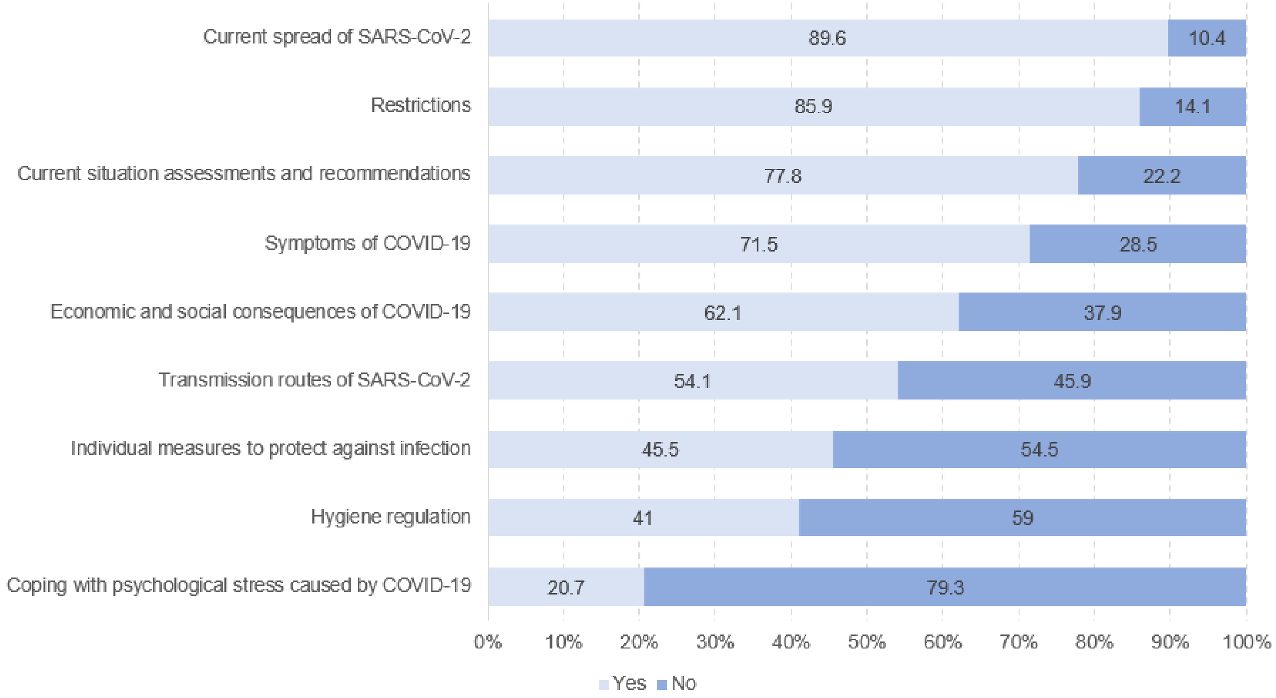

Figure 9. Frequency of use of internet sources for web-based health information seeking (n=14,012 to n=14,094), %.

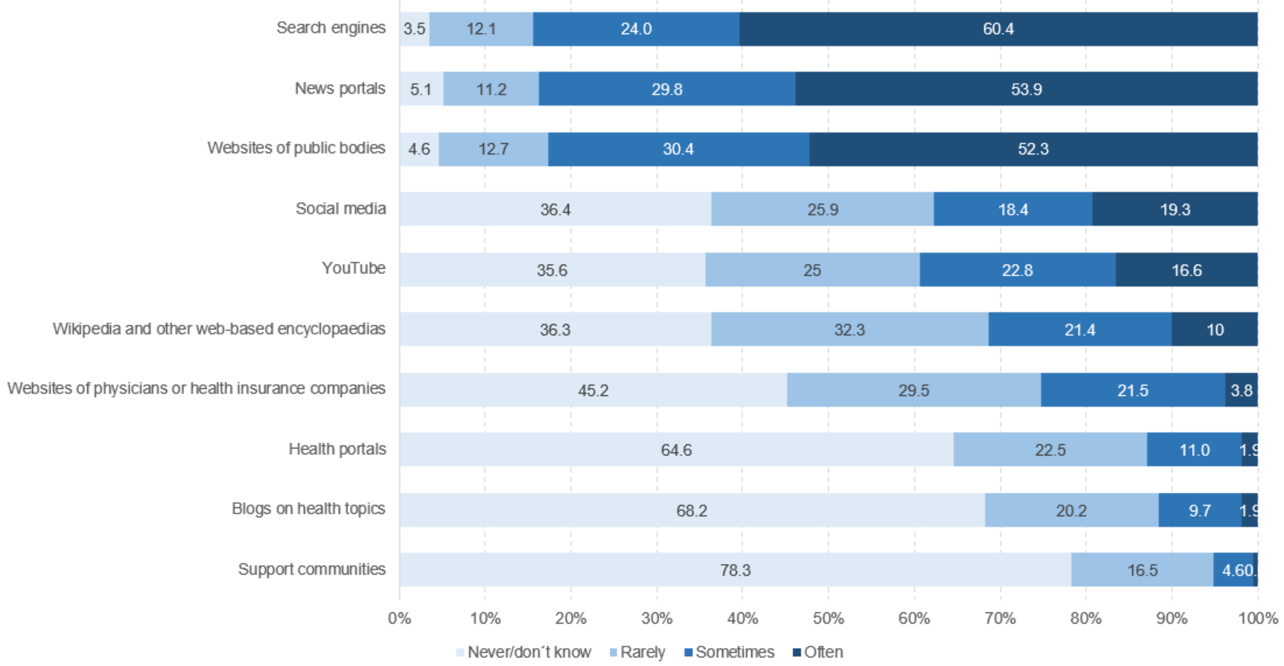

Finally, digital health literacy was stratified according to web-based information-seeking behavior. No relevant differences could be found for the topics that students searched for. Regarding the sources used for the search and the handling of health-related information, significant and relevant differences emerged for the DHLI subscale "evaluating reliability." Respondents with sufficient digital health literacy in that dimension reported using the websites of public bodies (eg, Robert Koch Institute) more frequently (t_{9344}=19.44, *P*<.001, *d*=0.37). The opposite could be observed for social media (Facebook, Instagram, Twitter) ($t_{10,019}$=–14.29, *P*<.001, *d*=–0.27) and support communities (t_{9028}=–12.06, *P*<.001, *d*=–0.23), which were more frequently used by respondents who reported more difficulties in evaluating the reliability of information (see Table 4 and Table 5).

Table 4. Sources used for COVID-19 information search stratified by digital health literacy level for the "information search" and "adding self-generated content" subscales.

Item	Information search				Adding self-generated content			
	Limited, mean (SD)	Sufficient, mean (SD)	*P*	*d*	Limited, mean (SD)	Sufficient, mean (SD)	*P*	*d*
Search engines (eg, Google, Bing, Yahoo!)	3.44 (0.79)	3.40 (0.85)	.003	–0.05	3.43 (0.82)	3.42 (0.83)	.21	N/A[a]
Websites of public bodies (eg, Robert Koch Institute)	3.20 (0.88)	3.36 (0.85)	<.001	0.18	3.24 (0.87)	3.35 (0.85)	<.001	0.12
Wikipedia and other web-based encyclopedias	1.99 (0.96)	2.08 (0.99)	<.001	0.09	2.03 (0.98)	2.07 (0.98)	.005	0.05

Discussion

To our knowledge, this study is the first to investigate the digital health literacy and information-seeking behaviors in university students during the COVID-19 outbreak in Germany. Nationwide and overall, university students show high levels of digital health literacy. However, one-third of all students (4282/14,098, 30.4%) reported having problems finding the correct information on a particular health-related topic. Also, almost half of all students (5964/14,103, 42.3%) had problems evaluating the reliability of web-based information, which includes difficulties in identifying commercial interests behind the information presented in the news (5489/14,097, 38.9%). Moreover, the greatest challenges were related to assessing the reliability of COVID-19–related information and to judging whether commercial interests were attached to this information. Female students reported more difficulties in searching and evaluating web-based COVID-19–related information than male students.

Although digital health literacy levels were sufficient in a large proportion of the respondents, the results must be viewed in a more differentiated way. Germany applied a very successful health communication strategy [4] based on easily understandable and easy-to-use health information regarding COVID-19 (eg, washing hands, physical distancing, wearing masks), which was of low complexity compared to other health or disease information [23]. The communication mode was primarily push-based, directing information toward people through all media and communication channels. In comparison, for noncrisis communication, people must supply themselves with information (pull communication) to a greater extent, which requires active searching for information and hence requires strong health literacy. The way in which communication was altered (push vs pull) could explain the lack of differences in digital health literacy levels in relation to socioeconomic status, which are usually found in health literacy studies [22,37]. In addition, our study reports on the state of students' digital health literacy levels during the early stages of the so-called first wave of the pandemic, at a time when adherence to policies of measures to protect against COVID-19 was high. However, this could change in the current second wave, when people lose trust in official sources and the support for compliance with official recommendations diminishes. Declining support of public measures can already be observed in Germany. Demonstrations against restrictions are taking place, and people are demanding a return to prepandemic conditions and the reopening of the economy, all of which manifests through a refusal to apply the recommended protective measures (eg, no physical distancing, no face masks) [38].

Data protection and security is also an important issue in the context of digitalization and of the digital transformation of society. Using digital health services and communicating about health topics on the internet and on social media requires particular communication technologies to ensure user safety and user-friendliness. Our findings indicate that one-third of all students (4768/13,589, 35.1%) reported problems judging whether a third party can read their messages posted on the web. Studies on web-based data protection in the German population showed that 72% of respondents doubted the safety of the personal data they shared on the internet [39]. Moreover, 55% even believed that they had no control over what happens to their web-based data [40]. Despite its importance, we were required to exclude the subdimension "protecting privacy" from further bivariate analyses due to low reliability. When introducing the original DHLI, van der Vaart and Drossaert [20] also reported an unsatisfactory Cronbach alpha for this subscale (α=.57). Although this supports the validity of our study findings, it also suggests a need for further refinement (eg, by reformulating the item "…do you find it difficult to judge who can read along?“ to "…do you find it difficult to judge how the security of your private information is secured by the media provider?" to emphasize the role of protective measures taken by the media provider).

The most preferred sources to look for web-based health- and COVID-19–related information among students included search engines, news portals, and websites of public bodies, followed by social media and video portals. Favorite search topics were the current spread of COVID-19 (12,648/14,114, 89.6%), restrictions (12126/14,114, 85.9%), recommendations and risk assessments (10,975/14,114, 77.8%), and COVID-19 symptoms (10089/14,114, 71.5%). Similarly to earlier studies on population health literacy, which focus on both generic health literacy [22,41] and health literacy in relation to COVID-19 [15,23], making a judgment about the reliability of COVID-19–related information in the media and identifying potential commercial interests represent the most difficult tasks. There is also a significant positive association between having sufficient levels of digital health literacy and accessing more trustworthy and thus more reliable web-based health content. Students with higher levels of digital health literacy in the dimension of "evaluating information reliability" accessed the official websites of public bodies and agencies more often and turned less often to sources such as support communities, including forums, and social media compared to students with lower competencies in this dimension. While the ability to seek information and to produce and provide information did not show any significant differences across digital health literacy levels, students with higher abilities to determine the personal relevance of the information they obtained show similar patterns to those shown for the subscale "evaluating reliability."

Interestingly, only one-fifth of students (2921/14,114, 20.7%) reported having searched for information related to psychological stress and the consequences of the COVID-19 pandemic on mental health. This finding is surprising, as other studies show that the COVID-19 pandemic has enormous effects on mental health [42,43], and an infodemic can trigger an epidemic of fear and anxiety [28]. On the other hand, it should be emphasized that this survey was conducted at the beginning of the first wave of the pandemic and that psychological problems became more important as the pandemic progressed. Therefore, reliable and trustworthy (mental) health information is key in this situation for citizens to act upon information and knowledge provided by governments, health authorities, and scientists, and thereby to help slow the spread of COVID-19 [14,16,44-47]. In this context, infodemiology becomes important to better understand communication patterns, information routes and content, and how they affect behaviors, attitudes, and health status [28]. Citizen behavior, however, must be facilitated by adequate government actions and policies that provide not only health information but also health, social, and economic services for citizens to cope with the situation [14]. The impact of the ongoing COVID-19 infodemic places an additional burden on web-based health information seekers. This threat amplifies the negative effects of low digital health literacy. In their representative survey of COVID-19–related health literacy during the pandemic, Okan and colleagues [23] found that 56% of the German population felt confused about the vast amount of information regarding COVID-19. Women, younger age groups, and families with children younger than 18 years in their household are significantly more affected. At the same time, people with lower income and who reside in federal states of the former East Germany were found to feel less informed than their counterparts. This ongoing study highlights that the infodemic must be acknowledged "as a meta-risk in its own right" that aggravates the current situation [23]. Therefore, this infodemic requires particular attention during the COVID-19 emergency, which includes public policy strategies aiming to address the toxic spread of misinformation and disinformation about SARS-CoV-2 and COVID-19 [14,15,23]. Moreover, producers, providers, and suppliers of health information must ensure that information is evidence-based and adheres to health literacy principles, including barrier-free and easy access, user-friendliness and ease of understanding, cultural appropriateness, and relevance for everyday public use [21,23]. Social media platforms should also counteract the spread of misinformation and disinformation about COVID-19. The fight against misinformation and disinformation should become an important issue in public policy [17,18]. As proposed by Gunter Eysenbach, the four pillars to fight an infodemic include (1) infoveillance (the monitoring of information), (2) strengthening health literacy and digital health literacy in the population, (3) applying constant knowledge refinement (eg, fact checking), and (4) adequate knowledge transfer and minimizing political and commercial influence on health information [45]. This is supported by the World Health Organization within their infodemic management framework, which suggests six policy recommendations to manage infodemics during an emergency such as the COVID-19 pandemic [46]. These recommendations include (1) basing interventions and messages on the latest evidence, (2) applying knowledge transfer and making health information easy to understand, (3) collaborating with communities to better understand their information needs, (4) analyzing information impact and cooperating with social media platforms, information suppliers, and civil society, (5) informing these actions by reliable information and adapt action based on the respective and latest narratives, and (6) further improving infodemic management by all means necessary and also through interdisciplinary research collaboration [46]. Skills to navigate digital information environments were already crucial before the COVID-19 pandemic to mitigate the effects of digital inequalities [47,48]. These skills have become even more essential during the pandemic, as the importance and use of communication technologies and media have changed massively since the outbreak of COVID-19 [14,16,45,48,49].

The most important finding of the stratified analyses is that among students with limited digital health literacy, female students reported having more problems finding the correct information and evaluating the reliability of COVID-19–related information. In Germany, women often have more care responsibilities and are generally more engaged with health issues than men [23], and they are also more active in searching the internet for health information [49,50]. This may lead them to be more critical vis-à-vis health information on COVID-19, as they have a more sensible awareness that not all information is reliable. In addition to this, a recent study showed that women are much more worried about the sheer amount of COVID-19–related information on the internet [23]. They were more concerned when they had children ≤18 years of age. Many young women are faced with difficulties and challenges when they search for and evaluate health information, especially because there is so much conflicting information on COVID-19 available on the web.

To sum up, the findings from this study raise concern and have important implications for public health. First, problems related to access to accurate and situation-specific information in the context of a public health emergency may lead to the use of invalid information, which is unhelpful or even detrimental to the causes of slowing infection rates and sustaining a successful infectious disease strategy. Second, when students access disinformation or false information and they have difficulty making judgments about the correctness of the information, they will most likely not identify that information for what it is (eg, “fake news,” commercial messaging). In turn, using the wrong information can again cause harm and impede engagement in effective health behaviors. Third, feeling safe in the digital world, especially when seeking health-related information and interacting with others about health concerns, is a critical issue. Many students expressed uncertainties regarding the safety of personal information shared on the web. These findings suggest the need to implement health education measures to strengthen students’ health literacy capacities. In addition, there is a need for more accurate public health information platforms to provide timely and evidence-based information with a view to inform individual behavior and system-level responses. Studies on health literacy in Germany conducted in 2011 [37], 2013 [41,50], and 2014 [22,41] have shown that half of the adult population, including both younger and older adults, have limited health literacy. In response, health literacy policy initiatives were launched, such as the science and civil society–led German National Action Plan on Health Literacy [51] and the Alliance for Health Literacy [52], which is led by the federal Ministry of Health. These initiatives focus on strengthening population health literacy, starting in early childhood and at school, to enable children to grow into health-literate adults. However, little progress has been made since then, and a health education curriculum that addresses health literacy is still lacking in Germany. Furthermore, people with lower education in Germany have more often lower levels of health literacy [22,37]. If students, who belong to a population group with higher education, already have difficulties with their digital health literacy, it can be assumed that people with less education are also vulnerable to having lower levels of health literacy and associated information tasks, such as finding, understanding, and evaluating COVID-19–related information on the web.

Our study has several limitations. The sample, although weighted, is not representative of all university students in Germany. We may have missed many students who use the internet less frequently and those who may have been troubled due to university closures and associated changes to their lives. The implications may not be transferable to other populations and age groups in Germany. Additionally, students in Germany are privileged in terms of educational achievement and therefore in terms of socioeconomic status compared to people seeking a tertiary education with non–degree level requirements. This survey was conducted in the early days of the first wave of the pandemic, when adherence was high; this could explain the finding that students perceived information tasks to be easy to undertake and therefore reported high levels of digital health literacy. This may not be the case in a second phase, after enduring lengthy restrictions on everyday and university life activities and rapidly emerging conflicting information on COVID-19, all of which could make judgment much more difficult. Due to the effects of the COVID-19 pandemic on physical contact and face-to-face meeting, we had to use a web-based survey in adherence to German COVID-19 policies, whereas the developers of the original questionnaire, van der Vaart and Drossaert [20], highlighted that the application of a web-based questionnaire may exclude people with weak digital competencies. Therefore, a potential bias in our sample is that it may have excluded students who use the internet to a lesser extent or those with lower digital competencies. Nevertheless, due to web-based activities related to their studies (eg, access to e-learning and university communication platforms) and given that most German universities provide their services via web-based systems, students in Germany in general represent a proportion of the population who have more intersections with the digital world, inevitably use the internet more often, and have a higher affinity to using web-based media content.

Our findings show that overall, the level of digital health literacy in relation to dealing with web-based COVID-19–related information was high. However, a significant proportion of university students still face difficulties with certain abilities to deal with information, such as finding the right information and evaluating its reliability. There is a need to strengthen the digital health literacy capacities of university students, particularly female students, using tailored interventions. Actions must also include the design of interventions to increase the quality of health information on the internet, to implement fact-checking strategies in web-based and social media, and to increase the health literacy of people who produce, supply, and provide health information and services on the web. For example, universities can provide courses on digital health literacy and health information to their staff and students and can also disseminate reliable news on COVID-19 through their web-based channels. Raising awareness among universities and education administrators might aid the emergency response, and it could also increase the health literacy responsiveness of organizations and students. The benefit of the COVID-HL survey is that it provides first-time knowledge that could help decision-makers develop policies and programs that foster healthy and protective behaviors, plan for preventive measures, and promote adherence to COVID-19 policies, on the basis of students' needs in terms of digital health literacy. Digital health literacy will empower university students and all other population groups to take greater control in the prevention and spread of COVID-19, which in turn is likely to lead to better health outcomes.

Authors' Contributions

KD and OO contributed equally and prepared the first draft of the manuscript. MM, AYML, RR, ED, and KR provided feedback on the first draft. KD, OO, and KR designed and conducted the survey. MM, AYML, RR, ED, and KR helped with the analyses and contributed to data interpretation. All authors contributed to writing and revising the manuscript and approved the final version for submission.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic has considerably altered the regular medical education curriculum while increasing the need for health care professionals. Senior medical students are being incrementally deployed to the front line to address the shortage of certified physicians. These students, some of whom will be fast-tracked as physicians, may lack knowledge regarding the initial management of time-critical emergencies such as stroke.

Objective: Our aim was to determine whether an e-learning module could improve asynchronous distance knowledge acquisition of the National Institutes of Health Stroke Scale (NIHSS) in senior medical students compared to the traditional didactic video.

Methods: A randomized, data analyst–blinded web-based trial was conducted at the University of Geneva Faculty of Medicine between April and June 2020. Fifth year medical students followed a distance learning path designed to teach the NIHSS. The control group followed the traditional didactic video created by Patrick Lyden, while the e-learning group followed the updated version of a previously tested, highly interactive e-learning module. The main outcome was the score on a 50-question quiz displayed upon completion of the learning material. The difference in the proportion of correct answers for each specific NIHSS item was also assessed.

Results: Out of 158 potential participants, 88 started their allocated learning path and 75 completed the trial. Participants who followed the e-learning module performed better than those who followed the video (38 correct answers, 95% CI 37-39, vs 35 correct answers, 95% CI 34-36, $P<.001$). Participants in the e-learning group scored better on five elements than the video group: key NIHSS concepts ($P=.02$), the consciousness – global item ($P<.001$), the facial palsy item ($P=.04$), the ataxia item ($P=.03$), and the sensory item ($P=.04$).

Conclusions: Compared to the traditional didactic video, a highly interactive e-learning module enhances asynchronous distance learning and NIHSS knowledge acquisition in senior medical students.

Introduction

The swift strengthening of public health policies in the context of the COVID-19 crisis has wrought deep changes in the regular medical education curricula of many countries [1-4] while also increasing the need for health care professionals, including physicians. Senior medical students are being incrementally used on the front lines to address the shortage of these professionals [5,6], and other students may soon be required to follow suit [7]. Accelerated graduation procedures have also been described in some regions [8]. Senior medical students as well as some of these fast-tracked physicians may lack knowledge regarding the initial management of specific emergencies such as stroke. Stroke is a time-critical emergency that must be treated swiftly to improve functional and vital prognoses [9]; however, disruptions in acute stroke pathways have been described in the wake of the COVID-19 pandemic [10]. The National Institutes of Health Stroke Scale (NIHSS) is widely used to assess stroke victims [11], and senior medical students as well as junior residents should be familiar with its application.

Traditional classroom or bedside teaching can be difficult to conduct in certain situations, such as a pandemic [12-14]. Many universities have strived to increase distance learning capabilities, thereby highlighting the potential benefits of electronic learning (e-learning) [15-17]. E-learning is a generic term that includes many types of technologically enhanced learning materials [18-20]. Asynchronous distance learning using these methods has yielded mixed results, probably due to differences in the quality of the content and the mode of delivery [21].

Since the release of Patrick Lyden’s didactic video in 1994 [22], the development of NIHSS teaching material has been rather limited. We have recently shown that compared to this didactic video, a highly interactive e-learning module improved NIHSS knowledge acquisition in paramedics [23]. We defined this module as “highly interactive” because it uses multiple learning mechanics to promote interaction and engagement. Among these mechanics, preventing content skipping [24] and providing feedback tailored to the user's answer were the most prominent [25]. Branching logic was extensively used to create this feedback.

This first study was performed with the participants present at the study site; therefore, they could immediately access technical support if needed. Moreover, although most results favored the use of the e-learning module, the control group was better at scoring the ataxia element than the e-learning group. Although video extracts were used within the e-learning module to demonstrate the assessment of almost all NIHSS items, the chapter regarding the ataxia element did not contain any video extracts. We therefore hypothesized that systematically embedding videos could improve NIHSS learning acquisition, and we updated the module accordingly.

Given the need for social distancing during the COVID-19 pandemic, our goal was to compare medical students’ asynchronous distance learning of the NIHSS using two different teaching tools: the gold standard didactic video and the updated version of our e-learning module.

Methods

Study Design and Setting

We performed a randomized, controlled, data analyst–blinded, web-based trial following the CONSORT-EHEALTH guidelines and incorporating relevant elements from the Checklist for Reporting Results of Internet E-Surveys (CHERRIES) checklist [26,27]. The study took place between April 28 and June 8, 2020, in Geneva, Switzerland. Fifth year medical students at the University of Geneva Faculty of Medicine (UGFM) were invited to take part in this trial on a voluntary basis.

Standard Protocol Approvals, Registrations, and Participant Consent

Because the study included no patients and as no health outcomes were recorded, trial registration was not required according to the International Committee of Medical Journal Editors guidelines. Although the participants were not part of a vulnerable group according to Swiss federal law on human research [28], we filed a jurisdictional enquiry, and the regional ethics committee issued a “Declaration of no objection” (Req 2020-00474). The study was also approved by the Board of the Teaching Committee of the UGFM. Informed consent was gathered electronically.

Enrollment

After gathering the necessary authorizations, the UGFM students’ secretary transmitted the exact number of fifth year medical students to MS, who performed a 1:1 computer assisted randomization without having access to any other data regarding the students. MS then created specific identifiers that were transmitted back to the UGFM along with a mailing template Multimedia Appendix 1. The UGFM staff were therefore unable to determine the students’ allocations or results. In addition, we were prevented from determining the students’ identities.

The students were informed of the goals of the investigation, were given information regarding data security and anonymization procedures, and were supplied with the email addresses of three investigators to allow them to ask further questions. Students who elected to browse the website were provided with additional information as well as with a link to a full 4-page consent form in PDF format that they could either print or save. Using their identifiers to log into the site was considered as acceptance to participate in the study. All participants were free to withdraw at any time. No financial incentive was provided.

Web-Based Platform and Learning Material

We created a specific web-based platform under the Joomla 3.9 content management system (Open Source Matters) [29]. The control was Patrick Lyden's original video, which was subtitled in French [22]. The experiment used version 21 of our e-learning module, which was developed using Articulate Storyline 3 (Articulate Global). This software enables the creation of many types of interactive content, including gamified modules and serious games [30,31], which can be accessed on regular computers as well as on smartphones and tablets.

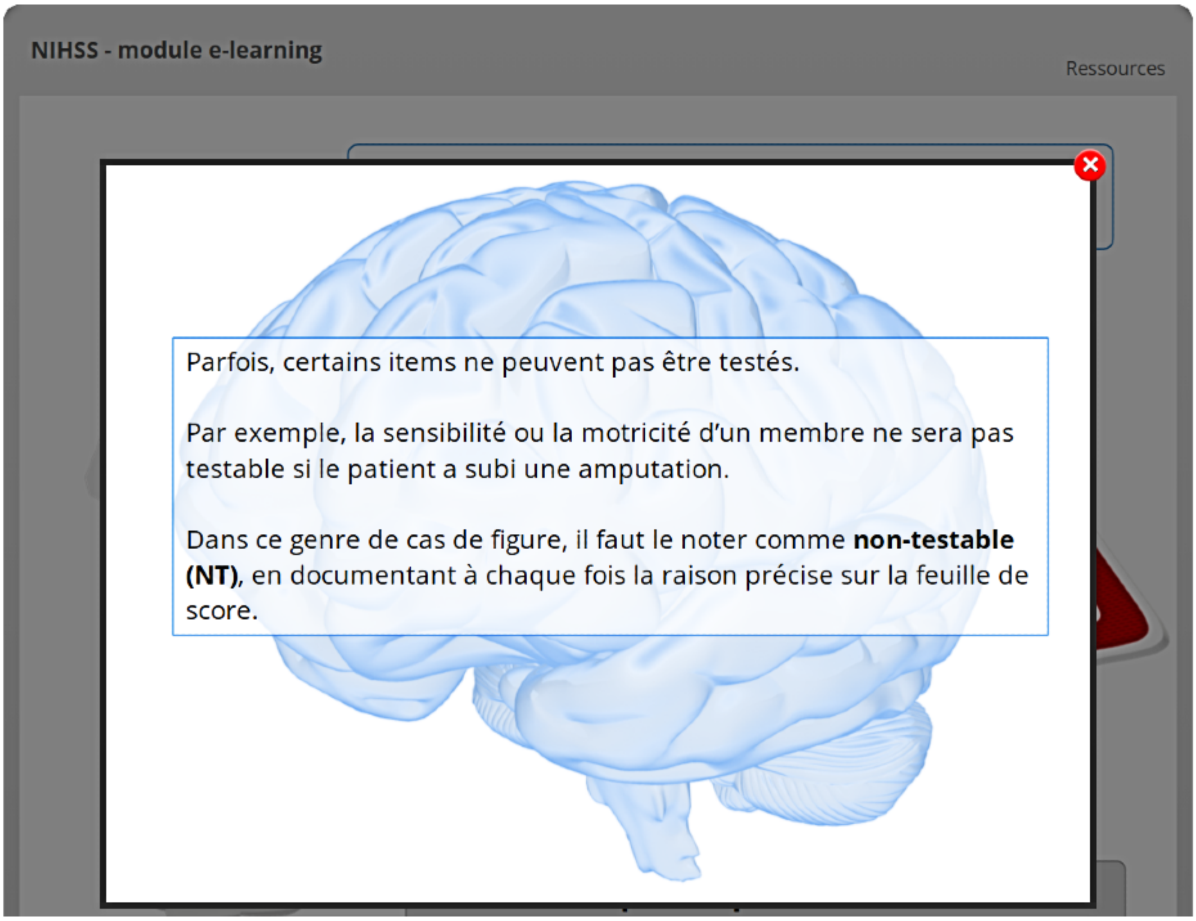
The e-learning module contains 16 independent chapters. The first chapter is the introduction, which is automatically displayed when the module is launched. Prevention of content skipping is the first learning mechanic used in the module, and it already appears in the introductory slides (Figures 1-3) [24].

A table of contents is displayed as soon as the user has completed the introduction. The user can then choose to review the introduction or to access any other chapter apart from the summary (Figure 4).

Figure 1. Prevention of content skipping. The user cannot click on the *Cliquez ici pour continuer* (Click here to continue) button until both blue buttons have been clicked.

Pour certains items, il faudra tenir compte de subtilités ! Cliquez sur les boutons pour les découvrir.

Figure 2. The user has clicked on one of the two buttons, and the learning content is now displayed in a lightbox. The *Cliquez ici pour continuer* (Click here to continue) button, which is slightly visible in the background, is still grey; therefore, it is inactive.

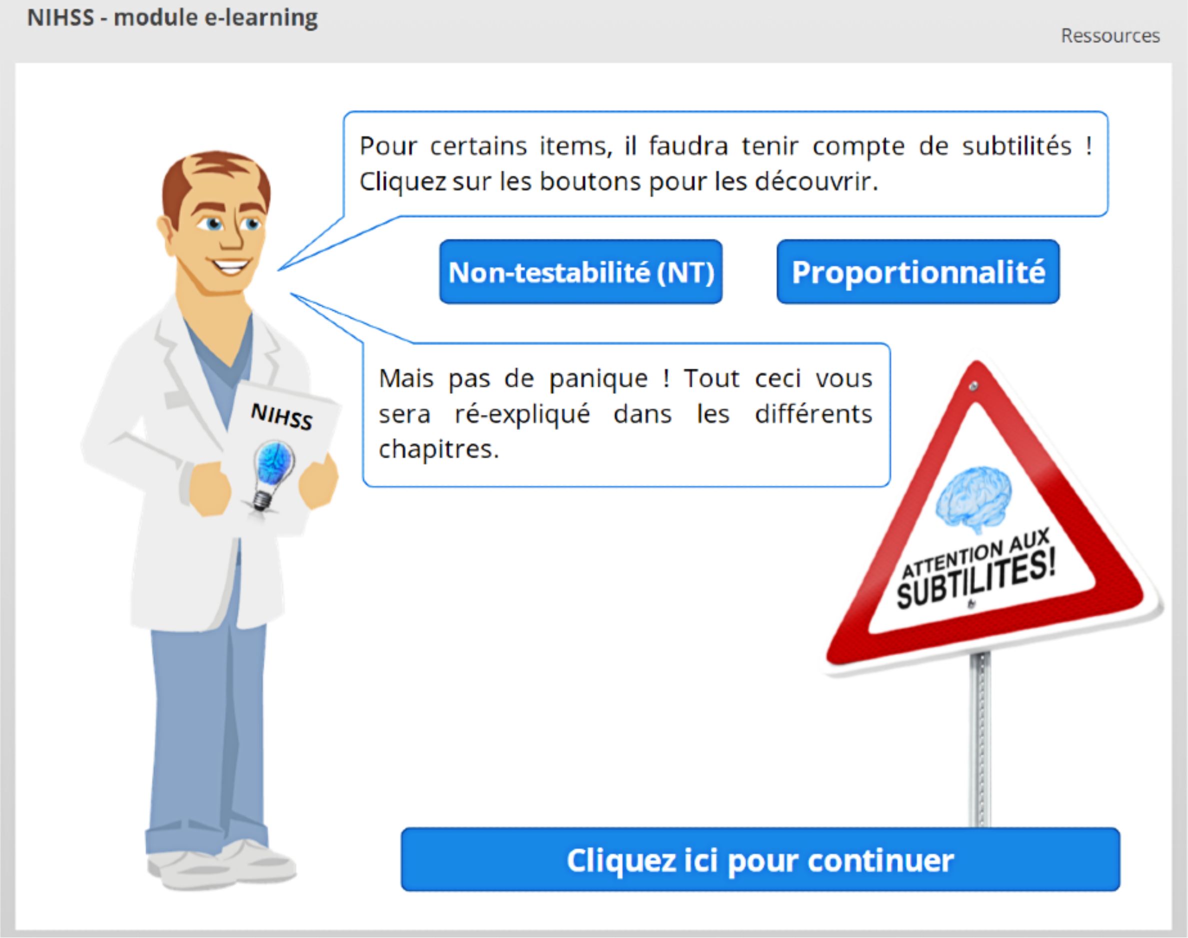


Parfois, certains items ne peuvent pas être testés.

Par exemple, la sensibilité ou la motricité d'un membre ne sera pas testable si le patient a subi une amputation.

Dans ce genre de cas de figure, il faut le noter comme **non-testable (NT)**, en documentant à chaque fois la raison précise sur la feuille de score.

Figure 3. Both buttons have been clicked, and the user has seen both lightboxed slides. The *Cliquez ici pour continuer* (Click here to continue) button has thus been activated and is now colored blue.



Pour certains items, il faudra tenir compte de subtilités ! Cliquez sur les boutons pour les découvrir.

Mais pas de panique ! Tout ceci vous sera ré-expliqué dans les différents chapitres.

Figure 4. Table of contents of the e-learning module. The *Résumé* (Summary) can only be accessed once all the other chapters have been completed.

NIHSS - module e-learning

Introduction

1A Etat de conscience – global
1B Etat de conscience – questions
1C Etat de conscience – consignes
2 Oculomotricité
3 Champ visuel
4 Paralysie faciale
5 Motricité des bras
6 Motricité des jambes
7 Ataxie
8 Sensibilité
9 Langage
10 Dysarthrie
11 Extinction et négligence
Score pour le coma

Résumé

Thirteen chapters are used to explain each specific NIHSS item (3 chapters are used to cover the first item, “consciousness,” which is divided into 3 elements). Although the chapters are numbered consecutively according to the NIHSS scoring logic, the user can freely elect the order in which to follow the chapters.

All chapters include at least two learning mechanics. First, each chapter begins by displaying the NIHSS score specific to the scoring item, and users are once again prevented from skipping content, as they must click on each numbered button to discover the score (Figure 5).

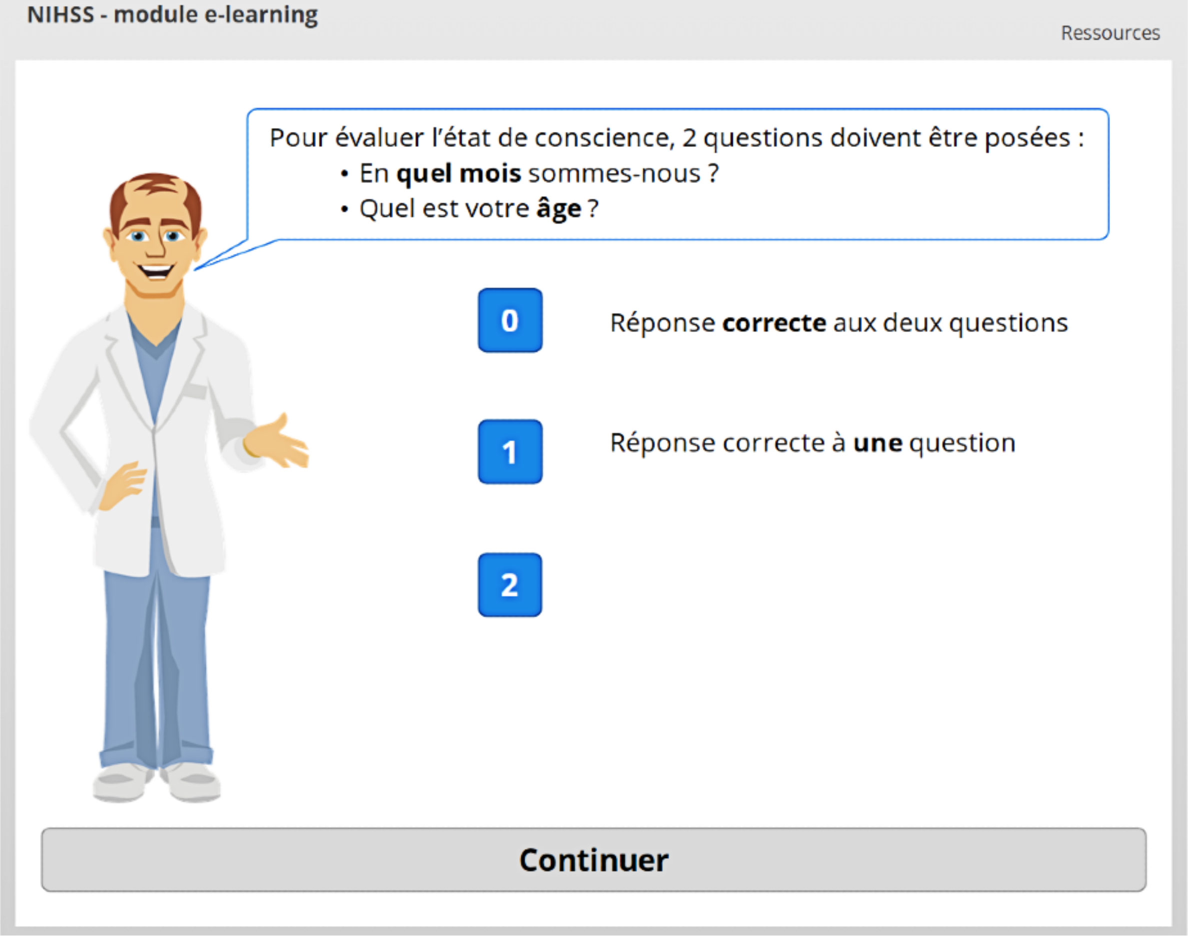
The second learning mechanic is linked to the use of subtitled videos. Video extracts are shown to the user, who must correctly score the NIHSS item (Figure 6). This version of the module contains video extracts in all chapters, including for the items related to dysarthria, level of consciousness – global, and level of consciousness – questions. In the previously studied version of our module (version 20), there were no video extracts for these items [23].

Feedback is provided for each question [25]: if the answer is incorrect, a clue is given (Figure 7), and the user has the opportunity to review the NIHSS item scoring.

If the answer was correct, feedback is also given to reinforce the message (Figure 8).

Specific interactions were designed to further illustrate particular elements, such as visual field deficits (Figure 9) or extinction and inattention (Figure 10).

Figure 5. Prevention of content skipping. The user cannot click on the *Continuer* (Continue) button until all the blue buttons have been clicked.



Pour évaluer l'état de conscience, 2 questions doivent être posées :

- En **quel mois** sommes-nous ?
- Quel est votre **âge** ?

0 Réponse **correcte** aux deux questions

1 Réponse correcte à **une** question

2

Figure 6. Video-based question. The user must choose the correct score for the patient displayed in the video before clicking on *Valider la réponse* (Validate the answer).

Quel est le niveau de conscience de ce patient?

Oui, un peu.

Figure 7. Wrong answer feedback and clue. The user can choose either to try again (*Réessayer*) or to review the scoring specific to this item by clicking *Cliquez ici pour afficher l'échelle* (Click here to display the scale).

NIHSS - module e-learning

Quel est le niveau de conscience de ce patient?

Mauvaise réponse

N'avez-vous pas l'impression que ce patient a un excellent état de conscience?

○ 0 ● 1 ○ 2 ○ 3

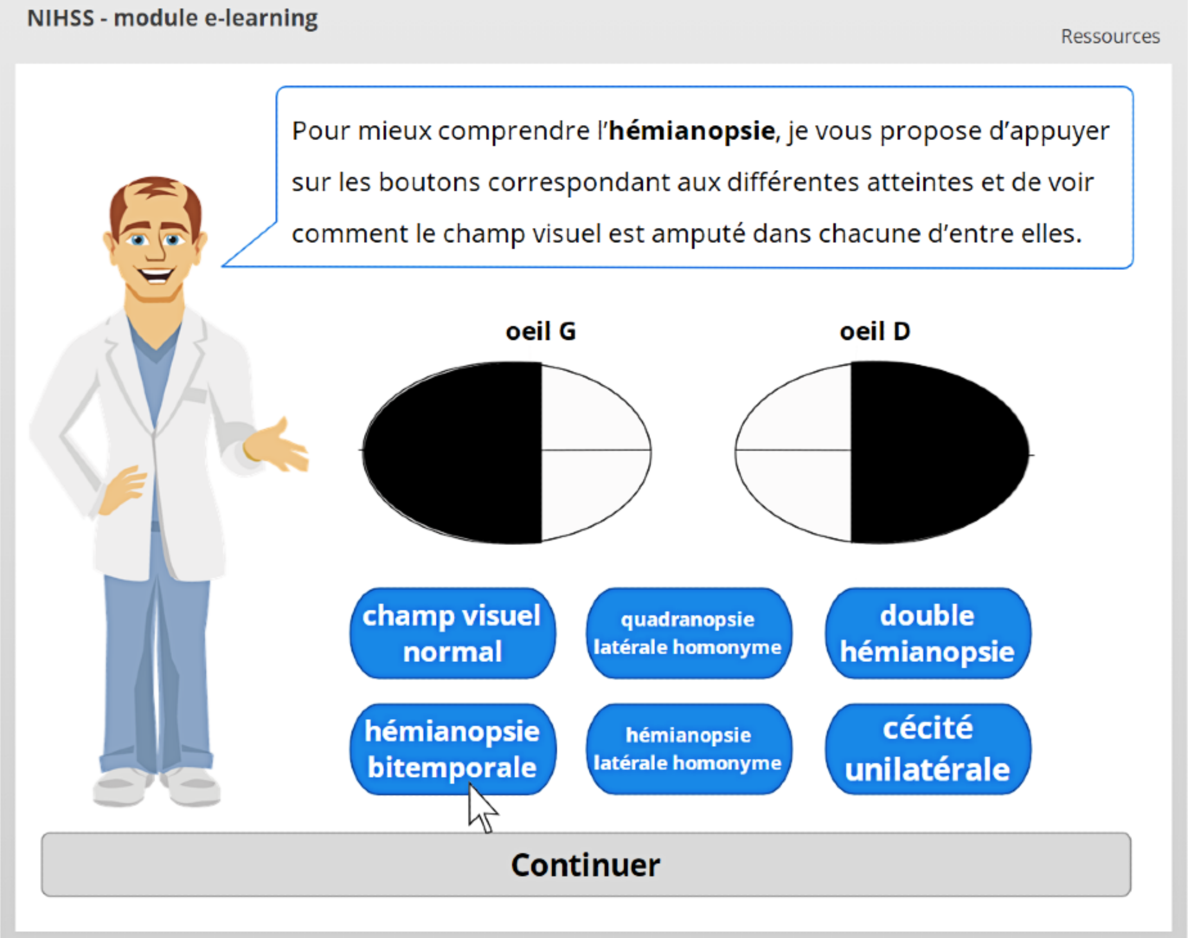
Figure 8. Positive feedback after a correct answer.

Quel est le niveau de conscience de ce patient?

Bonne réponse

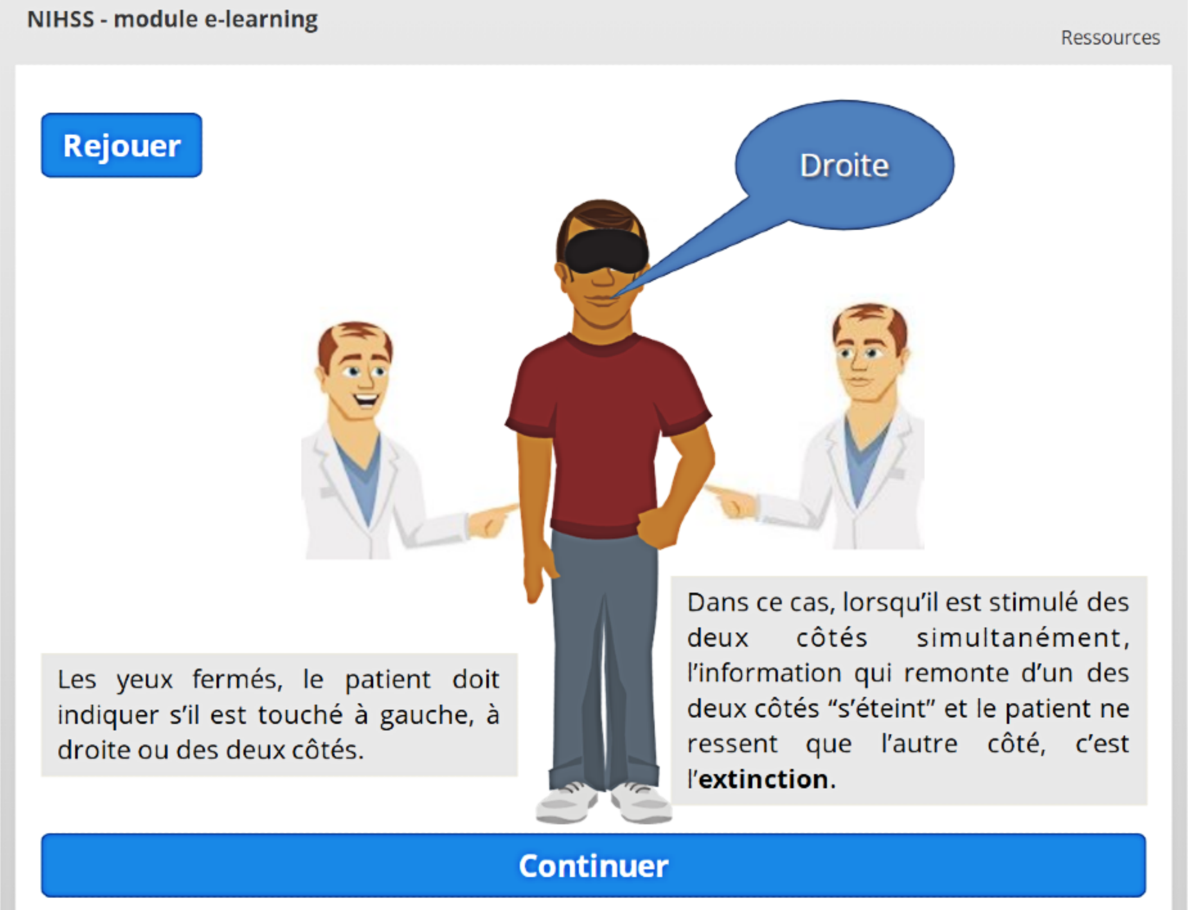
Bravo ! Vous avez sélectionné la bonne réponse. Ce patient est en effet alerte et a un état de conscience tout à fait normal.

Figure 9. Interactive explanation of visual field deficit.



Pour mieux comprendre l'**hémianopsie**, je vous propose d'appuyer sur les boutons correspondant aux différentes atteintes et de voir comment le champ visuel est amputé dans chacune d'entre elles.

Figure 10. Animation used to explain extinction and inattention.



Les yeux fermés, le patient doit indiquer s'il est touché à gauche, à droite ou des deux côtés.

Dans ce cas, lorsqu'il est stimulé des deux côtés simultanément, l'information qui remonte d'un des deux côtés "s'éteint" et le patient ne ressent que l'autre côté, c'est l'**extinction**.

The user can choose to exit the module at any time, as a prompt will be shown to allow the user to either resume the module or reset it. Before the summary chapter can be activated, users must complete a 14th chapter, which details the "coma score."

This e-learning module, along with its previously studied iteration, can be accessed freely on the internet [32].

Study Sequence

Immediately after login, the medical students learned which group they had been allocated to and were asked a first set of 6 questions displayed over a single page. Upon answering these questions, they could then access the learning material. No time limit was applied apart from the study end date (June 8, 2020). Once the learning material was completed, students were allowed to proceed to a 50-question quiz. This quiz was identical for all participants and contained five questions related to basic NIHSS concepts, followed by the clinical evaluation of 3 patients taken from Patrick Lyden's certification videos. The NIHSS elements were displayed and scored in sequence according to the NIHSS scoring logic. After finalizing the quiz, participants were given their overall score as well as the possibility to review all questions at will and were shown their answers along with the correct answers. Then, 4 questions, based on a 5-point Likert scale, were asked to assess secondary outcomes, such as satisfaction. Students were finally given access to both the video and the e-learning module to discover the other teaching modality and/or to review the one they had just followed.

Outcomes

The primary outcome of the study was the proportion of correct answers to the 50-question quiz. Secondary outcomes were the proportion of correct answers for each specific NIHSS item, user satisfaction, perceived adequacy of the time needed to complete the course, perceived difficulty of the course, probability that the participant would recommend the course, and whether the learning path had been completed over multiple days.

Data Collection and Curation

Data were securely stored on an encrypted MariaDB 5.5.5 database (MariaDB Foundation) located on a Swiss server before being extracted in comma-separated values (CSV) format. We used STATA (StataCorp) for data curation and anonymization.

Statistical Analysis

STATA 15.1 was used by L Stuby for statistical analysis. Incomplete answers to the 50-question quiz were not analyzed.

Normality was assessed by graphical evaluation and, if in doubt, we used the Shapiro-Wilk test. We applied the Fisher exact test to categorical variables and the Student *t* test or the Mann-Whitney U test to continuous variables according to normality. We considered a 2-sided *P* value <.05 as significant.

We used a convenience sample and calculated the power post hoc. We defined 4 sensitivity analyses a priori according to whether the participant had prior knowledge of the NIHSS, had already followed a specific NIHSS course, had worked in either an intensive care unit or in a neurology or neurosurgery ward for more than 3 months, or had completed the learning path over multiple days. This was defined as more than 12 hours elapsed between initiation and completion of the course.

Finally, we performed univariate followed by multivariable linear regression to look for possible confounding factors.

Data Availability

Our curated data file is available on Mendeley Data [33].

Results

Out of 158 potential participants, 75 (47.5%) completed the trial (Figure 11). Table 1 details their characteristics.

After the first mailing (April 28, 2020), 21 students completed the trial. The first reminder (May 11, 2020) led 29 more students to complete the course, while another 25 participated after the second and last reminder (May 18, 2020).

Table 1. Participant data (N=75).

Characteristic	Value	
	Video group (n=34)	E-Learning group (n=41)
Age, median (Q1-Q3)	24 (23-25)	24 (23-24)
Prior knowledge of NIHSS[a] application, n (%)	3 (9)	3 (7)
Specific NIHSS course followed, n (%)	4 (12)	2 (5)
E-learning NIHSS course followed, n (%)	0 (0)	0 (0)
Had worked in intensive care unit or neurology ward, n (%)	0 (0)	1 (2)
Missing data, n (%)	2 (6)	2 (5)

[a] NIHSS: National Institutes of Health Stroke Scale.

Participants who followed the e-learning module performed better than those who followed the video (38 correct answers, 95% CI 37-39, vs 35, 95% CI 34-36, *P*<.001). Participants in the e-learning group scored better on five elements than the video group: key NIHSS concepts (*P*=.02), the consciousness – global item (*P*<.001), the facial palsy item (*P*=.04), the ataxia item (*P*=.03) and the sensory item (*P*=.04). There was no such effect in the video group. Detailed results are shown in Table 2.

The rate of “very satisfied” participants was higher in the e-learning group (14/35, 40%; 95% CI 24%-56%) versus the video group (4/26, 15%; 95% CI 5%-25%, *P*=.02) (Figure 12).

Table 2. Quiz results.

Item	Video group (n=34)	E-Learning group (n=41)	*P* value
Overall score, mean (SD)	35 (3)	38 (3)	<.001
Overall score, 95% CI	34-36	37-39	N/A[a]
Detailed results by item, median (Q1-Q3)			
Key NIHSS[b] concepts	5 (4-5)	5 (5-5)	.02
Consciousness – Global	2 (2-2)	3 (2-3)	<.001
Consciousness – Questions	3 (2-3)	3 (3-3)	.70
Consciousness – Commands	2 (2-3)	3 (2-3)	.06
Gaze	2 (2-3)	3 (2-3)	.34

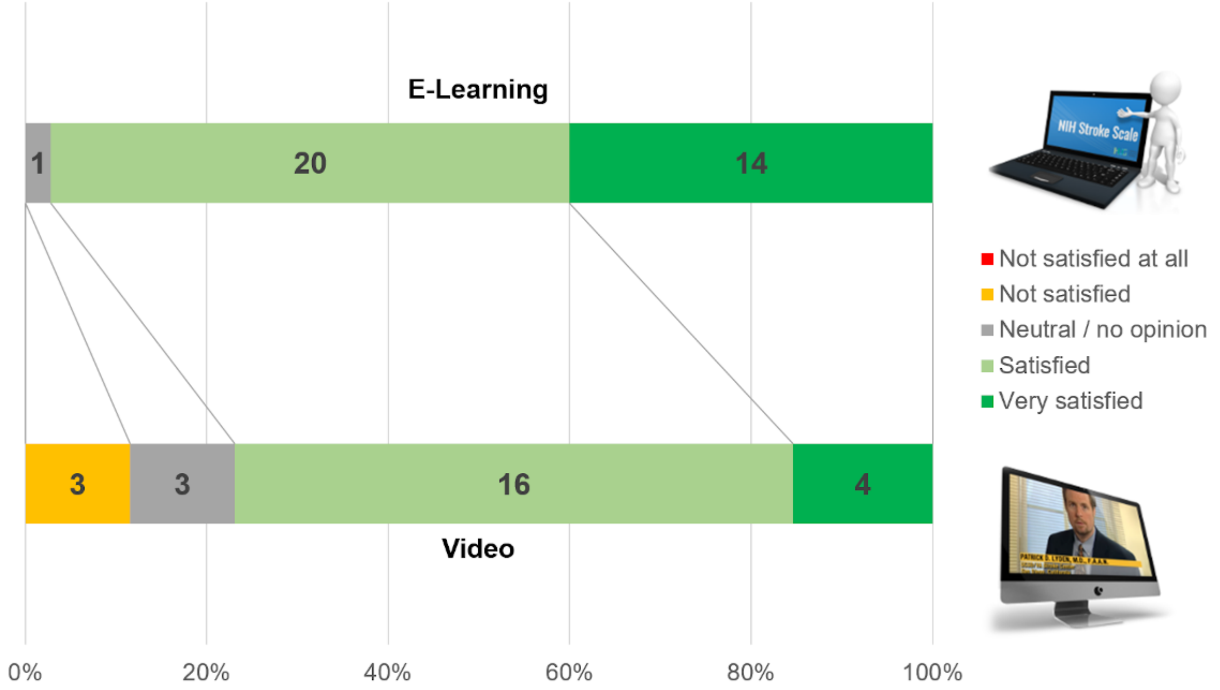
Facial Palsy	1 (0-2)	2 (1-2)	.04
Motor arm	4 (4-5)	5 (4-5)	.17
Motor leg	5 (4-6)	5 (4-5)	.23
Ataxia	1 (1-1)	1 (1-2)	.03
Sensory	3 (2-3)	3 (3-3)	.04
Language	1 (1-2)	1 (1-1)	.63
Dysarthria	2 (2-2)	2 (2-2)	.07
Extinction and inattention	2 (2-3)	2 (2-3)	.14

[a] N/A: not applicable.

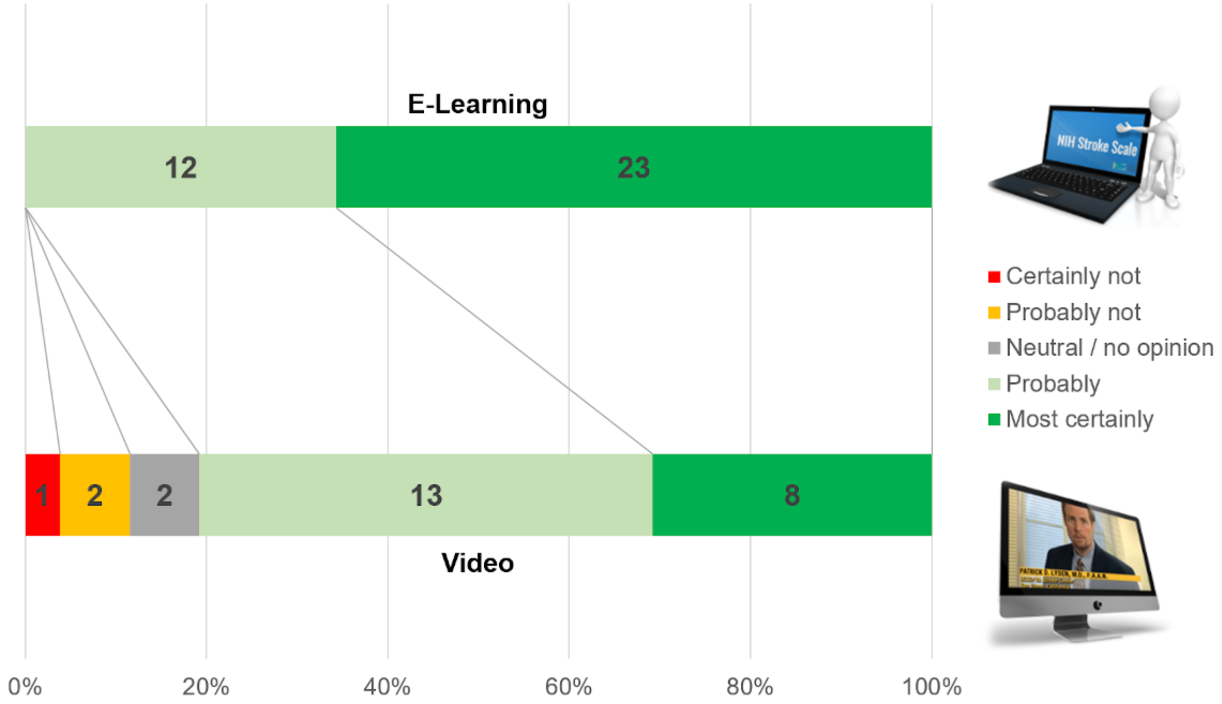
[b] NIHSS: National Institutes of Health Stroke Scale.

Figure 12. Satisfaction of the participants in the e-learning and video groups regarding the learning method.



Although the precise total learning time dedicated to either method could not be assessed due to the study design, no statistical difference regarding the perceived duration of the course was identified (80% (28/35) adequate in the e-learning group, 95% CI 67%-93%, vs 65% (17/26) 95% CI 47%-83%, *P*=.25). There was no significant difference regarding the perceived difficulty of the course, as 84% (16/19) (95% CI 68%-100%) found it “easy or very easy” in the e-learning group versus 53% (8/15) (95% CI 28%-78%) in the video group (*P*=.07). Participants who followed the e-learning method were more likely to recommend it to a colleague; 23/35 participants (66%) answered “Yes, most certainly” (95% CI 50%-82%), versus 8/26 (31%; 95% CI 13%-49%) in the video group, *P*=.007 (Figure 13). The proportions of participants in the two groups who followed the course over less than 12 hours were similar (58% (14/24) in the e-learning group, 95% CI 38%-78%, versus 52% (17/33) in the video group, 95% CI 35 to 69, *P*=.79).

Figure 13. Likelihood that the participants in the e-learning and video groups would recommend the course.



The post hoc calculation showed a power of 97%. None of the 4 preplanned sensitivity analyses showed any major changes in the direction of the effect. The multivariable linear regression only showed a minor change in the coefficient (<15%), confirming these results.

Discussion

Principal Findings

In this study, asynchronous distance learning using a highly interactive e-learning module yielded better results than following the traditional didactic video on the web. The superiority of a previous version of this module has already been established in Swiss paramedics following an onsite computer-based course [23]. The present study confirms the generalizability of these findings when using this method for asynchronous distance learning in a different population of learners, namely, fifth year medical students. Indeed, although paramedics follow a 3-year curriculum focusing on critical emergencies, baseline knowledge and understanding of neurosciences should be higher in students on the verge of obtaining their master of medicine degree [34]. This assumption is supported by the median score of the control group, which was higher by two points in this study than it was in paramedics [23].

The shortcomings we had identified in the previous iteration of the e-learning module seem to have been addressed, as embedding cutscenes from the original video into every chapter of the module improved the impact of the module on knowledge acquisition. The use of short videos associated with active learning activities such as guiding questions or interactive elements has been shown to enhance knowledge acquisition and retention [35]. Interactivity itself is also known to improve both engagement and performance in medical students [36,37].

Slightly less than half of all potential participants completed their allocated learning path. Considering that the learning material was optional and that students’ summative assessments of this semester were replaced by formative assessments, the participation rate is rather encouraging given the global lack of incentive. More encouraging still is the proportion of students who would recommend the course to their peers, as such mechanisms may increase students' involvement [38]. As many medical students actively helped on the front lines during the crisis, some of them may have been prevented from participating in this study owing to their high workload [39].

The quiz shown to the participants upon completion of the learning material included not only the full evaluation of 3 different stroke patients, but also 5 general questions we had designed Multimedia Appendix 2. While this could be considered as a potential bias in the study design, these questions were solely linked to key elements and basic principles of the NIHSS, and their understanding is essential to the correct application of the scale Multimedia Appendix 2. Our aim was indeed to evaluate whether knowledge acquisition was different when presenting similar content in different learning formats.

As the overall score regarding these questions was high in both groups, and as other significant results favored the e-learning method, there is little probability that these 5 initial questions induced a bias.

In many hospitals, the NIHSS is commonly used to triage stroke victims and help reduce both door-to-CT (CT: computed tomography) and door-to-needle times [9]. Decreasing these times is associated with better neurocognitive and functional outcomes [40]. Moreover, the adoption of a common scale between different specialists seems necessary to improve reproducibility and avoid the misinterpretation that can result from the use of different scores [41]. Swift acquisition and mastery of the NIHSS is therefore an essential skill for medical students, as most will be required to take care of stroke patients during their residency while working in the emergency department or in the neurology department. This is further strengthened by the fact that medical students often perceive neurology as the most difficult medical discipline, and the development of negative perceptions toward this specialty could lead to avoidance mechanisms when considering a career or treating a patient [42]. We might therefore assume that any kind of stroke-directed educational program could help raise awareness in non-neurologist physicians and thus increase the rate of correct treatment while decreasing door-to-needle time.

Limitations and Strengths

This study has limitations that must be acknowledged. The main limitation is that we only measured immediate knowledge acquisition; we were unable to assess knowledge retention due to the study design and the limited timeframe. As this latter parameter is critical to the clinical application of the NIHSS, further studies will be needed to assess whether the e-learning method improves retention and leads to more accurate application of the scale. Moreover, the precise time taken to complete either learning method was not evaluated in this study. While it can be argued that dedicating more time to learning given content should yield better results, studies have shown that engagement is the most important factor regarding knowledge acquisition [43]. Although time to learning material completion is an interesting outcome, we chose not to record these data for two main reasons: risk of unblinding and technical limitations. As the time required to watch the video is fixed unless the participants elect to use the video commands, and as most of them chose not to use this option in a previous study [23], we thought it better not to risk unnecessarily unblinding the data analyst. The technical aspect was linked to the web-based learning management system and to the mode of delivery of the teaching material. As access to the university premises was barred during the study period, participants followed the learning material from many different locations. Interruptions in the learning process may therefore have occurred; however, we had no means of recording recurrent short breaks in the group that followed the e-learning module, as pauses may also have resulted from taking notes, mulling over the content, or simply rereading some of the written paragraphs to better understand them. To mitigate this limitation, a sensitivity analysis comparing participants who completed the study path in less and more than 12 hours was performed. Reassuringly, no difference was noted.

Despite these limitations, this study also has several strengths, including the randomization, the blinding mechanisms, the electronic data acquisition, the originality of the learning method and its mode of delivery in the context of the COVID-19 pandemic.

Conclusion

Compared to the traditional didactic video, a highly interactive e-learning module enhances distant NIHSS knowledge acquisition in medical students.

Acknowledgments

The authors would like to thank Mr Daniel Scherly from the UGFM for his technical assistance as well as for dispatching the emails and reminders on our behalf.

None declared.

Editorial Notice

This randomized study was not registered. The authors explained that their study included no patients and no health outcomes were recorded. According to the ICMJE rules, if the purpose is to examine the effect only on the providers rather than patients, then registration is not necessary. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness.

Abstract

Background: The COVID-19 pandemic has disrupted the lives of millions and forced countries to devise public health policies to reduce the pace of transmission. In the Middle East and North Africa (MENA), falling oil prices, disparities in wealth and public health infrastructure, and large refugee populations have significantly increased the disease burden of COVID-19. In light of these exacerbating factors, public health surveillance is particularly necessary to help leaders understand and implement effective disease control policies to reduce SARS-CoV-2 persistence and transmission.

Objective: The goal of this study is to provide advanced surveillance metrics, in combination with traditional surveillance, for COVID-19 transmission that account for weekly shifts in the pandemic speed, acceleration, jerk, and persistence to better understand a country's risk for explosive growth and to better inform those who are managing the pandemic. Existing surveillance coupled with our dynamic metrics of transmission will inform health policy to control the COVID-19 pandemic until an effective vaccine is developed.

Methods: Using a longitudinal trend analysis study design, we extracted 30 days of COVID-19 data from public health registries. We used an empirical difference equation to measure the daily number of cases in MENA as a function of the prior number of cases, the level of testing, and weekly shift variables based on a dynamic panel data model that was estimated using the generalized method of moments approach by implementing the Arellano-Bond estimator in R.

Results: The regression Wald statistic was significant (χ^2_5=859.5, *P*<.001). The Sargan test was not significant, failing to reject the validity of overidentifying restrictions (χ^2_{294}=16, *P*=.99). Countries with the highest cumulative caseload of the novel coronavirus include Iran, Iraq, Saudi Arabia, and Israel with 530,380, 426,634, 342,202, and 303,109 cases, respectively. Many of the smaller countries in MENA have higher infection rates than those countries with the highest caseloads. Oman has 33.3 new infections per 100,000 population while Bahrain has 12.1, Libya has 14, and Lebanon has 14.6 per 100,000 people. In order of largest to smallest number of cumulative deaths since January 2020, Iran, Iraq, Egypt, and Saudi Arabia have 30,375, 10,254, 6120, and 5185, respectively. Israel, Bahrain, Lebanon, and Oman had the highest rates of COVID-19 persistence, which is the number of new infections statistically related to new infections in the prior week. Bahrain had positive speed, acceleration, and jerk, signaling the potential for explosive growth.

Conclusions: Static and dynamic public health surveillance metrics provide a more complete picture of pandemic progression across countries in MENA. Static measures capture data at a given point in time such as infection rates and death rates. By including speed, acceleration, jerk, and 7-day persistence, public health officials may design policies with an eye to the future. Iran, Iraq, Saudi Arabia, and Israel all demonstrated the highest rate of infections, acceleration, jerk, and 7-day persistence, prompting public health leaders to increase prevention efforts.

Introduction

Background

SARS-CoV-2, the novel coronavirus that causes the disease COVID-19, first presented in December 2019 in Wuhan City, China, and was declared a public health emergency of international concern on January 30, 2020, as it spread quickly around the globe through human-to-human transmission [1-4]. According to the World Health Organization (WHO), the first reports of COVID-19 in the Middle East and North Africa (MENA) included 8 cases in the United Arab Emirates between January 29, 2020, and February 9, 2020 [5] (Figure 1). It has since spread to every country in the region [6]. MENA is divided by large wealth disparities and regional conflicts, increasing risks to the COVID-19 pandemic that has no political or religious agenda [6]. Despite varying levels of health system preparedness in MENA countries, early implementation of strict containment measures helped to limit the spread of SARS-CoV-2. As of October 28, the WHO reported 43,540,739 confirmed cases of COVID-19, including 1,160,650 deaths worldwide [7]. There have been 2,982,597 confirmed cases in MENA, resulting in 75,737 deaths [7].

Many countries use a combination of containment and mitigation strategies, including isolation of cases, contact tracing, social distancing, border closures, masking, hand and surface hygiene, and travel restrictions [8]. In the absence of a vaccine, worldwide systemic public health surveillance that can reliably track cases and identify where outbreaks will occur is needed to inform disease control policy for COVID-19 prevention [4,9]. Global SARS-CoV-2 surveillance necessitates dividing the globe into separately surveyed regions. The World Bank, an international financial institution that aims to reduce poverty and increase sustainable prosperity in nations throughout the globe, divides the world into regions based on shared geographic, cultural, and historical qualities. The MENA region comprises Bahrain, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, the United Arab Emirates, Yemen, Algeria, Djibouti, Egypt, Libya, Morocco, and Tunisia [10].

Responses to COVID-19 in MENA have ranged from restrictive temporary lockdowns to denial and lack of organization [6,11]. Lessons learned from the severe acute respiratory syndrome (SARS), the Middle East respiratory syndrome (MERS), and the 2009 H1N1 outbreaks inform the current pandemic [12]. For example, in Saudi Arabia, the Ministry of Health established the Command and Control System and the Saudi Center for Disease Control and Prevention shortly after the rise of MERS [12]. Some countries repurposed surveillance resources to encourage COVID-19 containment. This is best illustrated in the United Arab Emirates where the "Oyoon" ("eyes" in Arabic) surveillance camera program, originally developed to track and prevent crime, was repurposed to check the temperatures of those passing by and to ensure people are social distancing [13].

The World Health Organization declares a public health emergency of international concern

Mid-Feb – First Cases
WHO announces 8 cases in the UAE between Jan 29 – Feb 9, 1 case in Egypt on Feb 14 and 2 deaths in Iran on Feb 19

Feb 26 – Saudi Arabia
Saudi Arabia suspends pilgrimages to Mecca and Medina

Early March – Lebanon
Lebanese Ministry of Social Affairs unveiled preventative plan to prevent the spread of the virus in refugee camps

Mar 16 – Lebanon
The World Bank approves re-allocation of $40 mil under the current Health Resilience Project to strengthen the Ministry of Public Health's capacity to respond to the crisis

Mid March – WHO
WHO releases assessment of COVID-19 preparedness, ranking MENA countries

Mar 25 – Tunisia
Tunisian prime minster annoucnes establishment of National COVID-19 Monitoring Authority

April 11 – WHO-EMRO
WHO-EMRO releases region-wide response plan including coordination with the Islamic Research Academy of Al Azhar Al Sharif in Egypt to provide advice on Ramadan practices

April 27 – Iran
Iranian government discloses deconfinement strategy with plan for schools and mosques to open May 3

April 27 – Lebanon
Lebanon announces five-step reopening plan

May 4 – Egypt
Ministry of Health announces country's isolation hospitals are at maximum capacity

May 4 – Saudi Arabia
Restrictions begin to ease including lockdown on Mecca

June 18 – Deconfinement
Most MENA countries begin to relax lockdown measures and plan deconfinement

June 18 – Saudi Arabia
Saudi Arabian Ministry of Health launches COVID-19 dashboard.

June 18 – Beirut, Lebanon
Warehouse explosion at Beirut's port kills hundreds, wounds thousands and displaces 300,000 people

Sep 17 – Israel
Israel becomes first nation to enter second lockdown as total cases surpass 172,000

Oct 5 – Lebanon
Lebanon registers a record 1321 new daily infections, pushing its already overwhelmed hosptials to the brink

Economics

Countries in MENA face a dual crisis from the COVID-19 pandemic and the collapse of oil prices [14]. These concurrent crises are exacerbated by structural economic challenges including large and inefficient public sectors, uncompetitive business environments, high youth and female unemployment, governance challenges, and regional conflicts [14]. Given these challenges, the World Bank released a report recommending a coordinated regional MENA trade integration framework that lays the foundation for global value chain integration and thus helps MENA's economic prospects [14]. Income disparities abound in MENA, which is home to the wealthy Persian Gulf nations and yet is one of the only regions in the world where extreme poverty has been rising since 2011, particularly in regions with violent conflicts [6,15]. Thus, as countries in MENA combat the COVID-19 pandemic, they do so in the context of falling oil prices and disparities in wealth and political stability.

Violent conflicts significantly weakened the health infrastructure in several countries across MENA, resulting in poor health worker capacity [12,16]. However, outside of conflict regions, MENA countries have some of the lowest proportion of health workers in the world with Egypt, Morocco, Iraq, Yemen, and Djibouti subject to low levels of doctors and nurses [11]. The health system capacity in MENA is facility based, which limits the surge capacity needed to respond to a crisis such as the COVID-19 pandemic [11]. Some MENA countries have limited public health infrastructure, including Egypt, Iraq, Djibouti, and Yemen that spend less than 5% of their government funding on health [11,17].

Middle Eastern populations have a high disease burden, which suggests a reduction in routine health service utilization results in increased mortality, a trend expected to hold true for COVID-19 [11,12]. Food insecurity poses a significant public health concern in countries with high refugee per capita concentration, such as Lebanon and Jordan [18-20]. Refugee populations are particularly vulnerable to COVID-19 as they are often concentrated in densely populated camps with poor hygiene measures and fragmented access to health care [12].

On August 4, 2020, a deadly warehouse explosion, caused by 2750 tons of ammonium nitrate stored at Beirut's port, killed hundreds, wounded and displaced thousands, left 5 hospitals in the area either nonfunctional or only partially functional, and destroyed 17 containers of WHO essential medical supplies [21-23]. The seeming carelessness with which this destructive material was stored for 6 years fueled public outrage and antigovernment protests throughout the city [24]. Since then, Lebanon has seen a 220% increase in COVID-19 cases [25]. As countries ease restrictions and a second wave of COVID-19 threatens to undo progress, it is particularly important to accurately track cases across MENA [26]. This is evident in countries such as Israel [27]. Ideally, advanced tracking and estimation of COVID-19 transmission will inform the implementation of public health policies. Though general public health surveillance is helpful and provides a proxy of the pandemic, surveillance data suffer from significant bias due to undercounts, reporting delays, testing errors, dearth of testing, asymptomatic carriers, and other types of data contamination [7,28-35]. In fact, surveillance systems are predicated on the fact that they tend to include the more severe cases and suffer from incomplete case ascertainment by missing the mild cases and undiagnosed infections and deaths.

Objective

The objective of our research is to provide additional surveillance metrics to add to the public health arsenal using dynamic panel modeling and method of moments to minimize sampling bias by measuring significant negative or positive weekly shifts in the increase, decrease, or plateaued transmission of SARS-CoV-2. We will apply novel indicators derived specifically to inform policy makers about the COVID-19 pandemic [3,36], including weekly shifts in the pandemic, speed, acceleration and deceleration, jerk, and 7-day persistence. These dynamic metrics will better inform public health policy when combined with standard surveillance measures.

Methods

This study relies on a longitudinal trend analysis of data collected from the Foundation for Innovative New Diagnostics (FIND) [37]. FIND compiles data from multiple sources across individual websites, statistical reports, and press releases; data for the most recent 8 weeks were accessed from the GitHub repository [38]. This resulted in a panel of 19 MENA countries with 30 days in each panel (n=570). An empirical difference equation was specified in which the number of new positive cases in each country on each day is a function of prior numbers of cases, level of testing, and weekly shift variables that measure whether the contagion was growing faster, at the same pace, or slower than the previous weeks. This resulted in a dynamic panel data model that was estimated using the generalized method of moments (GMM) approach by implementing the Arellano-Bond estimator in R (The R Foundation) [3,36,39].

Results

MENA Regression Results

Regression results are presented for 17 MENA countries in Table 1. Weekly surveillance data in Tables 2-7 are based on these regressions.

The regression Wald statistic was significant (χ^2_5=859.5, *P*<.001). The Sargan test was not significant, failing to reject the validity of overidentifying restrictions (χ^2_{294}=16, *P*=.99)

Table 1. Arellano-Bond dynamic panel data modeling of the number of daily infections reported by country, October 5-18, 2020.

Variable	Statistic	*P* value
L7Pos[a]	*r*=0.57	<.001
Cumulative tests	*r*=0.00012	<.001
Weekend	*r*=0.04	.95
Wald statistic for regression	χ^2_5= 859.5	<.001
Sargan statistic for validity	χ^2_{294}=16	.99

[a] L7Pos: the statistical impact of the 7-day lag of speed on today's value of speed. New cases per day tend to have an echo effect 7 days later, similar to the echo effect in the population pyramid caused by the baby boom. Reported as the weekly average number of new cases per day that are attributable to the weekly average of the 7-day lag of the number of new cases per day.

Tables 2 and 3 contain standard surveillance metrics for the weeks of October 5-11 and October 12-18. These metrics include new daily COVID-19 cases, cumulative COVID-19 cases, 7-day moving averages, rate of infection, new deaths, cumulative deaths, 7-day moving average of death rates, and rates of death per 1,000,000 population.

Table 2. Static surveillance metrics for the week of October 5-11, 2020.

Country	New COVID-19 cases, n	Cumulative COVID-19 cases, n	7-day moving average of new cases	Rate of infection	New deaths, n	Cumulative deaths, n	7-day moving average of death rate	Rate of death
Algeria	132	53,072	133.71	0.31	6	1801	5.86	0.01

Libya	945	48,790	868.29	13.94	26	725	13.43	0.38
Morocco	2721	173,632	3032.57	7.46	50	2928	46.14	0.14
Oman	1657	109,953	580.43	33.31	30	1101	9.00	0.60
Qatar	204	129,431	206.57	7.20	1	224	0.57	0.04
Saudi Arabia	348	342,202	419.29	1.02	20	5185	20.29	0.06
Tunisia	0	40,542	1140.86	0.00	0	626	21.14	0.00
United Arab Emirates	1215	115,602	1339.00	12.44	4	463	2.57	0.04
Region	17,615	2,563,321	18,397.14	4.39	504	63,292	516.71	0.13

In Table 3, we see the countries with the highest cumulative caseload of the novel coronavirus, which includes Iran, Iraq, Saudi Arabia, and Israel with 530,380, 426,634, 342,202, and 303,109 cases, respectively. To eliminate the week-end effect or delayed reporting, we look at 7-day moving average to understand the 7-day average number of cases. In the second week of our study, October 12-18, Iran reported 4329, Israel reported 1802, Iraq reported 3472, and Morocco reported 3033 new cases per day (weekly averages). The next closest country in terms of average new cases only has a third of those cases. We find that many of the smaller countries in MENA have higher infection rates than those countries with the highest caseload. For example, Oman had 33.3 new infections per 100,000 population while Bahrain had 12.1, Libya had 14, and Lebanon had 14.6. In order of most to least number of cumulative deaths since January 2020, Iran, Iraq, Egypt, and Saudi Arabia had 30,375, 10,254, 6120, and 5185, respectively. These countries are outliers when comparing them to the rest of the region, which all have less than 3000 cumulative deaths

The novel surveillance metrics are presented in Tables 4 and 5 and Figure 2 [40] and Multimedia Appendices 1-5.

Table 4. Novel surveillance metrics for the week of October 5-11, 2020.

Country	Speed[a]	Acceleration[b]	Jerk[c]	7-day persistence effect on speed[d]

The opinions expressed herein are those of the author(s) and do not necessarily reflect the views of the U.S. Agency for International Development.

Overall, the MENA region was more stable than other global regions, but metrics between October 5-18 indicate pending growth. The speed of new infections decelerated during the week of October 5-11 and remained stable during the week of October 11-18. In addition, in the latter week, there was a slight negative jerk. The persistence rate slightly decreased from 3.11 to 3.05 per 100,000 population over the study period, which directly measures those new cases that are statistically related to the number of new infections 7 days earlier. While the surveillance metrics for the MENA region as a whole are promising, they are averages and thus we must look to those countries with increasing rates of speed, acceleration, jerk, and persistence to understand which countries have outbreaks and less control of the pandemic. In Table 5, we note that Bahrain, Israel, and Lebanon decreased in speed or remained level between October 5 and 18. Jordan and the United Arab Emirates had significant increases in rates of infection. Tunisia had the best shift in the pandemic that resulted in a decrease in speed week over week. In addition, the rates reversed course and decelerated from October 5-11 to October 12-18, and Tunisia experienced a negative jerk in infection rates 2 weeks in a row, indicating a strong downward trend in COVID-19 infections. For Israel, the 7-day persistence effect for the week of October 12-18 (21 new cases) slightly overpredicts the speed or the actual number of new cases (n=20); coupled with a declining persistence rate relative to the prior week of October 5-11, this is indicative of a rapid descent from a recent period of explosive growth. On the other end of the spectrum, Bahrain had positive speed, acceleration, and jerk, indicating the outbreak is increasing and is leading toward a worsening pandemic.

Table 6. Seven-day persistence difference.

Country	7-day persistence	
	October 5-11, 2020	October 12-18, 2020
Israel	32.14	21.32
Bahrain	16.37	14.64
Lebanon	9.77	10.79
Oman	6.25	7.56
Iraq	6.15	—[a]
Jordan	—	7.48

[a] Not applicable.

Israel, Bahrain, Lebanon, and Oman had the highest rate of COVID-19 persistence, which is the number of new infections statistically related to new infections from 7 days ago. These 3 countries had higher persistence rates 2 weeks in a row. Finally, Egypt has the highest population in MENA (Table 7) and the potential for growth but has remained stable across the 2 weeks of this study, indicating that COVID-19 is not accelerating.

Table 7. Most populous countries in the Middle East and North Africa.

Country	Population as of 2020, n
Egypt	102,334,404
Iran	83,992,949
Algeria	43,851,044
Iraq	40,222,493
Morocco	36,910,560

Discussion

Principal Findings

Analysis at the country level indicates there are some nations that should increase their public health efforts to gain control of the COVID-19 pandemic. Iran, Israel, Iraq, and Morocco had the highest reported 7-day average per 100,000 population, which is significantly higher than other nations in the region. Iran, Iraq, Saudi Arabia, and Israel had the highest caseload at the end of October 18. Looking toward the future, Jordan, Iraq, and the United Arab Emirates have the fastest acceleration in new COVID-19 infections while Bahrain and Israel have the largest upwards jerk in infections, which can lead to explosive growth. Iran began the pandemic with explosive growth but during the last week of this study ending on October 18, Iran's acceleration rate has leveled off and its jerk has reversed lower; however, given the number of new cases and population size, the country could easily flare up in new outbreaks, especially considering the second wave of COVID-19 infections has just begun.

Limitation

Data are limited by granularity and collection method. Data were collected at the country level, which precludes local analysis of surveillance trends. Moreover, data collection mechanisms differ by country and may even differ by region within a given country. These different methods lead to week-end effects, missing data points, and other contamination.

Comparison With Prior Work

This study is part of a broader research program at Northwestern University Feinberg School of Medicine, *The Global SARS-CoV-2 Surveillance Project: Policy, Persistence, & Transmission*. This research program developed novel surveillance metrics to include rates of speed, acceleration, jerk, and 7-day persistence [3,36]. We have also derived surveillance metrics for all global regions.

Conclusion

Static and dynamic public health surveillance tools provide a more complete picture of pandemic progression across countries and regions. While static measures capture data at a given point in time, like infection rates and death rates, they are less successful at assessing population health over a period of weeks or months. By including speed, acceleration, jerk, and 7-day persistence, public health officials may design policies with an eye to the future.

MENA countries with the highest risk all shared a number of characteristics according to the surveillance data. There was a definite positive shift between October 5-11 and October 12-18. Iran, Iraq, Saudi Arabia, and Israel all demonstrated the highest numbers of cumulative infections, acceleration, jerk, and 7-day persistence rates. Looking ahead, policy makers in these countries and the region at large should be concerned about growth in the already substantial number of cases over the short term. Given the substantial 7-day persistence rates of Israel, Bahrain, and Lebanon, it is imperative that efforts be made to target super spreader events. Analysis of subsequent surveillance data using both static and dynamic tools can help confirm the efficaciousness of new policies.

Abstract

Background: China is at the forefront of global efforts to develop COVID-19 vaccines and has five fast-tracked candidates at the final-stage, large-scale human clinical trials testing phase. Vaccine-promoting policymaking for public engagement is a prerequisite for social mobilization. However, making an informed and judicious choice is a dilemma for the Chinese government in the vaccine promotion context.

Objective: In this study, public opinions in China were analyzed via dialogues on Chinese social media, based on which Chinese netizens' views on COVID-19 vaccines and vaccination were investigated. We also aimed to develop strategies for promoting vaccination programs in China based on an in-depth understanding of the challenges in risk communication and social mobilization.

Methods: We proposed a novel behavioral dynamics model, SRS/I (susceptible-reading-susceptible/immune), to analyze opinion transmission paradigms on Chinese social media. Coupled with a meta-analysis and natural language processing techniques, the emotion polarity of individual opinions was examined in their given context.

Results: We collected more than 1.75 million Weibo messages about COVID-19 vaccines from January to October 2020. According to the public opinion reproduction ratio (R_0), the dynamic propagation of those messages can be classified into three periods: the ferment period (R_{01}=1.1360), the revolution period (R_{02}=2.8278), and the transmission period (R_{03}=3.0729). Topics on COVID-19 vaccine acceptance in China include price and side effects. From September to October, Weibo users claimed that the vaccine was overpriced, making up 18.3% (n=899) of messages; 38.1% (n=81,909) of relevant topics on Weibo received likes. On the contrary, the number of messages that considered the vaccine to be reasonably priced was twice as high but received fewer likes, accounting for 25.0% (n=53,693). In addition, we obtained 441 (47.7%) positive and 295 (31.9%) negative Weibo messages about side effects. Interestingly, inactivated vaccines instigated more heated discussions than any other vaccine type. The discussions, forwards, comments, and likes associated with topics related to inactivated vaccines accounted for 53% (n=588), 42% (n=3072), 56% (n=3671), and 49% (n=17,940), respectively, of the total activity associated with the five types of vaccines in China.

Conclusions: Most Chinese netizens believe that the vaccine is less expensive than previously thought, while some claim they cannot afford it for their entire family. The findings demonstrate that Chinese individuals are inclined to be positive about side effects over time and are proud of China's involvement with vaccine development. Nevertheless, they have a collective misunderstanding about inactivated vaccines, insisting that inactivated vaccines are safer than other vaccines. Reflecting on netizens' collective responses, the unfolding determinants of COVID-19 vaccine acceptance provide illuminating benchmarks for vaccine-promoting policies.

Introduction

Background

Vaccines have been proven to be an extremely effective means of dealing with epidemics in the past [1]. However, over the past decades, the antivaccine or antivaccination movement has taken root in Europe and the United States [2,3]. The antivaccine movement, which encourages vaccine hesitancy, has emerged as a significant public health problem, topping the list of threats to global health [4]. For example, it fueled the contagious measles outbreak of 2019 [5,6]. In addition, antivaccination misinformation spreads more quickly than positive counterparts [7]. Immediately after declaring COVID-19 as a pandemic, numerous conspiracy theories were shared through social media [8-10]. In Pakistan, for example, two well-known political figures expressed anti–COVID-19 vaccine sentiments to the local community and further encouraged vaccine hesitancy [11]. Neil et al [12] proposed a heuristic map of COVID-19 vaccines' online contentions, which revealed a multisided landscape of unprecedented intricacies about vaccines. The reasons for vaccine refusal are complex and vary by geographical and sociocultural contexts.

Many studies have shown that even vaccinated individuals may have substantial doubts and concerns regarding vaccination [13-15]. Many experts believe that vaccination programs are threatened by growing concerns in the population regarding vaccines' safety and efficacy [16-18]. According to previous estimates, less than 5%-10% of individuals have strong antivaccination convictions [19]. However, a more significant proportion could be categorized as being vaccine hesitant [20]. Vaccine hesitancy, defined as individual-level reluctance to receive vaccines, may be fueled by a spectrum of held views regarding vaccination spanning from cautious acceptors to outright deniers [21-23]. Amin et al [24] proposed that values-based messages appeal to core morality, influencing individuals' attitudes on topics like vaccination. They showed via two correlational studies that harm and fairness are not significantly associated with vaccine hesitancy, but purity and liberty are. In addition, politics and public trust may affect public perceptions of vaccine risks. Larson [25] discusses the following aspects: some risks of vaccines, such as side effects, provoke anxiety, reluctance, and rejection of vaccination; when vaccines are regulated, and sometimes mandated, by the government, it is resisted by those who feel their freedom is being imposed upon. Those who do not trust the government sometimes extend their distrust to vaccines produced by pharmaceutical companies, which will generate profits and incite public concern about the motives of vaccine production. By examining the antivaccine situation in Texas, United States, Martin [26] also concluded that the antivaccine community, at large, believes that vaccines are a tool used for government control that makes big pharmaceutical companies wealthy and have side effects that can cause lasting damage. Among the barriers to universal vaccination, misinformation regarding the benefits, medicinal composition, and adverse effects of vaccination limits individuals' understanding and overall buy-in [27]. Vaccine safety concerns continue to be an essential driver of decreasing vaccine uptake in most contexts [28-30]. Several reports indicate that people's opinions of vaccination have a significant influence on a vaccine's development and marketing.

COVID-19 has been demonstrated to have high human-to-human transmissibility [31-33]. The ability of SARS-CoV-2 to infect people through asymptomatic carriers is difficult to detect, making the disease a confounding public health challenge [34-36]. Therefore, vaccine development studies have been carried out by the research teams of various companies and universities worldwide [37,38]. Among them, Chinese research on COVID-19 vaccines is a special case, which covers almost all types of vaccines. However, COVID-19 vaccine development has incited heated discussions [39]. Different countries have varying attitudes toward vaccine development. For example, the Japanese government is considering free COVID-19 vaccination for all residents when it becomes available [26]. In California, United States, some individuals carried placards with antivaccine slogans at rallies to protest against the lockdown. Subsequently, antivaccine movements have also taken place in London, United Kingdom, and other cities [40,41]. In China, although more than 90,000 families have been affected by the epidemic [42], no such movement has taken place. Yet, it does not mean that there is no contention about COVID-19 vaccines and vaccination. Hence, it is of great importance to uncover Chinese people's collective propensities in social dialogues and to aid authorities in making reasonable and informed decisions.

There will be considerable variation by country in terms of COVID-19 vaccine acceptance [43]. To this end, this country-specific study aims to explore the paradigm of public engagement about COVID-19 vaccination to develop practical strategies of preparedness in order to mitigate the pandemic in China. This study investigates the trending topics related to COVID-19 vaccines on Weibo, and obtains public opinions and propensities related to COVID-19 vaccines, such as vaccine price and side effects.

Study Objectives

We aim to examine what Chinese netizens are concerned about in terms of COVID-19 vaccines and vaccination by profiling pertinent topics on the microblogging platform Weibo. We took random samples of more than 10 million Weibo messages from January to October 2020 to address the following research issues: the affordability of the COVID-19 vaccine candidates; the efficacy of the COVID-19 vaccine candidates; and propensities concerning COVID-19 vaccination. We also aimed to unveil the underlying motives behind these public appeals and explore potential strategies of preparedness for health and risk communication.

Methods

Data Collection

Weibo is thought of as a natural experiment that profiles social responses to Chinese public health preparedness. As the leading Chinese social media characterized by heterogeneous communities, it is a crucial public opinion platform in China. As of December 2018, Weibo had 462 million active users per month, which has increased by more than 70 million for 3 consecutive years, and had 200 million active users with 130 million words posted per day [44]. Chinese netizens regard this platform as a preferred outlet for expressing their demands and appeals [45]. More and more messages were posted, read, forwarded, and commented on than any other platform. Clusters of messages can be found on different topics marked by the hashtag symbol (#), which groups similar content. By organizing the same information into a topic, users can quickly find what they want to understand or express, thus resulting in large-scale participation. This mechanism is also a routine way of compiling comprehensive reflections of peoples' opinions.

In this study, we retrieved more than 1.75 million Weibo messages with approximately 21.17 billion links posted worldwide from January to October 2020. In addition, we classified the reliability of the messages being circulated. The messages were in 108 languages from around the world, but because of our data filtering and enrichment procedures, the largest fraction of analyzed messages point to Chinese-language sources (Simplified Chinese and Traditional Chinese). Additionally, for each message, verification was performed by Sina Corporation to clearly identify accounts of public interest and certify their authenticity, according to China's real-name verification policy for the use of microblogs. The findings reported in this study mainly captured the social behaviors of the Chinese-speaking portion of Weibo users, including domestic Chinese and those living abroad.

We utilized natural language processing to screen all Weibo topics about COVID-19 vaccines from the end of January to the beginning of October and obtained 989 topics. Of those, the typical, pertinent, and clustered topics are highlighted in Table 1.

Table 1. Topics related to the COVID-19 vaccine, with metadata on topic name, reading quantity, and date.

Topic name	Readers (million), n	Date
#COVID-19 vaccine could be available in early 2021#	820	February 9
#Wei Chen’s Team conducts the Phase I clinical trial of COVID-19 vaccine#	243.8	March 20
#When will the COVID-19 vaccine be available#	50.9	April 14
#China’s COVID-19 vaccine has entered Phase II clinical trial#	33	April 14
#The first participant of the COVID-19 vaccine has not yet shown adverse reactions#	21	April 14
#The world’s first COVID-19 inactivated vaccine#	41.2	April 19
#What is the COVID-19 inactivated vaccine#	25.2	April 21
#Chinese first COVID-19 inactivated vaccine entered Phase II clinical trial#	4566.4	April 24
#Phase I clinical trial of the first Chinese COVID-19 vaccine has good results#	934.5	May 22
#The safety and effectiveness of the COVID-19 inactivated vaccine have been verified#	76.9	May 29
#More than 2000 people received the COVID-19 inactivated vaccine injection#	479.6	May 30
#COVID-19 inactivated vaccine is expected to be available at the end of this year or early next year#	162.1	May 30
#China developed another kind of COVID-19 inactivated vaccine#	2000	June 9
#World’s first COVID-19 inactivated vaccine participant produces antibodies#	39.4	June 17
#Chinese COVID-19 vaccine will be launched as early as 2021#	37.9	June 18
#CNBG’s COVID-19 inactivated vaccine is not affected by virus mutation#	1276.2	June 19

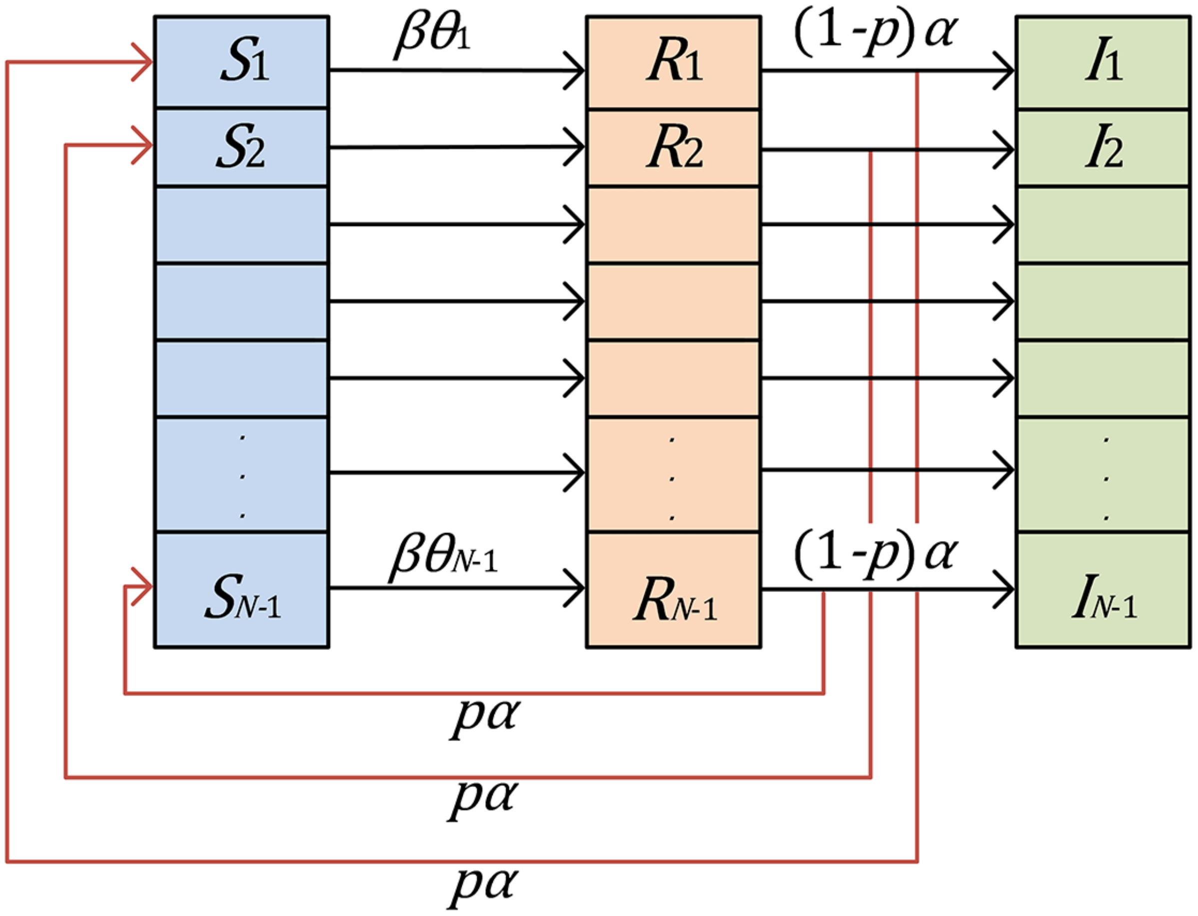
#COVID-19 vaccine may be available at the end of the year#	345.4	July 22
#World first officially releases Phase II clinical data of COVID-19#	238.3	July 23
#The price of the COVID-19 vaccine will not exceed $40#	888.9	July 29
#Russian COVID-19 vaccine will be free of charge#	20,000	August 1
#The first COVID-19 inactivated vaccine workshop passed safety inspection#	44.9	August 5
#Beijing COVID-19 inactivated vaccine production workshop can be put into production at any time#	45.5	August 5
#Half of the COVID-19 vaccines in Phase III clinical trials come from China#	150.6	August 7
#Gates required the COVID-19 vaccine to be priced below $3#	963.7	August 8
#Research Institute refutes rumors of COVID-19 vaccine 498 yuan an injection#	127.4	August 13
#COVID-19 vaccine not yet be available#	3	August 13
#COVID-19 inactivated vaccine two injections less than one thousand yuan#	3081.6	August 18
#Domestic COVID-19 inactivated vaccine is expected to be available at the end of December#	131.6	August 18
#Russian second COVID-19 vaccine starts Phase 2 clinical trial#	70.1	August 18
#COVID-19 vaccine two injections 1000 yuan is too expensive#	24.2	August 19
#The price of COVID-19 vaccine can only be based on cost#	17,000	August 23
#How to price the COVID-19 vaccine#	254.2	August 23
#CNBG declared COVID-19 vaccine is likely to be available at the end of this year#	354.6	August 23
#National Health Commission claimed that the price of COVID-19 vaccine was lower than two injections of 1,000 yuan#	65.9	August 23
#Domestic COVID-19 inactivated vaccine first appears#	19,000	September 5
#Domestic COVID-19 inactivated vaccine appears in CIFTIS#	5766.4	September 6

Topic name	Readers (million), n	Date
#The COVID-19 vaccine will be priced based on factors such as consumers’ ability to pay#	134.5	September 7
#Domestic COVID-19 inactivated vaccine inoculates hundreds of thousands of people with zero infection#	2102.4	September 11
#Oxford vaccine volunteers have side effects#	769.1	September 9
#The COVID-19 vaccine produced by Pfizer in America has side effects#	17,000	September 16
#The COVID-19 inactivated vaccine is expected to be available at the end of the year#	4319.2	September 8
#The COVID-19 vaccine price in China will be within the scope of public acceptance#	11,000	September 2
#The COVID-19 inactivated vaccine is only one kilometer away from success#	23,000	September 2
#Two injections 600 yuan for domestic COVID-19 vaccine #	7737	September 3
#The price of domestic COVID-19 vaccine is released#	4413.4	September 2
#Four COVID-19 vaccines in China enter Phase III clinical trials#	428.6	September 2
#China formally joins COVAX#	23,000	October 9

Behavioral Dynamics Model

On social media, the propagation and inline influence of various topics are involved. To track the derivative development of topics related to COVID-19 vaccines in China, we propose the dynamics model SRS/I (susceptible-reading-susceptible / immune) based on a complex network to investigate the landscape of public opinion transmission (Figure 1) [46]. The SRS/I model promises to profile the collective propensities of different populations in terms of different topics across various times on social media.

Figure 1. Inspired by infectious disease models, a network model diagram of information dissemination is proposed to simulate the transmission of information among the susceptible state (S), the reading state (R), and the immunized state (I).



We considered a reading population of Weibo users for topics about the vaccine, stratified in terms of three distinct stages: the susceptible state (S), in which users are unaware of but susceptible to the information about the event; the reading state

(R), in which users have actively read information to influence other users; and the immunized state (I), in which users have read the information and can trigger a new round of reading activities on the same topic. We obtain the following SRS/I reading dynamics model of vaccines topics:

where β refers to the average exposure rate of a susceptible user who can read topics about the vaccine. Since an active reading user will contact an average number of βN users per unit time and the probability of a contacted user being a susceptible user is $S(t)/N$, the number of new reading users is $\beta\langle k\rangle N(S(t)/NR(t)) = \beta\langle k\rangle S(t)R(t)$. Users can become inactive to the same topic with an average inactive rate α, with $1/\alpha$ being the average duration where an R-user remains active in reading. The average number of inactive users will be $\alpha R(t)$ per unit time, among which $p\alpha R(t)$ will re-enter the susceptible state where exposure to another Weibo message within the same topic can initiate a new round of reading, and $(1-p)\alpha R(t)$ will proceed to the immunized state directly, in which p reflect the re-entering probability for a reading user who can trigger a new round of reading activities on the same topic. θ is a parameter related to the topics' dissemination network of topics pertaining to vaccines. In this paper, we only considered the average degree $\langle k\rangle$.

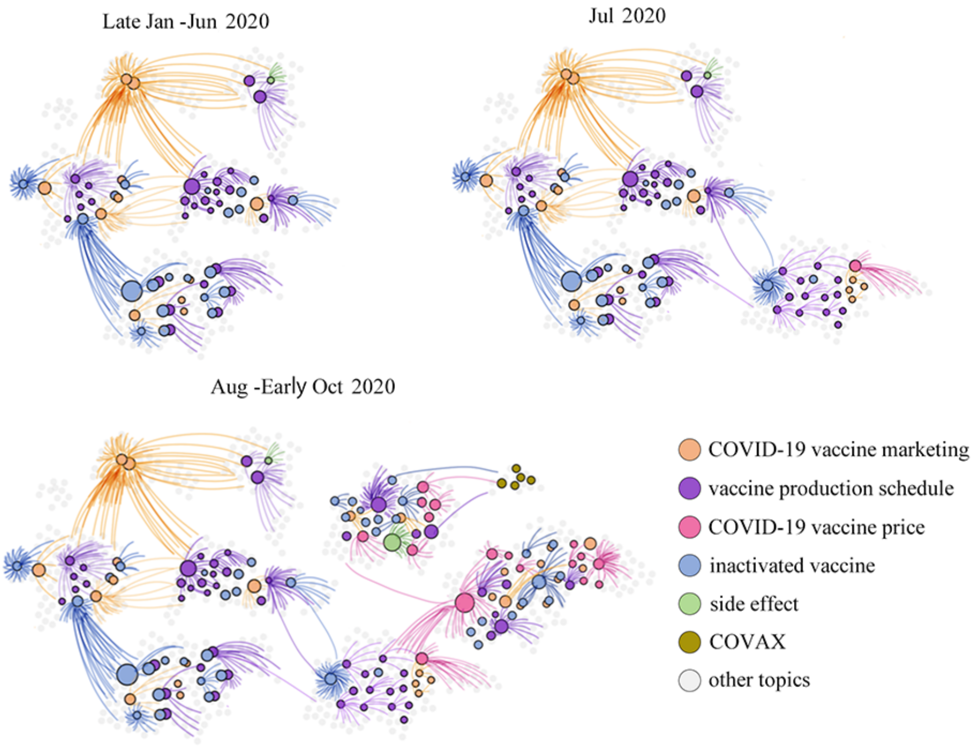
We extended the basic R_0 [47] of epidemiology to the field of information transmission. In our SRS/I dynamics model, we defined the public opinion R_0 as a measure of the potential impacts of topics in the initial propagation stage, which is given by $R'(0) = (\beta\langle k\rangle S_0 - \alpha)R(0)$, and the outbreak will never grow since $R'(0) = (\beta\langle k\rangle S_0 - \alpha)R(0) < 0$ due to the decrease of S. Then we deduce:

To further explore Chinese opinion about COVID-19 vaccines, we collected metadata, which includes the names and reading quantity of related topics from the end of January to the beginning of October, through an application programming interface provided by Weibo. Table 1 shows several specific topics related to COVID-19 vaccines with their posted date and reading quantity. The date can aid in identifying the continuity of topics over time, while the reading quantity could reflect the collective interest of the population.

The Landscape of Public Opinion Transmission

After numerical fitting and calculation, according to the basic R_0, we found that a paradigm shift emerged in July 2020. The R_0 value becomes large at this time, implying that Chinese netizens had become more interested in vaccines. Therefore, we divided the transmission process of vaccine-related topics into three periods: ferment period (stage 1, the end of January to June), evolution period (stage 2, July), and transmission period (stage 3, August to the beginning of October) (Figure 2). Their public opinion reproduction ratio is specifically expressed as R_{01}, R_{02}, and R_{03}, where R_{01}=1.1360, R_{02}=2.8278, and R_{03}=3.0729. It is evident that R_{03} is larger than R_{01} and R_{02} This is consistent with the fact that the topics in stage 3 have been disseminated more widely than those in stages 1 and 2. In stage 3, two sensitive topics came to our attention: vaccines' price and vaccines' side effects. Topics about vaccines' side effects (labels 44 and 45 in the Multimedia Appendix 1) reached more than 17,000,000,000 readers while topics about vaccine pricing (labels 24 and 25 in the Multimedia Appendix 1) have emerged in an endless stream and have been widely read. So, they incite continuous attention from Chinese netizens.

Figure 2. The landscape of public opinion transmission on vaccine-related topics. The colored dots represent the seven main topics. The lines between them represent mutual influence, and the density of the lines represents the degree of influence.



As shown in Figure 2, we obtained the metadata of 989 topics on Weibo. We considered the duration and content of topics that Chinese people are interested in. Topics were divided into seven categories based on content. We found topics connected with the same specific event are inline as time goes by. Namely, one topic, whether it has a strong positive or negative sentiment or is just a general announcement, may affect the sensitivity of Chinese netizens to the COVID-19 vaccine, thereby involving the population to facilitate the creation of new topics or a derivation of old ones.

Price Acceptance

We collected all messages and their likes on all price-related topics mentioned above. We set keywords and used the following formula to calculate the price tendency. After tokenization and the word extraction process, we obtain M words, which are synonyms for “expensive,” expressed as (E_1, E_2,…,E_M). By querying in the dictionary (Multimedia Appendix 2), we denoted the weight of the i_{th} word as a_i. Hence, the score of “expensive” is computed as:

Similarly, we obtained N words, synonyms for “cheap,” expressed as (C_1, C_2,…,C_N). After querying in the dictionary, the weight of the i_{th} word a_i was obtained. The score of “cheap” is expressed as:

The final expression of the price tendency score can be calculated as:

When $S>0$, the population regards the price as high, and when $S<0$, the collective attitudes toward price are acceptable.

Sentiment Polarity of Side Effects

We analyze the sentiment of 925 messages on topics related to side effects based on the general Chinese lexicon HowNet [48]. For the text sequence $x=\{w_1,\dots\dots,w_k,\dots\dots,w_K\}$, w_k indicates that the k-th word in sequence x, and K is the total word number for the sequence x. Then we obtained the corresponding sentimental values $Sen_x=\{S_U(w_1),\dots\dots, S_U(w_k),\dots\dots, S_U(w_K)\}$ of each word in x by sentiment lexicon rescores to synthesize the final sentence sentiment value S_x:

where $S_U(w_k)$ is the sentiment value for the k-th word in sequence x calculated by the sentiment lexicon we used, and S_x is the sentiment value of the sequence x. We turned S_x into polarity T_x as follows to easily judge the performance of our sentiment classification task:

where we count the sum of T_x of each case, denoted by NP, NN, and ZN, respectively. We further calculated the proportion of each sentiment tendency in all corpora:

where N is the total number of corpora, $pos(\%)$ and $neg(\%)$ are represented as positive and negative sentiment proportions, respectively.

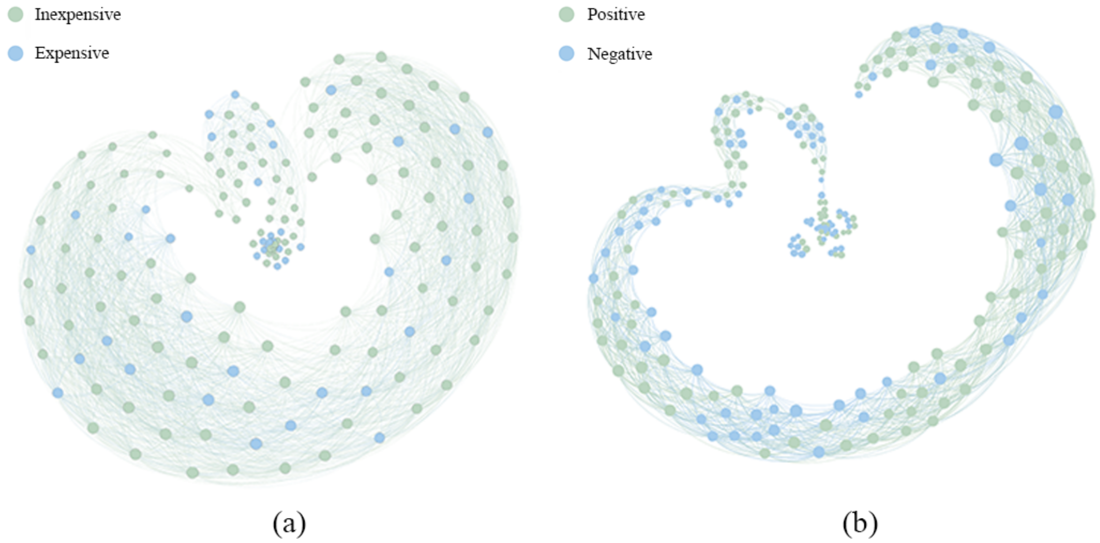
In the sampling inspection, due to the Chinese language's diversity, we validated the results of the sentiment lexicon–based method. We strictly followed the requirements of the double-blind experiment and invited three groups (A, B, and C) who had been trained to classify these Weibo messages by emotion. When the emotion judged by groups A and B was consistent, we took it as the correct result. When the judgment between groups A and B was inconsistent, group C made the final judgment. We marked positive Weibo messages as 1, and negative ones as –1, using the equations 10 and 11 to calculate manual labeling.

Results

Weibo's Attitude Influence Map

In the case of affordability and efficacy, we chose two topics—#The COVID-19 vaccine price can only be based on cost# (n=169 messages) and #The COVID-19 vaccine produced by Pfizer in America has side effects# (n=220 messages). We utilized the SRS/I model to draw the messages' attitude influence map (Figure 3). The colors represent the different attitudes. A topic is composed of individual Weibo messages, which have a content connection and time-sequence relationship. At first, the first Weibo message had the ability to promote subsequent publishing and dissemination. In Figure 3, we used points to represent Weibo messages, which appear clockwise in chronological order. In terms of price (Figure 3A), most people thought the pricing of vaccines was inexpensive. Nevertheless, it is worth noting that many still feel the pricing to be expensive, as seen by Weibo messages posted at various time periods. In terms of side effects (Figure 3B), positive Weibo messages dominated initially, but over time, positive and negative views alternated in being the majority, and the two views clashed during this time. Overall, positive dominates.

Figure 3. Weibo's attitude contagion map: (A) price and (B) side effects. Points represent Weibo messages that appear in the figure in clockwise order, ending with the point at the center of the figure.

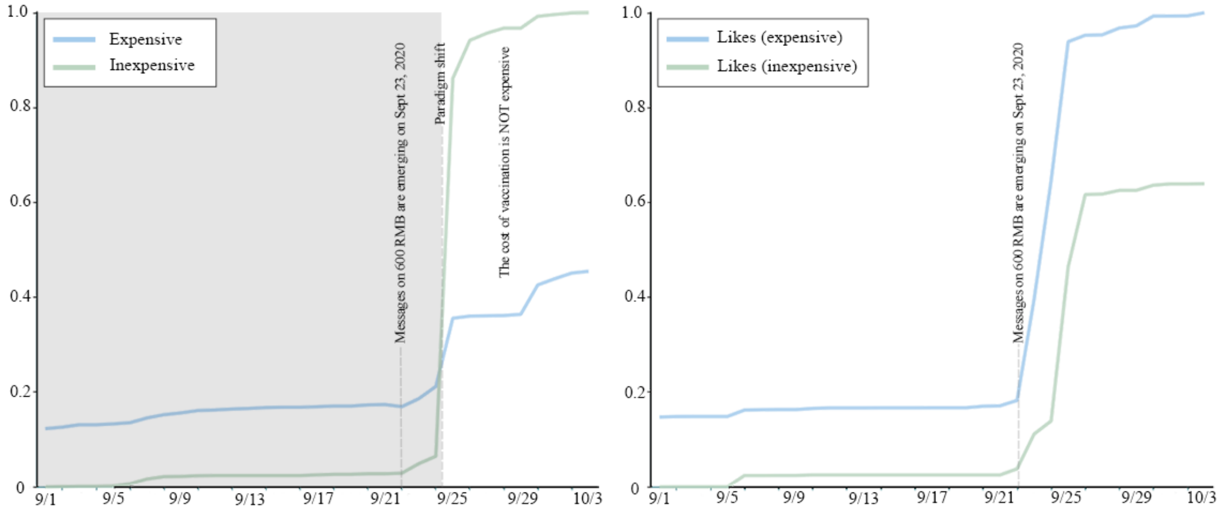


Affordability: The Price of Vaccines

We selected metadata during the period when the paradigm of price tendency dramatically changed and obtained 4925 related messages on Weibo. The final result is normalized (Figure 4).

Figure 4A shows that the collective attitudes toward COVID-19 vaccine pricing suddenly changed after September 23 from expensive to inexpensive. However, the population's likes displayed the opposite tendency, as shown in Figure 4B.

Figure 4. The paradigm shift in price tendency.



(a) (b)

On Weibo, the topic of COVID-19 vaccine pricing emerged in July 2020 and attracted hundreds of millions of onlookers in China. However, the number of messages that specifically address pricing is not very large.

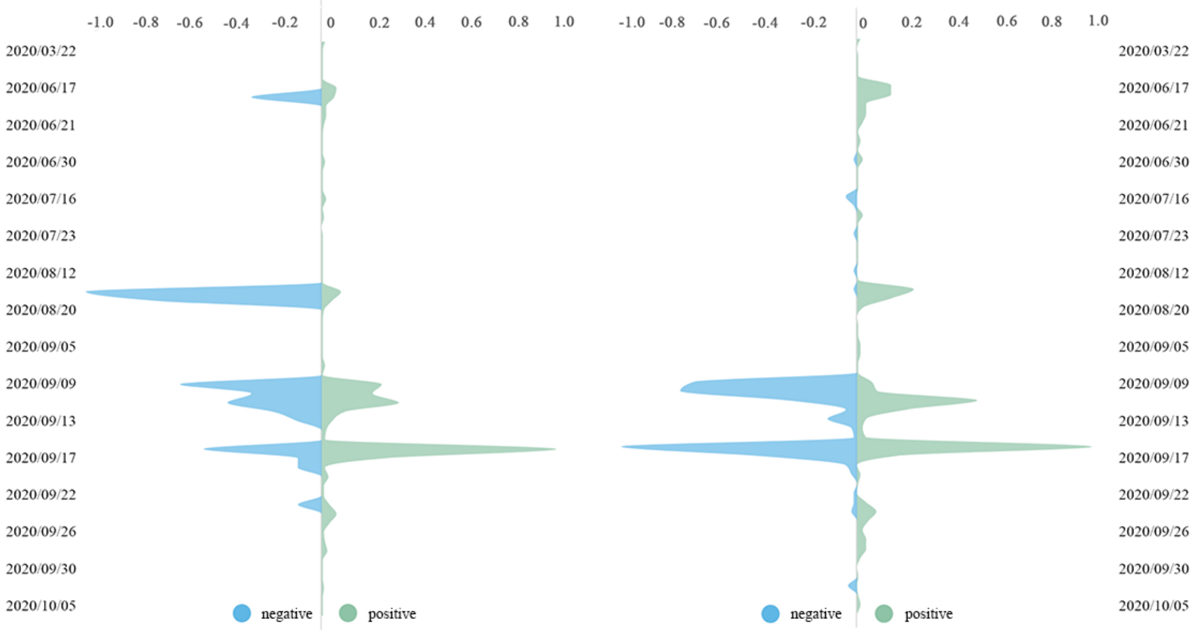
In August, the Chinese government claimed that the Chinese vaccine price would not exceed 1000 RMB (US $154). Therefore, the expected price was about 1000 RMB, and most people thought it was too expensive. Due to the one-child policy, young people may need to pay for their extended family. Although they believe that the cost of production is high, the cost of vaccination is not a small expenditure for ordinary families. After the Chinese COVID-19 vaccine fee was announced on September 23—600 RMB (US $90) for 2 shots—the number of relevant messages began to increase significantly (label 49 in Multimedia Appendix 1). As shown in Figure 4A, it is worth noting that the public had their own speculations about the prices of Chinese vaccines before this announcement. The public's attitudes reversed after this tipping point, and most people found the official price to be acceptable. Most people clicked "like" or posted Weibo messages to endorse previous views on Weibo rather than posting similar messages themselves. As shown in Figure 4B, the collective emotion polarity did not reverse with the increase in likes.

Certainly, the official price is still too expensive for some netizens. Comparatively speaking, citizens in developed countries have their own universal health insurance, or some countries promise to bear the costs of vaccinations. As a case in point, the Japanese and Russian governments have promised to pay to vaccinate its citizens (labels 25 and 52 in the Multimedia Appendix 1, respectively). Therefore, some Chinese netizens naturally hope that China will follow suit. The patterns in Figure 3A also confirm the above findings.

Efficacy: Side Effects of Vaccines

We plotted the lexicon-based sentiment classification results and the manually labeled sentiment classification method in Figure 5. Generally speaking, Chinese people are optimistic about vaccines. Interestingly, Chinese netizens seem to be accustomed to expressing their positive opinions in diverse ways. These utterances may undermine the accuracy rate of lexicon-based sentiment analysis, especially for negative sentiments (Figure 5). Potential uncertainties may cause a miscalculation of the accuracy rate of emotion-cause pair extraction and identification of ironic contexts. For example, comparing Figure 5A with Figure 5B, Chinese netizens tend to express their understanding of vaccine side effects using irony. In one Weibo post, for instance, a user wrote, "I think most people cannot even understand the title," while another wrote, "if you have a little common sense in pharmacology… Is it weird to have an adverse event (AE)? How can it be on the hot search?" These Weibo messages' authors believe that it is common sense for drugs to have side effects. They have a positive attitude toward side effects but scoff at those who have opposing opinions. However, these Weibo messages were judged neutral by the machine. There were also some Weibo messages judged to be negative, although their attitude toward side effects is positive. For example, one message read, "Even taking vitamins will increase the liver's metabolic burden. All drugs are somewhat toxic. If a drug has no side effects, it must be fake." They know the potential danger of side effects but think it is within the acceptable range. Thus, their attitude toward vaccines' side effects is positive. Due to irony, the results of the lexicon-based sentiment classification (Figure 5A) are inaccurate. Therefore, we only used the results obtained by manual labeling to determine Chinese netizens' attitudes toward side effects.

Figure 5. The collective attitudes toward side effects: (A) the results of the lexicon-based method and (B) the final results coupled with manual labeling.

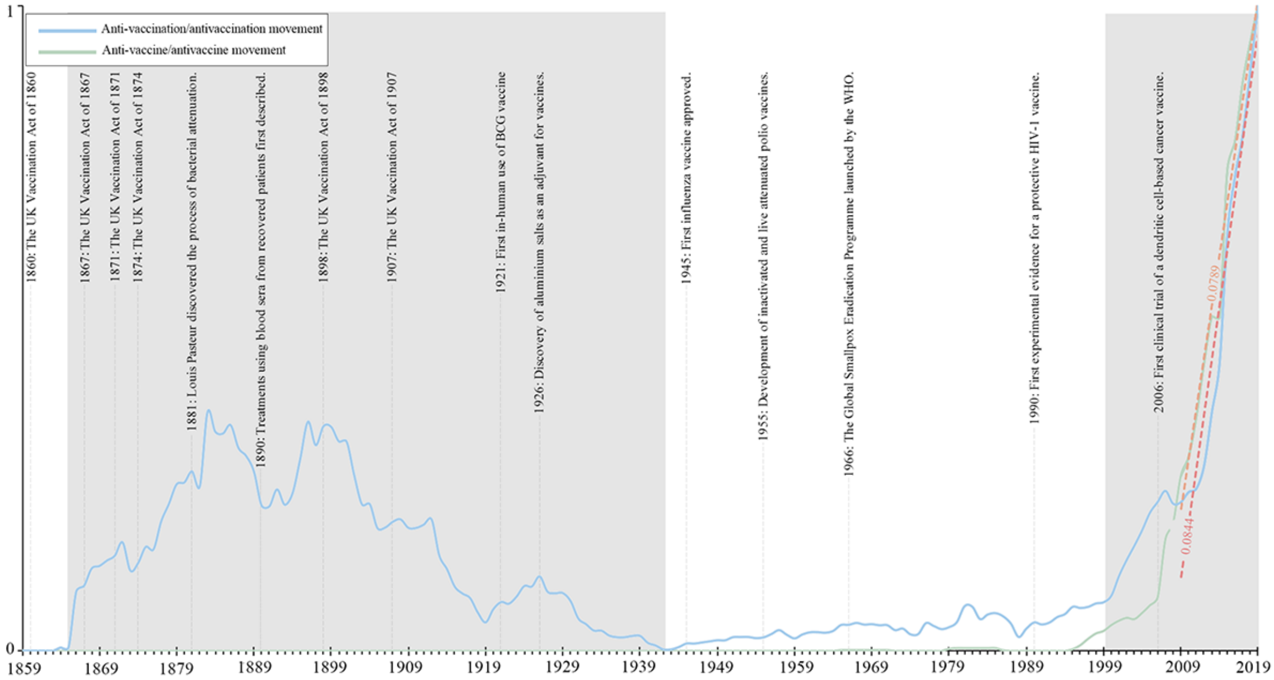


(a) (b)

Figure 5B shows four significant patterns in June, August, and September. The trigger events were #Chinese inactivated vaccine's Phase I/II trial was complete, and the participants had no adverse reactions# (June 16), #The chairman of Sinopharm said he was vaccinated and no adverse reactions# (August 18), #Oxford vaccine volunteers experienced adverse reactions# (September 9), and #The COVID-19 vaccine produced by Pfizer in America has side effects# (September 16), respectively. The topics were more active (ie, more messages posted) in September. From the perspective of emotion polarity, the messages' polarity about the side effects of COVID-19 vaccines can directly and positively affect people's emotion polarity. Over time, positive messages and negative messages became dominant in an alternating manner. In the end, Chinese views on side effects tended to be positive. The possible reason for this finding is that the positive emotions of prevailed messages on side effects result in herd behavior of followers [49]. After such information cascades, the population gradually accepted the existence of side effects and then reached a consensus (Figure 5B). Figure 3B shows similar patterns.

On the contrary, as *Nature News* reported, in high-income countries such as Europe, citizens' concerns no longer focus on the price but on safety [49]. Many people believe that vaccines will increase the immune system's burden, assuming that it exposes themselves to danger. In addition, a variety of other exaggerated rumors have spread on major social media outlets. According to Google Books Ngram Corpus (Figure 6), the co-occurrence of antivaccine and antivaccination movements has shown a clear upward trend in the past decades (the fitted slope of the antivaccination movement is 0.0844 and the antivaccine movement is 0.0789) [50]. The historical events that may have impacted the antivaccine and antivaccination movements in different eras are marked in Figure 6. It also shows that the concern for the safety of early vaccines has resulted in widespread protests. With the development of medical technology, vaccines have gradually become safer, and protests have decreased. Part of the reason for burgeoning movements in recent decades is due to ideological reasons [51]. However, as an exception, China has not experienced such scenarios. In view of this, in China, it is particularly important to collect public opinions via social media and improve policies in a timely manner.

Figure 6. Google Books Ngram Corpus facsimiles of word frequencies for "anti-vaccination/antivaccination movement" and "anti-vaccine/antivaccine movement" in the English corpus from 1859 to 2019. BCG: Bacillus Calmette–Guérin; WHO: World Health Organization.



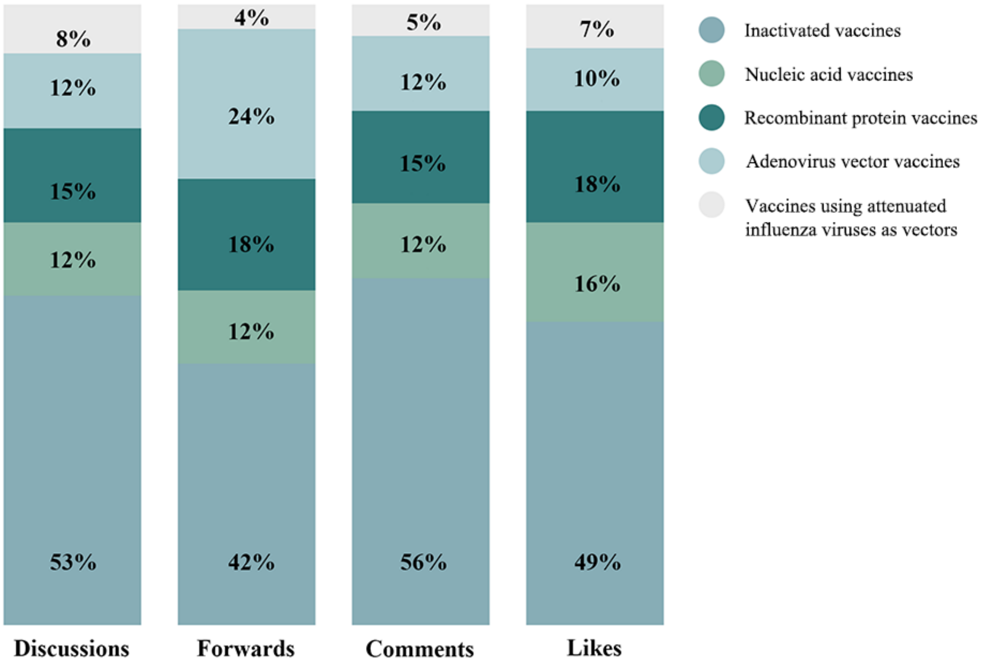
Hesitancy: Type of Vaccines

Vaccine hesitancy about COVID-19 vaccines is linked to populations who are reluctant or refuse to be vaccinated despite the availability of vaccination services [52]. The beliefs surrounding vaccine hesitancy are dynamic, complex, and context-specific, varying across time, place, and vaccine types, as well as complacency, convenience, and confidence. China is forging ahead in the race to develop COVID-19 vaccine candidates using five potential development routines: inactivated vaccines, adenovirus vector vaccines, vaccines using attenuated influenza viruses as vectors, recombinant protein vaccines, and nucleic acid vaccines (including RNA [ribonucleic acid] vaccines and DNA vaccines) [53]. China's National Medical Products Administration projected the country's production capacity of COVID-19 vaccines would reach 610 million doses annually by the end of 2020. Of these, the licensed vaccines for limited rollout would be inactivated vaccines [54].

Figure 7 shows the proportion of these five vaccines as mentioned by Chinese netizens. We have selected four dimensions—discussions, forwards, comments, and likes—to show the degree of attention on the different vaccines. Evidently, inactivated vaccines had substantially more discussions, forwards, comments, and likes than the other four vaccine types.

Compared with the other vaccines, inactivated vaccines are more acceptable to the public in China. The reason may be that the word "inactivated" in Chinese means "being killed" or "dead"; this gives people a sense of more security. For the same reason, the vaccines using attenuated influenza viruses as vectors, which means "alive influenza virus," has been rarely mentioned by netizens. It accounts for 8% (87/1117) of mentions (Figure 7 and Multimedia Appendix 3).

Figure 7. The distribution of netizens' attention to five different types of China-made vaccines.



Discussion

Principal Findings

Using rich random-sampling metadata of Weibo posts (more than 1.75 million messages with approximately 21.17 billion links), we conducted a country-specific study of real-time public awareness and behavioral responses to COVID-19 vaccines and vaccination from January to October 2020 in China. By studying the collective transmission behavior of Chinese netizens (domestic Chinese and those living abroad), this research revealed the paradigm shifts in public demand and events instigating public opinion in the context of the promotion of COVID-19 vaccination.

Beyond Affordability

Our findings strongly suggest that the Chinese public is divided in terms of vaccination prices and has differing expectations. Supporters accepted the current official price, whereas opponents claimed that it is unaffordable for their extended family. Arguably, the majority of people think that the price is lower than previously thought. If the Chinese government promises to pay for vaccination, taking 600 RMB per person as an example, the country would bear a financial burden of at least 840 billion RMB, considering its large population size. Therefore, introducing a policy for free COVID-19 vaccination is an extremely difficult decision for the Chinese government to make. If the government simply and directly included COVID-19 vaccines in medical insurance plans, it would impose a financial burden on hospitals, and the costs would eventually pass on to patients [55]. If commercial insurance is subsidized, another problem will arise: Chinese families will tend to insure children, who have a low risk of COVID-19, rather than high-risk elderly people [56,57].

Concerns Raised Over Efficacy

Our study is characterized by the striking feature that people's concerns about side effects tend to be positive over time. News of fast-tracked, China-made vaccine candidates are encouraging and helpful, but scientists urge caution [58]. Admittedly, the volunteers who received either the trial vaccine or placebo were low-risk, healthy adults rather than high-risk populations (eg, obese patients [59,60], patients with autoinflammatory syndrome [61], etc). Many scientists hold that there is uncertainty about the vaccine candidates' true efficacy when they are extended to the general populations [62]. More observations are needed to test the effectiveness of the vaccine [63,64]. On the contrary, the results of prevailing messages pinpoint that most Chinese people would accept the marginal risks (ie, side effects) with much confidence in the forthcoming vaccines.

Cognitive Dissonance Debunked

The literal meaning of the Chinese name for inactivated vaccines may provide a false sense of security. According to our survey, most Chinese people reached a consensus on the safety of inactivated vaccines due to cognitive dissonance. By contrast, people's expectations for inactivated vaccines were higher than other types of vaccines. There is no scientific evidence supporting the safety of inactivated vaccines compared to the other types. Furthermore, even when the vaccine is proven to be safe and effective, its acceptance will vary by group [65]. The World Health Organization has listed vaccine hesitancy as one of the top 10 threats to global health [66,67]. It is usually caused by the association of moral values in families [24,68], although this is unnecessary [69]. Nevertheless, the biggest problem in China is cognitive dissonance. Being echoed by daily communications, this finding indicates that this false cognitive predisposition may reinforce the tendency to vaccinate using inactivated vaccines and discourage vaccination via other types. Even worse, as vaccines lose their competitive advantages, people may not choose the most suitable one or even lose their right to choose. As rare events often attack the safety of vaccines [70], dissonance can lead to collective misbehavior.

Limitations

In this study, we retrieved more than 1.75 million Weibo messages in 108 languages; however, only messages in Simplified Chinese and Traditional Chinese were further investigated. These messages may come from domestic Chinese, those living abroad, or even foreign netizens living in China. Therefore, the findings reported in this study reflect COVID-19 vaccine acceptance in the Chinese-speaking population. However, each netizen account is authenticated according to the real-name verification policy of China, and the authenticity of the message can be guaranteed as they almost always come from real people rather than bots. With this in mind, this limitation does not undermine the significance of our findings.

The landscape of public opinion transmission is still ever-changing, especially in terms of price, side effects, etc. As the three major topics are still in the developing stage, a large number of messages and interactions showed up after study completion. However, the paradigm shifts of all the pertinent topics discussed here have been observed. Therefore, this limitation should not undermine the significance of the results either.

In addition, according to the 46th Statistical Report on Internet Development in China released by the China Internet Network Information Center in September 2020 [71] (Multimedia Appendix 4), only 10.3% of Chinese netizens are over 60 years of age. Therefore, to overcome the undersampling of the elderly population in this survey, the determinants of COVID-19 vaccine acceptance among older adults need to be further investigated [43].

Conclusions

At this critical moment in China, articulating the dynamic social paradigms of public engagement for COVID-19 vaccination is paramount for examining the practical strategies of social mobilization, wherein one sheds light on the other's significance. We scrutinized collective responses on COVID-19 vaccines and pertinent discourses in sociocultural paradigms to uncover collective propensities and consequences.

As an integral component of preparedness, the contextualized results reported in this study promise to provide illuminating benchmarks to bridge the gaps of health and risk communications. In China, the landscape of public opinion transmission on Chinese social media is unique, featuring a real-name verification policy. Therefore, the online collective propensities on COVID-19 vaccines and vaccination could resonantly echo daily responses in the real world, including those from domestic Chinese and those living abroad. Although there is no need for explicit antivaccine or antivaccination movements, the implicit channel of online public appeals is more vital than ever for improving policies.

The paradigms we identified to be the determinants of COVID-19 vaccine acceptance (eg, public appeals on affordability, efficacy, and preferences) could reframe a heuristic framework for extensive discussions, especially on vaccine-promoting policies in China. Reflecting on the unfolding findings, evidence communication is a heuristic way to nurture trustworthiness [72]. For instance, the government could consider using health insurance to balance state finances with individual expenditure. Making vaccine clinical trial data open and transparent is an effective way to assuage public skepticism. To eliminate strongly held but flawed cognitive predispositions, the government needs to increase the popularization of public science to communicate the side effects of drugs and strengthen publicity for all kinds of vaccines. Moreover, previous studies have indicated that once the vaccines are available, distributing them may become problematic [73-75]. The production capacity of vaccines has also been questioned by scholars. The impending worry is that new rounds of antivaccine and antivaccination movements will sprung up in a backlash of populism [58] and further undermine global efforts to curb the COVID-19 pandemic. Some scholars have turned their attention to disadvantaged groups and believe that the ethical framework needs to be improved to protect these groups' rights and interests during COVID-19 vaccination [75]. Arguably, affordable and effective vaccines offer hope for ending the pandemic, and open-minded and iterative policies fuel public engagement against the pandemic.

Abstract

Background: China was the first country in the world to experience a large-scale COVID-19 outbreak. The rapid spread of the disease and enforcement of public health measures has caused distress among vulnerable populations such as pregnant women. With a limited understanding of the novel, emerging infectious disease, pregnant women have sought ways to access timely and trusted health care information. The mental health status of pregnant women during this public health emergency, as well as how they responded to the situation and where and how they obtained antenatal care information, remain to be understood.

Objective: This study aimed to evaluate the mental health status of pregnant women during the COVID-19 epidemic in China by measuring their perceived stress, anxiety, and depression levels; explore the approaches used by them to access antenatal health care information; and determine their associations with maternal mental health status.

Methods: We conducted a web-based, cross-sectional survey to assess the mental health status of Chinese pregnant women by using the validated, Chinese version of Perceived Stress Scale, Self-Rating Anxiety Scale, and Edinburgh Depression Scale. We also collected information on the various approaches these women used to access antenatal care information during the early stage of the COVID-19 epidemic, from February 5 to 28, 2020.

Results: A total of 1873 pregnant women from 22 provinces or regions of China participated in the survey. The prevalence of perceived stress, anxiety, and depression among these participants was 89.1% (1668/1873; 95% CI 87.6%, 90.4%), 18.1% (339/1873; 95% CI 16.4%, 19.9%), and 45.9% (859/1873; 95% CI 43.6%, 48.1%), respectively. Hospitals' official accounts on the Chinese social media platforms WeChat and Weibo were the most popular channels among these pregnant women to obtain antenatal care information during the COVID-19 outbreak. Access to antenatal care information via the hospitals' official social media accounts was found to be associated with a significantly lower risk of perceived stress (adjusted odds ratio [aOR] 0.46, 95% CI 0.30-0.72; *P*=.001), anxiety (aOR 0.53, 95% CI 0.41-0.68; *P*<.001), and depression (aOR 0.73, 95% CI 0.59-0.91; *P*=.005). Access to health care information via hospital hotlines or SMS was found to be significantly associated with a lower risk of anxiety only (OR 0.77, 95% CI 0.60-0.98; *P*=.04).

Conclusions: During the COVID-19 outbreak in China, pregnant women experienced high levels of perceived stress, anxiety, and depression. During such public health emergencies, mental health care services should be strengthened to reassure and support pregnant women. Specific information targeted at pregnant women, including information on how to cope in an emergency or major disease outbreak, developed and disseminated by health care institutions via social media platforms could be an effective way to mitigate mental health challenges and ensure epidemic preparedness and response in the future.

Introduction

COVID-19 first emerged in Wuhan city in China in December 2019 [1,2]. Soon after, the Chinese government initiated the level-one (ie, the highest level) response to major public health emergencies [3], and the World Health Organization declared the COVID-19 outbreak as a Public Health Emergency of International Concern on January 30, 2020. By February 29, 2020, the number of confirmed COVID-19 cases in China reached over 79,000, with 2800 deaths reported and 20% of the cases classified as severe [4]. March onward, the COVID-19 outbreak spread to almost all nations worldwide and evolved into a full-blown pandemic [5]. By the end of August 2020, more than 28 million confirmed COVID-19 cases and over 900,000 deaths had been reported worldwide [6]. The Chinese government implemented timely measures, including city lockdown, self-quarantine, and social distancing across the nation to contain the transmission of COVID-19. People were advised to stay at home and avoid going to public places and social gatherings [7]. The rapid spread of the epidemic and the consequent enforcement of public health measures had unavoidably raised fear and panic reaction among the public [8-10].

Pregnant women and their unborn children are especially vulnerable to major epidemics or natural disasters [11,12]. During the early stage of the COVID-19 epidemic in China, with limited information and understanding about the new emerging infectious disease, pregnant women looked for different ways to access timely and trusted information regarding the causes, possible routes of transmission, prevention, and self-protection approaches to protect themselves and their unborn children [13]. Given the strict public health emergency measures such as travel restriction and social distancing, pregnant women had been isolated from their professional and social support, including hospitals that provided routine antenatal care services. Such interrupted contact with health institutions could exacerbate uncertainty among these women about service provision and their own health status. Routine maternal health services have often been affected during major infectious disease outbreaks in the past. For example, during the 2003 SARS outbreak, all antenatal services in Hong Kong, China, which were considered nonessential were suspended, and women were discharged as early as possible after childbirth [14]. Since the announcement of the level-one response to major public health emergencies was made in China in late January 2020 for COVID-19, some hospitals focused on containing the spread of COVID-19, and obstetric-related services were suspended as a result [15]. Furthermore, procedures of accessing maternal service were modified; for instance, most hospitals required prior online registration and some hospitals limited the number of family members accompanying the pregnant woman to her antenatal clinic appointment to a maximum of one person[16]. A previous review has shown that during infectious disease outbreaks, pregnant women are likely to experience psychological distress; they are often concerned about the wellbeing of their fetus, when faced with the decision of whether to comply with the recommended prevention and treatment guidelines with their effectiveness and potential side effects yet to be understood, and the disrupted routines of maternal health services [16]. Thus, timely access to information about antenatal care services and education about public health challenges, as well as knowledge of self-protection from trusted sources, could play important roles in reassuring and supporting pregnant women during a public health emergency.

Like the popularity of Facebook and WhatsApp in many countries, a number of homegrown social media platforms such as WeChat and Weibo have penetrated the daily lives of Chinese people. WeChat is now the most popular mobile phone app in China with over 654 million users as of 2019, followed by Weibo with nearly 360 million users as of 2019 [17]. An increasing number of private enterprises, government organizations, and hospitals have established WeChat or Weibo official accounts (WOAs) to disseminate service information and promote interaction with end users. WeChat and Weibo are also the two most popular social media platforms used by hospitals to inform the public about the services they offered and provide health education and counselling free of charge.

China was the first county in the world to experience the COVID-19 outbreak. Understanding how the epidemic and public health measures, including restricted mobility, affected maternal mental health and whether the ways of accessing antenatal care information affected the mental wellbeing of pregnant women would provide important scientific information to develop effective support strategies and preparatory mechanisms for future global public health emergencies. Therefore, the aims of this study were to (1) determine the mental health status of pregnant women during the early stage of the COVID-19 epidemic in China, by measuring their perceived stress, anxiety, and depression levels; (2) explore the various approaches used by them to access antenatal care information; and (3) determine their associations with the maternal mental health status.

Methods

Study Design

We conducted a web-based, cross-sectional survey from February 5 to 28, 2020, during the peak of the COVID-19 epidemic in China. The questionnaire was designed using the online survey tool Wenjuanxing platform [18]. The contents of the survey gathered participants' demographic characteristics and evaluated their COVID-19 self-protection behaviors, knowledge of antenatal COVID-19–related care, mental health status, and channels of obtaining antenatal care information. The study was approved by the Institutional Review Board of School of Public Health, Fudan University, Shanghai, China (IRB#2020-02-0803).

Data Collection

We used direct online and snowball recruitment methods through our research collaboration network in an attempt to achieve higher participation from different regions of China. We sent the quick response (QR) code or the link to the survey questionnaire to the heads of maternal and child health (MCH) departments of MCH hospitals and comprehensive hospitals; these included 2 district MCH hospitals in Shanghai and 1 municipal MCH hospital in Changzhou, Jiangsu Province; 1 county MCH hospital in Leping, Jiangxi Province; and 1 municipal comprehensive hospital in Xi'an, Shaanxi Province. These department heads sent the electronic QR code or the survey URL to the staff of their respective departments and posted the recruitment details on the walls of the antenatal clinics. Pregnant women who visited the antenatal clinics in these facilities during the survey period were invited to participate in the survey; they were required to either scan the QR code or access the URL via a mobile phone or other digital devices. On the first page of the survey, a brief introduction to the survey, including the purpose and contents of the web-based questionnaire and the estimated time to complete the survey, was provided. At this point, participants could either choose to continue to answer the questionnaire or close the page to exit the survey. Participants were also encouraged to share the survey QR code or URL with other pregnant women in their network. Upon clicking the "submit" button at survey completion, key antenatal care knowledge relevant to COVID-19 (which were also the answers to the questions) would be displayed on the screen.

Survey Design

Participants' sociodemographic and obstetric information, including age, education level, status of employment, parity, gestational age, and pregnancy complication, were collected. The survey comprised 10 questions regarding personal self-protection behaviors to prevent COVID-19 and knowledge of antenatal care required during the COVID-19 epidemic, based on the joint Chinese professional societies' guidelines [19]. The 4 behavior questions, including 2 multiple choice questions, were about (1) avoiding stepping out of the home, (2) wearing a face mask in public places, (3) practicing hand sanitization, and (4) practicing other protection behaviors such as avoiding using the public transport and avoiding contact with wild animals and consumption of wild animal meat. The 6 antenatal care questions, including 3 multiple choice questions, evaluate participant's knowledge of (1) whether the antenatal health visit should be cancelled, (2) whether pregnant women could undergo a computed tomography scan, (3) symptoms urging pregnant women to visit the hospital, (4) where to seek care in case of fever, (5) should newborn babies be quarantined if the mother is diagnosed with COVID-19, and (6) whether breastfeeding is recommended if the mother has COVID-19 (see Multimedia Appendix 1). Each question was assigned an individual score. The total score of self-protection behaviors was 4 and that of antenatal care knowledge was 6. Survey participants were categorized into the following 2 groups if their total scores were above the median score: better self-protection behavior group and higher antenatal care knowledge group.

Mental Well-Being Assessment

Perceived Stress

We used the validated Chinese Perceived Stress Scale (CPSS) to assess perceived stress among pregnant women [20]. The CPSS is a 14-item, self-reported questionnaire with 7 positive and 7 negative items measuring the degree to which individuals appraise situations in their lives as stressful [21,22]. Each item is scored on a 5-point Likert scale ranging from 1 ("never") to 5 ("very often") [22]. The total score of this scale is computed by summing the scores of all positive items and reverse-scoring all negative items. The cutoff point for CPSS for the Chinese population is 25. Therefore, participants who scored higher than 25 were considered to be experiencing perceived stress [22-24].

Anxiety

The validated, 20-item Chinese version of the Self-Rating Anxiety Scale (SAS) was used to measure participants' anxiety symptoms [25]. Each item on the SAS is scored using a 4-point Likert scale, with scores ranging from 1 ("a little of the time") to 4 ("most of the time"). Items 5, 9, 13, 17, and 19 are negatively keyed. The total score is computed by multiplying the sum of the scores of positive items and the reverse-scores of negative items by 1.25. The total score of SAS ranges from 20 to 80 [26]. Participants scoring 50 and above were considered to be experiencing anxiety [27,28].

Depression

The 10-item Chinese version of the Edinburgh Depression Scale (EDS) was used to evaluate maternal depression [29]. Each item was scored on a 4-point Likert scale, with scores ranging from 0 to 3. The total score ranges from 0 to 30, and the cut-off scores range from 9 to 13. For this study, we considered a cut-off score of 9. Participants with a score of 10 and above were considered to be experiencing depression [30-32].

Accessing Antenatal Care Information

The question on how participants accessed antenatal care information during the COVID-19 epidemic was in a multiple-choice format: hospitals' hotline, mobile phone SMS, hospitals' official WeChat accounts, hospitals' official Weibo accounts, WeChat or Weibo moments (an information sharing forum) posted by friends and family members, and digital message or verbal advice shared by friends and family members. Participants who selected either the hospitals' official WeChat or Weibo accounts were categorized as accessing information via hospitals' official accounts on social media platforms. Those who selected WeChat or Weibo moments from friends and family members or other means involving friends and family members were categorized as accessing information via friends and family members.

Accessing antenatal care information via hotlines or SMS represents accessing antenatal care information from a reliable source and using a traditional approach. Accessing health care information via hospital official accounts on social media represents accessing antenatal care information via a reliable source and using a social media approach. Accessing health care information via friends or family members represents accessing information from nonprofessional sources. Analysis of these 3 different approaches will help clarify the roles of both the information sources and access channels.

Quality Control

For the purpose of quality control of the web-based survey, we incorporated 1 question after the CPSS scale: "The purpose of this question is to verify if a participant has answered the question carefully. Please select 'always' as you are told." If a participant failed to answer the question as required, their questionnaire response would be regarded as invalid. Among the 2186 pregnant women who participated in the survey, 1873 returned a valid questionnaire.

Data Analysis

We evaluated the mean (SD) values for normally distributed continuous variables and median (P25-P75) values for non-normally distributed variables. Categorical variables were described in proportions. Chi-square test was used to analyze the categorical variables, and multiple binary logistic regression analyses were performed to examine the associations between different approaches of accessing antenatal care information and stress, anxiety, and depression after adjusting for social economic factors such as age; education; employment status; living in urban, suburban, or rural areas; province or region of current residence; obstetric conditions (eg, parity, trimester, and presence of complications); score of COVID-19 prevention self-protection behaviors; and score of COVID-19–related antenatal care knowledge. The significance level was set at $P<.05$, and data were analyzed using SPSS software for Windows (version 17.0; SPSS Inc.) and R Statistical Software (version 3.6.3).

Results

The mean age of the 1873 participants was 29 (SD 4.10) years. The distribution of women's current residence covered 22 provinces or regions of China, with the majority of participants based in Shanghai (1415/1873, 75.5%) and a small proportion based in Hubei Province (23/1873, 1.2%)—the most severely affected area due to the COVID-19 outbreak. The majority of women had completed college and above level of education, were employed, and primiparous. The number of pregnant women in their first, second, and third trimesters was almost evenly distributed. The median score of COVID-19 self-protection behavior was 3, with individual scores ranging from 1 to 4. The median score of antenatal care knowledge was 4, with individual scores ranging from 0 to 6 (Table 1).

Table 1. Characteristics of pregnant women and their approaches of accessing antenatal care information during the COVID-19 outbreak in China (N=1873).

[a] Percentages reported parenthetically are based on the sum of absolute values of each subcategory (or row) listed under “Characteristic.”

[b] Chi-square test.

[c] Data not available.

[d] The mean age of 29 years was used to categorize participants into the 2 groups: ≥29 and <29 years.

The mean score of perceived stress was 35.21 (SD 7.58), as measured by CPSS. The median scores of anxiety and depression as measured by SAS and EDS were 42.50 (IQR 37.50-47.50) and 9.00 (IQR 7.00, 11.00), respectively. The prevalence of perceived stress, anxiety, and depression symptoms among the participants was reported to be 89.1% (1668/1873; 95% CI 87.6%, 90.4%), 18.1% (339/1873; 95% CI 16.4%, 19.9%), and 45.9% (859/1873; 95% CI 43.6%, 48.1%), respectively. Univariate analysis showed that pregnant women who were employed, lived in Shanghai, had completed higher education, and had scored higher for COVID-19 prevention knowledge and self-protection behaviors showed a negative association for experiencing at least one form of the 3 mental health disorders assessed. On the other hand, pregnant women who were multiparous, resided in rural areas, and had pregnancy complications were more likely to experience at least one form of the 3 mental health disorders assessed, compared to those who were primiparous, lived in urban areas, and did not have pregnancy complications (Table 2).

[a] Percentages reported parenthetically are based on the sum of absolute values of each subcategory (or row) listed under “Characteristic.”

[b] Chi-square test.

[c] Data not available.

[d] The mean age of 29 years was used to categorize participants into the 2 groups: ≥29 and <29 years.

In all, 75.6% (1416/1873) of the participants reported having ever accessed antenatal health care information via hospitals' WOAs, and 63.2% (1185/1873) of the participants also selected WOAs as the most preferred way to access antenatal care information (Figure 1). Moreover, 47.3% (885/1873) of the participants reported they accessed antenatal care information via hospital hotlines or SMS, and 39.8% (746/1873) accessed this information via friends or family members. Results of the chi-square test showed that women who were relatively older, had received higher education, were employed, in their 1st or 3rd trimester, residing in urban areas, and living in Shanghai area were more likely to access information via hospitals' WOAs. All 3 different approaches of accessing antenatal care information were positively associated with a higher score of COVID-19 self-protection behaviors. Access to information via WOAs was positively associated with a higher score of COVID-19 antenatal care knowledge (Table 1).

Results of the multiple binary logistic regression analyses showed that participants who accessed antenatal care information via hospitals' WOAs were significantly associated with lower risk of perceived stress (odds ratio [OR] 0.46, 95% CI 0.30-0.72; *P*=.001), anxiety (OR 0.53, 95% CI 0.41-0.68; *P*<.001) and depression (OR 0.73, 95% CI 0.59-0.91; *P*=.005; see the table in Multimedia Appendix 2). Furthermore, participants who accessed health care information via hospital hotlines or SMS were found to be significantly associated with a lower risk of anxiety only (OR 0.77, 95% CI 0.60-0.98; *P*=.04;

see the table in Multimedia Appendix 3). Participants who accessed antenatal care information via friends and family members were found to be significantly associated with a higher risk of experiencing depression symptoms (OR 1.32, 95% CI 1.09-1.60; *P*=.004; see Figure 2 and the table in Multimedia Appendix 4).

Figure 1. Examples of antenatal care information provided via a health institution’s official WeChat account. Screenshots of antenatal care information shared via the official WeChat account of Shanghai Maternal and Child Health Center, China, introducing when, where, and how should pregnant women receive antenatal care and COVID-19 prevention strategies for pregnant women and infants.

一、什么是新型冠状病毒?

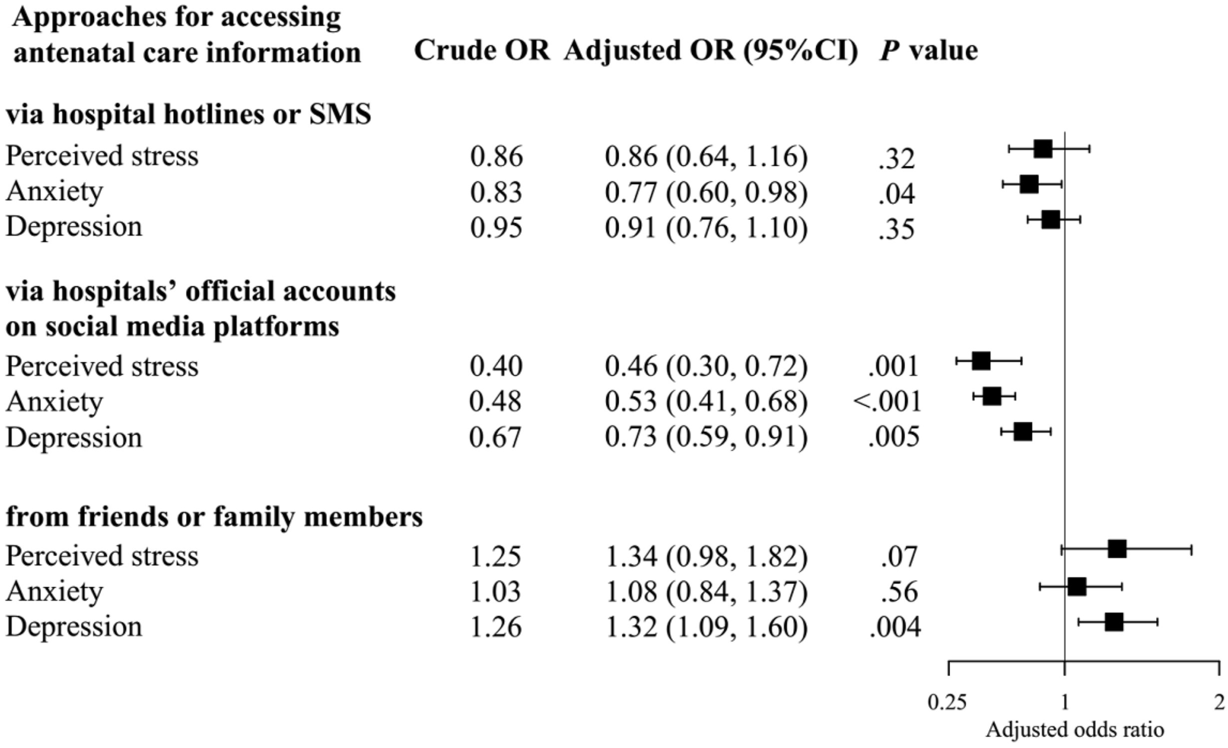
二、为什么如此重视新型冠状病毒?

群居性、传播性—传染病!
会不会人传人? --YES
乙类传染病—作为甲类防控

三、新型冠状病毒传染途径是什么?

飞沫传播：咳嗽、喷嚏等
接触传播：人、物
粪口传播

Figure 2. Approaches used by Chinese pregnant women to access antenatal care information and mental health disorders experienced by them during the COVID-19 epidemic (N=1873). Multiple binary logistic regression analysis controlled for age, education level, employment status, living area, current residence, gestational stage (trimester), parity, pregnancy complications, and scores of COVID-19 self-protection behaviors and antenatal care knowledge. OR: odds ratio.



Approaches for accessing antenatal care information	Crude OR	Adjusted OR (95%CI)	*P* value
via hospital hotlines or SMS			
Perceived stress	0.86	0.86 (0.64, 1.16)	.32
Anxiety	0.83	0.77 (0.60, 0.98)	.04
Depression	0.95	0.91 (0.76, 1.10)	.35
via hospitals’ official accounts on social media platforms			
Perceived stress	0.40	0.46 (0.30, 0.72)	.001
Anxiety	0.48	0.53 (0.41, 0.68)	<.001
Depression	0.67	0.73 (0.59, 0.91)	.005
from friends or family members			
Perceived stress	1.25	1.34 (0.98, 1.82)	.07
Anxiety	1.03	1.08 (0.84, 1.37)	.56
Depression	1.26	1.32 (1.09, 1.60)	.004

Multiple binary logistic regression analysis also showed that factors such as education level of college and above, current residence in Shanghai, and a higher score of COVID-19 antenatal care knowledge were negatively associated with at least one of the mental health disorders assessed in this study, compared with other factors such as a lower education level, current residence outside Shanghai, and a lower score of COVID-19 antenatal care knowledge. Moreover, pregnancy complications were found to be significantly associated with an increased risk of anxiety (Multimedia Appendices 2-4).

Discussion

Principal Findings

Our study provides a snapshot of the mental health status of pregnant women during the early stage of the COVID-19 epidemic in China. The prevalence of perceived stress, anxiety, and depression among the pregnant women was high, reported among 89.1%, 18.1%, and 45.9% of the participants, respectively. In addition, our survey results showed that the most popular way to access antenatal care information was via hospitals' official accounts on social media platforms such as WeChat and Weibo; women who accessed antenatal care information using this approach had a significantly lower risk of perceived stress, anxiety, and depression, after controlling for social economic factors such as age, education, and employment status; obstetric conditions such as gestational stage (trimester) and pregnancy complications; and scores of COVID-19 self-protection behaviors and antenatal care knowledge.

The proportion of women experiencing perceived stress, anxiety, and depression was higher in this study sample, that is, during the COVID-19 epidemic, than that reported in previous Chinese studies in the context of no public health emergency, using the same measurements. For instance, in previous studies, perceived stress was reported at 73.3% [33], anxiety at 11.3% [34,35], and depression at 17.6%-25.4% [32,36]. The higher prevalence of maternal mental health disorders in our study sample was consistent with the findings of other studies conducted during the COVID-19 outbreak [37-40]. The higher risk of maternal mental health disorders might be related to the concerns pregnant women have regarding the COVID-19 pandemic and its impact on the economic and individual social circumstances, such as prolonged stay-at-home, increased exposure to news or rumors, isolation from their social support network and health care facilities, limited access to self-protection resources (eg, face mask and sanitizers), and worry about contracting COVID-19 and mother-to-fetus transmission [16,37]. These concerns and fears could perpetuate stress and anxiety among pregnant women and contribute to increased rates of mental health disorders [38]. Furthermore, compared with the prevalence of depression symptoms (29.6%) in a Chinese study on pregnant women in late January 2020 (ie, at the beginning of the COVID-19 epidemic in China), the prevalence of depression symptoms in our study was much higher (45.9%) [39]. This difference might be due to the time difference between the two studies. Our study was carried out in February 2020, during the peak of the COVID-19 epidemic in China when the number of daily new confirmed cases reached new records and major public health disease control and prevention measures were universally implemented across the country. Although these measures were necessary to contain the spread of the infection, they could also aggravate negative psychological effects among pregnant women [40,41]. There is solid evidence for the link among maternal stress, anxiety, and depression, as well as a number of pregnancy complications and adverse pregnancy and birth outcomes (eg, susceptibility to infection, low birth weight, preterm birth, and impaired cognitive development of the child) [42-44]. The high prevalence of mental health disorders among pregnant women found in this study suggests the needs for timely intervention and preparedness for maternal mental health care in a public health emergency context. Further prospective studies are required to understand the effects of maternal mental health disorders during COVID-19 on pregnancy outcomes and the well-being of the child.

Our findings revealed that access to antenatal care information via hospitals' WOAs was significantly associated with a lower risk of all 3 measured mental health disorders (ie, perceived stress, anxiety, and depression). Obtaining health care information via hospital hotlines or SMS was found to be significantly associated with a lower risk of anxiety only. Nevertheless, both these approaches highlighted the importance of the source of antenatal care information. Hospitals usually are regarded as a reliable and credible source for obtaining health information. The antenatal care knowledge provided by hospitals during the COVID-19 pandemic is likely to enhance the confidence and self-efficacy of pregnant women to deal with the situation. Furthermore, the feeling of being connected with the hospitals and health care providers via hospital WOAs as well as hotline and SMS during the COVID-19 pandemic is likely to provide reassurance and comfort to pregnant women, which may help mitigate distress. However, unlike the hotline, WOAs allow pregnant women to access the information they need at any time as per their convenience. Moreover, compared with SMS, WOAs offer these women the flexibility to obtain more comprehensive information that meets their needs. WOAs can provide substantial information in various ways, including tips, articles, images, and links to videos. These might be some of the possible reasons why access to information via hospitals' WOAs was found to be associated with a higher reduction in mental health disorders among pregnant women compared with access to information via hotlines and SMS.

Surprisingly, we found that pregnant women who obtained antenatal care information via friends and family members were associated with a higher risk of depression. This finding could be partially explained by the fact that women experiencing depression symptoms are more likely to turn to their friends and family for help or that they received more concerns from their friends or family members. Nevertheless, this observation suggested the need for actively disseminating maternal health service information and involving family members in antenatal health education. Being able to access health information from a reliable and credible source has always been a primary service need of new and expecting mothers [45]. The findings of this study highlight the importance of both the trustworthiness of the source and the channels of information acquisition. The findings also suggest that during a public health emergency, reliable information provided by health professional institutions via social media platforms is a feasible and potentially effective way to deliver health care information and services to pregnant women. The findings also signify the importance and necessity of communicating authoritative information by health service providers via social media platforms as one component of epidemic preparedness and response in the future.

The Chinese government and many professional societies have responded swiftly to emergency maternal health interventions during the COVID-19 epidemic. Several professional organizations jointly issued management guidelines for pregnancy during COVID-19 on January 31, 2020 [19]. The National Health Commission of China released a province-wise list of designated hospitals for suspected or confirmed COVID-19 cases among pregnant women on February 12, 2020 [46]. Following these, many MCH institutions have posted service information and guidance for antenatal care on WOAs (Figure 1) [47,48]. However, training and capacity building is urgently needed for translating evidence-based information to health education materials in a timely manner such that it is comprehensible by the public. As an increasing number of health institutions choose to provide telemedicine services such as counselling and consultation, the quality of these remote-based services needs to be closely monitored. Thus, there is a need for more resources to be invested to promote quality antenatal care information dissemination and service provision via web-based platforms.

The findings of this study should be interpreted with caution. This is a web-based survey, wherein participants were self-selected, tended to have received higher education, possessed digital devices, and were possibly more health conscious, all of which might introduce selection bias and not be representative of all pregnant women. The results may also be subjected to recall bias, as the variables are based on self-reporting. The cross-sectional design of this study prevents significant causal associations to be demonstrated. Finally, the residence location of participants was not geographically evenly distributed; only a small proportion of pregnant women resided in Hubei Province—the region most severely affected area by COVID-19 in China.

Conclusions

In the early stage of the COVID-19 epidemic in China, a large proportion of pregnant women experienced high levels of perceived stress, anxiety, and depression. In addition, a significantly lower risk of maternal mental health disorders was found to be associated with accessing professional antenatal care information via hospitals' WOAs. These findings advocate for antenatal health service providers to develop evidence-based health care information and update service provision information on social media platforms in a timely manner. This should also form an essential component of public health preparedness and response to mitigate negative mental health outcomes among pregnant women.

Acknowledgments

This study was funded by the Key Discipline Program of Fifth Round of the Three-Year Public Health Action Plan (Year 2020-2022) of Shanghai (GWV-10.1-XK08). We are grateful to Prof Paul Garner for his immense support in interpreting the results. We are thankful to all participants and health staff involved in this study.

Authors' Contributions

HJ, XQ, and ML conceived the study. HJ, XQ, ML, XX, and LMJ designed the research tools. HJ, LMJ, XNL, WYC, FYY, XWZ, NA, XYL, XYL, ZYX, XLZ, and LLL contributed to the data collection. HJ, ML, XX, XGY, and XNL carried out data analyses and interpretation. HJ, ML, and LMJ drafted the manuscript. All authors have read and approved the final manuscript.

Abstract

Background: The death toll of COVID-19 topped 170,000 in Europe by the end of May 2020. COVID-19 has caused an immense psychological burden on the population, especially among doctors and nurses who are faced with high infection risks and increased workload.

Objective: The aim of this study was to compare the mental health of medical professionals with nonmedical professionals in different European countries during the COVID-19 pandemic. We hypothesized that medical professionals, particularly those exposed to COVID-19 at work, would have higher levels of depression, anxiety, and stress. We also aimed to determine their main stressors and most frequently used coping strategies during the crisis.

Methods: A cross-sectional online survey was conducted during peak COVID-19 months in 8 European countries. The questionnaire included demographic data and inquired whether the participants were exposed to COVID-19 at work or not. Mental health was assessed via the Depression Anxiety Stress Scales32 (23.53)–21 (DASS-21). A 12-item checklist on preferred coping strategies and another 23-item questionnaire on major stressors were completed by medical professionals.

Results: The sample (N=609) consisted of 189 doctors, 165 nurses, and 255 nonmedical professionals. Participants from France and the United Kingdom reported experiencing severe/extremely severe depression, anxiety, and stress more often compared to those from the other countries. Nonmedical professionals had significantly higher scores for depression and anxiety. Among medical professionals, no significant link was reported between direct contact with patients with COVID-19 at work and anxiety, depression, or stress. “Uncertainty about when the epidemic will be under control” caused the most amount of stress for health care professionals while “taking protective measures” was the most frequently used coping strategy among all participants.

Conclusions: COVID-19 poses a major challenge to the mental health of working professionals as a considerable proportion of our participants showed high values for depression, anxiety, and stress. Even though medical professionals exhibited less mental stress than nonmedical professionals, sufficient help should be offered to all occupational groups with an emphasis on effective coping strategies.

Introduction

Background

The death toll of COVID-19 topped 170,000 in Europe by the end of May 2020 [1]. Italy, Spain, France and the United Kingdom were among the worst affected countries with respect to high infection rates and overburdened health care systems [2-4]. Deaths of approximately 0.9 per 1 million inhabitants for Spain and France, 1.45 for Italy, and 3.94 for the United Kingdom were reported at the end of May. The death rate in Portugal was high as well with 1.32 deaths per million inhabitants [5]. Nevertheless, it was not one of the most affected countries [6,7]. Mortality in Germany was 0.47 deaths per 1 million inhabitants, Austria 0.52, and Switzerland 0.3 [5]; these values are lower but nevertheless alarming. As the number of cases soared, national governments introduced widespread restrictions to control the virus spread such as closing down borders, social distancing, travel restrictions, wearing of masks, working from home, and closure of public facilities [8,9]. The impending risk of infection, increasing number of COVID-19 cases, and the overburdening of health care systems created an unprecedented situation, which impacted not only everyday life but also the psychological welfare of the general population.

COVID-19 and Mental Health

A recent study in 41 countries showed high stress levels in the general population during the COVID-19 pandemic, similar to those reported during the severe acute respiratory syndrome (SARS) epidemic in 2003 [10]. Depressive symptoms increased from 8.5% before COVID-19 to 27.8% during COVID-19 in a US study [11]. Studies have shown a similar picture for Europe. An Italian study concluded that leaving home for work was associated with increased stress, which may be due to the fear of getting infected [12]. In a study from Spain during the lockdown, about 34% and 21% of the participants reported moderate to extremely severe depression and anxiety, respectively [13]. A study from the United Kingdom reported high mental distress during the lockdown [14]. The first part of a French study in March 2020 found that the prevalence of anxiety among the general population was twice as high as reported in a study before COVID-19 [15]. In comparison, a study in Hong Kong found that about one-third of SARS survivors still suffered from moderate to severe or severe anxiety and/or depressive symptoms 4 weeks after their recovery [16]. Even 30 months after exposure to SARS, psychiatric disorders were prevalent among SARS survivors [17].

COVID-19 and Medical Professionals

“Breathe. It’s what we all want these days, doctors and patients, nurses and care workers. All of us. We want air,” wrote an Italian frontline doctor from Milan in April during the peak of COVID-19 while sharing his routine of wearing a mask all the time [18].

Among the health care workers struggling to cope with the situation of doing their jobs while trying to protect themselves and their families [19], one would suspect doctors and nurses to be the most affected psychologically. During SARS, physicians who had direct contact with infected patients expressed greater mental distress, more stigmatization, and more worries about infecting their family [20]. This was confirmed during the COVID-19 pandemic in Italy where frontline health care workers reported posttraumatic stress symptoms [21]. Thousands of medical professionals were sent into quarantine after contracting COVID-19 in Italy, France, and Spain [22]. The fact that they came so close to the disease put their mental health at a higher risk than the general population [19]. The psychological challenges of the pandemic have been described for nurses and doctors in Europe [23,24]. Stronger effects on the mental health of medical health workers compared to nonmedical health workers [25] and a high prevalence of mental health symptoms among physicians and other medical staff have also been reported in China [26,27].

Coping Strategies and Major Stressors

A 2012 study with nurses showed that negative coping strategies led to higher levels of mental distress whereas positive coping was partly negatively correlated with depression and anxiety levels [28]. During SARS, physicians in Toronto were mainly concerned about disparities in the health care of non-SARS patients because of the special situation [20] while nurses in Taiwan experienced “endangering of colleagues” as a major stressor [29]. Getting information about the virus and sticking to infection control procedures seemed to be important coping strategies [20,29]. During the COVID-19 pandemic, coping strategies and stressors of health care workers have been investigated in China, showing that health care workers worried a lot about possibly infecting their families and were highly stressed by witnessing the deaths of infected patients. Adhering to protective measures and learning more about COVID-19 were most often used to cope [30,31].

Objectives

At a time when public health systems are overburdened in the fight against COVID-19 [2], physically and mentally healthy professionals are essential for the provision of reliable and efficient health care services. Physician burnout has been linked with medical errors [32] and further harmful effects for coworkers, patients, and the whole health care system [33]. The influence of COVID-19 on mental health in individual European countries and/or in individual population groups has been assessed, but a clear answer to the question of an overall impression of mental health in Europe during the peak months of the pandemic is still lacking. As global rates of infections rise once again and an effective vaccine remains unavailable, this question gains further relevance for determining mental health care needs for working professionals in the near future.

This study aimed to explore medical and nonmedical professionals' mental health in different European countries during the 3-month state of emergency due to the pandemic and whether or not it was influenced by exposure to the virus at work. We hypothesized that medical professionals, particularly those exposed to COVID-19 at work, would show higher scores in depression, anxiety, and stress compared to nonmedical professionals. Moreover, we investigated which aspects of the COVID-19 pandemic worried medical professionals the most while at work and which coping strategies they most frequently employed. By uncovering these stressors and coping strategies, it might be possible to devise policies to prepare and support medical professionals better for future crises.

Methods

Study Design

We used a cross-sectional, multilingual survey design to investigate the mental health of working professionals in 8 European countries (Germany, the United Kingdom, Spain, France, Portugal, Austria, Italy, and Switzerland) during 3 months of the COVID-19 crisis between April 1 and June 20, 2020. The focus was on medical professionals and whether they were exposed to COVID-19 at work. Additionally, we asked about the most stressful aspects of work and coping strategies most often used. Ethical approval for this study was granted by the Ethics Commission of the Medical Faculty of Heidelberg University (S-361/2020).

Participants

The participants were recruited online via public social networking groups and via the authors' European contacts with partner organizations from international joint projects.

The sample (N=609) included 354 people with medical professions, including 189 doctors and 165 nurses (including geriatric care), and 255 people with nonmedical occupations (eg, teachers, office staff, psychologists, retired persons, social workers). Participants were aged 18-84 years (median 41 years) with 151 males and 458 females.

The percentage distribution of participants and professional groups in different European countries is summarized in Table 1.

Table 1. Distribution of professional groups within European countries.

Country	Medical professionals, n (%)	Nonmedical professionals, n (%)	Total, n
Germany	100 (73.53)	36 (26.47)	136
Austria	6 (28.57)	15 (71.43)	21
Switzerland	33 (82.50)	7 (17.50)	40
France	15 (28.85)	37 (71.15)	52
Italy	142 (89.31)	17 (10.69)	159
Spain	28 (28.28)	71 (71.72)	99
Portugal	25 (54.35)	21 (45.65)	46
United Kingdom	5 (8.93)	51 (91.07)	56

Measurements

The survey consisted of a questionnaire derived from several validated instruments, with added items on demographics (eg, gender, age, marital status, etc) and a question on whether or not the participants were exposed to patients with COVID-19 at work.

Mental stress was assessed via the Depression Anxiety Stress Scales–21 (DASS-21)—a shorter version of the DASS-42 [34]—which is available in different languages. The DASS-21 consists of 21 items, which can be divided into 3 subscales, each containing 7 items to measure depression (eg, "I couldn't seem to experience any positive feeling at all"), anxiety (eg, "I was aware of dryness of my mouth"), and stress (eg, "I found it difficult to relax"). The responses are rated on a 4-point Likert scale ranging from 0 (did not apply to me at all) to 3 (applied to me very much or most of the time) to indicate how much the statement applied to the participant over the past week. According to Lovibond and Lovibond [34], the authors of the questionnaire, scores for the subscales are calculated by adding the answers of the 7 items for each subscale and then multiplying the result by 2 to get the total score for each participant for comparison to the DASS normative data [35].

To determine the most important stressors for medical staff, we used a questionnaire similar to the one used in a study by Lee et al [29] on SARS, which contains specific items for medical staff. The questionnaire consisted of 23 items. On a Likert scale from 0 (not at all) to 4 (very much), the participants indicated how often they thought about or were concerned about the individual stressors in their everyday life or at work. Given the focus of the study, this questionnaire was completed only by the medical staff participants.

Also based on Lee et al [29], we derived a questionnaire on coping strategies where participants could respond to 12 items using a scale from 0 (almost never) to 3 (almost always). Although all participants completed the coping strategies questionnaires, only results from the medical staff participants are presented here considering the aims and objectives of the study.

Procedure

All questionnaires were translated from English by native speakers or professional translators for use in the respective countries. The survey was made available online via the Soscisurvey.de [36] platform. Consent to participate was obtained online. The English and German questionnaires were distributed at the beginning of April 2020, followed shortly after by the Italian version. The surveys in Spain and Portugal were launched in mid-April and in France in mid-May.

Data Analysis

Using the Lovibond and Lovibond [34] method, the depression, anxiety, and stress subscales on DASS-21 were, according to individual sum scores, categorized as normal, mild, moderate, severe, and extremely severe [34]. These subscales were then grouped as normal/mild, moderate, and severe/very severe.

We created two groups: medical professionals consisting of doctors and nurses; and nonmedical professionals, which included other jobs in health care, volunteers, nonmedical staff, and community health care workers.

Descriptive analysis (including means, SDs, and frequencies) and inference statistics (multivariate analysis of variance [MANOVA]) were calculated using SPSS, version 24 (IBM Corp) [37].

Results

Distress Levels Across Surveyed European Countries

Across all surveyed countries, 65% (n=396) of the participants reported a normal/mild level of depression, followed by 18% (n=108) with moderate and 17% (n=105) with severe/extremely severe depression. Regarding anxiety, 63% (n=386) reported a normal/mild level of anxiety, 15% (n=91) a moderate level, and 22% (n=132) a severe/extremely severe level. In terms of stress, 59% (n=356) reported a normal/mild level, 14% (n=87) a moderate level, and 27% (n=166) a severe/extremely severe level. Tables 2-4 shows the mean scores for depression, anxiety, and stress for each of the 8 European countries as well as the percentage of participants assigned to the groups normal/mild, moderate, and severe/extremely severe.

Table 2. Depression levels in different European countries assessed using the Depression Anxiety Stress Scales–21.

Country	Mean (SD)[a]	Normal/mild, n (%)	Moderate, n (%)	Severe/very severe, n (%)
Germany	11.49 (8.91)	87 (63.97)	28 (20.59)	21 (15.44)
Austria	7.33 (8.23)	17 (80.95)	3 (14.29)	1 (4.76)
Switzerland	7.45 (8.68)	31 (77.50)	6 (15.00)	3 (7.50)
France	17.42 (11.63)	22 (42.31)	11 (21.15)	19 (36.54)
Italy	10.03 (9.30)	119 (74.84)	19 (11.95)	21 (13.21)
Spain	8.51 (8.98)	75 (75.76)	14 (14.14)	10 (10.10)
Portugal	12.26 (8.46)	24 (52.17)	14 (30.44)	8 (17.39)
United Kingdom	17.64 (11.04)	21 (37.50)	13 (23.21)	22 (39.29)
Total	11.34 (9.90)	396 (65.02)	108 (17.73)	105 (17.24)

Table 3. Anxiety levels in different European countries assessed using the Depression Anxiety Stress Scales–21.

Country	Mean (SD)	Normal/mild, n (%)	Moderate, n (%)	Severe/very severe, n (%)
Germany	8.44 (7.94)	85 (62.50)	19 (13.97)	32 (23.53)
Austria	4.86 (5.68)	15 (71.43)	5 (23.81)	1 (4.76)
Switzerland	4.10 (6.13)	34 (85.00)	3 (7.50)	3 (7.50)
France	11.39 (10.53)	27 (51.92)	10 (19.23)	15 (28.85)
Italy	7.64 (8.39)	110 (69.18)	25 (15.72)	24 (15.09)
Spain	10.04 (10.54)	60 (60.61)	12 (12.12)	27 (27.27)
Portugal	9.83 (8.59)	23 (50.00)	11 (23.91)	12 (26.09)
United Kingdom	10.36 (9.69)	32 (57.14)	6 (10.71)	18 (32.14)
Total	8.61 (9.00)	386 (63.38)	91 (14.94)	132 (21.67)

Table 4. Stress levels in different European countries assessed using the Depression Anxiety Stress Scales–21.

Country	Mean (SD)	Normal/mild, n (%)	Moderate, n (%)	Severe/very severe, n (%)
Germany	17.13 (9.94)	76 (55.88)	27 (19.85)	33 (24.27)
Austria	14.10 (7.96)	17 (80.95)	1 (4.76)	3 (14.29)
Switzerland	11.40 (11.29)	32 (80.00)	2 (5.00)	6 (15.00)
France	21.77 (12.24)	25 (48.08)	4 (7.69)	23 (44.23)
Italy	17.25 (10.46)	91 (57.23)	27 (16.98)	41 (25.79)
Spain	16.42 (10.45)	62 (62.63)	13 (13.13)	24 (24.24)
Portugal	20.78 (10.95)	24 (52.17)	3 (6.52)	19 (41.30)
United Kingdom	18.86 (10.13)	29 (51.79)	10 (17.86)	17 (30.36)
Total	17.40 (10.71)	356 (58.46)	87 (14.29)	166 (27.26)

Comparison of Medical With Nonmedical Professionals

A one-way MANOVA showed a significant main effect for profession ($F_{3,605}$=5.019, P=.002, Wilk's Λ=0.976). The effects were significant for depression ($F_{1,607}$=7.929, P=.005) and anxiety ($F_{1,607}$=5.87, P=.02], which indicated that medical professionals were less depressed (mean 10.39, SD 9.12) compared to nonmedical staff (mean 12.67, SD 10.77), as well as less anxious (mean 7.90, SD 8.36) than nonmedical staff (mean 9.65, SD 9.66). No statistically significant differences were found between medical professionals who had or had no exposure to COVID-19 at work ($F_{3,350}$=0.525, P=.67, Wilk's Λ=0.996).

Table 5 shows the 3 subscales of the DASS-21 and the percentage of medical and nonmedical professionals categorized as normal/mild, moderate, severe/extremely severe for each of these subscales.

Table 5. Overview of depression, anxiety, and stress levels for medical (n=345) and nonmedical professionals (n=255) assessed using the Depression Anxiety Stress Scales–21.

Participants	Mean (SD)	Normal/mild, n (%)	Moderate, n (%)	Severe/very severe, n (%)
Depression				
Medical professionals	10.39 (9.12)	246 (69.49)	60 (16.95)	48 (13.56)
Nonmedical professionals	12.67 (10.77)	150 (58.82)	48 (18.82)	57 (22.35)
Total	11.34 (9.90)	396 (65.03)	108 (17.73)	105 (17.24)
Anxiety				
Medical professionals	7.90 (8.36)	240 (67.80)	49 (13.84)	65 (18.36)
Nonmedical professionals	9.65 (9.66)	146 (57.26)	42 (16.47)	67 (26.28)
Total	8.61 (9.00)	386 (63.38)	91 (14.94)	132 (21.68)
Stress				
Medical professionals	17.10 (10.51)	208 (58.76)	55 (15.54)	91 (25.71)
Nonmedical professionals	17.80 (10.98)	148 (58.04)	32 (12.55)	75 (29.41)
Total	17.40 (10.71)	356 (58.46)	87 (14.29)	166 (27.26)

Stress Factors for Medical Professionals

The highest rated stressors were "uncertainty about when the epidemic will be under control" (mean 2.27, SD 0.85), "worry about inflicting COVID-19 on family" (mean 2.25, SD 0.99), "worry about nosocomial spread" (mean 2.02, SD 0.92) and a "frequent modification of infection control procedures" (mean 2.02, SD 0.89). Participants were least concerned about themselves (mean 1.12, SD 1.04) or coworkers (mean 1.25, SD 0.97) showing COVID-19–like symptoms, conflicts at work as the equivocal definition of responsibility between doctors and nurses (mean 1.19, SD 1.04), and blame from their commanding officers (mean 0.70, SD 0.95). An overview of all stressors in the order of reported severity can be found in Table 6.

Table 6. Stressors for doctors and nurses during COVID-19.

Items[a]	Responses, n	Mean (SD)
Uncertainty about when the epidemic will be under control	350	2.27 (0.85)
Worry about inflicting COVID-19 on family	351	2.25 (0.99)
Worry about nosocomial spread	348	2.02 (0.92)
Frequent modification of infection control procedures	350	2.02 (0.89)
Protective gears cause physical discomfort	349	1.75 (1.02)
Deterioration of patients' condition	347	1.70 (1.00)
Worry about lack of proper knowledge and equipment	349	1.67 (1.04)
Worry about being negligent and endangering patients	350	1.66 (1.07)
Worry about getting infected	349	1.62 (1.03)
Patients' emotional reaction	348	1.57 (0.96)
Worry about lack of manpower	348	1.56 (1.05)
Unclear documentation and reporting procedures	347	1.54 (1.01)
Patient families' emotional reaction	346	1.52 (1.01)
Coworkers being emotionally unstable	348	1.52 (0.97)
Being without a properly fitted environment	348	1.51 (1.08)
Conflict between duty and safety	348	1.49 (1.07)
Worry about being negligent and endangering coworkers	351	1.48 (1.03)
Be infected by colleagues	349	1.31 (1.02)
Protective gear being a hindrance to providing quality care	349	1.28 (1.05)
Coworkers displaying COVID-19–like symptoms	347	1.25 (0.97)
Equivocal definition of the responsibility between doctors and nurses	346	1.19 (1.04)
Yourself displaying COVID-19–like symptoms	347	1.12 (1.04)
Blame from commanding officers	345	0.70 (0.95)

[a] Responses to the question: "When you think about COVID-19 in your life and work, how often did you think or worry about the following things?" (0=not at all, 3=very much).

Coping Strategies of Medical Professionals

The most frequently used strategies were "taking protective measures" (mean 2.70, SD 0.57) and "actively acquiring more knowledge about COVID-19" (mean 2.34, SD 0.80). Alcohol and drugs were the least used strategy (mean 0.32, SD 0.60). Table 7 summarizes these results.

Table 7. Doctors' and nurses' coping strategies during COVID-19 (n=354).

Items[a]	Mean (SD)
Taking protective measures (washing hands, wearing a mask, taking own temperature, etc)	2.7 (0.57)
Actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc)	2.34 (0.80)
Video-chatting with family and friends by phone to share concerns and support	1.84 (0.87)
Engaging in recreational activities (online shopping, social media, internet surfing, etc)	1.62 (0.94)
Engaging in health-promoting behaviors (more rest, exercise, balanced diet, etc)	1.55 (0.99)
Switching thoughts and facing the situations with a positive attitude	1.54 (0.89)
Limiting oneself from watching too much news about COVID-19	1.37 (0.96)
Distracting oneself from thinking about COVID-19 issues by suppression or keeping busy	1.30 (0.92)
Acquiring mental health knowledge and information	1.01 (0.95)
Venting emotions by crying, screaming, smashing things, etc	0.50 (0.81)
Practicing relaxation methods (meditation, yoga, tai chi, etc)	0.46 (0.82)
Using alcohol or drugs	0.32 (0.60)

[a] Responses to the question: "When you think about COVID-19 in your life and work, how often did you use or try to use the following methods to handle the situation?" (1=almost never, 4=almost always).

Discussion

Overview

This study focused on doctors and nurses who were and are facing exceptional physical and mental challenges during the COVID-19 pandemic. In order to gain a deeper understanding of their situation, we investigated the perceived burden of different stressors on medical professionals as well as their coping strategies. Additionally, a general overview of the experienced stress, anxiety, and depression in various European countries during peak months of the pandemic was presented.

Mental Health of Medical Professionals

The majority of doctors and nurses reported a normal to mild level of psychological strain, but about one-third expressed a moderate to extremely severe level of distress. Mental distress is associated with patient safety and a higher probability of medical errors [32,33]. Considering that long-term effects such as posttraumatic stress disorders are not uncommon among this professional group [38] and that the COVID-19 infection rate may increase again, our results should be taken seriously.

However, surprisingly, the mean scores for depression and anxiety among health care professionals were significantly lower than among nonmedical professionals. Regarding the level of stress, there was no significant difference between the two groups. These results are encouraging in the sense that the medical professionals—although confronted with difficult challenges and risks [19,39,40]—seemed to be mentally well prepared to handle the pandemic situation. A possible explanation could be, however, that their medical background helped them to better understand and classify COVID-19–related information when compared to their nonmedical counterparts. When they could feel self-sufficient, the situation appeared more manageable for them. A study with SARS survivors concluded that a better sense of self-care and self-efficacy led to better psychological adjustment to the situation [41]. In accordance with our results, in a study from Singapore, nonmedical health care professionals had a higher prevalence of anxiety than medical health care professionals during COVID-19. The authors believed that nonmedical health care professionals might have had less access to psychological support, less direct information about the situation and received less training on personal protective equipment and infection control measures [42]. In addition, previous European studies show that there is also an increased psychological burden during COVID-19 in the general population. For example, female gender and younger age were identified as risk factors [43,44], which were represented in large numbers in our study population. It has therefore already been recommended to take care of the mental health of the general population as well as special population groups [44].

Interestingly, we did not find any significant association between direct contact with COVID-19–infected patients at work and scores for anxiety, depression, or stress among medical professionals despite a previous study with health workers during the pandemic reporting more psychological distress when there was direct exposure to infected patients [21]. Not only in medical departments specializing in COVID-19 but in all medical units, protective measures such as permanent wearing of face masks, bans on visits to hospitals and nursing homes, and stricter hygiene regulations were made obligatory for medical personnel in the surveyed countries. In addition, because of the considerable number of deaths of doctors and nurses [45], COVID-19 would have been perceived by medical professionals as a kind of ever-present threat and not only when in direct contact with infected patients.

Major Stressors and Coping Strategies

"Uncertainty about when the epidemic will be under control" and "worry about inflicting COVID-19 on family" were at the top of the list when medical professionals were asked about the most stressful things in their everyday life or at work during the pandemic. Possible infection of family is a major concern that has been reported several times before, for example, in the United Kingdom [38] or formerly among Taiwanese nurses during the SARS outbreak [29] and Chinese health care workers during COVID-19 [30]. Our results confirm the dilemma already mentioned by Perrin et al [19] during SARS: health care workers do their job by helping others but at the same time feel anxious about getting infected or infecting their families. Our participants were less worried about getting infected themselves than infecting their families with COVID-19.

The strategies most frequently used by medical professionals to deal with this unusual situation were "taking protective measures (washing hands, wearing a mask, taking own temperature)" and "actively acquiring more knowledge about COVID-19 (symptoms, transmission pathway, etc)." Effective protective measures were also the most common coping strategy among Taiwanese nurses during SARS [29] and Chinese health care workers during COVID-19 [30]. Another important strategy was "video-chatting with family and friends to share concerns and support," which apparently had a higher priority for the participants in our study when compared to the nurses in Taiwan ("chatting with family and friends by phone to share concerns and support") during SARS [29]. However, nowadays there are more possibilities, especially via social media, to be in touch digitally with friends and family compared to during the SARS outbreak. This has the advantage to get in touch directly with people experiencing mental burden, with the help of so-called e-mental health applications. The increasing role of these web-based interventions during the pandemic has already been observed [46]. While the acceptance of this development, especially among medical professionals, is high [47], different generations follow their own patterns of usage. However, all generations seek to stay related to their family members [48].

COVID-19 and Mental Health in Europe

Our results show that although the majority of respondents reported normal to mild levels of depression, anxiety, and stress, the mean overall level of mental strain experienced was up to 2x higher compared to the normative data means of the DASS-21 [49]. However, according to DASS guidelines, it should be noted here that there is no DASS-21 cut-off for clinical diagnostics [35].

Our results concur with earlier studies about COVID-19 that have reported elevated levels of psychological distress during the pandemic [12-15,50,51]. However, these studies report only about a particular European country, which makes it clear that COVID-19 has a negative effect on the psyche but neglects that there can be differences across countries. The descriptive cross-sectional overview of our study shows that there are differences among countries in the numbers of people belonging to the severe/extremely severe category for depression, anxiety, and stress.

Participants from the United Kingdom and France showed, on a descriptive level, the highest scores for depression, anxiety, and stress when compared to other countries. This may be because England and France were among the countries most affected by COVID-19 [2] with a case fatality rate of 19.2% for France and 14.7% for the United Kingdom by the end of May [5]. Similar to our study, a previous study in the United Kingdom found elevated scores for depression and anxiety during COVID-19 [51], and a study from France presented a considerable prevalence of anxiety 1 week after the start of the lockdown [15]. In Italy and Spain, even though the situation was worse, the participants in our study showed lower scores of psychological strain compared to France and the United Kingdom. One reason for their lower scores of depression, anxiety, and stress could be the high proportion of medical professionals in the Italian sample, whose overall mental health was significantly better than that of the nonmedical professionals. Another reason could be that the surveys started at different points of time in these countries and the peak of the pandemic was different for each country.

The lower levels of psychological distress among participants in Austria and Switzerland could be attributed to the countries' relatively lower number of cases per 1 million people [5]. In Germany, which had a higher number of cases [5] but less psychological strain, the health care system seemed to be better prepared as this is the country with the highest number of critical care beds in Europe [2,52].

Limitations

Although our findings support previous studies on the psychological burden of COVID-19, a few limitations should be considered. Links to the online survey were distributed via social media and via the personal and professional networks of the authors. Since the contact networks in the individual European countries were not equally strong and online distribution of a link was difficult to control, the number of participants for each country was different, leading to uneven distribution of professional groups per country.

Moreover, the surveys did not start simultaneously in all European countries and data could not be acquired when the COVID-19 outbreak peaked in each country. In addition, translating questionnaires into different languages always carries the risk that the individual translations are not completely identical. Since we also partially adapted the already translated versions of DASS-21 to our online format, this could have led to an additional language bias. Finally, the category "nonmedical professionals" was heterogeneous. Persons who worked in nonmedical sectors of the health care system were included in this category and might have been exposed to COVID-19.

Implications

The COVID-19 pandemic has caused fundamental changes in the health care and non–health care sectors and has put considerable strain not only on medical but also on nonmedical professionals. A sizeable part of participants expressed moderate to extremely severe symptoms of depression, anxiety, and/or stress while nonmedical professionals seemed to be more burdened than their medical counterparts. Targeted and personalized mental health services are needed not only for medical professionals but also for other professional groups during pandemics. When developing these services, specific needs and fears should be taken into account. One approach could be to examine the reasons why the medical staff are better at handling the pandemic situation and using these results to develop or optimize mental health services for future pandemics.

By providing the opportunity for medical professionals to carry out their own protective measures and by providing sufficient information about the virus, they might be able to better overcome such situations. Further research is needed to analyze the long-term consequences of the psychological strain of COVID-19 by using valid diagnostic tools and other research designs like longitudinal surveys or qualitative studies. In-depth interviews could provide additional valuable information on major stressors and coping strategies.

Acknowledgments

This study would not have been possible without the support of European health care institutions that helped us distribute the survey link. We thank our Spanish supporters Fundación INTRAS; the Regional Authority of Social Affairs (Castilla y León); the nursing homes ACALERTE and LARES; Hospital San Pedro en Logroño, La Rioja; the Fundación Rey Ardid (Aragón region); and the care organizations Pronisa, AFAVITAE, and ACyLNP. In France, we would like to thank the Marseille Public University Hospital System. In Austria, we thank the Sozialdienste Wolfurt for their support.

Conflicts of Interest

None declared.

Abstract

Background: Internet hospitals in China are being rapidly developed as an innovative approach to providing health services. The ongoing COVID-19 pandemic has triggered the development of internet hospitals that promote outpatient service delivery to the public via internet technologies. To date, no studies have assessed China's internet hospitals during the COVID-19 pandemic.

Objective: This study aimed to elucidate the characteristics of China's internet hospitals and assess the health service capacity of these hospitals.

Methods: Data on 711 internet hospitals were collected from official websites, the WeChat (Tencent Inc) platform, smartphone apps, and the Baidu search engine until July 16, 2020.

Results: As of July 16, 2020, 711 internet hospitals were developed in mainland China. More than half of these internet hospitals (421/711, 59.2%) were established during 2019 (206/711, 29%) and 2020 (215/711, 30.2%). Furthermore, about one-third (215/711, 30.2%) of internet hospitals were established at the beginning of 2020 as an emergency response to the COVID-19 epidemic. The 711 internet hospitals consisted of the following 3 types of hospitals: government-oriented (42/711, 5.91%), hospital-oriented (143/711, 20.11%), and enterprise-oriented internet hospitals (526/711, 73.98%). The vast majority of internet hospitals were traditional hospitals (526/711, 74%). Nearly 46.1% (221/711) of internet hospitals requested doctors to provide health services at a specific web clinic. Most patients (224/639, 35.1%) accessed outpatient services via WeChat. Internet hospitals' consulting methods included SMS text messaging consultations involving the use of graphics (552/570, 96.8%), video consultations (248/570, 43.5%), and telephone consultations (238/570, 41.8%). The median number of available web-based doctors was 43, and the median consultation fees of fever clinics and other outpatient clinics were ¥0 (US $0) per consultation and ¥6 (US $0.93) per consultation, respectively. Internet hospitals have provided various services during the COVID-19 pandemic, including medical prescription, drug delivery, and medical insurance services.

Conclusions: The dramatic increase of internet hospitals in China has played an important role in the prevention and control of COVID-19. Internet hospitals provide different and convenient medical services for people in need.

internet hospital; COVID-19; prevention; control; health care; China; cross-sectional; digital health; accessibility

Introduction

The outbreak of the novel COVID-19 disease was first reported in January 2020, and the disease has been spreading throughout the entire globe without any indication of stopping any time soon [1,2]. This epidemic has constituted a public health emergency of pandemic proportions [3], which has created major dilemmas in all areas of health care. Such dilemmas include a lack of hospital resources, the suspension of outpatient services, inconvenience in seeking medical treatment due to social isolation, and lockdown. In addition, the human-to-human transmission of the SARS-CoV-2 virus has become the primary transmission route of COVID-19 [4].

Strict prevention measures and effective therapeutics are urgently needed for the effective control of the COVID-19 pandemic. Such measures include the promulgation of Chinese government decrees that require domestic internet hospitals to vigorously develop telemedicine services [5]. Currently, internet hospitals have been developed as a new approach for the provision of health services, including outpatient services delivered through the internet or various digital technologies [6,7]. Internet hospitals surmount geographical obstacles and time-related barriers, thereby making it easy for Chinese patients to rapidly seek doctor services [8]. Additionally, internet hospitals reduce the chance of nosocomial cross infection by potentially keeping patients away from hospitals. This protects both clinicians and other patients, which is a practice that is welcomed by most Chinese people [9]. Internet hospitals have proliferated as Chinese people continue to seek health services and psychological assistance amid the COVID-19 pandemic.

China's new internet hospitals, which were established during the epidemic, have yet to be systematically and exhaustively assessed. In this study, we aimed to provide an overview of internet hospitals in China (ie, as of July 2020) through a national cross-sectional study that describes the characteristics of these hospitals. We also aimed to evaluate the health service capacity of internet hospitals during the COVID-19 epidemic.

Methods

Internet Hospital Eligibility

Data were collected by conducting a search on national websites, including the popular Baidu search engine and the official websites of the National Health Commission of the People's Republic of China and each provincial health commission. The search was conducted by using specific Chinese search terms, such as those for "Internet hospitals," "Internet health," "Internet medicine," "mobile medicine," "mobile health," "Telehealth," "digital medicine," "digital health," "Web hospitals," and "Cloud hospitals." All officially registered internet hospitals were eligible for inclusion. Data from October 10, 2006 to July 15, 2020 were collected. Additionally, we used a public WeChat (Tencent Inc) account and app stores (ie, the Apple App Store, Android App Store, Huawei App Store, Xiaomi App Store, and 360 App Store) to find medical care platforms and mobile health apps that were affiliated with internet hospitals. The study region included all of mainland China, except Hong Kong, Macau, Taiwan, and several islands in the South China Sea. Ultimately, we found 711 internet hospitals.

Data Collection

We searched for information about each internet hospital by using official websites, the WeChat platform (ie, one of the largest mobile social network apps in China, with more than 1 billion monthly active users), and smartphone apps (ie, if available). Collected data were recorded on a digital archive via Microsoft Excel. Information on internet hospital features included construction date, location, the identity of investors, hospital characteristics, and the role that the hospital played in combating COVID-19.

We assessed the consultation characteristics of internet hospitals, including access method (ie, website, app, WeChat, and other); consulting method (ie, video consultations, telephone consultations, and SMS text messaging consultations involving the use of both text and graphics); medical insurance, prescription, and drug delivery service provision; doctor source (ie, local hospital, medical union, district, and nationwide doctors); service time (ie, any time or specific times); the number of available web-based doctors who could deliver instant medical services; and the availability of outpatient departments.

In this study, the roles played by internet hospitals referred to whether the hospital provided COVID-19–related inquiries regarding fever clinic consultations, psychological counseling, the provision of COVID-19–related information, and whether there was an overseas version of an internet hospital that could help in the fight against COVID-19. When collecting information on fever clinics, we focused on how consultations were conducted (ie, manual, artificial intelligence, or both manual and artificial intelligence) and the fee per consultation. Additionally, we collected information on internet hospital–related policies and regulations that were released by the government, management agencies, medical institutions, and health care industry associations. This helped us to understand the actions taken by the health community in China during the COVID-19 outbreak and assess the role of internet hospitals in combating COVID-19. At least 2 researchers extracted data for each internet hospital independently. Any objections to the data were resolved via discussion.

Data Analysis and Visualization

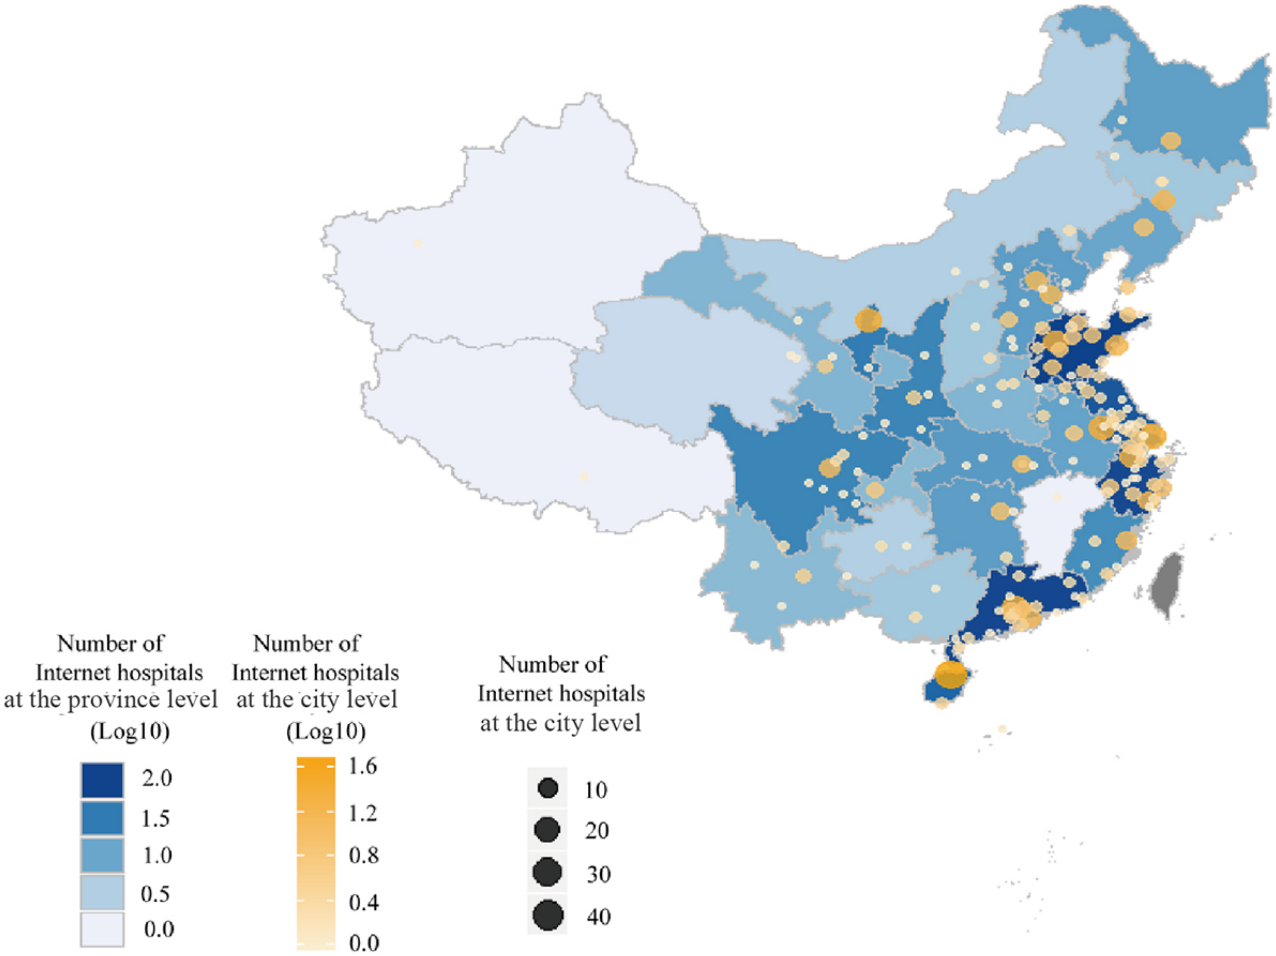
Data management and analysis were performed with Microsoft Excel 2017. Geographical and time distributions were drawn with R 4.0.2. Count data were expressed as number (percentage) and presented on bar charts, Venn diagrams, mosaic plots, Nightingale rose diagrams, and statistical maps. Skewed continuous data were expressed as median (interquartile range) and presented on Violin plots.

Results

Internet Hospital Characteristics

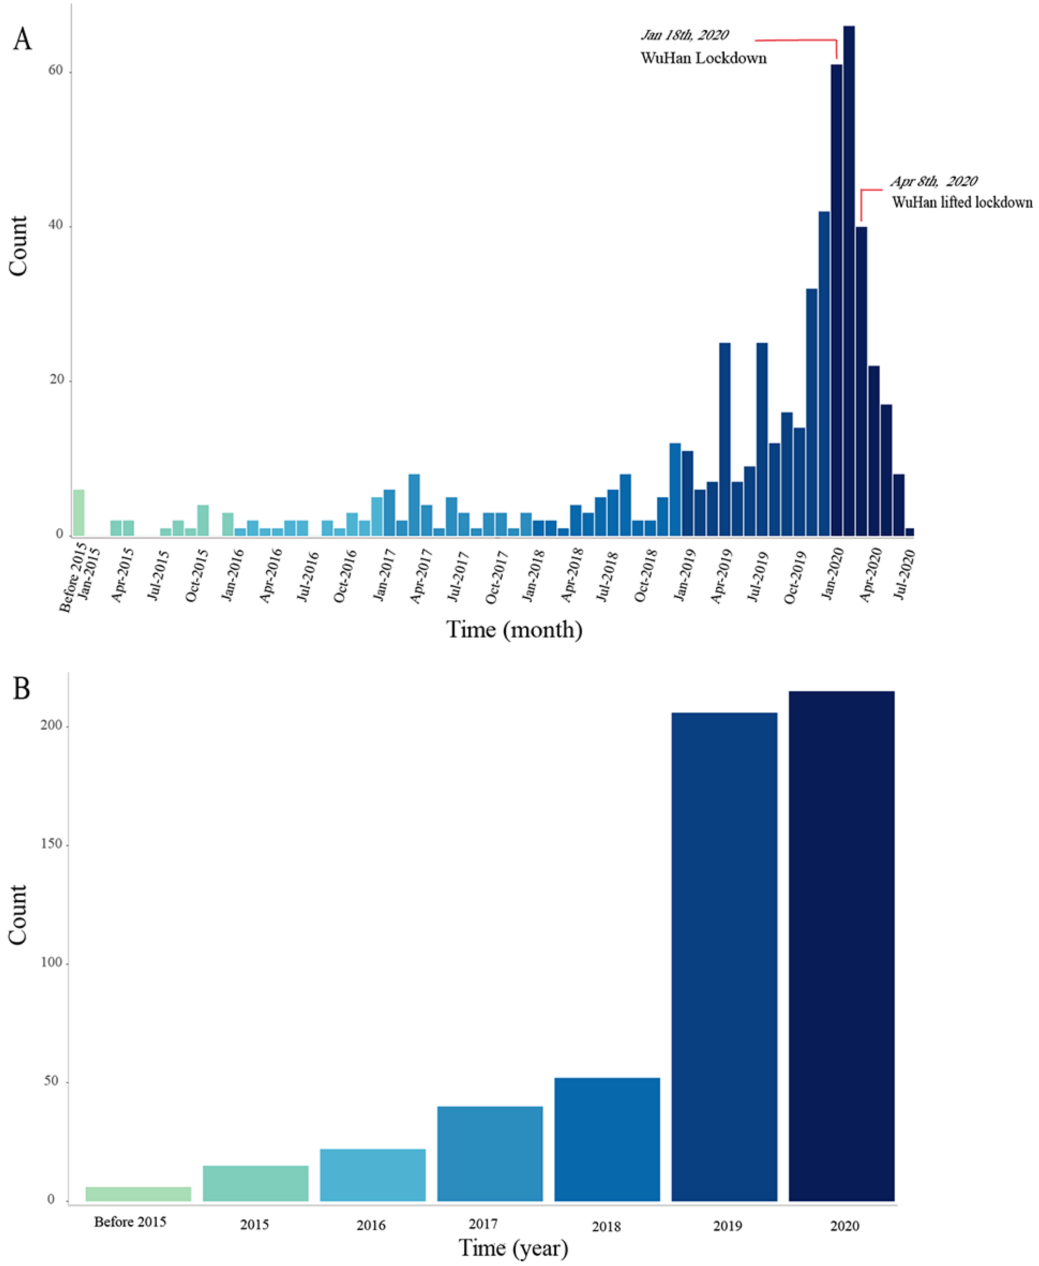
As of July 2020, data on 711 internet hospitals were collected. Generally, internet hospitals were mainly distributed in the east and southern coastal provinces (Figure 1). This distribution was closely related to the foundation and early development of internet hospitals in these areas [10]. However, internet hospitals were not limited to these first-to-try areas. At the time of this study, every province had at least 1 internet hospital. This reflects the trend of gradual development from coastal cities to inland regions (ie, the gradual spread of internet hospitals from the point of origin to mainland China).

Figure 1. Spatial distributions of internet hospitals in China. The different shades of blue denote the total number of internet hospitals in each province. The color (ie, the different shades of yellow) and size of the circles indicate the number of internet hospitals in each city.



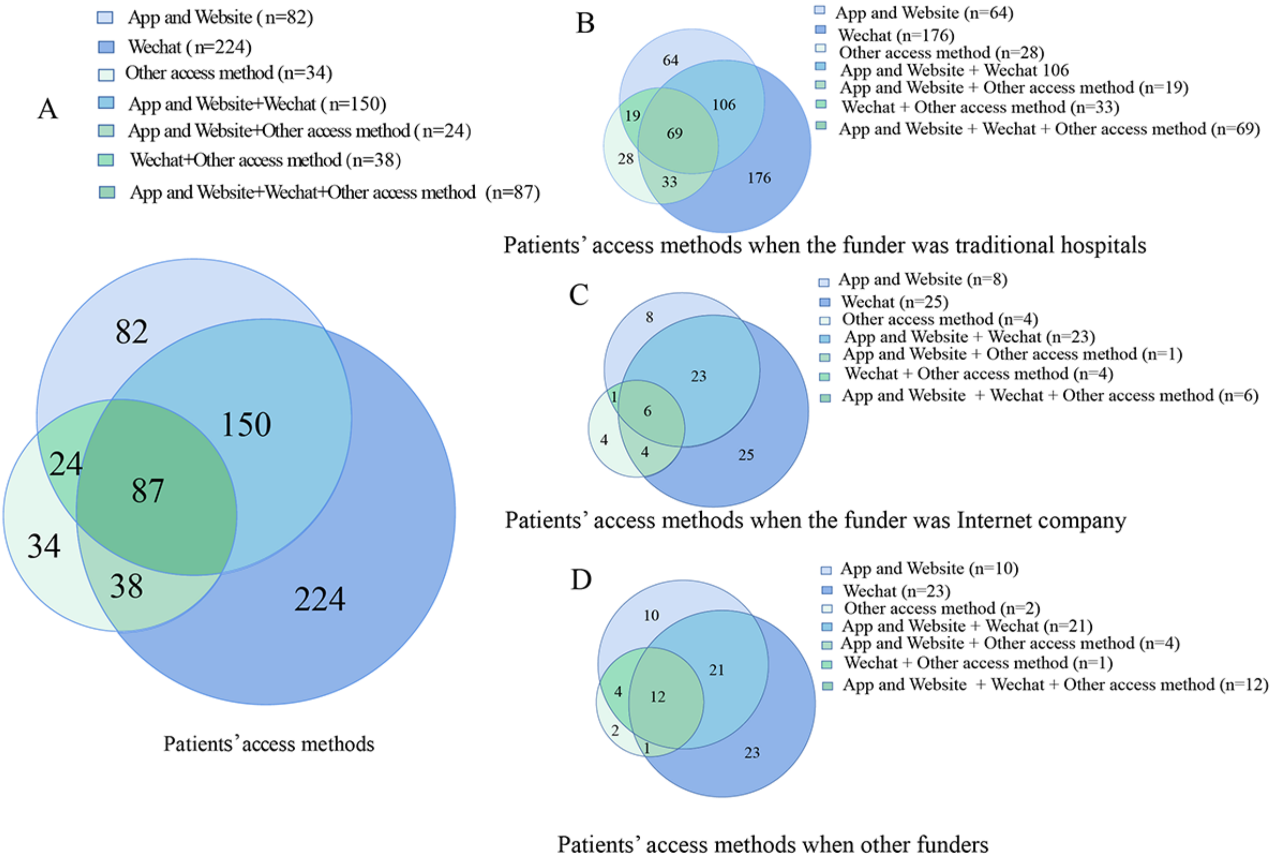
In recent years, internet hospitals have been rapidly developed. Of the 711 internet hospitals found in this study, 215 (30.1%) were established in 2020 (ie, after the beginning of the COVID-19 outbreak) and 5 (0.7%) were established before 2015 and until July 2020. Moreover, 2.1% (15/711), 3.1% (22/711), 5.6% (40/711), 7.3% (52/711), 29% (206/711) and 30.2% (215/711) of internet hospitals were established in 2015, 2016, 2017, 2018, 2019, and 2020, respectively (Figure 2; Table S2 in Multimedia Appendix 1). Notably, we could not identify the date of foundation for 21.9% (156/711) of internet hospitals. We concluded that there has been a growing trend for the establishment of internet hospitals up to July 2020. Additionally, the government has issued a series of policies that were conducive to the role of internet hospitals in combating COVID-19 (Figure 2).

Figure 2. The construction dates of internet hospitals in China. (A) The construction dates of internet hospitals in China by month. (B) The construction dates of internet hospital in China by year. The following important policies were issued during the COVID-19 epidemic in China: (1) Notice on internet diagnosis and treatment consultation services for COVID-19 prevention and control (February 6, 2020), (2) Notice on strengthening internet diagnosis and treatment consulting services for COVID-19 prevention and control (February 8, 2020), (3) Notice on the national telemedicine and internet medical center for the national remote consultation of critically ill patients with COVID-19 (February 21, 2020), (4) Notice on further promoting the development and standardized management of internet medical services (April 18, 2020), and (5) Notice on the technical specifications and financial management of the "Internet+ medical service" project of public medical institutions (May 8, 2020).



In terms of patients' (N=639) methods for accessing internet hospitals, 13.6% (87/639) of patients accessed internet hospitals by using apps, websites, WeChat, and other access methods simultaneously. Of note, 12.8% (82/639) of patients visited internet hospitals by exclusively using apps and websites, 35.1% (224/639) visited internet hospitals by exclusively using WeChat, and 5.3% (34/639) visited internet hospitals by using other access methods. Additionally, regardless of who funded the internet hospitals, the most widely used service that patients used to access outpatient services was WeChat, followed by apps or websites, and other access methods (Figure 3).

Figure 3. Methods for accessing internet hospitals. (A) Patients' access methods. (B) Patients' access methods when the funder was a traditional hospital. (C) Patients' access methods when the funder was an internet company. (D) Patients' access methods when the funder was another type of company.



Patients' access methods

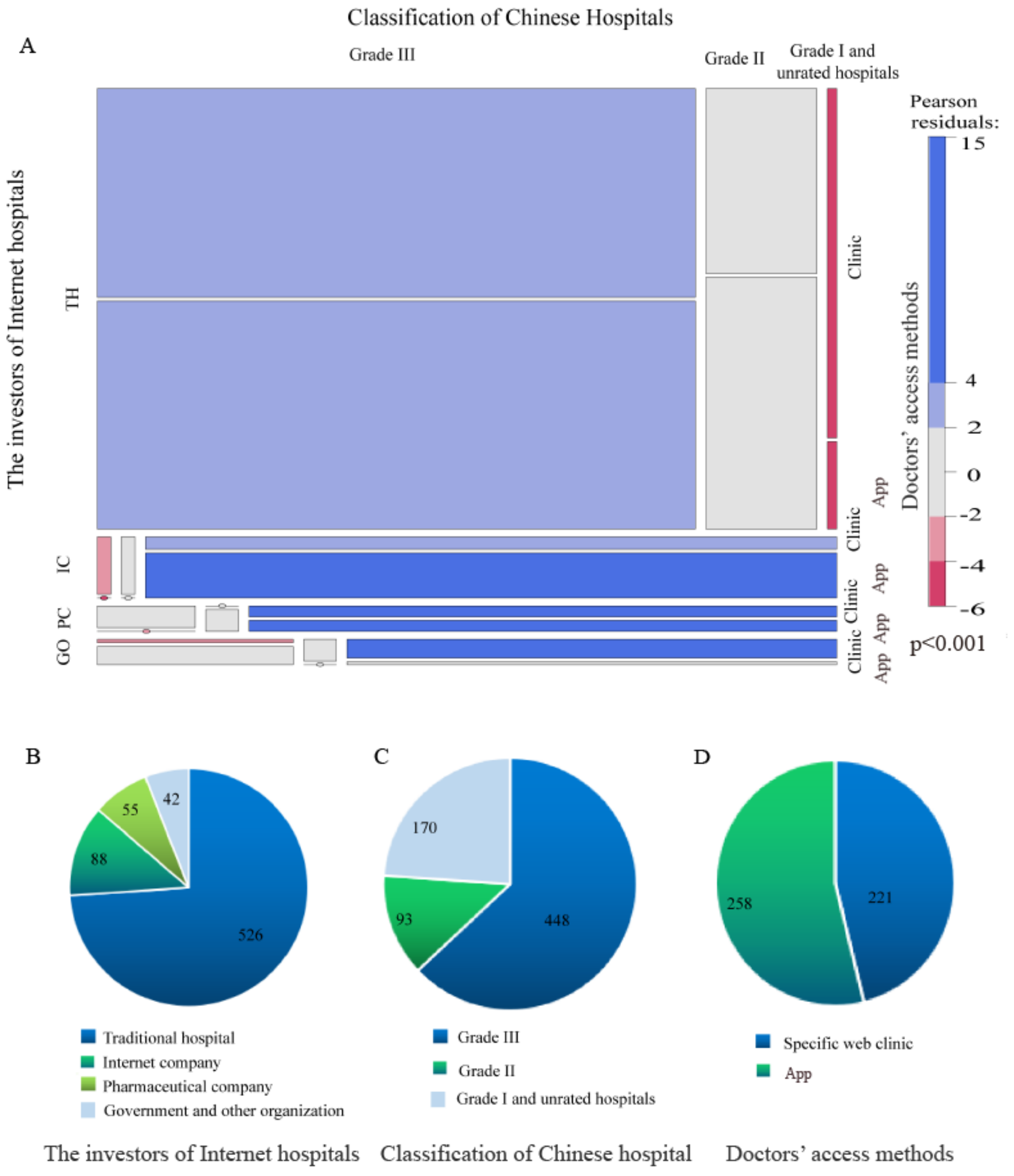
Patients' access methods when the funder was traditional hospitals

Patients' access methods when the funder was Internet company

Patients' access methods when other funders

The vast majority of internet hospitals were traditional hospitals (526/711, 74%). This finding shows that traditional hospitals were more capable of integrating internet hospital services into their infrastructure than other types of hospitals. Grade III hospitals, which have a large number of outpatients, superb medical technology, diverse and complex service types, and various business process requirements, accounted for a large proportion (448/711, 62%) of internet hospitals. Furthermore, government departments, such as health administrations, also supported the construction of internet hospitals. In terms of the consultation characteristics of the 711 internet hospitals, 221 (46.14%) hospitals asked doctors to provide medical services at a specific web clinic, whereas 258 (53.86%) adopted the use of apps for health service delivery (Figure 4).

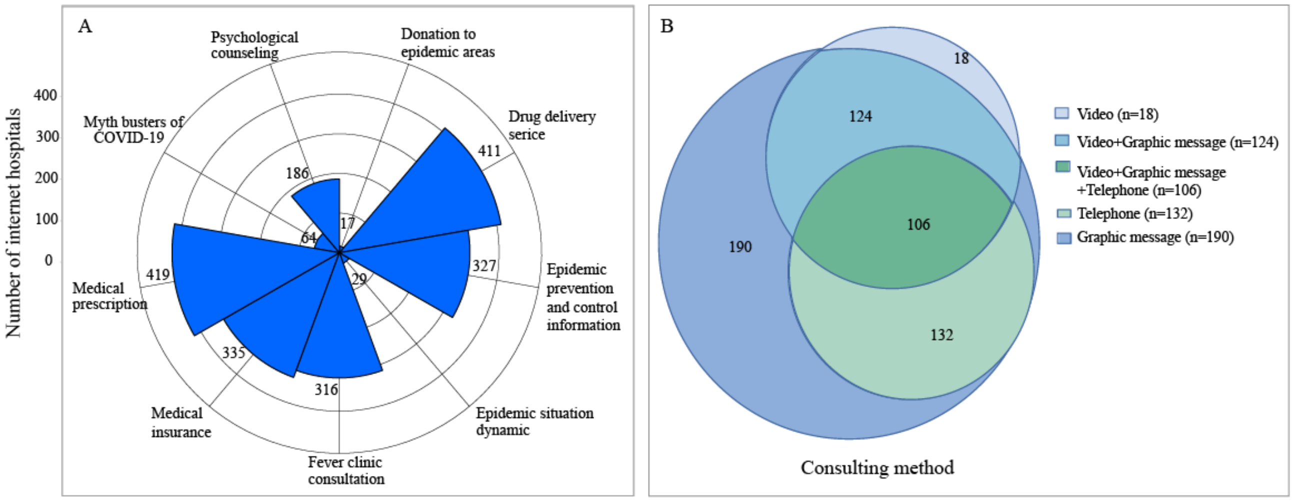
Figure 4. Characteristics of internet hospitals. (A) A mosaic plot with areas that show the proportion of doctors' web-based methods for accessing internet hospitals in China, stratified by the classification of Chinese hospitals and the structure of the main investment. The investors of internet hospitals include THs, ICs, PCs, and GOs. The classification of Chinese hospitals were as follows: Grade III, Grade II, and Grade I and unrated hospitals. Doctors provided medical services through a specific web clinic or app. (B) The investors of internet hospitals. (C) Classification of Chinese hospitals. (D) Doctors' access methods. GO: government and other organization; IC: internet company; PC: pharmaceutical company; TH: traditional hospital.



Medical Service Characteristics

With regard to the roles that the 711 internet hospitals played in combating COVID-19, most hospitals (419/484, 86.6%) provided medical prescriptions. Furthermore, 74.5% of hospitals (411/552) provided drug delivery services, 67.5% (335/496) provided medical insurance, 60.7% (335/496) provided epidemic prevention and control information, 60% (316/527) provided fever clinic consultations, 35.2% (186/529) provided psychological counseling, 13.3% (64/483) provided a myth busters of COVID-19 service, 20.6% (29/141) assessed epidemic situation dynamics, and 3.8% (17/443) made donations (Figure 4). Internet hospitals' consulting methods included SMS text messaging consultations involving the use of graphics (552/570, 96.8%), video consultations (248/570, 43.5%), and telephone consultations (238/570, 41.8%). Moreover, 18.6% (106/570) of internet hospitals offered 3 methods for patient consultations (Figure 5). It should be noted that several internet hospitals were missing pertinent data. As such, these hospitals were excluded from analysis.

Figure 5. Medical service characteristics of China's internet hospitals. (A) The roles that internet hospitals played in fighting COVID-19. (B) Internet hospitals' consulting methods.



Human Medical Resources

The distribution of the internet hospitals' human medical resources in China is shown in Figure 6. The median number of available web-based doctors was 43 (IQR 3-172; maximum: 563,881). The median consultation fees of fever clinics and other outpatient clinics (ie, excluding fever clinics) were ¥0 (US $0; IQR ¥0 [US$ 0]-¥0 [US $0]) per consultation and ¥6 (US $0.93; IQR ¥0 [US $0]-¥20 [US $3.09]) per consultation, respectively (Figure 6, Table 1). About half of the hospitals (204/422, 48.3%) provided services at any time. Furthermore, 80.9% (467/577) of doctors were from local hospitals and medical unions (Figure 6).

Figure 6. Human medical resources in China's internet hospitals. (A) Violin plots that show the number of doctors in China's internet hospitals. The numbers on the y-axis are logarithms to the base 2. (B, C) Violin plots displaying the consultation fees for a person who visited an internet hospital to find medical help (ie, consultation fees for fever clinics and other clinics). (D, E) Bar plots that show the distribution of doctors' service times and doctor sources with regard to internet hospitals, respectively.

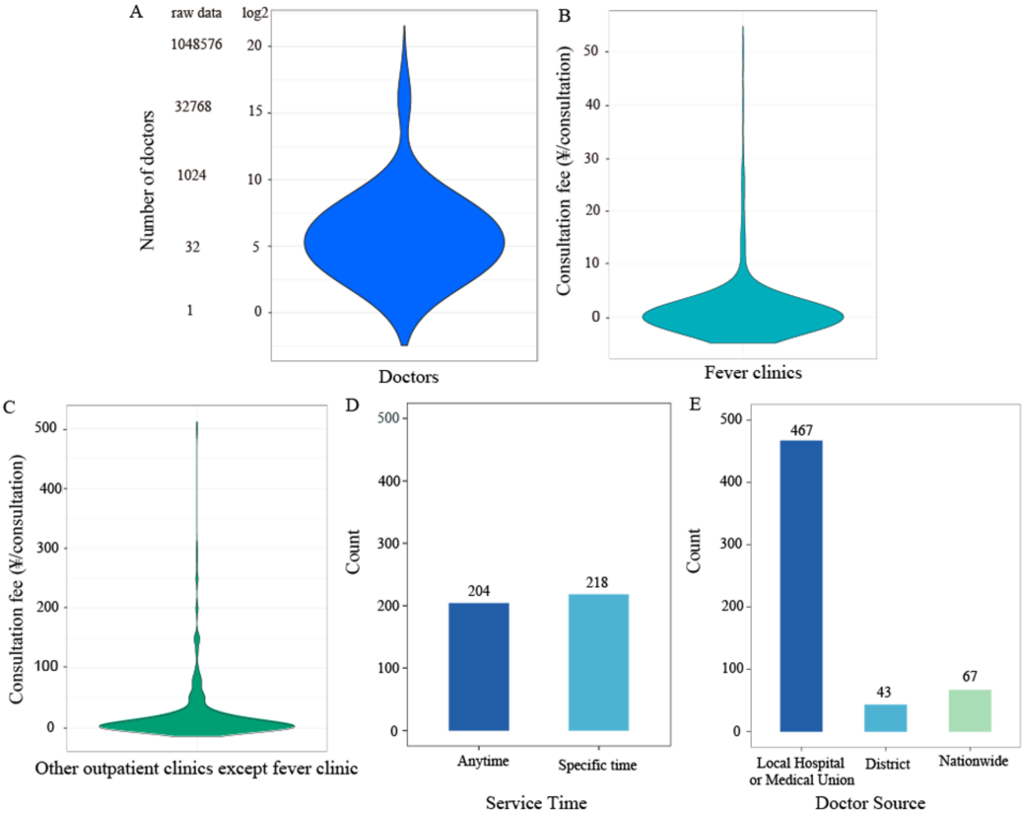


Table 1. Number of doctors and consultation fees for internet hospitals in China.

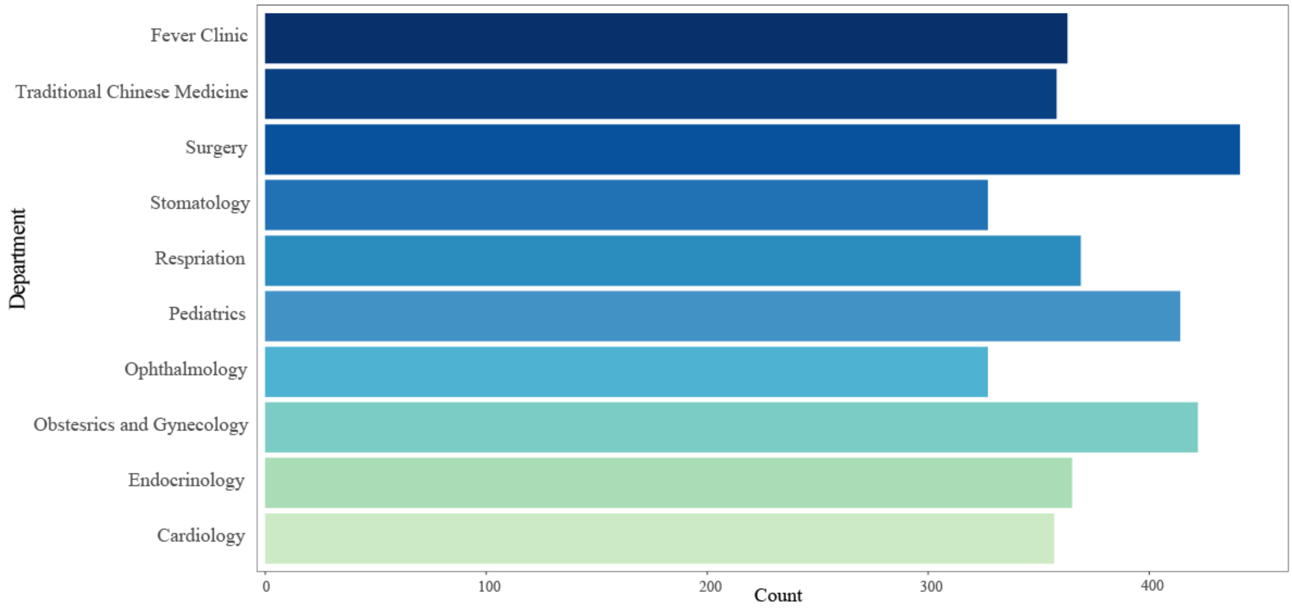
Variable	Minimum	5th percentile	25th percentile	50th percentile	75th percentile	95th percentile	Maximum
Number of available web-based doctors, n	1	3	11	43	172	1496.4	563881
Consultation fee of fever clinics, ¥[a]/consultation	0	0	0	0	0	8.9	50
Consultation fee of other outpatient clinics (ie, excluding fever clinics), ¥/consultation	0	0	0	6	20	120	500

[a] A currency exchange rate of ¥1=US $0.15 is applicable.

Multiple internet hospitals had different departments for patients; the department of surgery (441/711, 62%) was the most common. In contrast, the number of stomatology (327/711, 46%) and ophthalmology (327/711, 46%) departments was relatively small. Of the 711 internet hospitals, 363 (51.1%) introduced fever clinics in response to the COVID-19 pandemic (Figure 7).

Figure 7. A bar plot that depicts the number of available departments in internet hospitals.



Relation to COVID-19

With regard to the internet hospitals with available data, 60% (316/527) of internet hospitals provided telemedicine services for managing COVID-19. Internet hospitals mainly conducted manual consultations (209/289, 72.3%). In addition, 35.2% (186/529), 60.7% (327/539), 13.3% (64/483), and 3.8% (17/443) of internet hospitals provided psychological counseling, epidemic prevention and control information, myth busters services, and donations, respectively, in response to COVID-19. Furthermore, a number of internet hospitals supported medical prescription (419/484, 86.6%), drug delivery (411/552, 74.5%), and medical insurance (335/496, 67.5%) services to further enhance COVID-19 prevention and control (Figure 8).

Discussion

Principal Findings

This national cross-sectional study outlines the status of the internet hospitals established in China by July 2020. There has been a rising trend in the emergence of internet hospitals in China. This trend peaked in December 2019 after the China National Healthcare Security Administration promulgated the Guidance of the State Medical Security Bureau on improving the Internet+ medical service price and medical insurance payment policy [11]. Furthermore, the number of internet hospitals peaked in February 2020. This may have been the period with the largest number of internet hospitals established in a single month due to the epidemic.

Due to inequalities in medical resources, medical technology, and informatization level across the country, the status of internet hospitals in China varies greatly. Overall, the eastern and southern coastal provinces have the highest distribution of major internet hospitals. This distribution is closely related to the foundation and early development of internet hospitals in these regions [10]. However, internet hospitals are no longer limited to these areas. Jiangxi, Jilin, and other areas established the first batch of internet hospitals in 2020. This reflects the trend of gradual development from coastal cities to inland areas.

The vast majority of internet hospitals have been constructed by Grade III hospitals, which have a large number of patients, superb medical technology, and diverse and complex health services. The independent construction of an internet hospital system can meet the needs of individualized development. Moreover, the health administration department has been promoting the construction of internet hospitals. A concern however is that in most provinces, traditional hospitals make up a large proportion of internet hospitals; only Ningxia and Hainan are dominated by corporate-led internet hospitals.

The catalytic effect of the COVID-19 pandemic on the internet hospital industry has been obvious since 2020; the pandemic has resulted in major development opportunities for internet hospitals. Due to the need for epidemic prevention and control, the National Health Commission, the National Medical Insurance Bureau, and other health departments have intensively introduced a series of policies [12-16] to vigorously promote the development of internet hospitals. During the epidemic, internet hospitals have launched web-based fever clinics; chronic disease follow-up consultations, prescriptions, and drug delivery services; and several medical insurance reimbursement programs, and these have been continuously and urgently approved. Web-based medical treatment has promoted the public awareness of internet hospitals. Additionally, the epidemic has prompted people to develop a habit of using internet hospitals, to a certain extent [17].

Internet hospitals can reduce crowd gathering in physical hospitals through a variety of methods. Web-based medical services, such as web-based education, publicity, and psychological intervention, can not only help the public master basic anti-epidemic knowledge and skills, but also reduce social panic, thereby reducing the number of unnecessary physical hospital visits and enhancing psychological resilience [18]. By integrating web-based resources with offline epidemic control measures, internet hospitals can play a greater role in epidemic prevention and control [19].

With the launch of internet hospitals, the tension regarding offline medical resources has, to a certain extent, been relieved. With regard to upper first-class hospitals, the most direct role of internet hospitals has been shifting to providing returning patients with web-based services and improving the efficiency of medical treatment. Small and medium regional hospitals with a small number of outpatients or limited construction and operation capabilities have the choice of relying on regional internet hospitals or third-party, internet-based medical platforms. This approach is meant to reduce input costs by making full use of the advantages of internet hospitals, as internet-based platforms can help doctors concentrate on becoming the core resource for serving patients. As a result, internet hospitals and internet-based platforms will achieve the advantage of complementation and achieve a win-win situation.

After several years of development, China's internet hospitals can now overcome the limitations of time and space and provide various medical services with a high degree of accessibility for all patients [20]. Moreover, interdisciplinary and transregional exchanges and cooperation can be achieved with internet hospitals, thereby improving doctors' ability to deal with emerging diseases. The Chinese government encouraged internet hospitals to join epidemic prevention and control efforts at the beginning of the COVID-19 outbreak [11], and confirmed that internet hospitals are an important part of the joint epidemic prevention and control system [21]. To make better use of internet hospitals, more measures should be implemented, such as encouraging more doctors (ie, especially psychologists and pediatricians) to take part in web-based services, discovering the needs of the public in time to adjust response strategies, and developing more standardized consulting service guidelines. At the same time, there is a need to improve the availability of internet hospital services in a variety of ways, strengthen publicity efforts for expanding the internet hospital user base, and cooperate with community service centers and the Centers for Disease Control and Prevention to improve joint epidemic control and prevention mechanisms.

Conclusion

This study demonstrates how the concepts of medical service provision have been redefined by internet hospitals and internet-based technologies. Internet hospitals allow for the transferring of patients to medical centers that can provide medical services and health care without requiring people to leave their homes. Internet hospitals can provide different types of medical services to people seeking medical needs; offer essential medical support to the public during the COVID-19 outbreak, thereby regulating social psychology and easing social panic; maintain proper social distancing; and promote correct medical-seeking behaviors. These advantages result in the reduction of the incidence of cross-infection in hospitals. Thus, it is evident that internet hospitals play an important role in COVID-19 prevention and control.

Abstract

Background: The COVID-19 outbreak has increased challenges associated with health management, especially cancer management. In an effort to provide continuous pharmaceutical care to cancer patients, Sun Yat-sen University Cancer Center (SYSUCC) implemented a remote pharmacy service platform based on its already existing web-based hospital app known as Cloud SYSUCC.

Objective: The aim of this study was to investigate the characteristics, acceptance, and initial impact of the Cloud SYSUCC app during a COVID-19 outbreak in a tertiary cancer hospital in China.

Methods: The total number of online prescriptions and detailed information on the service were obtained during the first 6 months after the remote service platform was successfully set up. The patients' gender, age, residence, primary diagnosis, drug classification, weekly number of prescriptions, and prescribed drugs were analyzed. In addition, a follow-up telephonic survey was conducted to evaluate patients' satisfaction in using the remote prescription service.

Results: A total of 1718 prescriptions, including 2022 drugs for 1212 patients, were delivered to 24 provinces and municipalities directly under the Central Government of China between February 12, 2020, and August 11, 2020. The majority of patients were female (841/1212, 69.39%), and 90.18% (1093/1212) of them were aged 31-70 years old. The top 3 primary diagnoses for which remote medical prescriptions were made included breast cancer (599/1212, 49.42%), liver cancer (249/1212, 20.54%), and thyroid cancer (125/1212, 10.31%). Of the 1718 prescriptions delivered, 1435 (83.5%) were sent to Guangdong Province and 283 (16.5%) were sent to other provinces in China. Of the 2022 drugs delivered, 1012 (50.05%) were hormonal drugs. The general trend in the use of the remote prescription service declined since the 10th week. A follow-up telephonic survey found that 88% (88/100) of the patients were very satisfied, and 12% (12/100) of the patients were somewhat satisfied with the remote pharmacy service platform.

Conclusions: The remote pharmacy platform Cloud SYSUCC is efficient and convenient for providing continuous pharmaceutical care to patients with cancer during the COVID-19 crisis. The widespread use of this platform can help to reduce person-to-person transmission as well as infection risk for these patients. Further efforts are needed to improve the quality and acceptance of the Cloud SYSUCC platform, as well as to regulate and standardize the management of this novel service.

Introduction

China and the rest of the world are experiencing an outbreak of the highly infectious, novel COVID-19 [1-3]. To effectively combat the COVID-19 pandemic, Chinese health authorities have effected a series of preventive and control measures since January 21, 2020, including restrictions on people's movement, reduced transportation, entry and exit controls for towns and villages, and isolation requirements for travelers between various parts of the country [4]. However, for patients with cancer, restrictions on movement could result in disease upstaging and have considerable impact on cancer-specific death rates due to delayed diagnoses and the lack of or suboptimal cancer management. Therefore, the management of patients with cancer has become a crucial issue in cities with large-scale outbreaks of COVID-19 [5-7].

Since May 24, 2018, Sun Yat-sen University Cancer Center (SYSUCC) in China has implemented a hospital-based, mobile app called Cloud SYSUCC that enables remote medication consultation between doctors and patients, available both on Android and iOS mobile operating systems. This app includes 2 introductory screens: one for the medical staff (ie, therapeutic interface) and the other for patients (ie, patient interface; see Figure S1 in Multimedia Appendix 1). The therapeutic interface has been designed for doctors to check a patient's medical history, communicate with them, and order examinations; however, it did not provide access to medication prescriptions. For this reason, a multidisciplinary working group comprising senior hospital pharmacists, clinical experts, and information technology engineers was formed on January 23, 2020, to set up a remote pharmacy service platform based on the Cloud SYSUCC app. This platform would enable remote services such as web-based consultation, prescription, dispensation, and home delivery of oral anticancer medications, as well as offer standard administration instructions for the use of these drugs. In this paper, we introduce this remote pharmacy service system and describe its development and implementation in a tertiary cancer hospital in China.

To explore the advantages of the remote pharmacy service system for patients with cancer during public health emergencies, we analyzed the online prescriptions of outpatients at SYSUCC in Guangzhou City, Guangdong Province, China. We collected data from the first 6 months after the remote service platform was successfully set up, and we analyzed the characteristics, user acceptance, and initial impact of this new bundled approach during the COVID-19 outbreak.

Methods

Platform Development

The remote pharmacy service platform provides services to the public via the Cloud SYSUCC app, which has been deployed on a public cloud. A private cloud connects the public cloud with the internal hospital information system using a web services internet tool.

Data Sources

The total number of online prescriptions and their detailed information were obtained automatically from the hospital information system of Cloud SYSUCC. We collected data from February 12, 2020, to August 11, 2020. Patient's gender, age, residence, primary diagnosis, drug classification, weekly number of prescriptions, and prescribed drugs were included in the analysis. Furthermore, we also conducted a telephonic survey to evaluate patients' satisfaction with using the remote prescription service. We used SPSS software (version 16.0; IBM Corp) to summarize and analyze the data.

Results

Real-Time Medication Consultation

We integrated the therapeutic interface of Cloud SYSUCC with the internal hospital information system by using a web services internet tool. Each medical staff, including pharmacists, could access the platform by using their unique staff identification number and password. This integration allows clinical pharmacists to provide real-time patient consultation and check the patient's medical history when necessary (Figure 1). They can also query the patient's consultations status (eg, pending or reviewed), and their observations can be documented in the electronic clinical history.

Figure 1. Screenshot of real-time medication consultation between clinical pharmacists and patients.

3rd March 12:02

Hello, I have been prescribed Regorafenib at the hospital. But I don't know whether I use it everyday or only for a few days?

3rd March 12:21

Hello, you should take Regorafenib 160 mg po on days 1-21, followed by a 7-day rest period within a 4-week schedule. Please take Regorafenib at the same time each day. Swallow tablet whole half an hour after a low-fat breakfast and drink 100~200mL warm water.

What are the specific requirements for a low-fat breakfast ?

A low-fat breakfast allows no more than 600 calories and less than 30% of calories from fat.

3rd March 12:44

Thank you. Can I eat a meat bun, a bowl of oatmeal, and an egg in my breakfast?

I need to confirm whether you add milk in your oatmeal and egg in your meat bun.

3rd March 12:58

Yes, I add milk in my oatmeal.

Eggs may bring you too much fat content in your breakfast. We suggest you to have 100 gram meat bun, 100 gram oatmeal without milk and one-half of an egg for your low-fat breakfast.

Thank you for your helpful and detail suggestion.

Online Prescriptions

Considering patients' safety, effectiveness, and emergency medical needs, the Pharmacy and Therapeutics Committee at SYSUCC has approved 22 oral anticancer drugs and 9 adjuvant medicines; these medications are currently listed in the Cloud SYSUCC app (Table 1). Doctors can prescribe the required drugs through the app in compliance with the following guidelines. First, for prescription of chemotherapeutic drugs, their potential adverse events should be considered and adequate surveillance should be allowed; the duration of these prescriptions should not exceed 14 days. Second, nonchemotherapeutic drugs can be prescribed for a duration not exceeding 30 days. Third, to address the need to balance the safety and feasibility of chemotherapeutic drugs, each patient is allowed 2 remote chemotherapy prescription cycles, after which they are required to visit the hospital for adequate examinations before they can continue using the Cloud SYSUCC app. All prescriptions are pharmaceutically verified by an automated drug rationality review system integrated into our cloud-based hospital information system.

Table 1. Anticancer drugs (n=22) and adjuvant medicines (n=9) listed in the Cloud SYSUCC app.

Drug type and name	Dosage form	Dosage strength	Drug quantity	Disease name
Hormonal drugs				
Exemestane	Tablet	25 mg	14	Breast cancer
Anastrozole	Tablet	1 mg	14	Breast cancer
Letrozole	Tablet	2.5 mg	30	Breast cancer
Toremifene	Tablet	60 mg	30	Breast cancer
Tamoxifen	Tablet	10 mg	60	Breast cancer
Medroxyprogesterone	Tablet	500 mg	30	Breast cancer
Megestrol acetate	Tablet	80 mg	24	Breast cancer, endometrial cancer
Bicalutamide	Tablet	50 mg	28	Prostate cancer

Temozolomide	Capsule	20 mg	5	Glioblastoma multiforme
Temozolomide	Capsule	100 mg	5	Anaplastic astrocytoma
Antimetabolite drugs				
Capecitabine	Tablet	500 mg	12	Colorectal cancer
Tegafur	Tablet	50 mg	100	Gastric cancer, colorectal cancer, breast cancer
Tegafur/Uracil Monopotassium	Tablet	162 mg	20	Gastric cancer, colorectal cancer, breast cancer
Tegafur/Gimeracil/Oteracil Monopotassium	Capsule	20 mg	140	Gastric cancer
Angiogenesis inhibitors				
Thalidomide	Capsule	25 mg	48	Multiple myeloma
Kinase inhibitors				
Gefitinib	Tablet	250 mg	10	Lung cancer
Imatinib	Tablet	100 mg	60	Gastrointestinal stromal tumor, lymphoblastic leukemia

Drug type and name	Dosage form	Dosage strength	Drug quantity	Disease name
Icotinib	Tablet	125 mg	21	Lung cancer
Erlotinib	Tablet	100 mg	30	
		150 mg	7	
Apatinib	Tablet	250 mg	10	Gastric adenocarcinoma, gastroesophageal conjunctive adenocarcinoma
Afatinib	Tablet	30 mg	7	Lung cancer
		40 mg	7	

Drug Dispensation and Home Delivery Service

Once an online prescription is generated from the Cloud SYSUCC app, an alert system linked to the SYSUCC drug dispensing system is initiated. Then, the frontline pharmacists can print the drug dispensing orders with an automatically generated delivery service tracking number (SF Express Group Co., Ltd.; Figure 2). All drug orders are double-checked before being transferred to SF Express, which provides a quick, cost-effective, and meticulous Mainland China Express Service to ensure safe and efficient delivery. Patients can view live updates by using the tracking information of the drug orders they have placed via the Cloud SYSUCC app. To ensure the drugs are delivered correctly to patients, SF Express delivery agents verify the identity of the patients before handing out the packages. If the delivery of packages takes more than 3 days, the patients can simply request a refund for the express order charges.

Figure 2. Example of a drug dispensing order generated using the Cloud SYSUCC app.

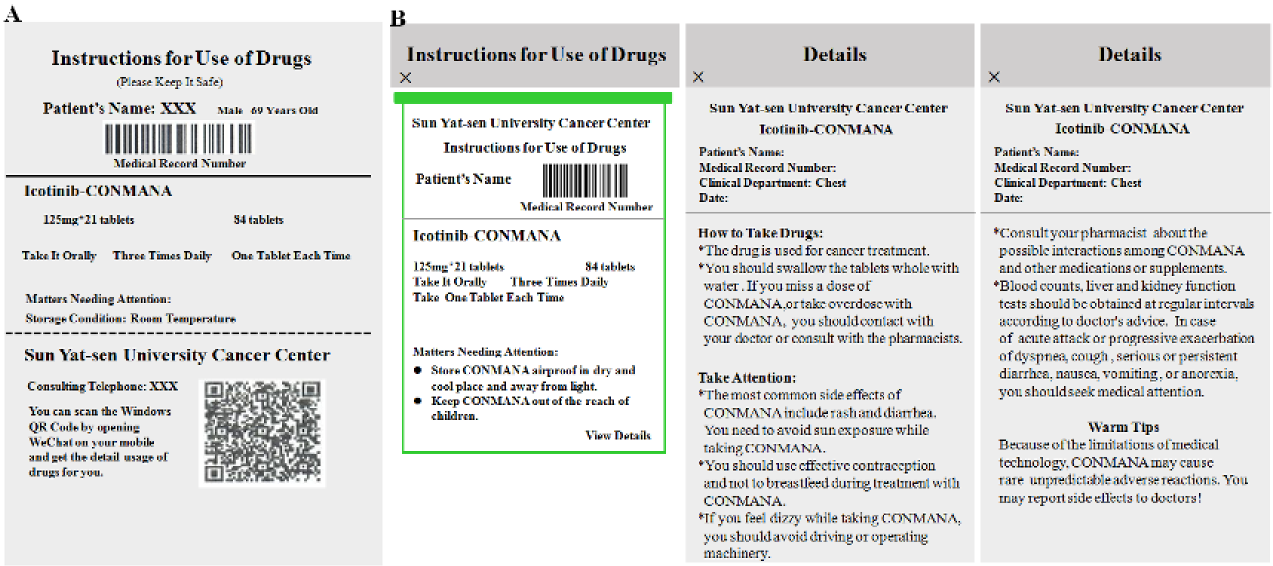
Standard Administration Instructions

To ensure safe handling of oral anticancer drugs by patients at home, clinical pharmacists have undertaken the following essential measures: (1) prescription directions are printed on each drug box; (2) detailed directions for the usage of drugs are made available on the patient's interface once the drugs are ordered (Figure 3A); and (3) patients can use their mobile phone's camera to scan a QR (quick response) code that will prompt a WeChat (Tencent Tech Shenzhen Co., Ltd.) window on their phone, wherein also detailed drug usage directions will be provided. These measures will ensure patients have easy access to the detailed instructions whenever they need (Figure 3B). If patients have any concerns regarding the drugs, they can consult with their treating doctors or clinical pharmacists using the Cloud SYSUCC app.

Figure 3. Screenshots of drug instructions shared with patients ordering drugs via the Cloud SYSUCC app: (A) printed version and (B) electronic version.



Instructions for Use of Drugs

(Please Keep It Safe)

Patient's Name: XXX Male 69 Years Old

Instructions for Use of Drugs

Patient's Name

Medical Record Number

Icotinib-CONMANA

125mg*21 tablets 84 tablets

Take It Orally Three Times Daily

Take One Tablet Each Time

Matters Needing Attention:

- Store CONMANA airproof in dry and cool place and away from light.
- Keep CONMANA out of the reach of children.

Details

Sun Yat-sen University Cancer Center

Icotinib-CONMANA

Patient's Name:
Medical Record Number:
Clinical Department: Chest
Date:

How to Take Drugs:

*The drug is used for cancer treatment.

*You should swallow the tablets whole with water . If you miss a dose of CONMANA,or take overdose with CONMANA, you should contact with your doctor or consult with the pharmacists.

Take Attention:

*The most common side effects of CONMANA include rash and diarrhea. You need to avoid sun exposure while taking CONMANA.

*You should use effective contraception and not to breastfeed during treatment with CONMANA.

*If you feel dizzy while taking CONMANA, you should avoid driving or operating machinery.

Details

Sun Yat-sen University Cancer Center

Icotinib CONMANA

Patient's Name:
Medical Record Number:
Clinical Department: Chest
Date:

*Consult your pharmacist about the possible interactions among CONMANA and other medications or supplements.

*Blood counts, liver and kidney function tests should be obtained at regular intervals according to doctor's advice. In case of acute attack or progressive exacerbation of dyspnea, cough , serious or persistent diarrhea, nausea, vomiting , or anorexia, you should seek medical attention.

Warm Tips

Because of the limitations of medical technology, CONMANA may cause rare unpredictable adverse reactions. You may report side effects to doctors!

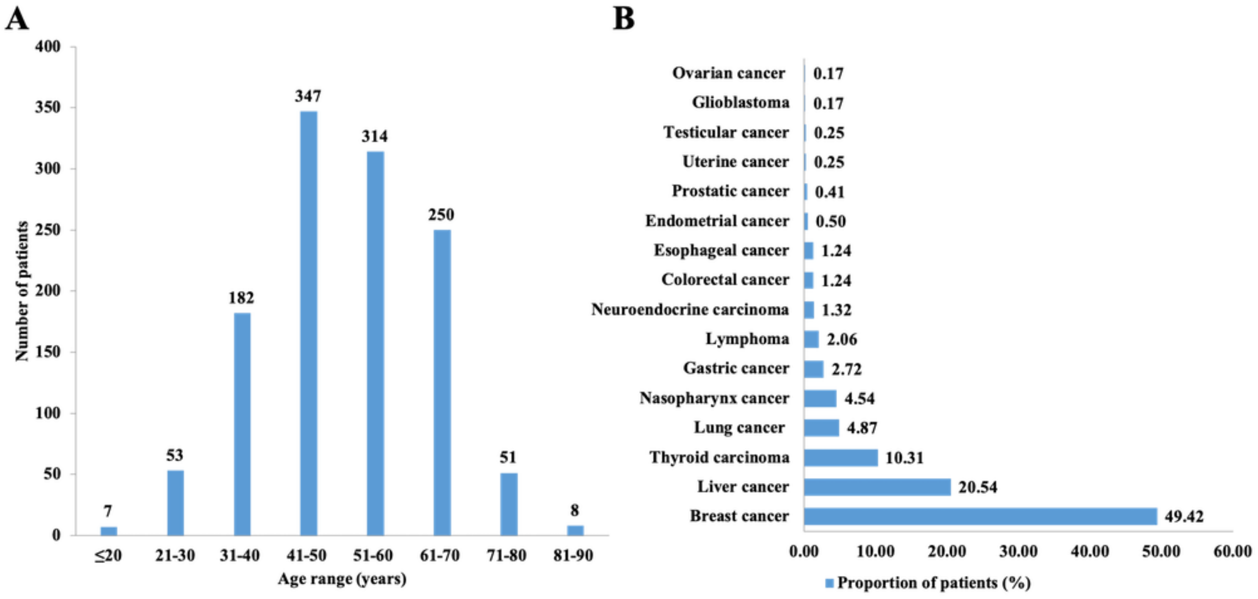
Patient Demographics and Distribution of Online Prescriptions

During the study period (February 12 to August 11, 2020), a total of 1718 prescriptions, including 2022 drugs for 1212 patients, were delivered to 24 provinces and municipalities directly under the Central Government of China. The patient demographics are shown in Table 2. The majority of patients were female (841/1212, 69.39%). The mean age of patients was 51.26 (SD 12.29) years (age range: 12-87), and 90.18% (1093/1212) of the patients were aged between 31 and 70 years old (Figure 4A). The distribution of patients based on their primary diagnosis showed that breast cancer, liver cancer, and thyroid cancer were the 3 most common types of cancers treated (49.42%, 20.54%, and 10.31%, respectively; Figure 4 B) with prescriptions using this remote platform.

Table 2. Characteristics of patients who received online prescriptions from the Cloud SYSUCC app (N=1212).

Characteristic	Value
Gender, n (%)	
Male	371 (30.61)
Female	841 (69.39)
Age (years), median (range)	51 (12-87)
Age group (years), n (%)	
0-10	0 (0.00)
10-20	7 (0.58)
21-30	53 (4.37)
31-40	182 (15.02)
41-50	347 (28.63)
51-60	314 (25.91)
61-70	250 (20.63)
71-80	51 (4.21)
81-90	8 (0.66)
Primary diagnosis, n (%)	
Breast cancer	599 (49.42)
Liver cancer	249 (20.54)
Thyroid carcinoma	125 (10.31)
Lung cancer	59 (4.87)
Nasopharyngeal cancer	55 (4.54)
Gastric cancer	33 (2.72)
Lymphoma	25 (2.06)
Neuroendocrine carcinoma	16 (1.32)
Colorectal cancer	15 (1.24)
Esophageal cancer	15 (1.24)
Endometrial cancer	6 (0.50)
Prostatic cancer	5 (0.41)
Uterine cancer	3 (0.25)
Testicular cancer	3 (0.25)
Glioblastoma	2 (0.17)
Ovarian cancer	2 (0.17)

Figure 4. Distribution of patients by age (A) and primary diagnosis (B) using data from the Cloud SYSUCC app (N=1212).



Of the 1718 delivered prescriptions, 1435 (83.5%) prescriptions were delivered to Guangdong Province, including 437 (25.4%) in Guangzhou city, and the remaining 283 (16.5%) prescriptions were delivered to other provinces in China (Figure 5). The top 5 provinces for out-of-province prescription deliveries were Hunan, Guangxi, Jiangxi, Hainan, and Fujian, all of which are located in southern China (Figure 5).

Figure 5. Regional distribution of prescription deliveries via the Cloud SYSUCC app (N=1718).

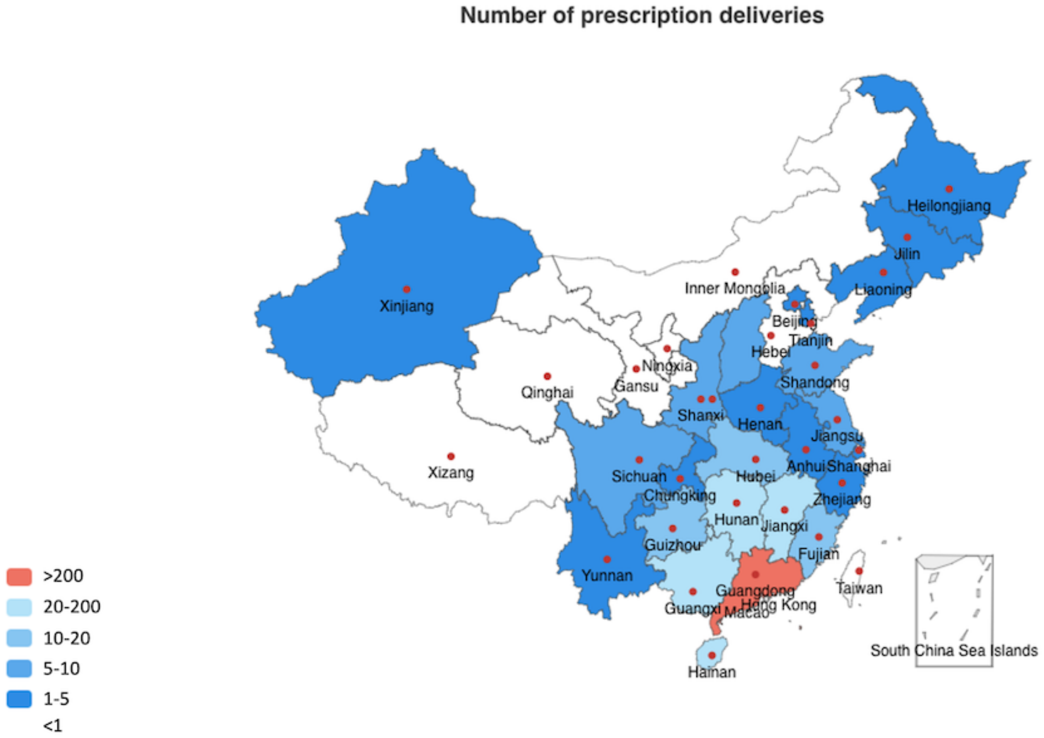


Figure 6 shows the distribution of drugs delivered (mean 1.19, SD 0.46; range: 1-6) to the 1212 patients based on drug classification. Among the 2022 drugs delivered, 1012 (50.05%) were hormonal drugs. Most hormonal drugs were used to treat breast cancer and thyroid cancer, which was consistent with the distribution of the patients by primary diagnosis.

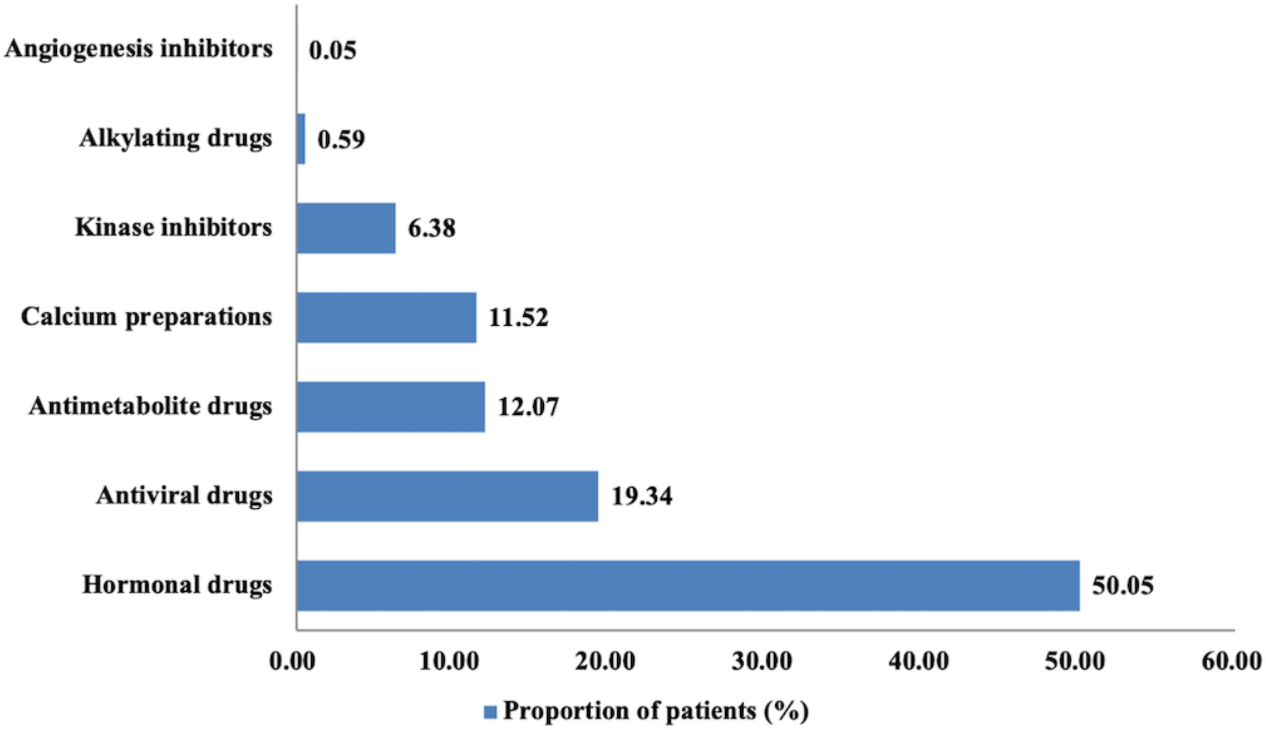
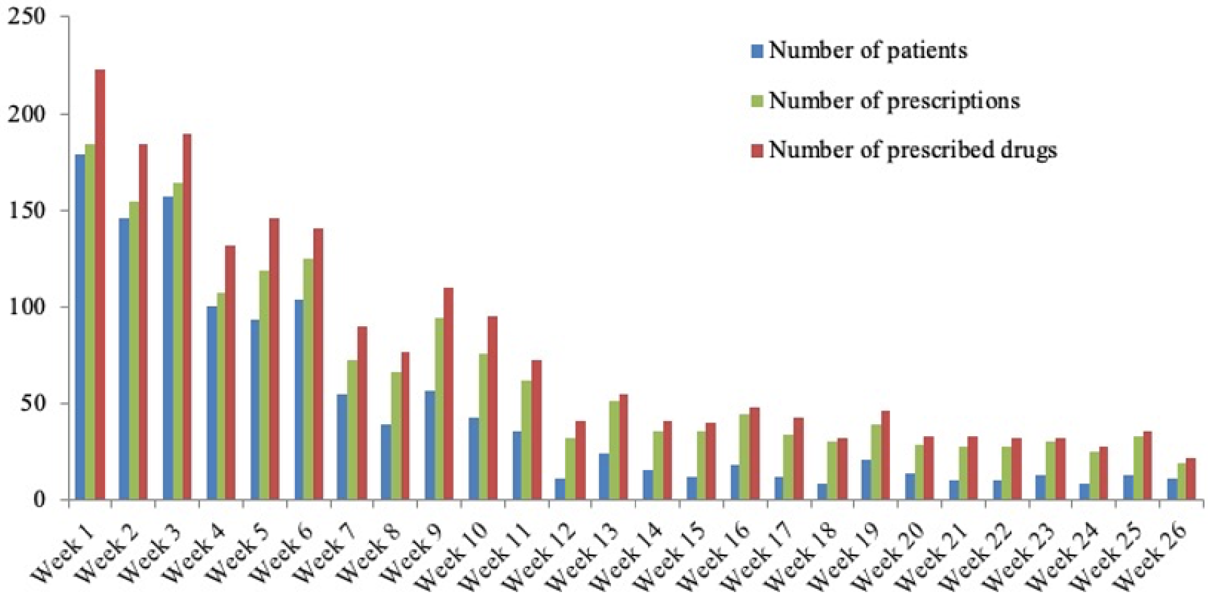
Figure 6. Distribution of online prescriptions by classification of drugs ordered via the Cloud SYSUCC app (N=2022).



The weekly number of prescriptions, prescribed drugs, and patients pertaining to these prescriptions are summarized in Figure 7. As the COVID-19 outbreak was brought under control in China, the general trend in the use of the remote prescription service considerably declined. The total number of patients who used the remote prescription service in the first 9 weeks of the outbreak was 930; this number was 3 times higher than the number of patients who used the service in the following 17 weeks.

Figure 7. Weekly number of patients who used the remote prescription system, medication prescriptions ordered, and prescribed drugs delivered via the Cloud SYSUCC app since February 12, 2020.



Telephonic Patient Satisfaction Survey Evaluating the Remote Prescription Service

A small-scale telephonic survey was conducted to obtain patients' views about the remote prescription service. A total of 100 patients were randomly selected from the total sample of 1212 patients over a 6-month period. These patients were contacted 7 days after their prescriptions were delivered. This time lag between prescription delivery and inquiry was intended to allow patients sufficient time to receive the drugs and reflect on their experiences. The survey contained only 1 simple question: “What do you think about the remote prescription service?” Patients were asked to choose from the following 5 multiple choice answers: (1) satisfied, (2) somewhat satisfied, (3) neutral, (4) somewhat dissatisfied, and (5) very dissatisfied. The survey question was very specific to the remote prescription service so that patients were clear about what was being asked and could accurately express their actual experience. If a selected patient declined to participate in the survey, another patient would be chosen to substitute him or her. The use of randomization to select the survey sample was to ensure a general representation of the population of study patients using the remote prescription service. Thus, bias in the patient sample, such as age, gender, and social class was reduced. We believe that this randomization of the sample enhanced the external validity of the survey results. The telephonic survey showed that 88% (88/100) of the participants were satisfied, whereas 12% (12/100) of them were somewhat satisfied. None of the patients selected a neutral, somewhat dissatisfied, or very dissatisfied response. Overall, these findings suggest a high level of user satisfaction with our remote pharmacy service platform.

Discussion

Principal Findings

We conducted a pilot evaluation of the remote pharmacy service platform in a tertiary cancer hospital in Guangzhou, China, during the first 6 months after work resumption. By September 20, 2020, the rapid spread of COVID-19 had resulted in 30,675,675 cases and 954,417 deaths worldwide. Traditional hospitals required patients to visit the hospitals for obtaining medications, which could potentially cause more infections and lead to severe health deterioration during an ongoing epidemic, particularly for patients with cancer who have a suppressed immune system. Studies have shown that patients with cancer have a higher risk of severe events than do other patients [8,9]. Moreover, a delayed diagnosis and suboptimal cancer management due to the pandemic could be life-threatening for these patients [5,6]. Therefore, access to timely medications has become a crucial issue during large-scale outbreaks of COVID-19. Our remote pharmacy service platform can prove beneficial for such use, with a good satisfactory response from patients with cancer. To our knowledge, this remote pharmacy service platform for patients with cancer is the first such information system introduced worldwide, comprising a collaborative mechanism that integrates the Cloud SYSUCC app with the internal hospital information system and facilitates remote consultation service by using a standardized format for ethical drug prescription and standard administration instructions.

From February 12, 2020, to August 11, 2020, a total of 60,968 users used the Cloud SYSUCC app, an average of 500 users per day. This resulted in 1718 prescriptions and US $3054 million in drugs fees. Most of the medical consultations were for prehospital services such as cancer diagnosis, cancer type detection, and cancer treatment. The number of online prescriptions recorded increased from the first week investigated to the 6th week (Figure 7), which indicates the acceptance of Cloud SYSUCC app among the users. The decline in prescription numbers since the 7th week might be the result of 2 factors, namely, the revision in the Cloud SYSUCC registration fee from US $7 to US $70 per user and the fact that the COVID-19 outbreak was brought under control.

Most patients using the prescription service were female with a breast cancer diagnosis, aged between 31 and 70 years, and had an existing prescription for hormonal drugs. Since hormone-receptor-positive, early-stage breast cancer is a chronic disease, continuous daily dosing of hormone therapy after surgery is very important in these cases. However, at the same time, hormone therapy may cause serious adverse reactions, not only affecting the patient’s quality of life but also eventually leading to therapeutic resistance. Therefore, timely evaluation and adaptation of treatment is needed for these patients. Hence, the Pharmacy and Therapeutics Committee at SYSUCC has authorized doctors to prescribe the required drugs through the Cloud SYSUCC app provided that the prescriptions are compliant with specific guidelines to balance safety and feasibility of the use of anticancer drugs. Moreover, exclusive medical education campaigns are carried out for older patients who were recommended to stay at home and avoid contact with other people for an extended period during the COVID-19 outbreak [10]. Our results showed that only 4.87% of the patients requiring online prescriptions were aged ≥70 years (Table 2). This may be due to the differences in public acceptance and uncertainty of physical conditions for older-aged populations.

Future Prospects

Thus far, the COVID-19 outbreak in China has been under control, and there is no rapid increase in the number of new cases. However, the possibility of a renewed spike in COVID-19 cases in individual regions cannot be ruled out. Therefore, more effort is needed to make better use of the Cloud SYSUCC–based remote pharmacy service during and after the current pandemic. Simple and clear instructions are necessary to improve acceptance of this platform by older patients. Improving financial support, such as by reducing the Cloud SYSUCC registration fee, can also promote increased adoption of the platform by the public. Moreover, timely web-based pharmaceutical care interventions and patient monitoring are required to ensure the safety of patients with cancer.

Conclusions

Currently, the world is fighting against the COVID-19 pandemic, which has affected over 200 countries and regions. The findings of this study suggest that the Cloud SYSUCC remote pharmacy platform is efficient and convenient for enabling continuous pharmaceutical care to patients with cancer. The widespread use of this platform can help reduce both person-to-person transmission of COVID-19 and the infection risk for patients with cancer.

Acknowledgments

We thank Prof Hong-Sheng Wang of the School of Pharmaceutical Sciences, SYSUCC, for their assistance with the revision of this manuscript. This research was supported by the National Natural Science Foundation of China (Grant No. 81672608), and the outstanding young talent promotion scheme for the construction of high-level hospitals in Guangdong Province (No. PT19210101).

Abstract

Virtual care, the use of videoconferencing technology to connect with patients, has become critical in providing continuing care for patients during the current COVID-19 pandemic. Virtual care has now been adopted by health care providers across the spectrum, including physicians, residents, nurse practitioners, nurses, and allied health care professionals. Virtual care is novel and nuanced compared to in-person care. Most of the health care providers who are delivering or expected to deliver virtual care have little to no prior experience with it. The nuances of virtual care involve regulatory standards, platforms, technology and troubleshooting, patient selection, etiquette, and workflow, all of which comprise critical points in the provision of health care. It is important to consistently deliver high-quality, equitable, and professional virtual care to inspire patients with the trust they need to continue follow-up of their care in these difficult times. We have been adopting virtual care in our clinical practice for over two years. In partnership with Canada Health Infoway, we have assembled a primer for virtual care that can serve as a guide for any health care provider in Canada and globally, with the goal of providing seamless transitions between in-person and virtual care.

Introduction to Virtual Care

As part of the response to the COVID-19 pandemic, health care organizations across Canada have cancelled elective and nonurgent clinics as a measure to reduce the risk of exposing patients to COVID-19 [1]. To provide safe, timely, and accessible ambulatory care, health care providers have adopted virtual care in Canada and globally [2-7]. Virtual care can be defined as any interaction between patients and members of their circle of care that occurs remotely, using any form of communication or information technology, to facilitate or maximize the quality and effectiveness of patient care [8-11].

Role of Virtual Care in Addressing Barriers to Health Care

Virtual care is novel and nuanced compared to in-person care. Virtual Care has significant benefits to patients, health care systems and society at large by offering patient-centered care [12-16]. Virtual care also helps increase health care capacity by optimal use of health care professionals' time, infrastructure, and reduced per capita health care cost [13]. Virtual care is more relevant during the COVID-19 pandemic because it provides access to medical care that is timely, convenient, efficient, and safe with reduced risk of transmission [17]. Despite all these advantages of virtual care, it is important to ensure that virtual care continues to provide equitable access to health care. Virtual care has the potential to remove some of the current barriers to health care with regard to availability, accessibility and affordability [13,18-20]. Geographical distance, travel burden and out-of-pocket expenses are some of the largest barriers to ambulatory health care access, and virtual care has great potential to address these [2,21]. However, sociodemographic characteristics such as age, sex, gender, level of education, and English proficiency, as well as socioeconomic status indicators such as race and ethnicity, can impact one’s ability to access and use the technology needed for participating in virtual care [22-24]. Virtual care has the potential to provide access to people who live in more rural areas, who tend to have lower socioeconomic status, are older, and have lower levels of education, but only if the patient can access video and audio equipment, spend the time to use and troubleshoot the equipment, and learn to use programs and hardware they may have never used before. There is a need for engagement and commitment from all stakeholders in the health care system to ensure that virtual care can successfully provide equitable access, closing the gap between rural and urban health care [25].

The Division of Neurology at Queen's University/Kingston Health Sciences Center has been an early adopter of virtual care for ambulatory services since 2016 for stroke, epilepsy, and sleep medicine, and it has an active virtual care research program [13,26]. Leveraging our long experience with virtual care, the Southeastern Ontario Academic Medical Organization and Kingston Health Sciences Center have enabled a rapid rollout of virtual care services for its 450 physicians, 575 medical residents, and 160 allied health care professionals over two weeks using the Reacts platform [27]. Many health care providers (physicians, residents, medical students, nurses, and allied health care professionals) are not familiar with using virtual care and have identified virtual care and digital health technologies as areas of emerging educational and training focus [9-11,27,28]. Here, we present a comprehensive, practical guide for any health care provider wishing to provide virtual care.

Guide to Virtual Care

Licensing and Regulatory Standards

At this time, no rigorous standalone virtual care guidelines have been established by licensing bodies in Canada [9]. Some guidelines have been temporarily developed as a response to the COVID-19 crisis and refer to pre-existing telemedicine guidelines that may require rejuvenation [29,30]. The Canadian Medical Association is providing guidance through the Virtual Care Playbook [31]. Provincial and territorial professional organizations for physicians have released some local guidance on virtual care [3,32-35]. In addition, an excellent pan-Canadian list of virtual care resources is available through the Royal College of Physicians and Surgeons [36].

Further information on medicolegal liability can be obtained from the Canadian Medical Protective Association (CMPA) [37,38]. Nonphysician health care providers (nurses, nurse practitioners, and other allied health care staff) are advised to refer to their own professional and licensing bodies for further guidance. It may be reasonable to refer to the above resources for general guidance on providing virtual care.

Types of Virtual Care and Platforms to Use

Secure messaging, secure email, and secure video conferencing are some of the most used virtual care modalities. These services can be delivered on multiple platforms and devices. The platforms are broadly divided into regulated and unregulated categories. Regulated platforms are those that comply with Canada's federal Personal Information Protection and Electronics Document Act (PIPEDA), as well as provincial and territorial privacy laws that apply to health or medical records, such as Ontario's Personal Health Information Protection Act (PHIPA). A comprehensive list of regulated platforms in Canada is available [3,36]. Unregulated platforms include those that do not meet the federal and provincial/territorial privacy standards (FaceTime, WhatsApp, Google Duo, etc).

For the virtual care provider, the choice of platform may depend on the features offered, such as secure messaging, video conferencing, patient portals, integration into electronic health records (EHRs), and integration with other remote monitoring devices and applications. Before finalizing a decision on a platform, we recommend that practitioners seek clearance from their own organization's privacy and security officer if available. Each organization and each individual provider will have a unique set of circumstances, resources, and abilities. It is essential for each provider to develop familiarity with the platform selected by their organization. The platforms currently used at Queen's University are the Ontario Telemedicine Network and Reacts [27].

Digital Privacy

It is important to ensure that the appropriate precautions are taken by the physician and the patient to ensure the privacy of health care information [39]. For additional information on privacy, security, and data stewardship considerations relating to digital health technologies in the outpatient setting, clinicians should consider guidance from the College of Family Physicians of Canada and the CMPA or from local or regional professional associations [40,41].

Equipment

The equipment (or hardware) required for delivering virtual care is widely available and includes smartphones, tablets, laptop computers, and desktop computers. Ideally, all these devices should have built-in or peripheral hardware for video conferencing (web camera, speaker, and microphone). The network (bandwidth) requirements must be confirmed before use, although most of these platforms enable the quality of the video conference to be adjusted to low bandwidth. In general, the faster and more reliable the internet connection, the better the experience will be for the provider and the patient.

The choice of the device used by the provider depends on multiple factors, including the physical location of the provider at the time of the virtual video visit. Although virtual visits can be conducted from any internet-enabled device, we suggest using a laptop or a desktop computer with a built-in camera and speaker. These devices typically provide the highest quality internet connection, a large screen, and a better speaker and microphone setup. However, this is highly dependent on the technology available to the patient, as modern-day tablets and smartphones have high-quality built-in cameras and speakers. Perhaps most importantly, the patient and provider should be familiar with their respective devices in case troubleshooting is required.

Patient Selection for Virtual Care

It is essential to identify when virtual care is most appropriate for patients. Virtual care is an effective alternative to in-person care for many but not all medical conditions and clinical scenarios. Some general guidelines on patient selection and screening are provided in table 1 [13]. Given the nuances of clinical medicine, with its multiple specialties and subspecialties, health care providers should use professional judgement when deciding which patients, medical conditions, and types of clinical encounters are most suitable for virtual visits [29,38]. As a general guide, virtual care is ideal for nonacute or routine clinical activities, such as reviewing test results and symptom follow-up.

Table 1. Guide to virtual care channel selection.

Virtual care channel	Ideal patient	Ideal conditions	Nonideal conditions
Video	• Has access to required technology and the internet • Is comfortable with using video technology • Has no physical/sensory/cognitive disabilities that would limit videoconference use (unless supported by family and/or friends)	• All clinical conditions or encounters that do not need hands-on physical examination • Follow-up of test results • Counselling • Discussing treatment options • Discussing prognosis • Follow-up of symptom severity	• Workup of complex physical conditions needing physical hands-on examination for diagnosis and therapeutic planning
Secure messaging/email/chat	• Has access to email/chat • Is comfortable with using the modality • Has physical or sensory disabilities that make video conferencing/in-person/telephone difficult • Has a busy work schedule	• Follow-up of routine test results that are normal and do not require intervention • Answering patient questions about medications • Conditions that need very frequent ongoing follow-up • Communication regarding upcoming test results	• Initial encounters with patients • Workup of new symptoms, especially complex ones • Discussing complex diagnostic/therapeutic plans • Initiating new treatments that are complex • Breaking bad news • Providing prognostic information on major medical illness
Telephone	• Has barriers to technology/internet access • Lacks comfort using video technology	• Follow-up of test results • Follow-up of symptom severity • Follow-up of treatment response • Counselling • Discussing treatment options • Treatment titration • Discussion of prognosis	• Initial encounters with patients • Workup of new symptoms, especially complex ones

Virtual Care Workflow: Registration, Appointment, Scheduling, and Documentation

It is mandatory in all jurisdictions to document all health care encounters as part of the patient's health care record. Provincial and territorial medical regulatory authorities and the CMPA consider appropriate documentation to be an essential communication skill and a core component of physicians' professional best practice.

Although some virtual care platforms integrate the video visit into the provider's EHR, patient portal, or hospital information system, this practice is not yet commonplace. Thus, two parallel workflows often coexist for the provider: the first for the virtual care platform, and the second for the provider's medical record system.

This “double workflow” ensures that the virtual care encounter details (registration, clinical documentation, follow-up plans, planned investigations, and therapeutic plans) are captured in the patient's health record.

Consent

It is necessary practice to discuss consent with the patient at the time they sign up for virtual care, covering subjects such as the inherent risks related to privacy and security as well as the limitations of virtual care [32]. There are two routes by which patient information could leave the circle of care. One route is the “real world.” Nonprivate, nonstandard locations on both the patient’s and clinician’s side are now used; this increases the risk that another party will hear the discussion, whether accidentally or intentionally. The precautions described within this article will help to reduce this risk. The other route is the “virtual world,” where there is an inherent risk in the web-based connection between the two parties. Internet and virtual care security have come a long way from their beginnings, and the weak link in information security often lies in the user’s hands. All our connections from the clinician’s side necessitate standard password complexity and 2-factor authentication, including on personal devices that may be used remotely. We also only use software designed and approved for the exchange of personal health information.

The limitations of virtual care should be made clear to the patient. It should be clear that when the clinician cannot see the patient physically, there is inherent risk of missing physical findings. This is only exacerbated by the potential for unstable network connections or poor quality/malfunctioning equipment. It should also be made clear to patients that with this in mind, should there be a requirement for in-person assessment, there may a delay relative to the traditional method of seeing the patient in-person. The option of seeing a clinician in person should always be given to the patient and should always be suggested by the clinician if they feel that the virtual visit was insufficient for the patient's care or may even have caused harm.

Generic consent forms are readily available on the web through many of the resources referenced in this paper [31,37,39], although consent is often obtained verbally given the context and must be documented in the subsequent notes. Although regulated health care software applications require the patient to consent at the time of account signup, informed consent should be obtained from the patient or substitute decision maker before beginning any virtual care interaction.

Patient Setup and Education

It is crucial to gauge the degree of a patient's or caregiver's comfort level with using technology before proposing the use of virtual care. Some health conditions can affect motor strength, coordination, language, vision, and cognition. All these challenges can adversely affect a patient's ability to use personal internet-enabled devices and participate in virtual care, even if the patient is proficient with technology. In addition, it is important to recognize that not all patients will have easy access to the ideal technology for virtual care, including video capability and a sufficiently fast internet connection. We have found that modern mobile phones are capable and ubiquitous but may have poor video and/or audio quality depending on the internet connection. Some patients have chosen to use audio-only telephone visits instead. As we transition to virtual care, we need to be keenly aware of patient-readiness for this transition. Although audio-only visits are shown to be useful, an unexpected change to an audio-based visit from a planned video-based visit may result in slight inconvenience at best and a delay in essential visual assessment and therefore care at worst. In cases of communication breakdown, an in-person visit is often suggested.

With the patient's consent, providers should explore the option of having a patient's family member or friend assist with facilitating a virtual visit [13]. Patients and their families who are interested in virtual care should be provided with information and education about signing up for and using the service.

It is also helpful to provide some tips for the patient to prepare for the virtual care visit. The patient's clothing should allow a reasonable range of motion if the provider requests physical maneuvers during the virtual visit. If the patient requires a hearing or visual aid, these should be readily available. For patients with hearing, visual, or cognitive challenges, it is often more challenging to see and hear via a screen and speakers, in contrast to an in-person visit. Patients requiring mobility aids should keep these devices close by and may benefit from the presence of a nondisabled individual to assist them as necessary.

Etiquette

Many health care providers are not familiar with how their patients will perceive them in a virtual visit. With this in mind, it is useful to be aware of the etiquette that is unique to virtual care [42,43]. The basic principles of developing a high-quality "webside manner" can be separated into two areas: technical considerations and communication skills.

Technical Considerations

Due to technical limitations, auditory and visual information can be lost during a virtual consultation. At the beginning of the session, both cameras should be directed so that the faces and shoulders of both the patient and the health care provider are framed. Remember that slower, broader movements decrease visual blurring, and obscuring the face and mouth should be avoided. The physician should be mindful that gazing at the patient's image on the screen can make it seem as though the physician is looking down at them. When possible, the physician should look into the camera.

Communication Skills

During the session, the interviewer must recognize the importance of clear communication. Virtual visits require communication adjustments. Physicians should speak slowly and use nonmedical terms for maximum clarity. They should be prepared for lags in communication for technical reasons. Recognizing these technical limitations reinforces the need for speaking clearly. It may be helpful for the interviewer to check in with the patient to see if they can hear and understand their messaging. Reiterating and summarizing what a patient has said may also be helpful. In addition, clear signposting by the interviewer can indicate the progress and direction of the session. For example, the interviewer could say, "I am now going to summarize what I understand of your history, then proceed to the physical exam."

The primary sensory modalities available in a virtual visit are limited to auditory and visual. However, touch is a standard method of communication during an in-person visit, especially during the physical examination. When requesting that patients perform physical examination maneuvers during a virtual visit, adjustments are required. The clinician should clearly state the movement that the patient is asked to perform. They should consider documenting the absent physical examination maneuvers that would have typically been included but were not feasible due to the virtual nature of the consultation. This suggests, at a minimum, that these steps have been considered. Also, the clinician should inform the patient before they navigate to another screen to look at laboratory or imaging data. When possible, screen-sharing modes should be used to show patients their images or laboratory results.

Last but certainly not least, kindness and compassion are paramount in a virtual visit. Listening carefully to a patient's concerns, taking time to clarify their statements, and following up on their questions are vital skills, regardless of what form of medical care is being offered.

Environment and Setting

Preparing one's virtual visit environment is vital for both patients and providers. Clinical administrative staff play a key role. Prior to the appointment, the staff should send a message to the patient with recommendations on setting up for a visit. Some recommendations are relevant to patients and virtual visit providers alike:

- The room should be reasonably private, with minimal potential for distractions. It may be helpful to notify other members of the household or building that space will be used privately for the duration of the appointment. If possible, adequate lighting, presenting oneself in an uncluttered room, and ensuring the visibility of one's face and shoulders are ideal. Background should be reduced to a minimum. This may include distancing from a louder area (kitchen, public area, open windows, etc). We recommend posting a notice at the entrance to the room indicating that a confidential meeting is occurring. Personal communication devices (ie, mobile phones and pagers) should be switched to silent mode to avoid distraction.
- If other parties are involved in the meeting, such as trainees, family members, and friends, they should be introduced prior the beginning of the meeting. As with standard in-office visits, the people who are involved in the meeting should be transparent and within the control of the patient and physician.

Other recommendations are more relevant to patients and can be tailored to their medical conditions and clinical scenarios (eg, postoperative vs chronic disease follow-up):

- For some clinical specialties, it may be helpful for the patient's room to have enough space to allow them to stand and move away from the camera, so their entire body is visible.
- It is helpful if the camera is high-definition (720p or higher) and wide-angle. The room should have a comfortable yet easily movable chair available for the patient to rest.
- If the consultation requires equipment, the patient should have an easily accessible area to place these materials.
- A high-quality internet connection within the selected room is also essential. A wired connection is ideal, but if only Wi-Fi is available, the room should not be too far from the wireless router to ensure a reliable connection.

Example Run-through of a Virtual Visit

Presession Preparation

During the presession preparation, attention must be paid to the equipment, environment, and external appearance. In addition to checking the equipment and network, it should be ensured that the general guidelines laid out in the above section with regard to etiquette and the environment are followed. The patient's information or EHR should be available within reach of where the video visit is happening.

A good habit is to check the platform appointment software to confirm that the patient or patients have been booked as expected. If there is an issue with connecting to the patient, it is always useful to have an alternative means of communication. Ideally, this will be a telephone number; however, email or instant messaging can be used. Most platforms allow the patient to join and wait in a virtual “room.” It is recommended to mute the microphone before the patient enters the appointment.

Session

The first thing to do when the patient logs in is to confirm that both parties’ cameras and microphones are working correctly and troubleshoot as necessary. In all first visits, it should be expected that there will be delays due to technological issues. Technical factors play a significant role in one’s ability to communicate effectively with a patient. It is vital for the medical professional to be familiar with the platform they are using, as it is not uncommon to have to walk through teaching a patient how to modify camera or audio settings. It is essential to explain the steps in a simple and organized fashion.

Formal introductions can be made next, in which it is essential to obtain consent for the virtual visit and establish the identity of the patient. The ID verification step may not be necessary for clinical scenarios in which the patients are well known to the interviewer (eg, family practices, specialist practices managing chronic diseases). Announcing who is involved in the meeting for both parties is useful, as some participants can be virtual and others can be physical but not visible (off-camera).

The history will likely feel very similar to an in-person visit. It is useful to be clear and intentional with questions, as information can easily be lost through the virtual connection. The physical examination will be a different experience, as traditional medical training in conducting examinations anticipates that the patient will be physically present. When the correct group of patient, diagnosis, and visit purpose are selected, a virtual physical examination is equivalent to an in-person visit examination. Investigations can be reviewed with the patient, including sharing the actual results and images directly via screen sharing. If discussions with colleagues or other staff are necessary, the patient may be notified and muted. At the end of the appointment, as with most appointments, the clinician should discuss and establish a plan. Most relevant in this context is whether a follow-up appointment will be a virtual visit or in-person visit. Because the patient will not be taking any items (prescriptions, requisitions, instructions, etc) with them, it is crucial to verify details with the patient (eg, pharmacy, next steps).

Postsession

If orders and prescriptions are integrated into the EHR, clinicians can follow their routine workflow. Otherwise, orders and prescriptions must be sent post-encounter (eg, secure messaging, email, electronic prescriptions such as PrescribeIT, faxes, or mail). It should be ensured that follow-up arrangements have been made. Finally, the encounter can be documented by clinicians as per typical workflow (handwritten, dictation, or typed in the EHR), clearly identifying the visit as an eVisit or virtual visit.

Textbox 1 demonstrates a checklist that summarizes what we have discussed in the above sample run-through visit. It forms a guideline to maintain the quality of a virtual visit across all patients but also serves as a tool to structure future quality improvement projects.

Textbox 1. Checklist for virtual care.

Before the virtual video visit (presession):

- Check that the device, video conferencing equipment, and network are working properly
- Ensure that the camera and microphone are positioned properly
- Ensure that the room is well lit and does not contain any distractions and that only professional objects are visible
- Ensure privacy during a virtual video visit:
    - Mute your mobile phone or place it on vibrate
    - Close the office door and place a “Do Not Disturb” or “Doing Video Visits” sign
- Ensure beforehand that you have access to the patient charts, results, and any other health information
- Mute the microphone until the videoconference starts
- Ensure that the patient’s telephone number is available should it be necessary

During the virtual video visit:

- Confirm that both parties’ videoconferencing technology is working and optimized for sound and video
- Introduce yourself and bring your photo ID close to the camera for the patient to see
- Ask the patient to show a valid photo ID (driver’s license or Health Card)
- Obtain verbal consent for the virtual visit
- Ask the patient to ensure their room is well lit and has enough space for movement
- Ask the patient to ensure privacy during the virtual visit:
    - Mobile phone(s) are placed on mute or vibrate
    - Doors are closed and indicate “Do Not Disturb”
- Ask the patient to adjust their position so they are framed adequately within the camera view
- Ensure that the patient has all objects and tools necessary for the full assessment
- Introduce any other health care providers or learners present in the room

After finishing the virtual video visit:

- Ensure that all reports and clinical documentation are complete
- Ensure that the planned investigations and medication prescriptions are ordered
- Ensure that follow-up plans have been made

Conclusion

Virtual care will become a reality in many future medical practices, and the COVID-19 pandemic is serving as a catalyst for this impending change. Virtual care is effective at removing barriers to access, especially to specialists who are typically located in larger centers, for the remarkably distributed rural and remote patients across Canada. As we have outlined, there are important nuances in the application of virtual care that help ensure patients receive at least equivalent care, or in some ways, more effective care than that received in the traditional in-person format. Many clinical organizations are working toward establishing baseline principles, guidelines, and protocols to guide Canadian physicians. This paper is intended to contribute to an emerging Canadian body of knowledge and to support optimal professional practice in an emerging and rapidly evolving field. Most importantly, virtual care should not fragment care. It should support both high-quality care, the foundation of which is an established trust-based physician-patient relationship, and continuity of care.

Abstract

Background: Although lockdown and mandatory quarantine measures have played crucial roles in the sharp decrease of the number of newly confirmed/suspected COVID-19 cases, concerns have been raised over the threat that these measures pose to mental health, especially the mental health of vulnerable groups, including pregnant women. Few empirical studies have assessed whether and how these control measures may affect mental health, and no study has investigated the prevalence and impacts of the use of eHealth resources among pregnant women during the COVID-19 outbreak.

Objective: This study investigated (1) the effects of lockdown and mandatory quarantine on mental health problems (ie, anxiety and depressive symptoms), (2) the potential mediation effects of perceived social support and maladaptive cognition, and (3) the moderation effects of eHealth-related factors (ie, using social media to obtain health information and using prenatal care services during the COVID-19 pandemic) on pregnant women in China.

Methods: An online cross-sectional survey was conducted among 19,515 pregnant women from all 34 Chinese provincial-level administrative regions from February 25 to March 10, 2020.

Results: Of the 19,515 participants, 12,209 (62.6%) were subjected to lockdown in their areas of residence, 737 (3.8%) were subjected to mandatory quarantine, 8712 (44.6%) had probable mild to severe depression, 5696 (29.2%) had probable mild to severe anxiety, and 1442 (7.4%) had suicidal ideations. Only 640 (3.3%) participants reported that they used online prenatal care services during the outbreak. Significant sociodemographic/maternal factors of anxiety/depressive symptoms included age, education, occupation, the area of residence, gestational duration, the number of children born, complication during pregnancy, the means of using prenatal care services, and social media use for obtaining health information. Multiple indicators multiple causes modeling (χ^2_{14}=495.21; *P*<.05; comparative fit index=.99; nonnormed fit index=.98; root mean square error of approximation=.04, 90% CI 0.038-0.045) showed that quarantine was directly and indirectly strongly associated with poor mental health through decreased perceived social support and increased maladaptive cognition (B=.04; β=.02, 95% CI 0.01-0.02; *P*=.001), while lockdown was indirectly associated with mental health through increased social support and maladaptive cognition among pregnant women (B=.03; β=.03, 95% CI 0.02-0.03; *P*=.001). Multigroup analyses revealed that the use of social media for obtaining health information and the means of using prenatal care services were significant moderators of the model paths.

Conclusions: Our findings provide epidemiological evidence for the importance of integrating mental health care and eHealth into the planning and implementation of control measure policies. The observed social and cognitive mechanisms and moderators in this study are modifiable, and they can inform the design of evidence-based mental health promotion among pregnant women.

eHealth; lockdown; quarantine; depression; anxiety; pregnant women

Introduction

Background

Lockdown and mandatory quarantine are commonly used and effective measures that are implemented by governments to contain the transmission of respiratory infectious diseases, including the COVID-19 disease [1,2]. Lockdown refers to general and widespread restrictions on movement, work, and travel for all people in a city, region, or country. Lockdown measures include travel restrictions, the mandatory closure of schools, and bans on nonessential commercial and social activities. Given the global spread of COVID-19 to 216 countries/regions, which has resulted in over 30.6 million infections and 950,000 deaths as of September 20, 2020 [3], more than 100 countries (eg, the United States, France, Australia, Thailand, and South Africa) have adopted various forms of lockdown measures to control the pandemic [4]. In mainland China, more than 80 cities in around 20 provinces and municipalities were put in lockdown [5], and over 780 million people were under certain travel restrictions [6].

Mandatory quarantine is a form of isolating people who are not ill, but may have been exposed to a disease that is dangerous to society [7]. People who had close contact with individuals who were confirmed/suspected to have COVID-19, and people with a history of travel were quarantined for 14 days in designated facilities (eg, governmental facilities and hotels) or home settings [8]. Globally, more than 140 countries (eg, the United States, the United Kingdom, Spain, Italy, and Singapore) have adopted mandatory quarantine measures for disease control [9-12].

The Impact of Lockdown and Mandatory Quarantine on Mental Health

Although lockdown and mandatory quarantine have played crucial roles in the sharp decrease of the number of newly confirmed/suspected COVID-19 cases [13-15], concerns have been raised over the threat that these measures pose to mental health, as these unprecedented measures have restricted daily routines and increased social isolation [16,17]. Empirical studies on the impact of lockdown/mandatory quarantine on mental health have yielded inconsistent results. According to the Office of National Statistics, more than 25 million people in the United Kingdom have experienced high levels of anxiety in late March 2020, which is when the lockdown was announced [17]. In a study conducted by Sibley et al [18], participants from New Zealand reported a slight increase in psychological distress, but less fatigue and no significant changes in rumination, feelings of belongingness, perceived social support, satisfaction with life, standards of living, future security, personal relationships, and health during the early phase of the nationwide lockdown compared to those during the pre-COVID-19 period. A study that was conducted in southern China during early February 2020 also found that people who were quarantined had a greater prevalence of anxiety and depression than those who were not affected by quarantine [19]. Furthermore, in mid-February 2020, Li et al [20] reported a positive association between perceived inconvenience to daily life caused by home quarantine and depression/anxiety among the general adult population in China. However, Zhu et al [21] reported that there was no significant differences in depression and anxiety between Chinese people who were and were not subjected to mandatory quarantine, and they concluded that although these mental health problems were not related to quarantine control measures, these measures did impact daily life. Another study in China even found a significantly lower prevalence of depression and anxiety among people under mandatory quarantine than among those who were infected by SARS-CoV-2 or the general public [22]. These inconsistent results highlight the importance of exploring potential underlying mechanisms (eg, the impacts of lockdown and quarantine on individuals) that may explain the relationship between lockdown and quarantine measures and mental health problems. We however did not identify such studies.

Pregnant women could be more susceptible to lockdown and quarantine measures and SARS-CoV-2 infection than the general population, due to their great need for social support and ongoing prenatal care services, concerns over fetal safety, immunocompromised status, and physiological and psychosocial adaptive changes during pregnancy [23]. Most studies on the mental health of pregnant women have small sample sizes (ie, 70 participants to around 560 participants), and these studies have only reported the prevalence of mental health problems during the COVID-19 pandemic [24-37]. We found 3 studies on the mental health of pregnant women that had larger sample sizes, with about ≥1000 respondents (ie, 946 participants to around 2421 participants) [24,25,30], and only 1 study (N=260) that investigated the impact of social isolation on mental health by simply asking pregnant women whether they believed that social isolation due to the pandemic affected their psychological well-being [27]. More studies that include large sample sizes and investigate the impact of lockdown/mandatory quarantine on the mental health of pregnant women during the COVID-19 pandemic are needed. Early detection and intervention can prevent the adverse impact that mental problems (eg, prenatal mental disorders) have on both mothers and children in the long term.

Potential Social and Cognitive Mechanisms

Social and cognitive mechanisms may play critical roles in mediating the relationships between lockdown/mandatory quarantine and mental health. First, lockdown and quarantine are isolation measures that, by their nature, may induce social isolation and reduce social resources, such as social support, and reductions in such social resources are a risk factor of mental health problems [16]. We found 2 studies with a sample size that ranged between 308 participants to around 403 participants. These studies investigated the association between social support and mental health problems among pregnant women during the COVID-19 pandemic, and both studies reported negative associations [26,28]. The mediation effects of social support are supported by the conservation of resources theory, which predicts that resource loss (eg, losses of social resources like social support) is the principal factor in the stress process and the cause of mental disorder development [38].

Second, the governmental implementation of unprecedented measures for disease control may be a stressful event for the public that induces maladaptive cognitive responses. According to the response styles theory, both depression and anxiety are related to faulty cognitive responses to stressors and negative emotions [39,40]. Rumination (ie, the repetition of the same feelings and thoughts) and catastrophizing (ie, having thoughts that explicitly emphasize the terror of what one has experienced) are common maladaptive cognitions, and responses to maladaptive cognitions emerge when individuals experience threatening and uncertain events [41]. When compared to the different kinds of maladaptive cognitive responses, anxiety has been found to be more related to catastrophizing, which focuses on future threats [42], and depression has been found to be more related to ruminative thinking, which concentrates on past negative experiences and emotions [43,44]. Empirical studies have also supported the mediation roles of rumination and catastrophizing between threatening events (eg, daily hassles) and depression/anxiety [41,45]. No study has assessed the mediation effects of rumination and catastrophizing in the context of COVID-19 or pregnant women.

eHealth-Related Moderators

eHealth refers to information and communications technologies in health care and the community. eHealth can be an optimal communication modality for people under stay-at-home orders, especially for those with time-sensitive health conditions, such as pregnancy [46]. eHealth and telemedicine services enable pregnant women to maintain their regular prenatal visit schedule and avoid the unnecessary risk of COVID-19 exposure [47]. Such online services may significantly affect individuals' coping resources, stress appraisals, and perceived or actual social support [48,49], and may reduce the influence of external and environmental stress on individuals' mental health during the COVID-19 pandemic. Thus, we hypothesized that the effects of control measures on interpersonal resources (eg, social support), cognitive status (eg, maladaptive cognition), and mental health might vary between pregnant women who use eHealth resources, such as using social media to obtain health information and online services to make appointments with doctors for prenatal care services during the COVID-19 pandemic, and those who did not use such resources. In addition, such extra resources may reduce the adverse effects of maladaptive cognition and enhance the protective effects of social support on mental health. We did not find any research that investigated the prevalence of eHealth resource use among pregnant women and the impact of using eHealth resources on the mental health of pregnant women.

Objectives

This study aimed to investigate the prevalence of mental health problems (ie, depression and anxiety) among a large sample of pregnant women recruited from multiple regions in mainland China. We also assessed the direct and indirect effects of lockdown and mandatory quarantine on mental health problems through perceived social support and maladaptive cognition. We hypothesized that lockdown (ie, model path H1) and mandatory quarantine (ie, model path H2) would be positively associated with mental health problems. We further hypothesized that lockdown and mandatory quarantine would be indirectly associated with mental health problems through reduced perceived social support (ie, model path H3) and increased maladaptive cognition (ie, model path H4). Moreover, this study aimed to assess the moderation effects of eHealth-related variables, including using social media to obtain health information, using online prenatal care services, and making appointments with doctors during the COVID-19 outbreak, on pregnant women for each model path.

Methods

Participant Recruitment and Procedure

In this study, the inclusion criteria for the sample were (1) female sex, (2) age ≥18 years, (3) the ability to speak Chinese, (4) current pregnancy, and (5) the use of maternal health care services provided by the Maternal and Child Health Hospitals of the Chinese Preventive Medicine Association. Pregnant women who planned to terminate their pregnancy were excluded from this study. An online cross-sectional survey was conducted from February 24 to March 10, 2020. Eligible participants were identified from the records of Maternal and Child Health Hospitals from multiple regions of China and were invited to take part in the online survey by doctors through WeChat (Tencent Inc), which is the most widely used social media platform in Chinese populations. Interested participants visited the online survey through a link or quick response code and read the informed consent form before starting the survey. They were informed that clicking the "starting the survey" button implied informed consent. They were also informed that the study was anonymous and confidential, and that refusal to take part in the survey would not affect any services they would obtain. The survey took about 15 minutes to complete. No incentive was provided. A total of 19,515 pregnant women from all 34 provincial-level administrative regions in China (eg, 2127 pregnant women from Beijing, 4015 from Shandong, 3659 from Zhejiang, 1886 from Guangdong, 1250 from Hunan, 3178 from Shanxi, etc) completed the survey, with a valid response rate of 87.7%. This study was approved by the Survey and Behavioural Research Ethics Committee of the Chinese University of Hong Kong (Number SBRE-19-395).

Measures

Sociodemographic and maternal information, including age, education level, occupation, the area of residence, gestational duration, the number of children born, complication during pregnancy, the major means of using prenatal care service during the COVID-19 pandemic (ie, using online services, making appointments with doctors, and going to a hospital as usual), and the frequency of using social media to obtain health information in the past week, were obtained from the survey. Participants also reported on their lockdown and mandatory quarantine status by answering the following questions: (1) “Had the city, town, or county where you currently live been put under lockdown by the local government because of the COVID-19 epidemic” (response score: 0=no and 1=yes); and (2) “Had you been under mandatory quarantine (e.g., governmental facilities-, hotel- or home-quarantine) because of the COVID-19 epidemic” (response score: 0=no and 1=yes)?

Perceived social support was measured by 2 dimensions (ie, general social support and perceived change in social support during the COVID-19 pandemic compared to those during the pre-COVID-19 period). The following 2 survey items were used to assess this: (1) “Overall, to what extent did you receive social support from families, friends, and others during the COVID-19 epidemic” (response scale: 1=very poor to 10=very good); and (2) “To what extent did your social support become poorer or better during COVID-19, compared to that before the outbreak of COVID-19” (response scale: 1=much poorer to 5=much better)? Similar survey items have been used in previous studies [50].

Maladaptive cognition related to COVID-19 was measured with the short-form Cognitive Emotion Regulation Questionnaire (CERQ) [51]. The CERQ was developed to evaluate the cognitive aspects of emotion regulation when one experiences stressful or unpleasant events. Sample items from the CERQ include “I am preoccupied with what I think and feel about what I have experienced” and “I keep thinking about how terrible it is what I have experienced.” These items are rated on Likert scales (ie, 1=almost never to 5=almost always). The subscales of rumination and catastrophizing were used in this study. The Chinese version has been validated in previous studies [52]. The reliability of the 2 subscales was acceptable for our sample (Cronbach α=.66; Cronbach α=.84, respectively).

Depression was measured using the Patient Health Questionnaire-9 (PHQ-9) [53]. Respondents evaluated the presence (PHQ-9 response scale: 0=none to 3=almost every day) of 9 criteria for a depressive episode that occurred in the past 2 weeks, in accordance with the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) (eg, “Feeling bad about yourself—or that you are a failure or have let yourself or your family down?”). The cutoff points for mild, moderate, moderately severe, and severe depression were total PHQ-9 scores of 5, 10, 15, and 20, respectively. The Chinese version has been used in previous studies [54], and it had good internal consistency (Cronbach α=.83).

Anxiety was measured by the Generalized Anxiety Disorder 7-item (GAD-7) scale [55]. It is based on DSM-IV criteria and is used to measure the severity of generalized anxiety disorder based on the past 2 weeks. Participants respond according to a 4-point Likert-type scale (ie, 0=none to 3=almost every day). The cutoff points for mild, moderate, and severe anxiety were total GAD-7 scores of 5, 10, and 15 respectively. The Chinese version has been validated in previous studies [56]. It had a Cronbach α of .90 with our sample.

Data Analyses

Descriptive statistics, including frequency, means, and standard deviations, were computed for participants’ sociodemographic characteristics. Differences in depression scores and anxiety scores based on sociodemographic characteristics were compared by either an independent 2-tailed *t* test or analysis of variance. The effect size (ie, Cohen *d* or Cohen *f*) was reported. Bivariate correlations between the key variables were presented. The effect size was considered low if the value of *r* varied around .10, medium if *r* varied around .30, and large if *r* varied by more than .50 [57]. Multiple indicators multiple causes (MIMIC) modeling was conducted to test the proposed mediation model. The goodness of fit was tested, and standardized path coefficients (ie, β) were reported. The mediation hypotheses were tested by bootstrapping analyses. The 95% confidence intervals of the indirect effects were obtained from 5000 bootstrap samples. The effect size (ie, proportion of mediation [PM]) was reported. Multigroup analyses were conducted to test the proposed moderators; *P*<.05 in the Chi-square difference test ($\Delta\chi^2/\Delta df$) would suggest a significant moderation effect. The missing data rate was below 5%, and all missing values were replaced by using multiple imputation. The level of statistical significance was .05, and SPSS version 21.0 (IBM Corp) and Amos Version 26 (IBM Corp) were used for data analyses.

Results

Sociodemographic and Maternal Characteristics

Tables 1-3 present the sociodemographic and maternal characteristics of the participants. Of 19,515 participants, 13,885 (71.1%) were aged 26-35 years, 11,627 (59.6%) had an education level of college or above, 10,741 (55%) did not have a baby before this pregnancy, and 17,856 (91.5%) did not experience any complications or comorbidities during pregnancy. Additionally, 5394 (27.6%) participants were unemployed/housewives (27.6%) and 5193 (26.6) were technical/administrative personnel (26.6%). The distribution of participants’ areas of residence was approximately even (municipality/provincial capitals: n=5930, 30.4%; general cities: n=6855, 35.1%; counties: n=6730, 34.5%). Participants’ average gestational duration was 25.4 weeks (SD 9.8 weeks).

Table 1. Sociodemographic and maternal characteristics of the participants (N=19,515).

Characteristics	Value
Age (years), n (%)	
<26	3781 (19.4)
26-30	8202 (42)
31-35	5683 (29.1)
>35	1849 (9.5)
Education, n (%)	
Middle school or below	4014 (20.6)
High school	3874 (19.9)
College	5222 (26.8)
University or above	6405 (32.8)
Occupation, n (%)	
Technical personnel	3053 (15.6)
Administrative personnel	2140 (11)
Civil servant	320 (1.6)
Soldier	22 (0.1)
Business/service personnel	1778 (9.1)
Self-employed/private business owner	1455 (7.5)
Farmer/migrant worker	746 (3.8)
Unemployed/housewife	5394 (27.6)
Student (undergraduate/postgraduate)	51 (0.3)
Other	4556 (23.3)
Area of residence, n (%)	
Municipality/provincial capital	5930 (30.4)
General city	6855 (35.1)
County	6730 (34.5)
Number of gestational weeks, mean (SD)	25.4 (9.8)
Gestational duration (weeks), n (%)	
1-10	1523 (7.8)
11-20	4986 (25.5)
21-30	5858 (30)
>30	6518 (33.4)
Not sure	630 (3.2)
Number of children born before pregnancy, n (%)	
0	10741 (55)
1	7796 (39.9)
>1	978 (5)
Complication during pregnancy, n (%)	
Yes	1659 (8.5)
No	17856 (91.5)

Table 2. Sociodemographic and maternal characteristics of the participants (N=19,515) based on eHealth-related variables.

eHealth-related variables	Value
Means of using prenatal care service, n (%)	
Went to hospital as usual	10189 (52.2)
Made appointment with doctor	7568 (38.8)
Online prenatal care	640 (3.3)
Not sure	1118 (5.7)
Used social media to obtain health information, n (%)	
Never	1781 (9.1)
Sometimes	10605 (54.3)
Always	7129 (36.6)

With regard to the means of using prenatal care services during the COVID-19 epidemic, 10,189 (52.2%) participants went to the hospital for prenatal care as usual, 7568 (38.8%) made appointments with doctors, 640 (3.3%) used online services, and 1118 (5.7%) were uncertain. Most participants (n=17,734, 90.9%) used social media to obtain health information in the week before the survey.

Of the 19,515 participants, 12,209 (62.6%) participants reported lockdown in their areas of residence; 737 (3.8%) were subjected to mandatory quarantine; 8712 (44.6%) had probable mild to severe depression; 1442 (7.4%) had suicidal ideations, as measured by question 9 in the PHQ-9; and 5696 (29.2%) had probable mild to severe anxiety.

Table 3. Sociodemographic and maternal characteristics of the participants (N=19,515) based on psychosocial variables.

Psychosocial variables	Value
Lockdown in the area of residence, n (%)	
Yes	12209 (62.6)
No	7306 (37.4)
Subjected to quarantine, n (%)	
Yes	737 (3.8)
No	18778 (96.2)
General social support, mean (SD)	8.51 (2.07)
Social support change, mean (SD)	4.05 (1.06)
Rumination, mean (SD)	3.11 (0.86)
Catastrophizing, mean (SD)	2.76 (1.09)
Depressive symptoms, mean (SD)	0.56 (0.56)
Depressive symptoms (total PHQ-9[a] score), n (%)	
Minimal (0-4)	10803 (55.4)
Mild (5-9)	5565 (28.5)
Moderate (10-14)	2053 (10.5)

[c] Based on item 9 in the Patient Health Questionnaire-9.

Level of Mental Health Problems Based on Sociodemographic Characteristics

As seen in Tables 4 and 5, factors that positively significantly associated with both depressive and anxiety symptoms included young age, being a student, residing in counties, being in the early or final stages of pregnancy, using means of prenatal care other than making appointments with doctors, using social media to obtain health information, experiencing lockdown in the areas of residence, and being quarantined. Other factors that were significantly associated with greater anxiety included low education levels (*P*=.01) and complications during pregnancy (*P*<.001). With regard to the number of children born, participants who were giving birth for the first time reported significantly more depressive symptoms than those who were not giving birth for the first time (*P*<.001). They also reported more anxiety symptoms than those who had given birth to 1 child before this pregnancy (*P*=.002).

Bivariate Correlations Between the Key Psychosocial Variables

As seen in Table 6, living in an area under lockdown had significant positive associations with all the key psychological variables, including perceived general social support (*P*<.001), social support change (*P*<.001), rumination (*P*<.001), catastrophizing (*P*<.001), depression (*P*=.01), and anxiety (*P*=.03). Being quarantined was significantly and negatively associated with perceived general social support (*P*<.001) and social support change (*P*=.01), while it was significantly and positively associated with catastrophizing (*P*<.001), depression (*P*<.001), and anxiety (*P*<.001). However, all the correlations associated with lockdown and quarantine had small effect sizes. Both perceived general social support and social support change had small to moderate negative correlations with depression (*r*=−0.17, *P*<.001; *r*=−0.16, *P*<.001, respectively) and anxiety (*r*=−0.17, *P*<.001; *r*=−0.15, *P*<.001, respectively). Both rumination and catastrophizing had moderate positive correlations with depression (*r*=0.25, *P*<.001; *r*=0.28, *P*<.001, respectively) and anxiety (*r*=0.26, *P*<.001; *r*=0.31, *P*<.001, respectively).

Table 6. Bivariate correlations (Spearman ρ, Pearson *r*, and *P* values) between the key psychosocial variables.

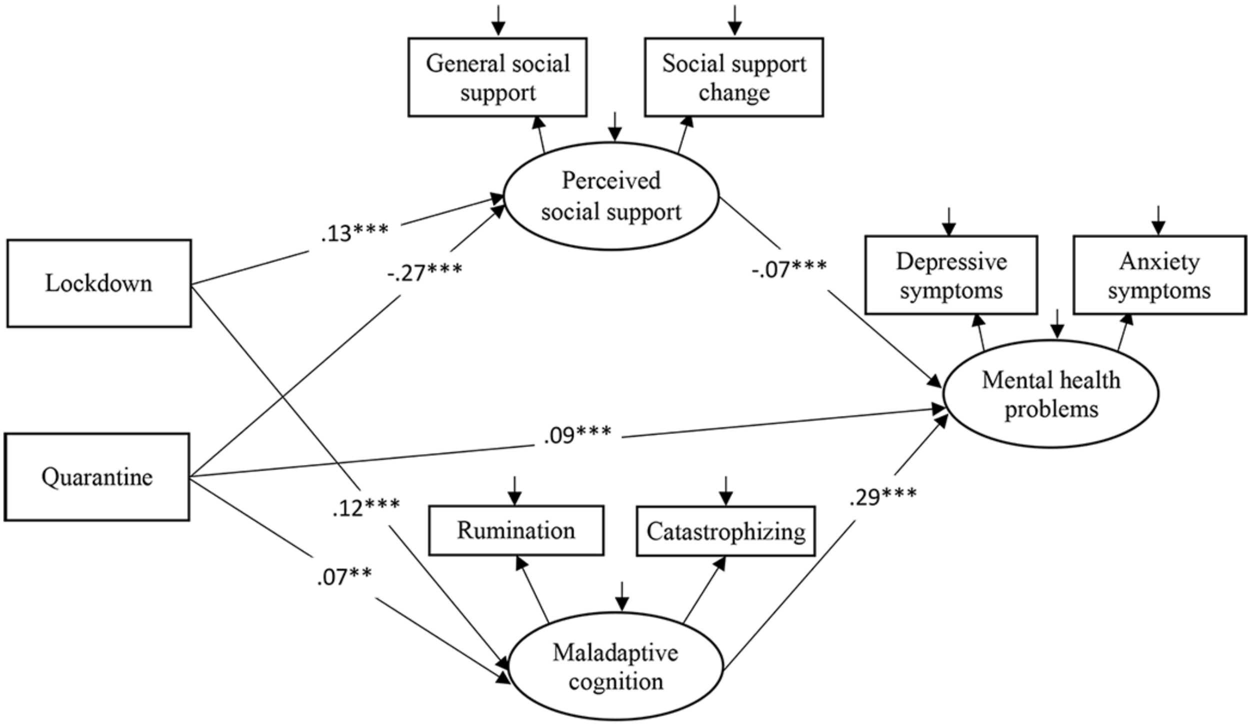
MIMIC Modeling Analyses for the Proposed Model

MIMIC modeling showed that both the measurement model (χ^2_{12}=411.75; comparative fit index [CFI]=.99; nonnormed fit index [NNFI]=.98; root mean square of error approximation [RMSEA]=.04, 90% CI 0.038-0.045) and structural model (χ^2_{14}=495.21; CFI=.99; NNFI=.98; RMSEA=.04, 90% CI 0.038-0.045) (Figure 1) fit the data well. Lockdown was significantly and positively associated with perceived social support (B=.13; β=.04; *P*<.001) and maladaptive cognition (B=.12; β=.09; *P*<.001), but not with mental health problems (B=.01; β=.01; *P*=.33). Mandatory quarantine was associated with low perceived social support (B=−.27; β=−.03; *P*<.001), great maladaptive cognition (B=.07, β=.02, *P*=.01), and great mental health problems (B=.09; β=.04; *P*<.001). Perceived social support was negatively associated with mental health problems (B=−.07; β=−.23; *P*<.001), while maladaptive cognition was positively associated with mental health problems (B=.29; β=.39; *P*<.001). Detailed results regarding regression weights are provided in Multimedia Appendix 1.

Figure 1. Proposed mediation model with unstandardized path coefficients. The nonsignificant path is not shown for simplicity reasons. **P*<.05, ***P*<.01, ****P*<.001.



Mediation Test

The indirect effects of lockdown (B=.03; β=.03, 95% CI 0.02-0.03; *P*=.001; PM=78.8%) and quarantine (B=.04; β=.02, 95% CI 0.01-0.02; *P*=.001; PM=30.1%) on mental health problems were statistically significant. Specifically, the indirect effect of lockdown on mental health problems through perceived social support was negative (B=−.01; β=−.01; *P*<.001), and the indirect effect of lockdown on mental health problems through maladaptive cognition was positive (B=.03, β=.04, *P*<.001). The indirect effects of quarantine on mental health problems through perceived social support (B=.02; β=.01; *P*<.001) and maladaptive cognition (B=.02; β=.01; *P*<.001) were positive. The total effects of lockdown (B=.03; β=.03; *P*=.001) and quarantine (B=.13; β=.05; *P*=.001) on mental health problems were statistically significant.

Moderation Test

The use of social media for obtaining health information during the COVID-19 pandemic significantly moderated the association between perceived social support and mental health problems ($\Delta\chi^2$=18.58, Δdf=2) (Multimedia Appendix 2). Specifically, the negative associations between perceived social support and mental health problems became stronger with the increased frequency of using social media (never: B=−.05; β=−.18; *P*<.001; sometimes: B=−.06; β=−.22; *P*<.001; always: B=−.08; β=−.27; *P*<.001).

The means of using prenatal care services during the COVID-19 pandemic significantly moderated the 3 model paths (Multimedia Appendix 3), including the paths from lockdown to maladaptive cognition ($\Delta\chi^2$=20.10, Δdf=3; went to hospital as usual: B=.16; β=.12; *P*<.001; made appointment with doctor: B=.07; β=.05; *P*<.001; online prenatal care: B=.13; β=.09; *P*=.03; uncertain: B=.05; β=.04; *P*=.25), the paths from mandatory quarantine to perceived social support ($\Delta\chi^2$=8.12, Δdf=3; went to hospital as usual: B=−.30; β=−.03; *P*=.004; made appointment with doctor: B=−.07; β=−.10; *P*=.504; online prenatal care: B=−.78; β=−.12; *P*=.01; uncertain: B=−.43; β=−.06; *P*=.07), and the paths from maladaptive cognition to mental health problems ($\Delta\chi^2$=11.48, Δdf=3; went to hospital as usual: B=.30; β=.41; *P*<.001; made appointment with doctor: B=.26; β=.37; *P*<.001; online prenatal care: B=.35; β=.42; *P*<.001; uncertain: B=.32; β=.38; *P*<.001).

Discussion

In this large-scale study, we report on the high prevalence of depression and anxiety in Chinese pregnant women during the COVID-19 pandemic and the potential sociodemographic, maternal, eHealth-related, control measure-related, cognitive, and social factors that affect them. Furthermore, we found that control measures were associated with depression and anxiety through social support and maladaptive cognition, and that the use of social media to obtain health information and the means of using prenatal care services were potential moderators of these associations.

Anxiety and depression are the most common mental disorders that occur during pregnancy, affecting between 10%-30% of pregnant women in China and other countries [58-61]. Our results suggest that the COVID-19 pandemic has resulted in a substantial increase in pregnant women’s risk of mental health problems, as 44.6% (8712/19,515) and 29.2% (5696/19,515) of our participants had probable mild to severe depression or anxiety, respectively. The significant background factors of anxiety/depression, including age, socioeconomic status, pregnancy-related status, and health service use, are in line with recent COVID-19 studies and non-COVID-19 studies [25,58,59,62]. In general, our results suggest that women with less social capital, experience in pregnancy, or health service resources/access experience more mental distress during the COVID-19 pandemic than those without such issues. In addition, this is the first study to reveal the associations between eHealth-related activities (ie, using online prenatal care services, making appointments with doctors, or using social media to obtain health information) and anxiety/depressive symptoms among pregnant women during the COVID-19 pandemic. We found that about half of the participants (10,189/19,515, 52.2%) went to hospital for prenatal care services as usual, while only 3.3% (640/19,515) used online prenatal care services. This may suggest that there is an urgent need to improve the quality of online prenatal care services and eHealth literacy and popularize the use of such services among pregnant women. These services allow pregnant women to access maternal health care with minimum COVID-19 exposure risk, which is desirable during the outbreak [63]. We found that 7.4% (1442/19,515) of pregnant women had self-harm/suicidal ideations in the past 2 weeks, which is slightly higher than the 5.2% prevalence rate reported before the COVID-19 epidemic [64]. Future studies should identify the causes of these mental health problems and the long-term impact of mental health problems on pregnant women. Tailored and timely interventions for mental health promotion are warranted, especially for vulnerable subgroups, such as pregnant women.

It is intriguing that in our study, lockdown and mandatory quarantine affected mental health problems in different ways through different underlying mechanisms. First, the total effect and indirect effects of lockdown on mental health problems were statistically significant, but the direct effects of lockdown were not. Lockdown increased the incidence of mental health problems through enhancing maladaptive cognition, which is consistent with previous studies on maladaptive cognition in the context of other stressful events (eg, daily hassles) [41,45]. Interestingly, we found that lockdown might increase perceived social support, which in turn might reduce the prevalence of mental health problems. However, a study in New Zealand found a nonsignificant change in perceived social support during the nationwide lockdown compared to that during the pre-COVID period [18]. The different associations between lockdown and perceived social support in the New Zealand study and our study may be partially due to the differences in study designs and samples, or the fact that the severity of lockdown measures and concomitant supporting measures varied across countries [1,2]. The positive association between lockdown and perceived social support in our study may be due to the fact that lockdown prohibits people from leaving an area, which might have increased participants' time and opportunities to stay and communicate with their families. A study conducted on April 2020 in Ireland (N=70) also reported that pregnant women improved their relationships with their partners by talking more, exercising together, and sharing tasks during lockdown [29]. In addition, governmental support has increased during the COVID-19 pandemic, and this has had a protective effect against anxiety among Chinese residents [65]. Thus, increased family support and governmental support during lockdown might explain why lockdown had a positive association with perceived social support and a negative indirect effect on mental health problems among Chinese pregnant women. These explanations should be assessed in future work, such as qualitative studies and case studies.

Second, as hypothesized, mandatory quarantine was significantly associated with a greater incidence of mental health problems. This result is consistent with several previous studies [19,20,66,67]. Furthermore, we found that reduced perceived social support and increased maladaptive cognition may explain this association, which is consistent with a study conducted by Zhu et al [21], who argued that the impacts of quarantine on daily life may explain the effect of quarantine on mental health problems. Quarantine is different from regional or nationwide lockdowns, as quarantine means that individuals are not allowed to leave the building or receive visitors. This difference may partially explain why lockdown increased perceived social support and mandatory quarantine reduced perceived social support in our study. Mandatory quarantine may also substantially affect other aspects of daily life, such as difficulties with quarantine compliance, inadequate information on prevention measures, decreased physical activity, the perceived high risk of COVID-19 infection [68], increased concerns over fetal safety, and difficulties in receiving prenatal care [23], which in turn aggravate mental health problems among pregnant women. Future studies should investigate these potential mediators and identify the cause of postquarantine changes in mental health status (eg, posttraumatic stress disorder development and increased stress).

Our findings highlight the importance of social and cognitive mechanisms in understanding the associations between lockdown/mandatory quarantine and mental health. In terms of our sample, the mediation effects of social and cognitive mechanisms accounted for large proportions of the total effects in the model. In general, the mediation model is supported by the conservation of resources theory [38] and the response styles theory [39,40], which explain how control measures for COVID-19 influence mental health. Based on these theories, future studies may explore other mediators, such as the loss and gain of other types of resources (eg, financial/personal resources) and other types of cognitive responses (eg, positive reappraisal). It is particularly important to identify modifiable psychosocial mediators because COVID-19 might become a persistent health threat, and such control measures might be inevitable [69]. Furthermore, our findings have important practical clinical and political implications. Since referrals are not feasible in the context of the COVID-19 pandemic, mental health first aid and brief non-face-to-face intervention services, such as the screening of mental distress in high-risk groups, counselling hotlines, and online education for problem-solving and stress-coping skills, should be made available for pregnant women and other vulnerable populations. In addition, it is important to guarantee that pregnant women who stay in areas under lockdown or mandatory quarantine can maintain regular communication with their significant others through social media, and receive adequate social support from both significant others and health/social care staff. More intensive therapies, such as cognitive behavioral therapy for cognitive restructuring and adaptive skill training, may be needed for those who experience great anxiety or depressive symptoms, such as the 29.2% (5696/19,515) and 44.6% (8712/19,515) of participants who had probable mild to severe anxiety or depression in our sample, respectively. Several environmental and structural factors, such as adequate preventive facilities, timely and accurate health information, access to multiple health service resources, and mass publicity for properly promoting accurate information on COVID-19, may also help pregnant women to reduce maladaptive cognition and facilitate positive reappraisal. Our results highlight the importance of integrating mental health care and eHealth into the implementation of control measures.

We also found that the use of social media for obtaining health information and the means of using prenatal care services during the COVID-19 pandemic were significant moderators in the model paths. Specifically, social media use strengthened the protective effect of perceived social support on mental health, and making appointments with doctors for prenatal care might buffer the adverse effects of lockdown and mandatory quarantine on maladaptive cognition and perceived social support, respectively. Furthermore, making such appointments might also buffer the adverse effects of maladaptive cognition on mental health. Using social media and making appointments with doctors may imply that people have various ways to access multiple health information and health service resources, which play an important role in buffering the stress appraisal and coping processes. These alternatives may be particularly useful for pregnant women during the COVID-19 pandemic, as high-quality and ongoing prenatal care is essential in supporting a healthy pregnancy and detecting risks early [70]. They are also helpful in reducing the risk of infection and related concerns among pregnant women [46]. In general, our results suggest that virtual visits and telemedicine should be included as part of a bundled care model.

Ours is one of the very few studies to assess pregnant women who experience and do not experience lockdown/mandatory quarantine and explore how such experiences might influence pregnant women’s interpersonal, cognitive, and mental statuses. Although our study adds to the literature on disease control and mental research, it has several limitations. First, the cross-sectional design prohibits causal inferences; the mediation model is exploratory and should not be interpreted as a causal mediation model. Our findings are intended for the generation of future research questions and provision of preliminary insights for when longitudinal studies are less feasible. Second, given the large sample size, the associations between small effect sizes could be statistically significant. Therefore, the interpretation of our results should be based on both statistical significance and effect size. Third, single items were used to assess perceived general social support and social support change; psychometric properties could not be established. Finally, the nonrandomly selected sample may have introduced selection bias, and the generalization of the study findings to other populations should be made cautiously. However, the large sample was recruited from all 34 provincial-level administrative regions in China. Therefore, our sample may accurately represent the population of China at a national level.

In conclusion, quarantine was strongly directly and indirectly associated with poor mental health status through decreased perceived social support and increased maladaptive cognition, while lockdown was indirectly associated with mental health through increased perceived social support and maladaptive cognition among pregnant women. The use of social media for obtaining health information and the means of using prenatal care service were significant moderators in the model paths. Follow-up studies are warranted to examine the long-term impacts of lockdown/quarantine control measures. The Chinese context of this study and the present global situation may differ in terms of the number of confirmed cases, the types and severity of control measures, and public responses toward COVID-19 and control measures. The validation of our findings and identification of similarities and differences across different countries are warranted.

Acknowledgments

We greatly appreciate Zhou Feng Rong from the Shandong Province Hospital for Women and Children's Health, Wu Ying Lan from the Hunan Provincial Maternal and Child Health Care Hospital, Zhao Juan from the Beijing Obstetrics and Gynecology Hospital Capital Medical University, Tian Hong from the Women and Children's Health Care Hospital of Liaoning Province, Qiu Li-qian from the Women's Hospital of the School of Medicine of the Zhejiang University, Xia Jianhong from the Guangdong Women and Children Hospital, Wang Lan from the Chongqing Health Center for Women and Children, and Li Fen from the First Affiliated Hospital of Medical College of Xi’an Jiaotong University for their assistance in data collection.

Authors' Contributions

XY conceived the research questions, conducted the statistical analysis, and drafted the manuscript. WQ and JTFL designed this study and assembled the team of collaborators. WQ supervised the project’s implementation. All authors assisted in questionnaire design, data collection, and data interpretation, and all authors provided comments with regard to the intellectual content of the manuscript.

Abstract

Background: Eliminating disparities in the burden of COVID-19 requires equitable access to control measures across socio-economic groups. Limited research on socio-economic differences in mobility hampers our ability to understand whether inequalities in social distancing are occurring during the SARS-CoV-2 pandemic.

Objective: We aimed to assess how mobility patterns have varied across the United States during the COVID-19 pandemic and to identify associations with socioeconomic factors of populations.

Methods: We used anonymized mobility data from tens of millions of devices to measure the speed and depth of social distancing at the county level in the United States between February and May 2020, the period during which social distancing was widespread in this country. Using linear mixed models, we assessed the associations between social distancing and socioeconomic variables, including the proportion of people in the population below the poverty level, the proportion of Black people, the proportion of essential workers, and the population density.

Results: We found that the speed, depth, and duration of social distancing in the United States are heterogeneous. We particularly show that social distancing is slower and less intense in counties with higher proportions of people below the poverty level and essential workers; in contrast, we show that social distancing is intensely adopted in counties with higher population densities and larger Black populations.

Conclusions: Socioeconomic inequalities appear to be associated with the levels of adoption of social distancing, potentially resulting in wide-ranging differences in the impact of the COVID-19 pandemic in communities across the United States. These inequalities are likely to amplify existing health disparities and must be addressed to ensure the success of ongoing pandemic mitigation efforts.

Introduction

Treatment options and vaccines are being developed to address the COVID-19 pandemic [1]. However, while the ability to detect new infections remains limited by testing capacity and the lack of nationwide syndromic surveillance capabilities [2], nonpharmaceutical interventions represent the only immediate tools public health agencies can use to limit the size and spatial scale of the outbreak [3]. In the United States, state and local governments are primarily responsible for measures such as school or business closures [4]. Historically, similar measures have been used to respond to pandemics, including during plague outbreaks in the Middle Ages [5] and during the 1918 Spanish influenza pandemic [6]. Data collected during the early part of the ongoing COVID-19 pandemic, in particular on the dynamics of the outbreak in China, indicate that nonpharmaceutical interventions can be successful in limiting the size of COVID-19 outbreaks [7] and in delaying large-scale spread [3].

However, social distancing may be adopted differently across communities, especially in the United States, where workers in sectors such as transportation and food retail receive lower wages and represent a larger fraction of workers deemed essential than those in other sectors of the workforce [8,9]. Assessing this differential impact requires the use of fine-scale mobility data, a stream of information that has proven useful in the early assessment of social distancing measures in the United States [10], Italy [11], and France [12]. Digital technologies have taken center stage in the response to COVID-19 [13], and mobility data in particular have enabled assessment of the responses to nonpharmaceutical interventions [14,15]. Previous studies report large-scale reductions in movement, with numbers quickly reaching values typically observed during holiday periods [10]. Furthermore, in the United States, changes in mobility were associated with reductions in COVID-19 cases [16,17] and in the reproduction number of the disease [18], and mobility data also revealed that these changes were largely already underway when state or county stay-at-home orders were issued [16,19,20]. Previous studies using mobility data have also suggested potential inequalities in the ability to practice social distancing based on income [21], race and education [20], or the availability of health care providers [22]. However, most of these studies consider these determinants in isolation and do not allow to disentangle the potential additive effects of the socio-economic make-up of counties on the ability of their populations to practice social distancing. These studies have also largely focused on understanding how social distancing was influenced by local or regional decisions and whether socioeconomic factors changed the responses to state and local interventions.

Here, we focus on an ecological understanding of how mobility varies with socioeconomic characteristics rather than assessing what drives these changes. As outlined above, multiple studies have aimed to understand the causes of mobility behavior changes. However, we seek to understand how the patterns of mobility vary across socioeconomic characteristics (regardless of the cause) during different stages of the pandemic response. In particular, we ask how quickly, how deeply, and for how long mobility changes occurred in locations according to their socioeconomic characteristics. Our approach does not seek to differentiate between spontaneous changes in mobility, such as in response to news coverage, or changes in response to state- or county-mandated orders. Rather, we focus on the resulting changes in mobility and how these differ by location and socioeconomic status.

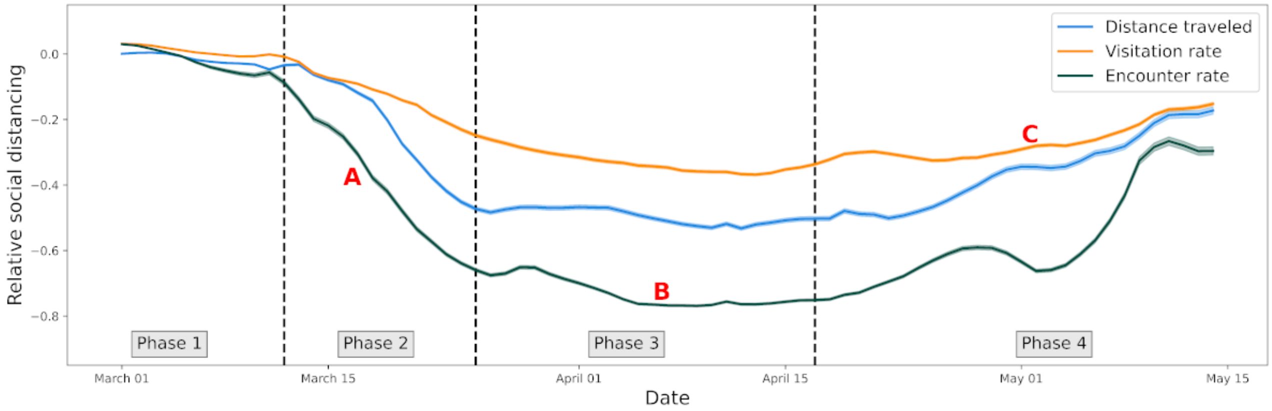
Methods

To measure mobility, we obtained daily county-specific mobility data for the United States from February 24 to May 14, 2020—the period during which most of the United States was simultaneously engaged in social distancing—through a partnership with Unacast [23]. The data set is based on the GPS location data collected from applications installed on tens of millions of devices, and it complies with the General Data Protection Regulation and the California Consumer Privacy Act [24]. The data set was shown to be representative by geographical location, income level, sex, and age in an analysis conducted by Unacast [25]. The fraction of all devices observed varies by location and time, and this has been captured in our analysis (details below).

As outcome measures, we considered data on the changes in three measures of mobility provided by Unacast: daily distance traveled (hereafter, “distance traveled”), rate of visitation to nonessential places (hereafter, “visitation rate”), and rate of encounters between devices within a 50-meter radius within an hour (hereafter, “encounter rate”). Distance traveled reflects the average distance between the home locations of users and locations visited in 1 day. Visitation rate reflects the number of visits to nonessential locations; the definition of nonessential venues is based on state-specific guidelines and policies and includes all locations other than those deemed essential (eg, food stores, pet stores, and pharmacies; more information can be found on Unacast’s website [26]). Encounter rate measures the likelihood of proximity between any two users within 50 meters over a one hour period. Each change is calculated relative to a county-specific baseline calculated from values obtained during a period of several weeks prior to the onset of major COVID-19–related changes in mobility in the United States (February 10 to March 4, 2020 for distance traveled and visitation rate; February 24 to March 4, 2020 for encounter rate). The resulting data set covers 3054 counties for the distance traveled and encounter rate and 2067 counties for the visitation rate. The county-level data on each measure described above can be accessed by contacting Unacast [23], and our model-processed data and the code used for the statistical analysis are available on GitHub [27].

To summarize the mobility time series, using the `fbprophet` package [28], we first fit a nonlinear model to the county-level social distancing time series, including a weekly trend to account for workweek variation. This package fits a piecewise regression while allowing setting the number of potential changepoints, and makes it possible to assess where breaks in the trend occur over the course of the social distancing time series. Most counties follow a dynamic similar to that of the mobility measures aggregated at the country level (Figure 1). In short, the underlying trend can be separated into four phases (ie, four breaks in the trend): phase 1, the baseline period; phase 2, the period of entry into social distancing, measured by the rate of mobility decrease; phase 3, the social distancing period, described by a sustained reduction in mobility outcomes; and phase 4, the period of exit from the social distancing phase, measured by the rate of mobility increase after sustained social distancing. This dynamic is specific to 2020; these four phases are not evident in 2019 (Figure S1 in Multimedia Appendix 1). From these model fits, we extracted several values that enabled us to characterize the changes in mobility during entry into and exit from the social distancing phase, as well as the mobility level during the period of sustained mobility reduction (see Figure 1 for details). Counties with no detectable increase in mobility after sustained social distancing (ie, where the slope of the trend at the end of the time series remains nonpositive) were not included in the phase 4 analysis. Each county time series was thus summarized by 3 values (or 2 values for the counties with no detectable phase 4 increase), which were used in the statistical analysis. We do not distinguish whether these changes are spontaneous in response to the COVID-19 pandemic or occur in response to public health policies; we only define the phases based on changes in mobility rates. That is, we do not seek to explain why the mobility changed but rather how it changed.

Figure 1. Time series of three mobility measures aggregated at the country level. We show a 7-day rolling mean of distance traveled (blue), visitation rate (orange), and encounters rate (green), with the solid line representing the mean and the shaded area two standard errors of the mean. The 4 phases in the mobility time series are delimited by dashed vertical lines in the figure and were generated from the model fit in each county independently. These phases allow us to calculate three summary measures for each time series: the slope of decline in phase 2 (A), the mean level of mobility during social distancing (B), and the slope of increase in mobility during exit from social distancing (C).



Our exposures of interest relate to the socioeconomic composition of each area: racial composition, population density, proportion living below the poverty level, and proportion of the workforce in industries designated as essential. Thus, our exposures of interest are area-level features, not individual features. We obtained information on racial composition and population density from the 2018 American Community Survey [29] and on the proportion of people below the poverty level from the Small Area Income and Poverty Estimate program [30]. We estimated the proportion of workers in industries designated as essential [31] from the Quarterly Census on Employment and Wages for the fourth quarter of 2019 [32].

We also adjusted for the fractions of devices observed in each county because sampling of mobile devices tends to vary geographically and over time.

We ran linear mixed models to analyze the associations between the social distancing summary values and the socioeconomic variables with state as a random effect using the standard 0.05 significance threshold. In the main analysis, we investigated independent associations with each covariate, and the resulting linear mixed model is of the form:

$$Y = X_i\beta_i + Z_\mu + \varepsilon$$

In our case, the response variable Y is one of the social distancing summary measures (the slope in phase 2, mean value in phase 3, or slope in phase 4). The socioeconomic predictors are included as the fixed effects X_i and the state as the random effect Z. The ε term captures the residuals. We ran independent models for each of the mobility measures (distance traveled, visitation rate, and encounter rate) and for each of the social distancing summary measures. We also performed a post hoc secondary analysis in which interaction terms between covariates were added to elucidate findings from the main analysis. Finally, as a sensitivity analysis, we fit an alternative linear model with state as a fixed effect rather than a random effect to adjust for any additional unmeasured state-level features. All analyses were conducted in Python 3.6.

The research presented in this paper was approved by the Georgetown-Medstar Institutional Review Board (study id STUDY00003041).

Results

Social distancing is heterogeneous at the county level (Figure 2). In counties with a higher proportion of people in poverty, social distancing was weaker: mobility was less restricted during the period of sustained mobility reduction, and the change occurred more slowly during the period of entry into social distancing for all three measures of mobility. Additionally, the resurgence in mobility was faster during the period of exit from sustained reductions in mobility for 2 of 3 measures of mobility (Figure 3). Counties with higher proportions of essential workers saw weaker social distancing adoption for all mobility markers during the period of sustained mobility reduction and a slower entry into social distancing based on two mobility markers. The rate of exit from the social distancing phase is less predicted by the proportion of essential workers. Contrastingly, in counties with a larger proportion of Black individuals or a higher population density, social distancing is stronger, with a faster entry into social distancing, lower mobility levels during the period of sustained mobility reduction, and a slower resurgence during the period of exit from the social distancing phase (Figure 3). The results were not significant for the encounter rate for the proportion of Black individuals in the population. Full statistical details are provided in Table S1 (Multimedia Appendix 1).

When interaction effects are added to the model of distance traveled in the period of entry into mobility reductions, all variables follow the same qualitative and quantitative patterns (Table S2, Multimedia Appendix 1). We found a significant positive interaction between the proportion of essential workers and the Black population, and we found a negative interaction between essential workers and low-income workers. The interaction between the proportions of Black people and low-income workers is not significantly associated with mobility.

Figure 2. Heterogeneity in mobility during social distancing. The map shows the average mobility during social distancing due to COVID-19 at the county level in the continental United States relative to the pre–COVID-19 baseline. A positive value indicates an increase in distance traveled, and a negative value indicates a decrease in distance traveled. Counties for which data are not available are shown in grey. The color map is centered at the 90% percentile of the decrease in mobility.

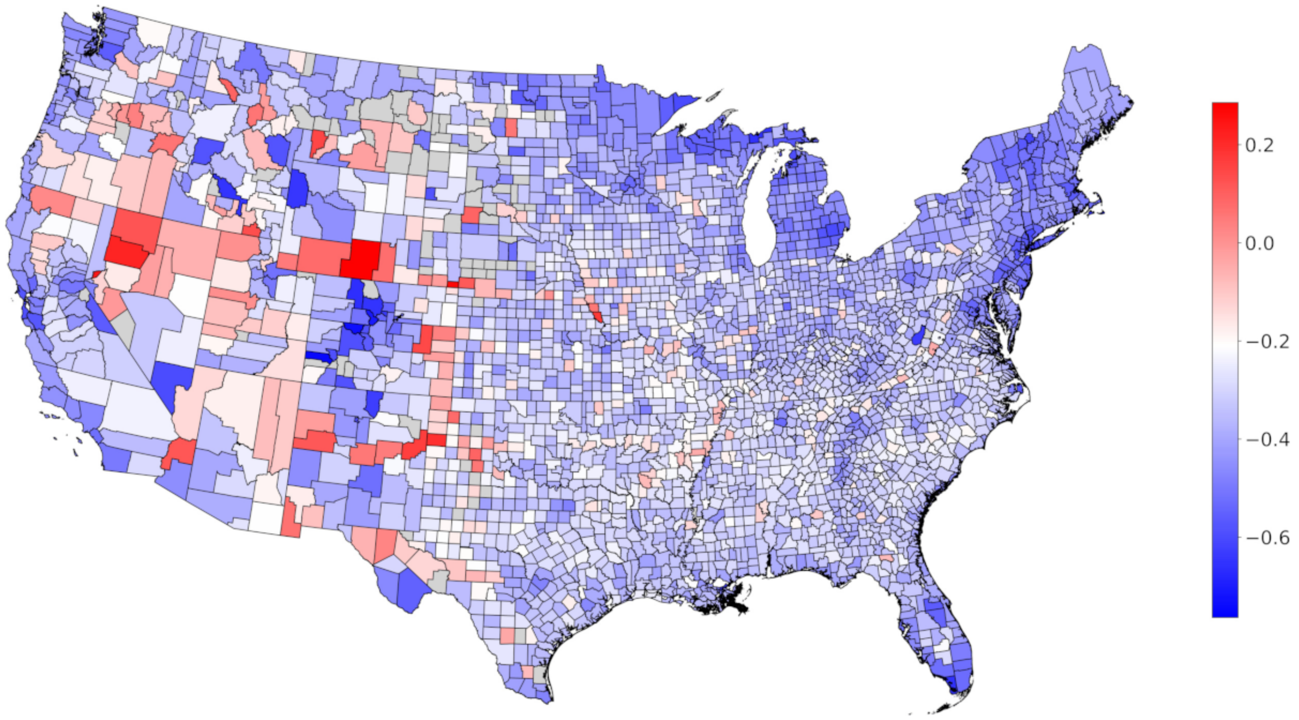


Figure 3. Regression coefficients of distance traveled, visitation rate, and encounter rate for the 4 socioeconomic factors associated with social distancing: (A) mobility during social distancing (phase 3); (B) decline in mobility during entry to the social distancing phase (phase 2); and (C) resurgence in mobility during exit from the social distancing phase (phase 4). The marker denotes the mean coefficient, and the error bars show the 95% confidence interval. A positive association (above the dashed line) indicates that an increase in a given factor leads to a weaker implementation of social distancing. A negative association (below the dashed line) indicates that an increase in the given factor is associated with a stronger implementation of social distancing measures.

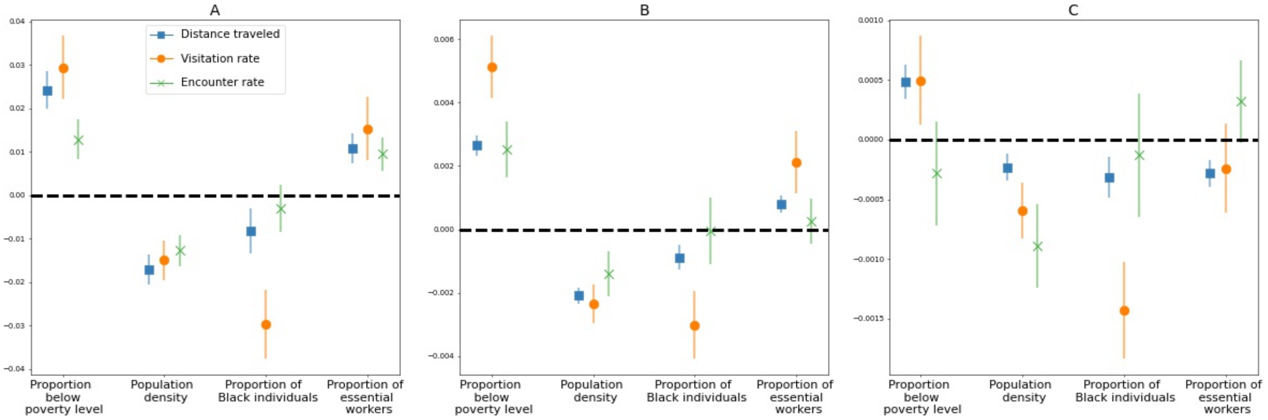

Substituting the random effect state with a fixed effect yielded very similar results. There were only three differences of note: the association between the mobility resurgence measure as the visitation rate in the period of exit from the social distancing phase and the proportion of low-income workers became nonsignificant, while the associations between the resurgence in encounter rate in the period of exit from the social distancing phase and the proportions of essential and of low-wage workers became significant.

Discussion

The COVID-19 pandemic has highlighted significant health disparities in the United States, similar to the health inequities driven by income inequality and racial injustice that previously existed in the country [33]. Understanding the role of behavioral interventions in driving variations in the COVID-19 burden is crucial to our current and future outbreak response. Our study shows that changes in interaction in response to the pandemic are geographically heterogeneous and are associated with county-level socioeconomic factors. This is true for both the level of mobility restriction implemented during the social distancing phase and for the rate at which populations enter (“response engagement“) and exit (“response fatigue”) the social distancing phase.

Our analysis reveals that the occupational composition of the counties is associated with how deeply and for how long social distancing is maintained. Populations including more essential workers, who maintained food services, public transportation, and health care services during the pandemic [8], understandably participate less in social distancing and thus experience greater risk. Additionally, lower-income populations participate less in social distancing, likely in part because low-wage workers may have less access to job protections or paid leave. Our results provide further nuance to the analysis by Lou et al [9], who found that lower-wage workers were unable to reduce their work trips, in large part because businesses classified as essential tended to pay lower wages. Our results may help explain why lower-income counties have suffered a disproportionately high death burden from COVID-19 [17]; however, these results also need to be taken in light of the more general role that low income plays in negative health outcomes [21]. Reduced access to employer-sponsored health care [34] could further limit testing and treatment-seeking behavior and potentially worsen outbreaks in these communities. In rural communities (those with low population density in our study), the need to travel farther to access essential supplies and services such as food or health care [35] may also limit social distancing and would further confirm the existing disparity whereby rural counties suffer from poorer health outcomes than their more urban counterparts [36].

Importantly, we also found that counties with larger Black populations showed stronger adherence to social distancing measures during all phases, after controlling for the effects of income, occupation, and density. Our finding is supported by more local observations of differences between predominantly Black and White neighborhoods, such as Detroit [37]. We also found that social distancing remains more limited in populations that combine high proportions of Black individuals with high proportions of essential workers, possibly because minorities may be overrepresented in certain essential occupations [8]. Despite stronger distancing, there is growing evidence that African American communities experience higher rates of infection and death from COVID-19 [17,38,39]. We advocate for additional work on the structural racism that is at the root of these health disparities [40] and on the role of privilege in the differential burdens imposed by COVID-19 on a variety of communities [22,41].

There is a risk of the ecological fallacy if our results are interpreted as applying to individuals with the attributes we investigated rather than the share of attributes in communities. Survey and qualitative studies would help explain how individual, community, and public policy-level factors explain these associations.

Without large-scale test-trace-isolate programs or other interventions, intermittent social distancing will continue to be needed to contain cases and minimize the strain on health systems [42]. Technological solutions are being suggested and to an extent implemented [13-15]; however, these solutions are not without their limitations. The large-scale use of mobility data and other digital technologies (eg, for contact tracing) has opened up a debate on the responsible use of these emerging data streams [13,43], for instance to ensure that privacy concerns are properly assessed and addressed. These technologies would also likely be most effective with the implementation of a spatially and socially homogeneous testing strategy. Similarly, the long-term success and equity of a mitigation strategy hinges on paying more attention to the geographic heterogeneity in outbreak mitigation and focusing on the role of social and employment policies that affect the ability of individuals to engage in behavioral interventions.

Abstract

Background: In the United States, the rapidly evolving COVID-19 outbreak, the shortage of available testing, and the delay of test results present challenges for actively monitoring its spread based on testing alone.

Objective: The objective of this study was to develop, evaluate, and deploy an automatic natural language processing pipeline to collect user-generated Twitter data as a complementary resource for identifying potential cases of COVID-19 in the United States that are not based on testing and, thus, may not have been reported to the Centers for Disease Control and Prevention.

Methods: Beginning January 23, 2020, we collected English tweets from the Twitter Streaming application programming interface that mention keywords related to COVID-19. We applied handwritten regular expressions to identify tweets indicating that the user potentially has been exposed to COVID-19. We automatically filtered out “reported speech” (eg, quotations, news headlines) from the tweets that matched the regular expressions, and two annotators annotated a random sample of 8976 tweets that are geo-tagged or have profile location metadata, distinguishing tweets that self-report potential cases of COVID-19 from those that do not. We used the annotated tweets to train and evaluate deep neural network classifiers based on bidirectional encoder representations from transformers (BERT). Finally, we deployed the automatic pipeline on more than 85 million unlabeled tweets that were continuously collected between March 1 and August 21, 2020.

Results: Interannotator agreement, based on dual annotations for 3644 (41%) of the 8976 tweets, was 0.77 (Cohen κ). A deep neural network classifier, based on a BERT model that was pretrained on tweets related to COVID-19, achieved an F_1-score of 0.76 (precision=0.76, recall=0.76) for detecting tweets that self-report potential cases of COVID-19. Upon deploying our automatic pipeline, we identified 13,714 tweets that self-report potential cases of COVID-19 and have US state–level geolocations.

Conclusions: We have made the 13,714 tweets identified in this study, along with each tweet’s time stamp and US state–level geolocation, publicly available to download. This data set presents the opportunity for future work to assess the utility of Twitter data as a complementary resource for tracking the spread of COVID-19.

Introduction

In the United States, the rapidly evolving COVID-19 outbreak, the shortage of available testing, and the delay of test results have presented challenges for actively monitoring the spread of COVID-19 based on testing alone. An approach that has emerged for detecting cases without the need for extensive testing relies on voluntary self-reports of symptoms from the general population [1]. Considering that nearly one of every four adults in the United States already uses Twitter, and nearly half of them use it on a daily basis [2], researchers have begun exploring tweets for mentions of COVID-19 symptoms [3-8]. However, considering the incubation period of COVID-19 [9], detecting cases based on symptoms may not maximize the potential of Twitter data for real-time monitoring. The objective of this study was to develop, evaluate, and deploy a natural language processing (NLP) pipeline that automatically collects tweets reporting personal information more broadly—that is, beyond symptoms—that might indicate exposure to COVID-19 in the United States. In this paper, we present a publicly available data set containing 13,714 tweets that were identified by our automatic NLP pipeline between March 1 and August 21, 2020, with each tweet's time stamp and US state–level geolocation. This data set presents the opportunity to explore the use of Twitter data as a complementary resource "to understand and model the transmission and trajectory of COVID-19" [10].

Methods

Data Collection and Annotation

The Institutional Review Board (IRB) of the University of Pennsylvania reviewed this study and deemed it to be exempt human subjects research under Category (4) of Paragraph (b) of the US Code of Federal Regulations Title 45 Section 46.101 for publicly available data sources (45 CFR §46.101(b)(4)).

Between January 23 and March 20, 2020, we collected more than 7 million publicly available tweets that mention keywords related to COVID-19, are posted in English, are not retweets, and are geo-tagged or have user profile location metadata. We developed handwritten regular expressions (Multimedia Appendix 1)—search patterns designed to automatically match text strings—to identify a subset of the 7 million tweets that indicate that the user potentially has been exposed to COVID-19. Our query patterns were designed primarily to help identify potential cases of COVID-19 that are not based on testing and, thus, may not have been reported to the Centers for Disease Control and Prevention (CDC) [11]. The regular expressions matched approximately 160,000 (2%) of the 7 million tweets. Approximately 30,000 (19%) of the 160,000 matching tweets were then automatically removed using a system we developed in recent work [12] for filtering out "reported speech" (eg, quotations, news headlines) from health-related social media data.

In preliminary work [13], two annotators annotated a random sample of 10,000 of the 130,000 filtered tweets, and annotation guidelines (Multimedia Appendix 2) were developed to help the annotators distinguish between three classes of tweets. However, since then, we have removed 1024 of the annotated tweets that were collected from the Twitter Streaming application programming interface (API) based on a keyword that we have stopped using, and we have unified two of the classes. "Potential case" tweets include those that indicate that the user or a member of the user's household was denied testing for COVID-19, showing symptoms of COVID-19, potentially exposed to presumptive or confirmed cases of COVID-19, or had had experiences that pose a higher risk of exposure to COVID-19. "Other" tweets are related to COVID-19 and may discuss topics such as testing, symptoms, traveling, or social distancing, but do not indicate that the user or a member of the user's household may be infected. Among the 8976 tweets, 3644 (41%) were annotated by both annotators. Upon resolving the annotators' disagreements, 1456 (16%) of the tweets were annotated as "potential case" and 7520 (84%) as "other." Textbox 1 presents (slightly modified) sample tweets that match our handwritten regular expressions and were manually annotated as "potential case."

Textbox 1. Sample (slightly modified) tweets that match our handwritten regular expressions and were manually annotated as potential cases of COVID-19.

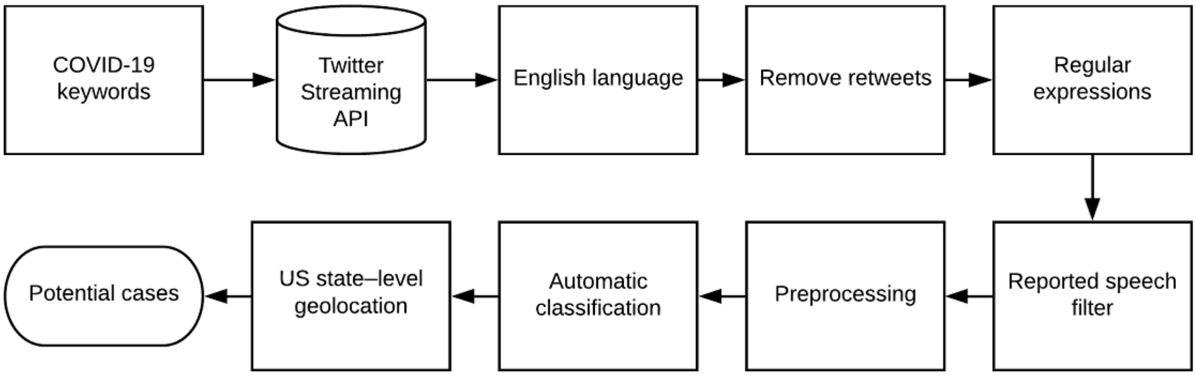
1. Nearly two weeks ago I had a fever, sore throat, runny nose, and cough. I want to know if it was coronavirus or just the common cold
2. My coworker in next office probably has #coronavirus. He and his wife have the symptoms, but they went to the hospital to get tested and were refused.
3. This girl in my class had the coronavirus, so I'm making an appointment with my doctor for a check up
4. Pretty sure I had a patient tonight with Coronavirus. Had all the symptoms and tested negative for the flu.
5. Why can celebrities, sports athletes & politicians without symptoms get tested, but my symptomatic child who has a compromised immune system cannot? #coronavirus
6. Since getting back from Seattle I've been sick and want to get a #coronavirus check. Called my PCP, they said to call health dept. Called them, they said I need to go thru my PCP. Called my PCP again, they said they can't help me
7. I'm convinced I have coronavirus. I've been to NYC, Phoenix, and San Diego in the last few weeks. I have a cough, a runny nose, and I'm really hot #covid19
8. Scared of the coronavirus because I have a sore throat and a headache I think its just a cold but I take the tube 4 times a day
9. Can't even get testing SCHEDULED while self-quarantined (my decision) and having coronavirus symptoms I take train thru New Rochelle to Manhattan
10. I have a bad cold. I went to the doctor, got some medications, the norm. But they couldn't rule out coronavirus because they don't have the tests.

As Textbox 1 illustrates, our handwritten regular expressions are based on query patterns designed to identify tweets that report personal information that may be useful for tracking potential cases of COVID-19, including not only symptoms (tweet 1), but also exposure to potential cases and a lack of access to COVID-19 testing. For example, our regular expressions retrieve tweets reporting that the user may have come in contact with coworkers (tweet 2), classmates (tweet 3), patients (tweet 4), and family members (tweet 5) who may have COVID-19, and potential exposure to COVID-19 through traveling (tweets 6 and 7) and commutes (tweets 8 and 9). Our regular expressions also retrieve tweets reporting that the user (tweet 9 and 10), a family member (tweet 5), or someone else that the user has been in contact with (tweet 2) was denied access to testing, even though they are sick. Since none of the tweets in Textbox 1 report being tested for or diagnosed with COVID-19, they represent potential cases that may not have been reported to the CDC.

Automatic Classification and Geolocation

We split the 8976 annotated tweets into 80% (7181 tweets) and 20% (1795 tweets) random sets—a training set (Multimedia Appendix 3) and held-out test set, respectively—for automatic classification. We used the *ktrain* [14] Python library to train and evaluate two supervised deep neural network classifiers based on bidirectional encoder representations from transformers (BERT): BERT-Base-Uncased [15] and COVID-Twitter-BERT [16]. After feeding the sequence of tweet tokens to BERT, the encoded representation is passed to a dropout layer (dropping rate of 0.1), followed by a dense layer with 2 units and a softmax activation, which predicts the class for each tweet. For training, we used Adam optimization with rate decay and warm-up. We used a batch size of 64, training runs for 3 epochs, and a maximum learning rate of 1×10^{-5}. We fine-tuned all layers of the transformer model with our annotated tweets. Prior to automatic classification, we preprocessed the tweets by normalizing usernames and URLs, and lowercasing the text. Figure 1 illustrates our automatic NLP pipeline for detecting tweets that indicate potential cases of COVID-19 in the United States. We deployed the pipeline on more than 85 million unlabeled tweets that were continuously collected between March 1 and August 21, 2020. We used Carmen [17] to infer the geolocation—at the US state level—of tweets that the classifier predicted as potential cases.

Figure 1. Automatic natural language processing (NLP) pipeline for detecting tweets that self-report potential cases of COVID-19 in the United States.

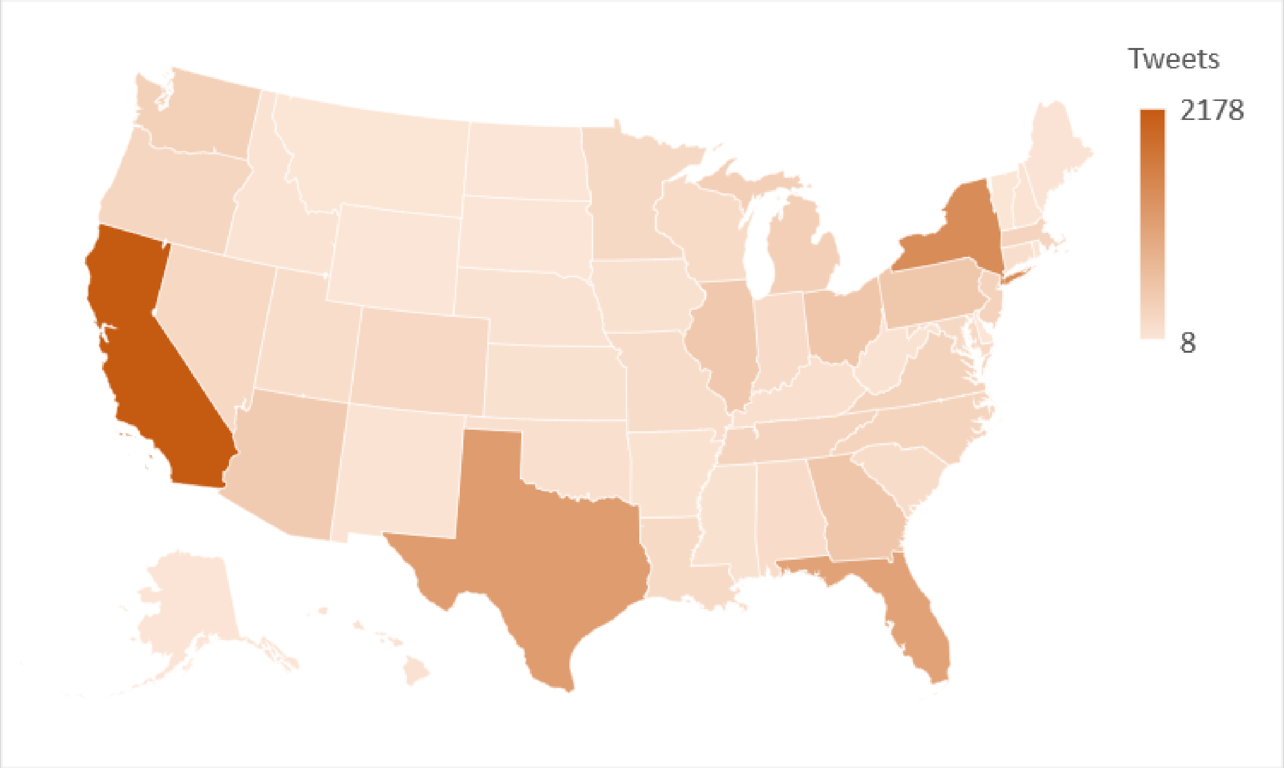


Results

Interannotator agreement, based on dual annotations for 3644 (41%) of the 8976 tweets, was 0.77 (Cohen κ), considered "substantial agreement" [18]. We evaluated two deep neural network classifiers on a held-out test set of 1795 (20%) of the 8976 tweets. The classifier based on the BERT-Base-Uncased pretrained model achieved an F_1-score of 0.70 (precision=0.72, recall=0.67) for the "potential case" class, and the classifier based on the COVID-Twitter-BERT pretrained model achieved an F_1-score of 0.76 (precision=0.76, recall=0.76), where:

We deployed our automatic pipeline, using the COVID-Twitter-BERT classifier, on more than 85 million unlabeled tweets that were continuously collected from the Twitter Streaming API between March 1 and August 21, 2020. Among the subset of tweets that were posted in English, not retweets, matched the regular expressions, and were not filtered out as reported speech, the COVID-Twitter-BERT classifier detected 13,714 "potential case" tweets for which Carmen inferred a US state–level geolocation. Figure 2 illustrates the ranges of "potential case" tweets that were automatically detected per state. We automatically detected "potential case" tweets from all 50 states, with the highest numbers posted in California, New York, Texas, and Florida.

Figure 2. Tweets self-reporting potential cases of COVID-19 in the United States, by state, between March 1 and August 21, 2020.



Discussion

Principal Findings

While Twitter data has been used to identify self-reports of symptoms by people who have tested positive for COVID-19 [3,4], the shortage of available testing and the delay of test results in the United States motivated us to assess whether Twitter data could be scaled to identify potential cases of COVID-19 that are not based on testing and, thus, may not have been reported to the CDC. There are studies that have not limited their exploration of COVID-19 symptoms on Twitter to users who have tested positive for COVID-19 [5-8]; however, limiting the detection of potential cases to symptoms may still underutilize the information available on Twitter. Our automatic NLP pipeline has detected potential cases of COVID-19 across the entire United States that are neither based on testing nor limited to symptoms, providing the opportunity to explore the utility of Twitter data more broadly as a complementary resource for tracking the spread of COVID-19. An analysis based on this data set is beyond the scope of this study. The 13,714 “potential case” tweets identified in this study can be downloaded using a Python script [19] and the input file in Multimedia Appendix 4, which contains the user ID, tweet ID, time stamp, and inferred state-level geolocation for each tweet. The script downloads the tweets that are still publicly available.

Conclusions

This paper presented an automatic NLP pipeline that was used to identify 13,714 tweets self-reporting potential cases of COVID-19 in the United States between March 1 and August 21, 2020, that may not have been reported to the CDC. This publicly available data set presents the opportunity for future work to assess the utility of Twitter data as a complementary resource for tracking the spread of COVID-19.

Abstract

Background: Senior centers and other types of clubs provide activities for older adults to address boredom, social isolation, and loneliness. Due to the COVID-19 pandemic, most of these activities have been cancelled. A limited range of web-based activities have been offered as alternatives. However, the effectiveness of these web-based group activities for older adults has scarcely been researched.

Objective: We aimed to understand the extent to which web-based activities for older adults provide an adequate substitute for in-person activities.

Methods: In this telephone survey, we interviewed 105 older adults in Israel who had been offered the opportunity to participate in web-based activities after routine activities closed due to the COVID-19 pandemic. Of the total sample, 49/105 (46.7%) participated in the activities and 56/105 (53.3%) did not. We inquired about the respondents' background characteristics, satisfaction with the activities, and reasons for participation or nonparticipation.

Results: The respondents who participated in the web-based activities tended to be highly satisfied with at least some of them. They rated the enjoyment derived from the content of the activity as the most important motivator, followed by maintaining a routine and by enjoying the group and the presence of others. Over 50% of the participants (28/49, 57%) wished to continue with the exercise programming after the end of the COVID-19 pandemic, and 41% (20/49) wished to continue with the web-based lectures. Participants were more likely to report partaking in alternative activities than nonparticipants (*P*=.04). The most common reasons cited by nonparticipants were being unaware of the web-based program (24/56, 43%) despite a notification having been sent to the entire sample, lack of interest in the content (18/56, 32%), and technical issues (13/56, 23%), such as not owning or being able to fully use a computer. Both participants and nonparticipants were interested in a wide range of topics, with many being very particular about the topics they wished to access. Approximately half expressed willingness to pay for access; those who were willing to pay tended to have more years of education (*P*=.03).

Conclusions: Our findings suggest a need for web-based activities for countering boredom and feelings of isolation. The main factors that influence the use, efficacy, and sustainability of online activities are access, motivational and need-fulfilling factors, and whether the activities are sufficiently tailored to individuals' preferences and abilities. Challenges in substituting in-person services are promoting social relationships that are currently not sufficiently incorporated into most web-based programs, accommodating a wider range of topics, and increasing the accessibility of current programs to older adults, especially those who are homebound, both during and after the COVID-19 pandemic.

Introduction

Background

The COVID-19 pandemic has harsh implications for the quality of life of older adults. Stay-at-home orders, closure of senior centers, and restrictions on visits by friends and relatives have increased social isolation and loneliness in this population [1-3]. Some of the stressors experienced by older adults as a result of the COVID-19 pandemic are related to being confined to home, concern for the health and safety of family and friends, and boredom [4]. The latter has also been reported as an impact of quarantine restrictions [5]. Homebound older adults, who are unable to leave the house due to illness or other impairments, may be at higher risk of feeling lonely during the pandemic [6] and at other times [7,8].

Social isolation and loneliness increase older people's risk of anxiety, depression [9], mortality [10], and dementia [11]. Activity and social engagement are important for psychological well-being [12], training of memory and executive function [13], greater happiness, and reduced mortality [14] of older adults.

Web-based technologies have been proposed as a way to address these issues while protecting older adults from COVID-19 infection [2,3]. These technologies are also cost-effective [15] and may benefit older adults in particular [16] because their social networks tend to be geographically less proximal [17].

Two categories of barriers have been identified concerning internet use among older adults: First, personal characteristics such as cognitive and physical impairments may limit their ability to use conventionally designed computer equipment [18,19]. Socioeconomic, educational, and cultural backgrounds influence older adults' ability to access computers as well as the extent of their pre-existing knowledge of technology and their experience using it [20,21]. Living arrangements are also an important factor [22], as people who live alone are less likely to use the internet [20], and complete beginners and frail older adults require extensive support and assistance [23].

Second, attitudes of older adults toward the internet and technology, including computer anxiety [24] and concern about data security and privacy, can present obstacles [25,26]. Older adults may find themselves excluded from the "digital world" due to lack of knowledge and skill in the use of modern technologies, which stems from a lack of assistance and training as well as from technology designs that fail to consider their needs, knowledge, and background [27-29].

Studies investigating the impact of pilot social web-based interventions reported positive effects on loneliness [30,31]. Information and communication technologies were found to reduce depression [32], and smart technologies increased self-efficacy, empowerment, and confidence in using technology [33].

However, most of these studies are qualitative, with small sample sizes; thus, they may be less conclusive. In addition, the positive impact of these interventions on social support and connectedness has been found to be short in duration [34]. Although the frequency of internet use was associated with reduced loneliness, it did not impact perceptions of social isolation [35]. The type of web-based activity influences impact, as only social activities (eg, connecting with family and friends) were associated with decreased loneliness [36] and enhanced life satisfaction [37], whereas internet use for informational purposes or instrumental functions (eg, banking) were not. Recreational activities were the only type of activity with a significant correlation with older adults' well-being after controlling for background variables [38].

Research on web-based group activities for older adults is scarce. We found only 2 studies that examined the impact of web-based physical exercise activities in different settings, comparing individual and group training [39,40]. Baez et al [39] reported high usability of a group intervention but did not find a decrease in loneliness attributable to the group intervention itself. Importantly, the web-based group exercises in these two studies [39,40] included avatars in a virtual gym instead of live video communication, which may have impacted the perceived quality of social contact and hence loneliness.

Aims of the Study

There is a need to further investigate the potential of web-based activities to enhance the well-being of older adults, particularly during the COVID-19 pandemic, where personal contact and interaction are severely restricted. Our specific research foci are (1) reasons older persons use or do not use web-based activities; (2) the effectiveness of various web-based activities in achieving user satisfaction and the use of alternative web-based activities; and (3) older persons' activity preferences and their willingness to pay for web-based activities.

Methods

The Healthy Aging Web-Based Activity Program

An opportunity to examine these issues arose when we heard that after Healthy Aging, Ltd (*Beseva Bria*), a for-profit organization providing rehabilitation services to older persons, was forced to close its doors due to COVID-19 regulations, they started providing activities via the internet platform Zoom (Zoom Video Communications), which facilitates video group meetings. Web-based activities were initially offered free of charge when staff volunteered to provide older persons with activities and companionship after senior centers closed during the COVID-19 crisis. Thereafter, these Zoom meetings were offered for a small subscription fee.

Healthy Aging's Zoom activities took place 5 days per week, with 3 activities per day, each lasting 30 minutes, between 10 AM and 11:30 AM. The first activity was always a type of exercise that could be performed while seated.

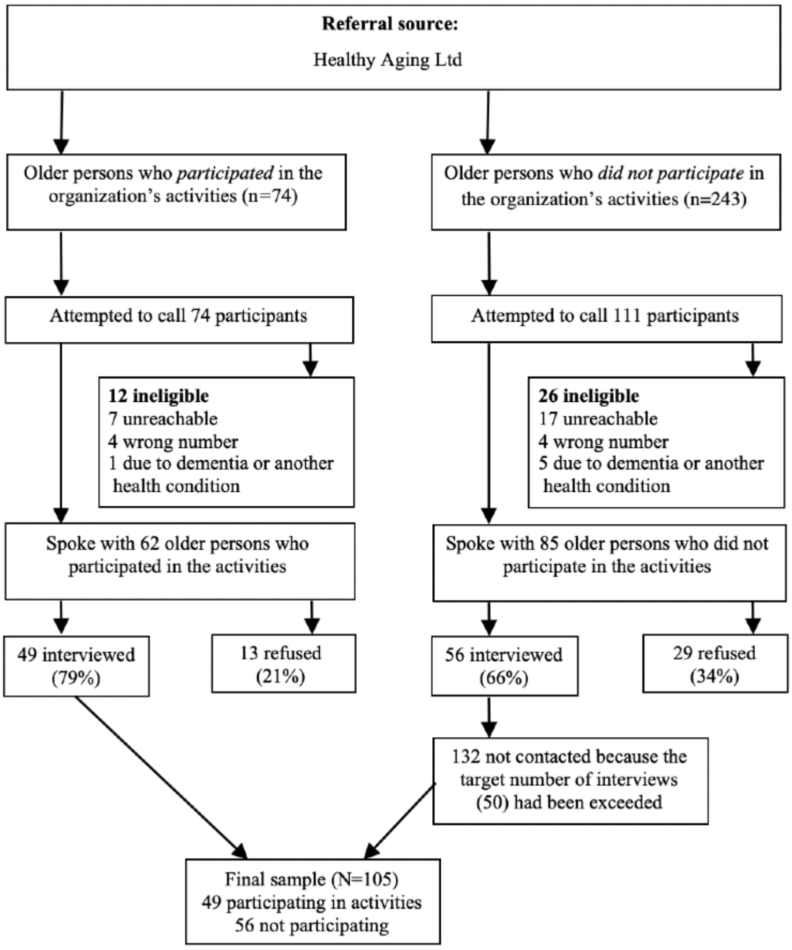
The other activities varied, including mindfulness, musical tai-chi, self-help, and lectures about topics such as world travel, history, health, and mental health. When deemed appropriate by Healthy Aging, some participants were invited to present lectures. Starting at 9:30 AM, some participants engaged in an informal chat via the same Zoom meeting. In the lectures and mindfulness activities, participants were encouraged to participate in discussions. The vast majority of the participants did not know each other, nor did they know the organization prior to connecting to the web-based program.

Recruitment

After Healthy Aging agreed, we embarked on a pilot study to examine the utility of Zoom activities for the older population served by the organization. Ethical approval was obtained from the Institutional Review Board of Tel Aviv University.

Healthy Aging sent letters informing prospective interviewees of this study and offering them the opportunity to opt out of being contacted for it. Letters were sent to all persons who participated in the organization's web-based activities or were offered the opportunity to participate. Healthy Aging then provided us with their contact information. The recruitment process is described in Figure 1. Although the percentage of people who declined to be interviewed was higher among people who did not participate in the activities (34%) than among activity participants (21%), this difference was not statistically significant (*P*=.08). We interviewed 49 participants and 56 nonparticipants.

Figure 1. Participant recruitment process for the study.



Assessments

Separate questionnaires were developed for participants and nonparticipants based on our research foci (Multimedia Appendix 1 and Multimedia Appendix 2, respectively). Interviews for both groups were conducted via telephone and lasted for approximately 20 minutes. Both interviews started with an explanation of the interview and a request for verbal informed consent. Both questionnaires included queries about the respondent's demographic background. When someone other than the older person was the interviewee, questions were asked about the reason for this and the relationship of the interviewee to the older person.

The remainder of the questionnaire for activity participants included 37 closed- and open-ended questions, such as “How often have you participated in the activities?” rated on a scale of less than once a week, once or twice a week, three or four days a week, and every day. Comments offered in response to open-ended questions were transcribed. The topics covered were ease of using technology, frequency of participation, content of the activities, reasons for participation and their importance, satisfaction with particular activities, participation in alternative activities, desire for promotion of social relationships through the Zoom activities, and willingness to pay for web-based activities.

The questionnaire for respondents who did not participate in the activities included 25 similar questions, including their reasons for nonparticipation.

Analytic Approach

Statistical analysis involved descriptive statistics using SPSS (IBM Corporation). The two groups were compared via *t* test for ordinal and interval data and via chi-square test for nominal-level data. When answers to 2 questions overlapped, such as “Why do you not participate in Healthy Aging’s online activities?” and “What changes or improvements in the online format would have motivated you to participate in particular activities?” the responses were combined. Open-ended responses were coded using an emergent coding strategy [41] whereby two research staff members read, coded, and categorized the responses independently and then revised the codes through discussion until agreement was reached. Their findings were reviewed by another staff member, and the main themes were ultimately agreed upon by all researchers. Open-ended responses are presented as quotations where they inform the quantitative findings.

Results

Demographics

As shown in Table 1, both groups had a mean age of approximately 74 years (participants, mean 74.3 years, SD 6.6; nonparticipants, mean 74.8 years, SD 8.7) and approximately 15 years of education (participants, mean 15.3 years, SD 4.2; nonparticipants, mean 15.2 years, SD 3.6). Over 80% of the respondents (89/105, 84.8%) were female. Over 90% (92/97, 95%) lived in their homes, and 60% (57/95) lived with a spouse. Demographic differences between those who participated in the web-based activities and those who did not were generally not significant. There was a trend for a larger percentage of nonparticipants (8/50, 16%) to require help in walking, compared to 2/47 participants (4%; *P*=.06) and in requiring help reaching places outside of walking distance (10/51 nonparticipants, 20%, vs 3/47 participants, 6%; *P*=.054). In 10/56 interviews (18%) with nonparticipants, someone other than the older person completed the interview, compared to 2% (1/49) in the case of participants (*P*=.008). In 13% (7/46) of interviews with nonparticipants who answered for themselves, the interviewer thought the respondent had some cognitive difficulties, compared to 2% (1/49) among participants (*P*=.04).

Table 1. Background variables of the study participants (N=105).

Variable	Participating in activities (n=49)	Not participating in activities (n=56)	Total sample (N=105)	Difference between groups (*P* value)
Age (years), mean (SD)	74.3 (6.6)	74.8 (8.7)	74.6 (7.8)	.77
Education (years), mean (SD)	15.3 (4.2)	15.2 (3.6)	15.3 (3.9)	.91
Female gender, n (%)	43/49 (87.8)	46/56 (82.1)	88/105 (84.8)	.42
Born in Israel, n (%)	26/47 (55.3)	32/52 (61.5)	58/99 (58.6)	.53
Married (%)	27/46 (58.7)	28/51(54.9)	55/97 (56.7)	.71
Residence (%)	43/45 (95.6)	49/52 (94.2)	92/97 (94.8)	.77
Living situation, n (%)				.55
With spouse	27/45 (60.0)	30/50 (60.0)	57/95 (60.0)	
Alone	15/45 (33.3)	16/50 (32.0)	31/95 (32.6)	
With caregiver	3/45 (6.7)	2/50 (4.0)	5/95 (5.3)	
With other family member	0/50 (0.0)	2/50 (4.0)	2/95 (2.1)	
Can walk without help, n (%)	45/47 (95.7)	42/50 (84.0)	87/97 (89.7)	.06[a]
Can reach places farther than walking distance without help, n (%)	44/47 (93.6)	41/ 51(80.4)	85/98 (86.7)	.054[b]
Working, n (%)	9/46 (19.6)	16/52 (30.8)	25/98 (25.5)	.20
Older person answered questions themselves, n (%)	48/49 (98.0)	46/56 (82.1)	94/105 (89.5)	.008[c]
Impression of interviewer: cognitive impairment of person interviewed “Not at all,” n (%)	48/49 (98.0)	49/56 (87.5)	97/ 105 (92.4)	.04[d]
Impression of interviewer: accurate information given, n (%)	49/49 (100.0)	53/56 (94.6)	102/105 (97.1)	.10

[a] χ^2_1=3.6.

[b] χ^2_1=3.7.

[c] χ^2_1=7.0.

[d] χ^2_1=4.1.

Feasibility: Extent of and Reasons for Participation and Nonparticipation

Of the 49 participants who participated in the activities, 27 (55%) reported participating in the activities every day, with 11 (22%) reporting participation 3 or 4 days per week; 37 (76%) had participated in the activities for over 20 days at the time of the interview.

Most of the 49 participants (34, 69%) were able to access Zoom on their own; however, 15 (31%) had difficulties, mostly in activating Zoom and starting the activities. These participants were helped by family members (9/49, 18%); by staff from Healthy Aging (4/49, 8%); by paid caregivers (1/49, 2%); or by a hired technician (1/49, 2%).

Respondents who participated in the activities rated enjoying the content of the activity as the most important motivator (mean score 4.4 on a scale of 1-5); as one participant commented, “This way you are exposed to interesting lectures and new people” [#162, age 74 years, female]. This was followed by maintaining a routine (mean score 3.6), as in “[It helps me] get up on time. …It provides me with a framework and routine” [#131, age 77 years, female]; enjoying the group and the presence of others (mean score 3.1); relief from loneliness (mean score 2.6), such as “Company during a time of loneliness” [#129, age 73 years, female]; and being motivated by family members or friends (mean score 1.8). One participant commented that the web-based activities helped her avoid loneliness and depression (#133, age 87 years, female).

Similar to the above ratings, the most common reasons for engaging in the web-based activities reported by participants were interest in the activities and relief from boredom for 30/49 (61%) (Table 2), followed by opportunity to exercise, access to activities from home, and maintaining a daily routine. Only 8/49 participants (16%) mentioned social activity or relief from loneliness as a reason for participating.

Table 2. Study participants' reasons for participating (n=49) and not participating (n=56), n=105.[a]

Category and reason	Participants, n (%)
Reasons for participating (n=49), 82 total responses	
Motivation	
Interest in content/relieving boredom	30 (61)
Providing exercise	15 (31)
Maintaining a daily routine	11 (22)
Social interest/relief of loneliness	8 (16)
Activities appropriate for older persons	2 (4)
Access	
Activities accessible from home	14 (29)
Convenient hours	2 (4)
Reasons for not participating (n=56), 102 total responses	
Access	
Never heard of Healthy Aging	24 (42)
Technical issues[b]	13 (23)
Inconvenient time or duration of the activities[c]	12 (21)
Not willing to pay	3 (5)
Motivation	
Lack of interest in the content of the activities	18 (32)
Participation in other activities/organizations	9 (16)
The activities are designed for older persons ("I'm too young for these")	5 (9)
Abilities	
Problems due to cognitive impairment[d]	7 (13)
Hearing/vision problems[d]	4 (7)
Concerns	
Reluctance to take part in group activities	3 (5)
Reluctance to participate in activities with a camera	1 (2)
The organization seems too commercial	1 (2)

[a] Participants could provide multiple answers.

[b] Out of 13 participants, 8 (62%) did not know how to operate a computer/phone, 3 (23%) indicated they did not relate to technology and Zoom, and 2 (15%) had no computer.

[c] Out of 12 participants, 8 (67%) reported participating in other activities, 1 (8%) reported working, and 1 (8%) reported having no time due to caregiving for a spouse with dementia.

[d] Two persons reported cognitive reasons *and* hearing/vision problems.

Nonparticipants gave an average of 1.8 reasons for not participating (range 1-4, SD 0.9). The most common reasons were related to lack of access and awareness, such as not having heard of the activities sponsored by Healthy Aging (24/56, 43%) and technical issues (13/56, 23%), such as not owning a computer and inability or lack of knowledge of how to connect to Zoom. Motivational factors, such as lack of interest in the content of the offered activities, also played a role (Table 2), as did participants' involvement in other activities (eg, "The activities offered are not as good as other activities I have and do" [#214, age 61 years, female]). Other reasons reported less often were cognitive and sensory problems and the perception that the activity was appropriate for an older group (Table 2). Respondents who felt the activity was appropriate for older persons expressed a preference for activities such as home repairs, yoga, and belly dancing. The average age of these respondents was 72.8 years (range 66-85 years), compared to 74.6 years for the full sample.

Efficacy and Avenues for Upgrade: Participants' Satisfaction With Web-Based Activities and Their Ideas for Improvement

As shown in Table 3, exercise was rated as the most satisfying activity (4.4 on a 5-point scale), and these activities were attended by most participants: "There is great diversity, every day, a different part of the body" [#110, age 75 years, female]. Mindfulness received the lowest ratings, with an average score of 3, denoting moderate satisfaction; one participant stated, "I do not relate to it" [#112, age 77 years, female]. The ordinal order of the levels of satisfaction for the different activities is roughly reflected in the attendance levels (Table 3), with the highest attendance at exercise and professional lecturer activities. The lowest attendance was reported for lectures provided by group members.

Out of the 49 activity participants, 28 (57%) expressed interest in continued participation in exercise activities after the COVID-19 pandemic was over, followed by interest in lectures, while other activities drew less interest. These reflect the same order of satisfaction with the activities (Table 3).

Table 3. Reported levels of satisfaction and desire to continue each type of activity offered by Healthy Aging after the COVID-19 pandemic (n=49).

Type of activity	Reported satisfaction levels per type of activity,[a] mean (SD)	Number attending, n	Would like to continue the activity after the pandemic, n (%)
Physical exercise	4.4 (0.7)	44	28 (57)
Lecture[b] (professional lecturer)	4.3 (1.0)	37	20 (41)
Lecture (lecturer from the participants' group)	3.8 (1.0)	17	13 (27)
Self-care exercises (eg, head massage)	3.8 (1.4)	26	10 (20)
"Travel from the couch" lecture by a tour guide	3.7 (1.1)	25	14 (29)
Mindfulness	3.0 (1.5)	24	7 (14)

[a] 1, not at all; 2, a little; 3, moderately satisfied; 4, satisfied; 5, very satisfied.

[b] Lectures included diverse topics, such as current art, memory, nutrition, the Bible, sexuality in old age, and history.

Participants indicated several ways through which their interest in participating in the activities could be increased, such as enhancing social contacts, enriching the content of activities, and improving technical and scheduling features. In terms of encouraging social contact, 42% (20/48; one participant did not answer this question) thought that social contact should be a goal of activities. In terms of the content of the activities, 33% of participants (16/49) viewed it as insufficiently interesting; in contrast, 2% (1/49) described the content as too complicated. Moreover, 2/49 participants (4%) considered the delivery to be too fast, and the same number requested more pictures and music in the presentations (2/49, 4%). Requests for additional types of content were especially common (13/49, 27%), as presented in Table 4, which includes requested content expressed by participants and by nonparticipants. The most popular specific topics were exercise, such as "I love Pilates" [#296, age 72 years, female]; culture, such as "lectures in museums" [#121, age 85 years, male]; music, such as "series of lectures about jazz" [#108, age 78 years, female]; art, such as "activities in the field of painting" [#224, age 86 years, male], and travel, such as "lectures on trips around the world" [#225, age 85 years, male]. However, this is not a perfect categorization, because many participants requested very specific activities, such as "play Remi," "Nordic walking," or "psychology of the brain." Finally, 3 out of 49 participants (6%) mentioned problems with their computer, Zoom, or sound quality, and some requested simpler presentation formats, such as television. Out of the 49 activity participants, 10 (20%) sought programming at different times and during more time slots or recording of activities for later viewing.

Table 4. Preferred areas of interest of participants (n=49) and nonparticipants (n=56) in web-based activities (n=105).

Total (N=105), n (%)	Nonparticipants (n=56), n (%)	Participants (n=49), n (%)	Topic
33 (31.4)	13 (23.2)	20 (40.8)	Lectures—general
29 (27.6)	15 (26.8)	14 (28.6)	Exercise
25 (23.8)	10 (17.9)	15 (30.6)	Art/culture/music
12 (11.4)	6 (10.7)	6 (12.2)	Travel
6 (5.7)	2 (3.6)	4 (8.2)	History/philosophy
6 (5.7)	3 (5.4)	3 (6.1)	Coaching/body-mind
19 (18.1)	6 (10.7)	13 (26.5)	Other[a]

[a] Includes games/mind games/bridge (4 participants and 1 nonparticipant), literature (2 participants and 1 nonparticipant), science/technology (3 participants and 0 nonparticipants), education/social sciences (1 participant and 2 nonparticipants), religion (2 participants and 0 nonparticipants), food/cooking (0 participants and 2 nonparticipants), language study (1 participant and 1 nonparticipant), current affairs (1 participant and 0 nonparticipants), business (0 participants and 1 nonparticipant), gardening (1 participant and 0 nonparticipants), and wills (1 participant and 0 nonparticipants).

Sustainability: Competing Activities and Willingness to Pay for Activities

Web-based activity participants were significantly more likely to report partaking in alternative activities (38/48, 79%) than nonparticipants (34/56, 61%; χ^2_1=4.1; P=.04). Of those participating in Healthy Aging's web-based activities, 10/38 (21%) reported not participating in other activities. Of those not involved with Healthy Aging web-based activities, 22/56 (39%) reported not participating in any activities. Of these 22 individuals, 10 (45%) reported either cognitive, sensory, or technological problems. Alternative activities (Table 5) were accessed via television, such as a show with exercise instruction, or YouTube, Zoom, and websites of different organizations. Some participants reported that the activity was a continuation of a class they had taken in person prior to the COVID-19 pandemic. Sponsors of alternative activities varied, such as universities (eg, "Lectures on a film, and then [watching] the film" [#110, age 75 years, female]), museums (eg, "I have a subscription… and I listen to their lectures" [#120, age 63 years, female]), municipalities, synagogues (eg, "Prayer in the Synagogue via Zoom" [#103, age 79 years, female]), not-for-profit and for-profit organizations, and private individuals.

Table 5. Characteristics of the alternative activities engaged in by the study participants (n=73).

Activity or provider	Participants (n=39), n (%)	Nonparticipants (n=34), n (%)	Total (n=73), n (%)
Platform			
Zoom	20 (51)	8 (24)	28 (38)
Television	1 (3)	2 (6)	3 (4)
YouTube	1 (3)	4 (12)	5 (7)
Organization website	7 (18)	4 (12)	11 (15)
Provider of activity			
University/museum	9 (23)	8 (24)	17 (23)
Municipality	13 (33)	3 (9)	16 (22)
Synagogue	1 (3)	0 (0)	1 (1)
Not-for-profit organization	3 (8)	3 (9)	6 (8)
Private person/organization	26 (67)	22 (65)	48 (66)

Of 47 respondents participating in web-based activities, 60% (n=28) said they were willing to pay for them, and 26% (n=12) were unwilling; meanwhile, 6 participants (13%) said "maybe," and 1 (2%) said "I don't know." Among the interviewees who participated in the beginning of the program, 7 said they had stopped participating after Healthy Aging introduced a small subscription fee, while 14 reported that they were paying for participation at the time of the interview. Those who paid cited fairness and wanting or needing the service:

> *It's worth it to me, it's fair, and you get a lot for it* [#103, age 79 years, female]
>
> *I have no choice. If not for the activities, I'll be lost… So as not to be left alone [I choose to continue]* [#133, age 87 years, female]

Reasons for not wanting to pay varied, including the availability of alternatives (eg, "So far, I didn't feel the need to pay because there are a lot of options" [#138, age 68 years, female]); an ideological assertion that such services should be free at the time of a pandemic (eg, "Healthy Aging began [the program] nicely but then asked for money. I think it should continue for free until the end of COVID" [#121, age 85 years, male]); and "double billing":

> *I used to participate in the exercise of Healthy Aging, but stopped when they required payment. I am not willing to pay because I am still paying a lot to my gym, despite not being able to go there.* [#116, age 79 years, female]

Out of the 56 nonparticipants, 20 (36%) indicated willingness to pay for Zoom activities; however, 12 (26%) responded in the negative. Although these percentages reflect less readiness to pay for such activities than reported by the activity participants, the difference is not statistically significant (P=.33). Those who were willing to pay tended to have more years of education (mean 15.8 years, SD 3.5) than those who said they would not or did not know if they would pay (mean 14.2 years, SD 3.6; P=.03).

Discussion

Principal Findings

Participants in Healthy Aging's web-based activities reported very high levels of satisfaction with the exercise and lecture programs. Over 50% of the participants (28/49, 57.1%) wished to continue with the exercise sessions after the end of the COVID-19 pandemic, and over 40% (20/49, 40.8%) wished to continue with the lectures, citing the benefits of maintaining physical vitality, participating in interesting activities, and maintaining a daily routine. These results suggest that web-based activities are a viable substitute for the pre–COVID-19 activities of older adults. This finding aligns with Whitehead and Torossian's [4] report that digital social contact was among the most commonly reported sources of joy or comfort for older adults during the COVID-19 pandemic. However, the results of our sample suggested insufficient provision of social contact and preventing loneliness—a benefit mentioned by only 16%

of the participants (8/49). The lack of social cohesion may have also been reflected by the low attendance when lectures were presented by other participants. This finding supports previous studies that examined web-based exercise group activities and found no impact on loneliness [39,40,42] and research results indicating that older adults generally prefer face-to-face interactions [43,44]. The extent to and the conditions under which web-based activities can prevent loneliness should be explored in future research. However, the lack of social interaction in web-based activities is not unlike that at senior centers, which provide live lectures, concerts, or exercise classes; many participants arrive to these activities alone and leave without having had significant social interaction [45]. Strategies to promote social interaction both on the web and in person should be examined in future research.

Conceptual Framework

Based on our findings, we have developed a conceptual framework that captures factors affecting the use, efficacy, and sustainability of web-based activities, as summarized in Table 6.

Table 6. Conceptual model: Factors affecting the use, efficacy, and sustainability of web-based activities.

Category	Factors
Factors affecting use	
Access	• Knowledge about program availability • Sensory abilities (natural or modified) • Technology access (personal or assisted) • Sufficient funds to pay for subscription (real or perceived) • Convenient hours and duration
Concerns	• Group activities • Privacy: use of camera
Factors affecting use, efficacy, and sustainability	
Fulfilling needs/motivational	• Relieving boredom • Providing physical activity • Providing social interaction, relief of loneliness
Tailoring activities to individuals’ preferences and abilities	• Topic fit (interest) • Level fit (difficulty match) • Physical abilities • Cognitive abilities • Educational level • Presentation fit (speed, timing, etc)

The main factors influencing the use of web-based resources were access and awareness. A sizable proportion of nonparticipants denied having heard of Healthy Aging’s web-based activities, despite having been notified about them by Healthy Aging. Further study should explore how to effectively promote and advertise web-based activities for older persons to ensure knowledge and comprehension of the activities by prospective users.

Another component of access was the technological challenges web-based activities pose for older persons, as reported by 31% (15/49) of the web-based activity participants—who nevertheless managed to participate—and 23% (13/56) of the nonparticipants, for whom technology was a complete barrier to participation. While this barrier might be overcome through the help of family members, caregivers, or staff from organizations, lack of such support remains a major barrier to internet and computer use by older persons [23]. Simplifying the process of use and adapting it to cognitive and sensory limitations may also aid in overcoming technological barriers. Indeed, sensory abilities, natural or modified, also affected participants’ access to web-based activities, as reported by 7% of nonparticipants (4/56). The extent to which compensation for these limitations can help disabled persons benefit from web-based activities needs to be examined.

Half of the nonparticipants (28/56, 50%) and 60% (28/47) of the participants said they would be willing to pay for web-based programming. Others were not inclined to pay for a range of reasons, including the availability of cost-free programs. A portion of this population may not be able to afford subscription fees.

Certain concerns emerged as factors that affected use. Some persons in our sample were reluctant to participate in activities involving a camera or a group. Such privacy concerns were previously reported as reasons for older adults’ hesitation to use the internet [25,26].

We identified physical activity, social interaction, and relief from boredom and loneliness as central motivational and needs-fulfilling factors that affected the use, efficacy, and sustainability of web-based activities. The preference for group activities, the importance of social interaction [40], and the opportunity to exercise were identified as motivators in previous research on in-person group exercises for older adults [46].

The final factor that we identified was tailoring activities to individuals’ preferences and abilities. The activities provided by Healthy Aging were an extension of its mission as a rehabilitation facility. Accordingly, programs focused on activities such as seated physical exercise, head massage, and stimulating lectures. However, for some respondents, these types of programs were considered to be relevant only to an older, frailer population.

Both participants and nonparticipants were interested in a wide range of topics, and many were very particular about favored topics, suggesting the commercial feasibility of developing wide-ranging lecture series; 50% of our sample were willing to pay for web-based activities. The suitability of the activity topics and content in our sample emerged as an important factor not previously identified in the literature.

The match between activity participation and participants' cognitive and physical abilities as well as educational background proved to be critical. Cognitive or sensory problems interfered with the ability of some respondents to benefit from the web-based activities, consistent with prior literature [18,19]. Cognitive issues appeared to be more prevalent for nonparticipants, for whom both the percentage of interviews via third persons and the percentage of interviewees for whom interviewers suspected cognitive difficulty were significantly greater than in the case of the web-based activity participants.

Limitations

This study is limited by its relatively small sample that is confined to one country and by its focus on a single rehabilitation organization that developed web-based activities for older persons during the COVID-19 pandemic. However, this narrow focus afforded us important insights into the experience of those who participated and those who declined as well as into the future potential of web-based programs for older persons.

Conclusions

The closing of social clubs, senior centers, libraries, and gymnasiums due to COVID-19 critically affected the living experiences of older persons, who were instructed to limit social contact, stay at home, and decline visitors. Television and web-based activities were the main venues left to help older persons remain engaged and somewhat active. Our findings suggest that this alternative provides valuable substitute activities to a large portion of older persons who were required to limit outdoor activities due to the COVID-19 pandemic.

This study provides a preliminary investigation of the feasibility, efficacy, and sustainability of web-based activities among older persons. Each of these aspects of the study deserves a study of its own. Feasibility issues pertain to how to improve publicity and access to web-based programming. Efficacy relates to how to improve the match between the activities and the participants' needs and wishes, as well as how to facilitate social interaction and to decrease loneliness. Finally, sustainability raises issues regarding funding, including participant contributions, to develop and present high quality activities that appeal to older persons.

In terms of enhancing access to web-based activities, training and support are needed for some older persons to access web-based programs [47,48]. In addition, it has been argued that improving older adults' access to technology involves reducing the costs of computers, smartphones, and other equipment as well as adjusting their design to be more user-friendly to older adults [49]. As Seifert et al [49] aptly stated, older adults are impacted by "double exclusion"—social and digital—during the COVID-19 pandemic. These issues need to be explored in future research into the most effective means for increasing access to older populations with different types of limitations.

The results of this study have implications beyond the COVID-19 pandemic as a modality to address the needs of homebound older persons. The main challenges in substituting in-person services include the challenges of promoting social relationships within web-based platforms, accommodating a wider range of activities and contents on the web, and making current programs accessible to an underserved population that needs them, both through better marketing and via improving access to technology.

Acknowledgments

We would like to thank the Healthy Aging staff and study participants for their cooperation in facilitating this study. This work was supported by the Minerva Foundation.

Abstract

Background: To minimize the spread and risk of a COVID-19 outbreak, societal norms have been challenged with respect to how essential services are delivered. With pressures to reduce the number of in-person ambulatory visits, innovative models of telemonitoring have been used during the pandemic as a necessary alternative to support access to care for patients with chronic conditions. The pandemic has led health care organizations to consider the adoption of telemonitoring interventions for the first time, while others have seen existing programs rapidly expand.

Objective: At the Toronto General Hospital in Ontario, Canada, the rapid expansion of a telemonitoring program began on March 9, 2020, in response to COVID-19. The objective of this study was to understand the experiences related to the expanded role of a telemonitoring program under the changing conditions of the pandemic.

Methods: A single-case qualitative study was conducted with 3 embedded units of analysis. Semistructured interviews probed the experiences of patients, clinicians, and program staff from the Medly telemonitoring program at a heart function clinic in Toronto, Canada. Data were analyzed using inductive thematic analysis as well as Eakin and Gladstone's value-adding approach to enhance the analytic interpretation of the study findings.

Results: A total of 29 participants were interviewed, including patients (n=16), clinicians (n=9), and operational staff (n=4). Four themes were identified: (1) providing care continuity through telemonitoring; (2) adapting telemonitoring operations for a more virtual health care system; (3) confronting virtual workflow challenges; and (4) fostering a meaningful patient-provider relationship. Beyond supporting virtual visits, the program's ability to provide a more comprehensive picture of the patient's health was valued. However, issues relating to the lack of system integration and alert-driven interactions jeopardized the perceived sustainability of the program.

Conclusions: With the reduction of in-person visits during the pandemic, virtual services such as telemonitoring have demonstrated significant value. Based on our study findings, we offer recommendations to proactively adapt and scale telemonitoring programs under the changing conditions of an increasingly virtual health care system. These include revisiting the scope and expectations of telemedicine interventions, streamlining virtual patient onboarding processes, and personalizing the collection of patient information to build a stronger virtual relationship and a more holistic assessment of patient well-being.

Introduction

Shifting Societal Views on Essential Health Services

The unprecedented magnitude of the COVID-19 pandemic has shifted the focus of the health care system toward patients infected with SARS-CoV-2 [1]. Through these uncertain times, to minimize the spread and risk of a COVID-19 outbreak, societal norms have been challenged in terms of what health services are considered *essential* [2]. Specifically, health care systems have been faced with a significant challenge whereby in-person visits, surgeries, and treatments once considered *essential* have either been cancelled or postponed to reduce the likelihood of virus transmission [2,3]. With the implementation of these public health measures, patients with chronic conditions relying on traditional models of clinic-based care are now at higher risk of health deterioration [4,5]. These patients have been reported to face a higher risk of severe illness when infected with COVID-19. Thus, maintaining patient health status in the context of the current health care reconfigurations represents a significant challenge [5,6].

Virtualizing Care During the COVID-19 Pandemic

To ensure access to care in light of restrictions to in-person visits, innovative virtual care models have been used during the pandemic as a necessary alternative [4,6]. The value of virtual care has been demonstrated in a number of studies through its ability to provide timely care that enables patients to maintain physical distancing while also conserving health care resources [6,7]. Among virtual care technologies, telemonitoring is being increasingly promoted as a tool to assist patients who need more frequent care touchpoints [7]. In the field of telehealth, telemonitoring has been defined as the use of technology to remotely monitor and transmit data relating to patient health status in geographically separated settings. With features enabling providers to closely monitor patient symptoms and vital parameters at home, the use of telemonitoring has been viewed as a valuable addition to the management of patients [8,9].

Since the pandemic started, large organizations such as the Canadian Cardiovascular Society and the Heart Failure Society of America have recommended transitions to virtual modes of care to meet the needs of patients during the pandemic [4,5]. In New York City, where high transmission of COVID-19 has been reported, telemonitoring was found to be an important component of the medical response to the pandemic because it reduced the demand on strained health care staff and enabled the meeting of patient needs at home [10]. As the health care system began to recognize the new reality and the presence of physical distancing restrictions, potential arose for virtual services such as telemonitoring to play an important role in patient management [3,10]. However, it is important to recognize that many telemonitoring programs were originally designed under the conditions of a pre–COVID-19 model of care that may no longer be available due to the limitations on in-person visits. With this growing shift to increasingly virtual health systems, there is a need to evaluate the functionality of a program under changing circumstances to optimize its use for conditions both during and beyond the pandemic.

The objectives of this paper were to (1) understand how telemonitoring is being used during the pandemic through the rapid expansion of a heart failure telemonitoring program, (2) report the barriers and facilitators related to the new virtual delivery of the telemonitoring program, and (3) evaluate the components of the telemonitoring program that require adaptation to sustain its use during and after the pandemic. In reflection of these objectives, the research question was: *With the changing conditions associated with the COVID-19 pandemic, what are the experiences and perceptions of patients, providers, and staff regarding the use of a telemonitoring program to support care needs?*

Methods

Setting

With the growing concern regarding COVID-19, the Peter Munk Cardiac Centre (PMCC) Heart Function Clinic at the Toronto General Hospital began to transition many of its services to a virtual care model. The majority of in-person appointments were rescheduled or replaced by videoconferencing visits or telephone calls. Clinicians affiliated with the PMCC Heart Function Clinic also had the option to enroll patients in the existing "Medly" program, a mobile phone–based telemonitoring program designed to provide remote clinical support for patients with heart failure [11,12]. The Medly program currently does not have any strict clinical criteria dictating patient eligibility for enrolment. Instead, cardiologists use their clinical judgement to refer patients they deem would benefit from the program. With Medly, patients use a smartphone with the Medly app, a weight scale, and a blood pressure monitor to record daily physiological readings and symptoms (Figure 1). Using these devices, patients are instructed to take daily weight and blood pressure readings as well as to record their symptoms through a series of self-report questions on the Medly app [12]. A rules-based algorithm uses these data to automatically generate individualized self-care instructions for the patients while simultaneously alerting clinicians when there are changes in the patient’s health status beyond their set clinical parameters [12]. Clinical alerts, delivered via email or the Web-based Medly dashboard, are mostly managed by the Medly Coordinator, a registered nurse within the Heart Function Clinic, with alerts being escalated to the cardiologists as needed. As the Medly system is a class II Health Canada–approved medical device, all data collected from the system are stored in the secure servers at the University Health Network, whereby patient information can only be accessed by the Medly Coordinator and the rest of the patient’s clinical team.

The Medly Coordinator also plays a fundamental role in the onboarding process, where during an in-person clinic visit, the treating cardiologist first presents the program to the patient and gains their approval for enrolment. The Medly Coordinator then meets with the patient to review the program processes (ie, account creation, training, study consent) and to assess their equipment needs [12]. Patients who require all equipment to be provided receive a full Medly kit, whereas other patients follow the bring your own device model and use some or all of their own devices (ie, smartphone, weight scale, blood pressure cuff) [12]. To support the rapid expansion of the Medly program during the COVID-19 pandemic, two nurses from the cardiology department within the Toronto General Hospital were seconded to assist with the foreseen increase in patient enrollment. As of March 8, 2020, the program had previously served 565 patients; however, in preparation for the uncertain impact of the pandemic and the need for remote support, plans were made to enable the Medly program to accommodate a rapid increase of up to 1000 patients. From March 9 to June 8, 2020, a total of 117 new patients were onboarded.

Figure 1. Screenshots of the Medly app displaying the patient self-care tasks, the symptom questionnaire, and the resultant self-care feedback after all tasks are completed and processed by the algorithm.

Follow your doc's orders to take 1.25 mg metolozone. Restrict salt & fluids.

Study Design

This study used a qualitative case study design [13] with the case defined as the telemonitoring program at the Heart Function Clinic at the Toronto General Hospital. The uses of an existing telemonitoring program by patients, clinicians, and operational staff were selected as the units of analysis to better understand the ways in which the pandemic has impacted their use and satisfaction of the Medly program.

Recruitment of Participants

Patients were purposefully identified and recruited according to a range of demographic characteristics, including age, gender, location of residence (rural, suburban, urban), ethnicity, income, and comfort with technology. Although enrolment in the Medly program is at the discretion of each patient’s cardiologist, patients were considered eligible for this study if they spoke English and were users of the Medly program. We aimed to recruit patients who were onboarded to the Medly program both before and during the pandemic. To ensure that the patients onboarded during the pandemic had some experience using the system, only patients enrolled in the program for at least 20 days were considered to be eligible for the study. All 12 clinical staff members and 4 operational staff members of the telemonitoring program were invited to participate. All participants were recruited in alignment with an existing quality improvement study evaluating the telemonitoring program (University Health Network Research Ethics Board 16-5789 and University of Toronto Research Ethics Board 39449). Eligible patient participants were recruited until data saturation was reached, as in, no new perspectives or ideas were generated from the data. Specifically, as the data collection and data analysis processes were conducted on a continual basis, data saturation was deemed complete when no new insights were found from the latest 3 patients interviewed. This included, but was not limited to, patient feedback related to their experience using the program as well as challenges associated with the pandemic.

Data Collection and Analysis

To accommodate physical distancing measures, in-depth semistructured interviews were conducted over the telephone by two authors experienced in qualitative research (AS and SW). Interview guides were developed based on the core components from the Benefits Evaluation Framework using semistructured, open-ended questions [14]. Each interview guide was developed and tailored for the patient, clinician (nurses and cardiologists), and operational staff participant groups. During each interview, participants were asked to comment on their experiences with managing heart failure both before and during the COVID-19 pandemic, as well as their experiences with the Medly telemonitoring program. Interviews were conducted between May 4 and June 18, 2020, and lasted approximately 30 minutes. All interviews were digitally recorded and professionally transcribed verbatim for analysis.

Interview transcripts underwent inductive thematic analysis at the semantic level according to the iterative 6-phase approach outlined by Braun and Clarke in 2006 [15]. Eakin and Gladstone’s “value-adding” approach to qualitative analysis was also used to enrich the analytic interpretation of the study findings and enhance the level of contextualization to the knowledge generated [16]. By using analytic devices such as reflexivity and generative coding to review each transcript, the authors were able to deepen their interpretation of the data in more abstract terms. Three authors were involved in the data analysis process (AS, MG, SW). Throughout the research process, all authors engaged in both procedural and analytical memoing to improve the overall trustworthiness of the analysis [17]. Transcripts and analytic memos were then entered into NVivo 9 (QSR International) to initiate the organization and analysis of the data. To gain a holistic perspective on all the data collected, one author (MG) independently analyzed all interview transcripts, whereas in parallel, two authors independently analyzed either the patient (AS) or clinician and staff (SW) transcripts. All authors subsequently met to discuss and compare codes for each participant group. Following the initial discussions, the codes were then grouped into categories to identify themes relating to the research question. After five analytic discussions, the research team collectively developed four themes. The four core themes were then individually reviewed by the study team to ensure internal coherence, consistency, and approval [15].

Results

Participant Characteristics

A total of 29 participants were interviewed: 16 patients, 9 clinicians (ie, cardiologist, registered nurse), and 4 operational staff. The characteristics of the interviewed patients are shown in Table 1. These data were collected via a self-report questionnaire as part of an existing quality improvement evaluation of the Medly program.

Table 1. Characteristics of the patient interview participants (N=16).

Interview Findings

During the analysis of all participant data, four themes were identified: (1) providing care continuity through telemonitoring; (2) adapting telemonitoring operations for a more virtual health care system; (3) confronting virtual workflow challenges; and (4) fostering a meaningful patient-provider relationship.

Providing Care Continuity Through Telemonitoring

With the significant reduction of in-person clinic visits, the use of telemonitoring had become more desirable, as it provided clinically relevant patient data to help support virtual visits or the postponement of a visit. Although there are no strict clinical criteria guiding patient eligibility for Medly beyond requiring the patients to be followed by the Heart Function Clinic, clinicians increased the number of patients they referred to the program during the pandemic. With the limitations created by COVID-19, cardiologists were less selective in patient referrals to Medly, as their previous concerns for onboarding no longer weighed as heavily on their decision-making. Consequently, despite provider concerns, program nurses reported that patients with less familiarity with technology were able to use the application with minimal assistance:

> *One of the determining factors for me to onboard someone on Medly before COVID was if I had concerns about patients not being able to adhere to the daily weights reliably for whatever reason, I would hesitate to on-board them. Now that plays less of a role in my decision-making.* [Cardiologist 3]
>
> *Some of the patients are not always the most tech-savvy but they're trying their best. And a few explanations on the phone and, you know, they're good with it, you know?* [Nurse 1]

For many patients, with the heightened fear of contracting COVID-19 and the lack of accessibility to care services, Medly provided patients with a sense of security and comfort for their care management. New patients onboarded onto Medly appreciated the continual monitoring provided by the telemonitoring program, as it created a clinical safety net during a time when society was left in a state of uncertainty. The convenience and ease of being able to directly connect with a health care provider who was familiar with their medical history was also highlighted as a key value of the program:

> *It would be a wonderful thing for a lot of people in here to have somebody that had to check on them in the morning. I feel it's almost doing [it] to me because my vital signs don't change that much but at least it checks that I'm still alive and breathing.* [Patient 2]
>
> *My patients really liked the opportunity to be enrolled and be involved, they didn't know that it [Medly] existed before because they were sort of lower-risk*

> *patients who I hadn't thought to enroll in Medly before and now that they have some way to send in their vitals and have someone keep track of them a little more closely for a lot of patients, that gives them a lot of added security.* [Cardiologist 1]

Although clinicians were able to connect with patients through other modes of virtual engagement (ie, telephone calls, videoconferencing), they felt that Medly's continual monitoring provided a more comprehensive picture of patient health compared to virtual visits alone. Specifically, clinicians using the Medly system were able to monitor trends in patient heart rate, blood pressure, weight, and symptoms, all of which helped detect worsening health and the potential need for patient follow-up. With the conditions of the pandemic and the absence of in-person visits, the metrics provided by Medly were highlighted to help provide a level of care continuity and context to support clinician decision-making:

> *I think it's driving with your eyes open rather than closed and, to some degree, a lot of what you're trying to do in terms of adjusting medications is to try and keep their weight within range and blood pressure and heart rate and their symptoms under control, and you can get all [of] that from Medly and track their trends over time.* [Cardiologist 2]

Beyond the usual benefits of telemonitoring, clinicians valued that Medly enabled them to make clinical assessments or changes in patient care that would usually be completed in-person. In the context of COVID-19 limitations, treatment optimization was still feasible, whereby clinicians were able to effectively titrate mediation without in-person patient visits to the hospital. Both patients and clinicians felt reassured that the quality of care had not been jeopardized under the shifting conditions of a virtual care model:

> *We've been able to titrate medication remotely, which is probably one of the biggest things because previously we would see patients in the clinic and then we wouldn't change a new med until maybe the next time they were seen or a couple months down the road. I've been keeping track of many patients who are in the titration phase in their medication and we've been able to optimize their medications on a pretty rapid basis, like biweekly, to achieve triple therapy medication optimization, all while doing everything remotely.* [Nurse 3]

Adapting Telemonitoring Operations for a More Virtual Health Care System

With the rapid push for virtual care, many of the Medly program's in-person processes were quickly virtualized to meet COVID-19 safety requirements. Despite common belief that the telemonitoring program was already functioning under a fully remote/virtual model, operational staff highlighted that while the onboarding process previously required patients to be introduced to the program following a clinic visit, these in-person procedures were now converted into a series of telephone calls with the Medly Coordinator ahead of a virtual visit. Clinicians and operational staff reported mixed patient reactions to the remote onboarding process; some reported that patients expressed confusion regarding why they were being enrolled in the program. Overall, the clinicians felt that patients had a more negative reaction in the early weeks of the pandemic, mainly because they had been preemptively contacted by the nurse coordinator for onboarding without receiving a contextual introduction from their cardiologist:

> *I think when patients have been seen in the clinic, in their virtual clinic, and then are enrolled onto Medly, their response is much better because they've already heard about it from their physician. Like, if they had had a clinic in the morning and then if you told them the nurse will call you today and get you set up, I want to remotely monitor you. That response has been really positive.* [Nurse 3]

One member of the operational staff reflected on the benefits of remote onboarding and found that the use of a low-contact setup enabled many patients to participate in the program without needing to leave their home. Specifically, with this new virtualized onboarding process, after the Medly Coordinator identified the type of Medly kit needed (eg, full kit, weight scale only), this equipment was delivered directly to the patient. However, clinicians and operational staff reported that this new process also resulted in delayed patient participation in the program, as some patients were unable to report their measurements due to their equipment still being in transit:

> *And then we've had to, like, mail out a lot of equipment to people who need it, and especially right now because people were not necessarily willing to go out and get their own equipment during COVID.* [Staff 2]
>
> *So, there's a bit of like waiting involved whereas like normally you kind of expect the patients to be taking measures like the next day. In this case, it's like potentially like one to two weeks later and then even then it's kind of like, oh do you still not have your equipment yet or like how is that going?* [Staff 1]

As the pandemic progressed, clinicians and program staff reflected on the current operations of the Medly program and found that a number of patient tasks were more challenging within the context of COVID-19. For instance, many patients were required to obtain blood work for remote titrations; however, they felt that the risk associated with leaving their home outweighed the benefit of their treatment optimization. In addition, when patient symptoms worsened beyond their clinical parameters, clinicians or the automated Medly self-care feedback would direct patients to go to the hospital. However, this self-care advice was found to no longer be suitable, given the fear and heavy concern regarding virus exposure:

> *There are a number [of patients] that were quite concerned about going to get blood work, so they didn't want to leave the house…It is a delicate balance on how much can we do through the phone, through Medly, make changes, but in the end we still need to get some of that data in order to make those clinical decisions.* [Cardiologist 1]
>
> *Patients have been also scared of going to hospitals. Even when we want them to come to the hospital to*

> *be assessed in person or to go to the emergency room many of them have pushed back and said that they'd rather deal with their symptoms at home rather than coming to the emergency room and expose themselves to a potential exposure to COVID-19.* [Nurse 1]

With physical distancing requirements in place, many program staff also noticed that patients residing at home were more often alone, without the presence of a caregiver. This loss of social support led many patients to experience a greater need for technical and emotional assistance that was normally provided by a visiting family member. With this, operational staff indicated that during the introductory period of the program, patients onboarded during the pandemic made more telephone calls requesting technical support than patients onboarded before the pandemic:

> *Some of the elderly patients have difficulty with technology where they haven't been exposed to smartphones and that kind of thing. One of them actually said to me that he would usually get his kid to like show him how to do stuff or set stuff up on his phone, but because of COVID they haven't been able to visit so he hasn't been able to sort of get them to help.* [Staff 1]

Confronting Virtual Workflow Challenges

Clinicians experienced many challenges when using Medly in combination with other dedicated systems (eg, the electronic medical record, laboratory systems). Due to the lack of integration between the various systems, clinicians were required to navigate through multiple technologies to obtain up-to-date patient information. Clinicians felt that reviewing the patient information in a single system would not provide them with sufficient information to make a comprehensive clinic assessment. Thus, increased clinical workload was required to access multiple systems to fill the information gaps in their patient profiles:

> *When [radiology and cardiography] don't appear it's much harder to piece things together. So, when you're seeing a patient, which is where it usually comes up, you want the data in one place. Like the last thing in the world I want to do is, I see a patient and I'm like "OK, I'm going to adjust the meds" –. But you [have] to go out of the EMR [electronic medical record]…then you have to log into the Medly platform which requires another password. You're all doing this with the patient on the phone; it's completely clunky.* [Cardiologist 4]

To accommodate the influx of patients during the rapid expansion, two nurses within the Toronto General hospital cardiology department were seconded to support the Medly program. The additional nurses enabled better balancing of the patient caseload. However, several issues regarding patient profile accessibility were reported. Specifically, the nurses indicated that it was difficult to access information about patients who were not part of their caseload. The nurses strongly desired a way to access information for patients not assigned to them to make it easier when they had to cover for one another:

> *[One nurse] watched through all the alerts and so, with the ramping up of numbers more coordinators coming on, we had to find a way to change the caseloads and find who was watching [which patients]. So, there was a way where they changed it so we could easily identify which coordinator was the one watching which patient.* [Nurse 3]

> *[…] finding ways to look at different patients if they're not your own. They're separated [now], but there [should be] a way to follow up with other patients if you were covering for another nurse and need to look up other patients.* [Nurse 4]

Even with the increase in nursing staff, clinicians perceived an increase in their workload during the pandemic. Cardiologists were responsible for monitoring patient alerts over the weekends; however, responding to alerts became even more challenging with the increase in patient caseload. Ultimately, the clinicians thought that as more alerts would accumulate over the weekend, there could be a delay in the response time to contact the patients compared to during weekdays:

> *I have somewhere between 180 and 200 patients on Medly. So, on the weekend, without the nurse support, there's a little bit more work for me to do.* [Cardiologist 5]

Fostering a Meaningful Patient-Provider Relationship

With the transition to a fully virtual model, patients onboarded during the COVID-19 pandemic felt that there was a lack of clarity regarding their purpose of enrollment into the program. Due to the restrictions associated with the pandemic, the Medly Coordinator was unable to provide patients with the initial face-to-face touchpoint that previous patients had received. Thus, many patients that were previously only seen every 6 months to a year were confused in regard to why they were required to input symptoms on a daily basis or form a relationship with the Medly Coordinator, who was previously not part of their care:

> *[Patients tell me], why do you suddenly want to hear from me every single day when prior to this you only saw me once a year… So, there are no negative responses; just a few people skeptical, "who are you and why are you calling me," if they hadn't been pre-warned by their physician.* [Nurse 1]

Clinicians also expressed that it was challenging to build a relationship with patients who were new to the Medly program. Multiple clinicians felt that they were not able to establish a personal connection or objectively assess their patients' condition over the phone, as there was an absence of visual cues or caregiver support to obtain patient information. Clinicians indicated that patient body language often provided a good depiction of their well-being, and in cases where the patient was unable to vocalize their health issues, a caregiver would often assist in relaying relevant health information. Clinicians were concerned that without face-to-face visits or caregivers present, they would be unable to establish a relationship with patients or assess their condition accordingly:

> *What I have noticed is that, for new patients, it's very hard to establish a good relationship... I called them a couple of times and we couldn't establish a kind of personal relationship. And I think that that was a bit of a problem. I think that that can increase their chances…of non-compliance.* [Cardiologist 2]

Regarding the frequency of interactions needed, clinicians had mixed views about how often they should be contacting patients over the telephone. One clinician found that a greater frequency of patient interactions strengthened the trust and basis of their patient relationship. However, other clinicians noted that most of their patient interactions were triggered by system alerts, and any further touchpoints with their patients would be burdensome to their workload:

> *Because the case load has increased, you do over time get a bit of an understanding for your … like any relationship, you need to kind of understand … what they prefer, what they are going through and how they would react.* [Nurse 3]

For patients, the perception of alert-driven relationships meant that they assumed clinicians would often assess patient well-being by the clinical parameters entered into the telemonitoring system. A lack of feedback from the nurses was usually perceived as a validation that the patient was doing well. However, patients who were not experiencing severe heart failure symptoms, and thus were not generating telemonitoring alerts, were dissatisfied because they were unable to establish a strong connection with their clinician. These individuals felt that many factors that contribute to their health were not being taken into consideration (eg, pain management, sleep, living conditions). With the influx of patients due to the pandemic, this issue around alert-driven relationships was further exacerbated, as clinicians faced an increase to their workload that made patient follow-ups beyond system alerts impractical:

> *If I'm the doctor and I'm sitting there, and I've got 100 people to talk to and I got a lot of things to do and all my numbers are perfect, [and I ask] "how are you feeling?" If [my doctor] was to ask me the question like [that] and I'm saying "well I'm not doing very well because I'm feeling like I've got severe pain and spasms in my hip, and my butt. And you're not addressing them.* [Patient 3]

Discussion

Principal Findings

Virtual care interventions have been implemented to provide solutions to the health delivery challenges posed by the COVID-19 pandemic [2,6]. Despite the push for virtual care and the previous support for its use, few studies have explored the perception of these technologies within the contexts of both before and during the pandemic [4]. In this study, we aimed to understand how changes to a heart failure telemonitoring program in response to the COVID-19 pandemic were perceived. From this study, we found that the expansion of the Medly telemonitoring program enabled clinicians to provide a level of cardiac care that would not be possible without telemonitoring. Our findings identified that to sustain the value of a telemonitoring program, it would be necessary to adapt its operational components according to the contextual circumstances (ie, required physical distancing due to the pandemic).

Prior to the COVID-19 pandemic, most health care encounters between patients and providers occurred face-to-face; thus, the incentive for virtual care was limited. The findings from this study indicate that by removing the safety net of in-person care, the restrictions of the pandemic acted as an enabler of virtual care adoption. We observed that many patients who would normally not be considered ideal candidates for the program were readily onboarded despite concerns regarding their technological or health literacy levels. Patients of varying backgrounds used the program beyond expected levels of success; this finding helped challenge the paradigm regarding the characteristics of an "ideal" program candidate [18]. Often, with these biases, many virtual care interventions fail to serve patient groups that are most in need of support [19]. Our findings suggest that re-evaluating the assumptions of who can benefit from a telemonitoring program may help expand the range of patient groups it serves.

While Medly was able to fill a void in patient care, it is important to recognize that the program team was in a unique position to adapt many of its underlying in-person operations. By virtualizing the onboarding process and the delivery of program equipment, the Medly team was able to accommodate the rapid expansion under the province's physical distancing requirements. Other studies have reported that many heart failure clinics attempted to virtualize in-person practices but were unable to maintain these services due to the lack of infrastructure and clinical support available [4]. However, despite the Medly team's success virtualizing the onboarding process, several systems (ie, Medly automated feedback) and clinician instructions were still deemed inappropriate (eg, laboratory work at a local clinic, advice to go to the hospital) in the context of the pandemic. Due to these challenges, similar studies have recommended the development of communication channels or regular consultations with patients to enable them to voice their concerns [20]. Providing patients with these opportunities would help to re-evaluate program components to meet their changing needs and would further empower them to manage their care.

Despite significant efforts to prepare for the rapid expansion, the lack of system integration and established collaborative processes led to escalation of the level of virtual workflow inefficiencies within the program [21]. While the additional nursing staff helped support the patient caseload, the telemonitoring program was operating under a fragmented ecosystem of virtual technologies (ie, the EMR, the Medly system, videoconferencing) that increased the complexity of clinical practices. With these technical challenges, recent research has recommended shifting traditional clinical workflows to a more digitally assisted pathway [6]. Specifically, to prevent duplicating tasks or spending excessive time navigating different systems, the adoption of dedicated communication channels and tailored workflows across multiple platforms would help to increase clinician collaboration and streamline data access.

While the rapid expansion was able to provide access to care and consistent remote management for a larger group of patients, the model of care did not change with disease severity. The clinical parameters were individualized to the patients; however, some perceived that the program was built on the principle of *problem-centered care* [22]. Many patients did not understand the purpose of their enrollment in the program, especially those who were not producing alerts, and they felt that this lack of clarity jeopardized their virtual relationship. Recent studies have attributed similar findings to the widening of the scope of telemonitoring programs to accommodate the limitations posed by the pandemic without considering the impact of the changes on clinical effectiveness or patient satisfaction [6]. We argue that to sustain telemonitoring adoption, clinicians should begin to clarify the specific objectives of the telemonitoring program to prevent possible misconceptions among patients. In addition, a more holistic assessment of each patient's condition should be explored to enhance patients' perceived value of the intervention. For instance, the investigation of psychosocial outcomes has been encouraged in the context of chronic illnesses [23], as monitoring a broader set of health indicators (eg, pain, sleep, mental health) has been reported to contribute to an objective assessment of a patient's well-being [24].

Recommendations

Patient self-management and remote monitoring tools represent an important avenue to deliver high-quality care in the community [25]. With no clear end in sight for the pandemic, health experts are now warning that physical distancing restrictions and other safety measures may be required for many more months or even years [6,26]. In light of our study findings, we offer four recommendations that can be used to help proactively adapt and scale up telemonitoring programs in the context of the increasingly virtualized health systems.

Revisit Scope and Eligibility for the TM Program

Consult with clinicians, staff, and patients to evaluate the scope and expectations of the program under the conditions of the pandemic and beyond. Reflect on how this scope will impact or influence potential expansion efforts to scale the program to other health care settings (ie, disease of focus, intervention delivery). In line with this new scope, consider revisiting the patients served by the program in terms of age, ethnicity, gender, and geographical location to improve accessibility to more underserved groups [27].

Expand Information Modalities Available to Streamline the Remote Onboarding Process

Create an unsupervised (ie, self-paced) dynamic or static tool demonstration, such as an interactive in-app tutorial, to walk patients through key application features. These modalities should emphasize the purposes and patient-specific benefits of the program to foster a greater sense of connection with their care team (eg, recorded audio or video messages from clinicians, surveys to understand equipment needs and difficulties). Ensure that common troubleshooting scenarios are included in the demonstration (eg, expected response to an alert, how to manage a loss of connectivity) to help standardize the onboarding process for all patients.

Support Efficient Modes of Clinician Communication and Patient Management

Consult with clinicians to develop direct communication channels and pathways to streamline navigation across multiple virtual platforms (ie, synchronized and automatically updated EMR and telemonitoring dashboard data). To facilitate task-sharing, nurses should be given access to all patients' profiles without shifting responsibilities for their assigned patient alerts.

Personalize Frequency and Patient Information Collected

Based on the evolving scope of the program, consider monitoring other health indicators (eg, pain, sleep, depression) to provide a more nuanced assessment of patient well-being in the absence of worsening heart failure symptoms. Consult with patients and clinicians to assess the frequency of touchpoints needed based on individual characteristics that may not be driven by alerts. Patient preferences regarding modes of communication, including video, text message, or audio, should also be incorporated to personalize care delivery.

Limitations

There are a number of limitations to this study. First, among the group of clinicians who agreed to participate, 3 were unable to complete the interview due to scheduling challenges. Second, due to challenges posed by COVID-19, we used telephone-based recruitment and interview processes, which may have biased our patient sample toward individuals who are more comfortable with technology. Third, despite our intent to purposefully recruit patients across a range of demographic characteristics, patients in this study were mainly young, White, suburban, and/or college-educated. We recognize that the population of patients at the Heart Function Clinic is largely White and educated; therefore, our sample of patients for this study is reflective of the clinic population but may not be representative of the broader heart failure population in relation to age, ethnicity, rurality, and education. Finally, the recommendations from this study may not be reflective of all the requirements to adapt and scale telemonitoring programs, as it was based solely on the findings of one telemonitoring program for heart failure self-care. With this, we recognize that the recommendations outlined above may describe a subset of the key requirements to proactively adapt and scale telemonitoring programs under the context of increasingly virtualized health care systems due to the pandemic.

Conclusions

The emergence of the COVID-19 pandemic has required society to re-evaluate virtual services as essential. The removal of traditional safety nets for in-person care has provided an opportunity for virtual services such as telemonitoring to demonstrate their value. In this study, we found that the rapid expansion of a telemonitoring program enabled patients to access cardiac care while maintaining physical distancing measures. Telemonitoring was able to fill a void for consistent patient monitoring, although the metrics provided by the system did not always represent an accurate picture of the patients' well-being. Under the conditions of the pandemic, issues surrounding unintegrated, siloed systems (eg, EMR, laboratory systems) were escalated, as they contributed more to the clinician workload burden. To optimize the use of telemonitoring under the conditions of a "virtual world," we present a series of recommendations to help sustain telemonitoring adoption through improvements in workflow efficiency and personalized care. These recommendations may not be inclusive of all the requirements to support the scalability of telemonitoring interventions; however, they will help serve as a foundational guide to better adapt program design. Ultimately, the intent of these recommendations is to improve care delivery for patients of varying needs and capabilities and to better support more patient-centered care both during and after the pandemic.

Abstract

Background: Physical activity is an important health behavior, due to its association with many physical and mental health conditions. During distressing events, such as the COVID-19 pandemic, there is a concern that physical activity levels may be negatively impacted. However, recent studies have shown inconsistent results. Additionally, there is a lack of studies in Australia on this topic.

Objective: The aim of this study is to investigate changes in physical activity reported through the 10,000 Steps program and changes in engagement with the program during the COVID-19 pandemic.

Methods: Data between January 1, 2018, and June 30, 2020, from registered members of the 10,000 Steps program, which included 3,548,825 days with step data, were used. The number of daily steps were logged manually by the members or synced automatically from their activity trackers connected to the program. Measures on program usage were the number of new registered members per day, the number of newly registered organizations per day, the number of steps logged per day, and the number of step entries per day. Key dates used for comparison were as follows: the first case with symptoms in Wuhan, China; the first case reported in Australia; the implementation of a 14-day ban for noncitizens arriving in Australia from China; the start of the lockdown in Australia; and the relaxing of restrictions by the Australian Government. Wilcoxon signed-rank tests were used to test for significant differences in number of steps between subgroups, between engagement measures in 2019 versus 2020, and before and after an event.

Results: A decrease in steps was observed after the first case in Australia was reported (1.5%; P=.02) and after the start of the lockdown (3.4%; P<.001). At the time that the relaxing of restrictions started, the steps had already recovered from the lockdown. Additionally, the trends were consistent across genders and age groups. New South Wales, Australian Capital Territory, and Victoria had the greatest step reductions, with decreases of 7.0% (P<.001), 6.2% (P=.02), and 4.7% (P<.001), respectively. During the lockdown, the use of the program increased steeply. On the peak day, there were more than 9000 step entries per day, with nearly 100 million steps logged per day; in addition, more than 450 new users and more than 15 new organizations registered per day, although the numbers decreased quickly when restrictions were relaxed. On average per day, there were about 55 new registered users (P<.001), 2 new organizations (P<.001), 25.6 million steps (P<.001), and 2672 log entries (P<.001) more in 2020 compared to the same period in 2019.

Conclusions: The pandemic has had negative effects on steps among Australians across age groups and genders. However, the effect was relatively small, with steps recovering quickly after the lockdown. There was a large increase in program usage during the pandemic, which might help minimize the health impact of the lockdown and confirms the important role of physical activity programs during times of distress and lockdowns.

exercise; pandemic; lockdown; eHealth; physical activity; COVID-19; engagement; behavior

Introduction

Physical activity is an important health behavior due to its association with many physical and mental health conditions, such as cardiovascular diseases, cancers, diabetes, depression, and anxiety [1-3]. It is recommended that people should engage in at least 150 minutes of moderate to vigorous physical activity per week [1]. During the COVID-19 pandemic, nearly all aspects of society were impacted. Lockdowns with social isolation measures may result in higher levels of stress and a decline in physical activity [4]. However, it may also mean that time saved from less social gatherings and commuting to work could be used to be more physically active. As physical activity improves mental health [1], it may also be used as a coping mechanism against higher levels of stress and anxiety during the pandemic. In addition, people may engage in physical activity more frequently as it was one of a few accepted reasons for leaving home during the March 2019 lockdown in Australia.

Recent studies have shown inconsistent results regarding changes in physical activity during this pandemic. A report by Fitbit with data from 30 million users worldwide showed a decrease in steps across many countries, including a 4% reduction among Australians [5]. However, the analysis only focused on data during the week of March 22, 2020, and effects of other key events on steps were not reported. In addition, detailed analysis was either not conducted or not reported for Australians. Similarly, a worldwide decrease in mean steps of 5.5% (287 steps) within 10 days and 27.3% (1432 steps) within 30 days of the pandemic declaration was also found among 455,404 smartphone users from 187 countries [6]. Again, very limited information was reported for Australia.

In contrast, one survey among 12,913 participants from 139 countries between March 24 and March 30, 2020, found an increase in frequency of exercising by 88% among those who normally exercise 1 to 2 times per week and 8% among those who normally exercise 3 times per week, but a decrease of 14% among those who normally exercise 4 or more times per week [7]. There were also reports that online searches for topics relating to exercise dramatically increased in Australia, the United Kingdom, and the United States starting on March 23, 2020, when lockdowns started in Australia and the United Kingdom [8]. Data among 50,000 subscribers to the WHOOP platform also showed an increase of 1.1% in exercise frequency and 1.8% in time spent on higher-intensity exercise [9]. Finally, a survey among 1491 Australians found that 49% self-reported a decrease in physical activity, whereas 20.7% reported an increase, during the pandemic, indicating that the impact of COVID-19 may not be consistent among population groups with different demographic characteristics [10].

Given inconsistent findings and lack of detailed studies on this topic in Australia, this study used data from the 10,000 Steps Australia program to investigate (1) changes in physical activity reported through the 10,000 Steps platform during the COVID-19 pandemic and (2) changes in the engagement with the 10,000 Steps program during the COVID-19 pandemic. These findings will improve our understanding of the effect of distressing events on physical activity and engagement in physical activity programs and, therefore, inform health policies and tailored intervention design to better deal with future crises.

Methods

Data Sources

The 10,000 Steps program is a web- and mobile-based physical activity promotion program that is funded by the Queensland State Government [11]. To date, the program has registered over 463,000 members (ie, about 3000 new registrations per month), with a total of more than 237 billion steps logged (ie, about 40 million per day). Members register an account with the program website, set a daily step goal, use activity trackers (eg, pedometers, Fitbit, and Garmin) to self-monitor their progress, and participate in challenges to stay motivated. A 10,000 Steps smartphone app is also available for both Apple (iOS) and Google (Android). Any data recorded through the app automatically syncs with the 10,000 Steps website. A detailed description of the program has been published elsewhere [11].

This study used data from new and existing registered members of the program between January 1, 2018, and June 30, 2020, which included 3,548,825 days with step data. Step counts of less than 1000 indicate that the trackers were not worn all day, as even very sedentary people would be expected to accrue more than a 1000 steps a day; in addition, step counts of more than 40,000 are considered as extremely high (eg, technology bug, entry errors, or overreporting) [12,13]. As a result, days with logged steps that were fewer than 1000 steps per day (77,311 days) or more than 40,000 steps per day (10,802 days) were considered invalid and excluded. Data from people not living in Australia (399,711 days), aged less than 18 years or above 80 years (52,551 days), or having less than 7 days of logged data (12,833 days) were also excluded. As a result, 2,995,617 days (84.4%) of data between January 1, 2018, and June 30, 2020, were included in the analysis.

Measures

Demographic characteristics, including date of birth, gender, and state or territory, were self-reported by the members at the time of registration. Age was calculated by subtracting date of birth from June 30, 2020, and converting to years. Age was then dichotomized into two groups based on the average age: 18-45 years and >45-80 years. Location referred to states and territories in Australia, including, New South Wales, Victoria, Queensland, Northern Territory, Western Australia, South Australia, Tasmania, and Australian Capital Territory.

The number of daily steps was either logged manually by the members (45% through the website and 25% through the app) or synced automatically (30%) from the activity trackers connected to the program. As the 10,000 Steps website and app only extract steps from those using activity trackers (ie, Fitbit and Garmin), and given that many members use mechanical pedometers that only track steps, moderate to vigorous physical activity was not used in the analysis. Other measures used to represent the engagement with the 10,000 Steps program were the number of new registered members per day, the number of newly registered organizations per day, the total number of logged steps per day, and the number of step entries per day [14,15].

Key event dates were selected based on their potential influence on physical activity. The list of COVID-19-related events in Australia is presented in Table 1. The nationwide lockdown was imposed about two months after the first case was reported in Australia at the end of January 2020. During the lockdown, in addition to social distancing guidelines [16], nonessential businesses, such as gyms, indoor sports facilities, and clubs, were closed [17]. People were allowed to be outside only for exercise or other essential needs. Restaurants and cafes only offered takeaway and delivery services.

Table 1. Key event dates related to the COVID-19 pandemic.

Date	Description
December 1, 2019	First case with symptoms in Wuhan, China
January 25, 2020	First case in Australia reported
February 5, 2020	A 14-day ban for noncitizens arriving in Australia from China implemented
March 2, 2020	Lockdown starts in Australia
May 8, 2020	Australian Government starts relaxing restrictions

Data Analyses

Python, version 3.7.6 (Python Software Foundation), was used to process and analyze the data. Mean steps were calculated across users for each day. To smooth out daily fluctuations, a 7-day moving average for daily mean steps was calculated and used to create a time series plot showing the trend in steps over time for the entire sample and for each age group and gender. Key event dates were also marked on the plot. Average steps of 7 and 30 days before and after each event date and percentage of change were calculated and used to indicate the impact of an event on steps. The percentage of change in steps 7 and 30 days before and after the event were reported separately for each age group and gender, as well as for each state and territory. Data on the use of the 10,000 Steps program, including the number of new registered users per day, the number of newly registered organizations per day, the total number of logged steps per day, and the number of step entries per day, were also plotted using 7-day moving averages. Wilcoxon signed-rank tests were used to test for significant differences in steps between subgroups, including men versus women, those 18-45 years of age versus >45-80 years of age, and engagement measures in 2019 versus those in 2020 (ie, the number of new registered users, new registered organizations, total logged steps, and step entries). Significant differences in steps before and after an event as well as before and after the lockdown in each state were also tested using Wilcoxon signed-rank tests. All *P* values were two sided and considered significant if <.05.

Results

Of 60,560 members logging step data for at least 7 days, 59.7% (n=36,165) were aged between 18 and 45 years and 67.0% (n=40,583) were women. Of 2,995,617 days with step data that were logged between January 1, 2018, and June 30, 2020, about 63.4% (n=1,898,352) were provided by women and 53.1% (n=1,592,021) were provided by those aged between 18 and 45 years.

Figure 1 shows the average number of steps per day, zooming in on the period between July 1, 2019, and June 30, 2020. In general, there was a downward trend from the peak at the beginning of December 2019, and the bottom was reached in early April 2020. Since then, an increasing trend was observed. However, the difference in 7-day moving averages between days with the highest and lowest steps was small (ie, <1500 steps). A decrease in steps was also observed after the following events: the first case with symptoms in Wuhan, the first case in Australia reported, and the start of the lockdown in Australia. An increase was observed after a 14-day ban for noncitizens arriving in Australia from China. The steps at the time the Australian Government started relaxing restrictions appeared to have already returned back to the level before the lockdown. With regard to the subgroups, men and those above 45 years of age logged more daily steps than women (difference=505 steps; *P*<.001) and younger adults (difference=930 steps; *P*<.001). However, the trends were consistent for the subgroups and indicated that the effects of COVID-19 were not different for genders and age groups (see Figure 2).

Figure 1. Daily mean steps over time and key COVID-19 pandemic events. (1) First case with symptoms in Wuhan, China; (2) First case in Australia reported; (3) A 14-day ban for noncitizens arriving in Australia from China implemented; (4) Lockdown starts in Australia; (5) Australian Government starts relaxing restrictions.

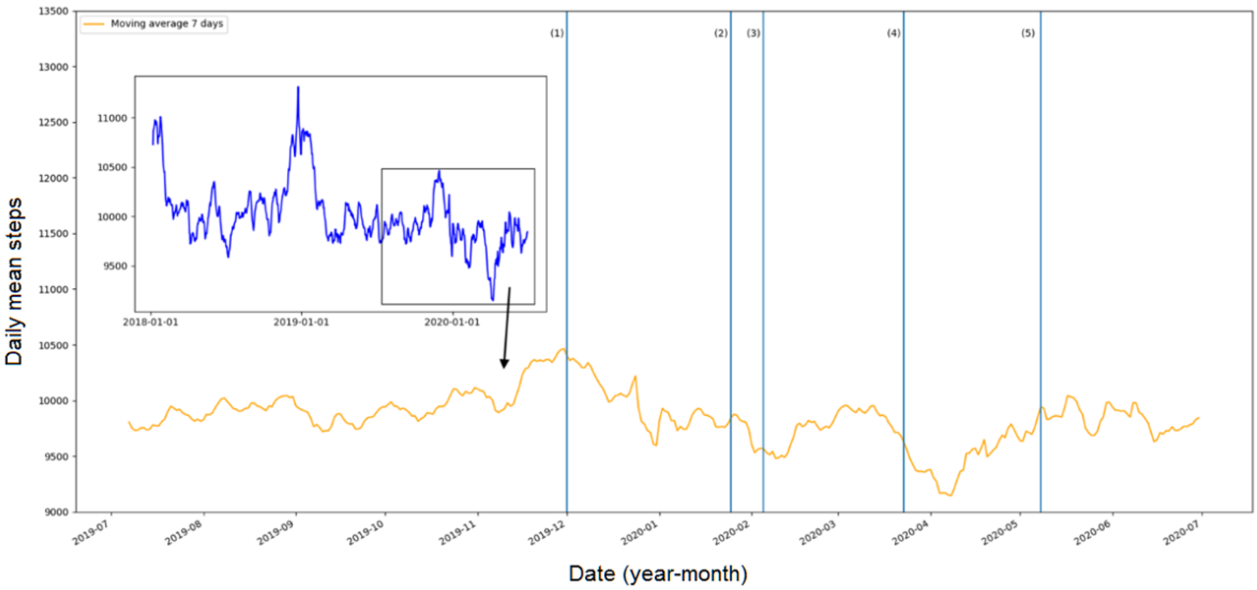

Figure 2. Daily mean steps for subgroups over time and key COVID-19 pandemic events. (1) First case with symptoms in Wuhan, China; (2) First case in Australia reported; (3) A 14-day ban for noncitizens arriving in Australia from China implemented; (4) Lockdown starts in Australia; (5) Australian Government starts relaxing restrictions.

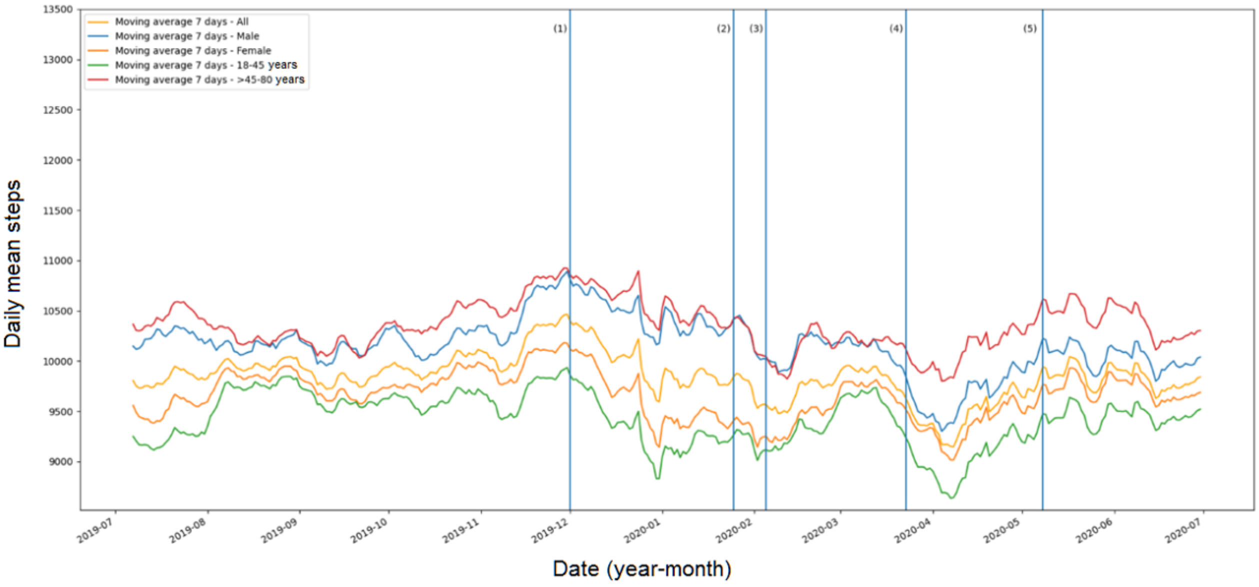

Table 2 shows the average steps of 7 and 30 days before and after an event and for each subgroup. In general, the effects were small for the key events regardless of age group and gender. After the first case was reported in Australia, there was a decrease of 1.5% (*P*=.02) in step average 7 days before and after this date. However, the event with the biggest negative impact on steps was the lockdown starting at the end of March 2020. The reduction was observed for average steps of 7 days (3.4%; *P*<.001) and 30 days (5.0%; *P*<.001) before and after the lockdown. It is also worth noting that the negative impact of a lockdown on steps appeared to be about two times (ie, average of 30 days) larger among those aged between 18 and 45 years compared to older adults. The announcement by the Australian Government to start relaxing restrictions saw a small increase in the step average of 7 days (1.3%; *P*<.001) and 30 days (3.8%; *P*<.001).

Table 2. Average daily steps of 7 and 30 days before and after each event.

Event and participants	Step average of 7 days				Step average of 30 days			
	Before, n	After, n	Difference, %	*P* value	Before, n	After, n	Difference, %	*P* value

>45-80 years	10,322	10,415	0.9	.02	10,106	10,446	3.4	<.001

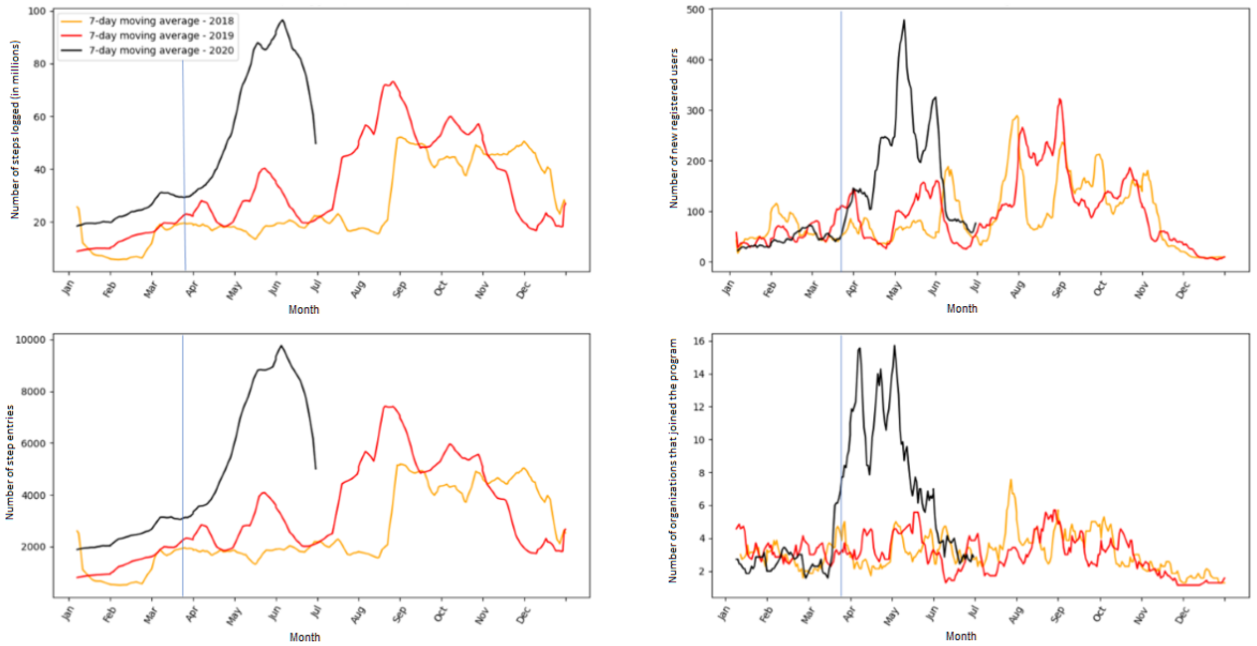
Table 3 shows differences in step averages of 7 days and 30 days before and after the start of the lockdown for each state and territory. A significant decrease was observed in both 7-day and 30-day averages, respectively, for New South Wales (7.0%; *P*<.001 and 5.3%; *P*<.001), Victoria (4.7%; *P*<.001 and 8.1%; *P*<.001), Queensland (1.3%; *P*<.001 and 3.4%; *P*<.001), South Australia (3.2%; *P*=.04 and 2.1%; *P*=.01), Tasmania (3.2%; *P*=.01 and 8.3%; *P*<.001), and Australian Capital Territory (6.2%; *P*=.02 and 10.0%; *P*<.001). The largest decrease for 7 days was seen in New South Wales (about 7%) and the largest decrease for 30 days was seen in Australian Capital Territory (about 10%). No significant difference was found for either Northern Territory (*P*=.15) or Western Australia (*P*=.36).

Table 3. Differences in step averages of 7 and 30 days before and after the start of the lockdown for each state.

State	Step average of 7 days				Step average of 30 days			
	Before, n	After, n	Difference, %	*P* value	Before, n	After, n	Difference, %	*P* value
New South Wales	9343	8686	–7.0	<.001	9528	9021	–5.3	<.001
Victoria	9671	9213	–4.7	<.001	9960	9150	–8.1	<.001
Queensland	9216	9098	–1.3	<.001	9399	9084	–3.4	<.001
Northern Territory	9475	8279	–12.6	.15	9744	8969	–8.0	.07
Western Australia	10,519	10,396	–1.2	.36	10,416	10,424	0.1	.69
South Australia	9914	9596	–3.2	.04	10,028	9816	–2.1	.01
Tasmania	9859	9539	–3.2	.01	10,059	9222	–8.3	<.001
Australian Capital Territory	9545	8955	–6.2	.02	9540	8590	–10.0	<.001

On the other hand, the use of the 10,000 Steps program increased during the pandemic (see Figure 3). The number of steps logged per day and the number of step entries increased steeply since the start of the lockdown. At the same time, the number of new registered users and organizations that joined the program also increased sharply. On the peak day, there were more than 9000 step entries with nearly 100 million steps logged per day; in addition, more than 450 new registered users and 15 new organizations registered per day. However, a sharp decrease in the number of logged steps, step entries, and new registered users and organizations was observed since June 2020. On average per day, there were about 55 new registered users (*P*<.001), 2 new registered organizations (*P*<.001), 25.6 million steps (*P*<.001), and 2672 log entries (*P*<.001) more in 2020 compared to the same period in 2019.

Figure 3. The total number of steps logged, step entries, and new registered users and organizations over time. The vertical line in each graph indicates the start of the lockdown.



Discussion

Principal Findings

This study investigated changes in physical activity among the Australian 10,000 Steps members and the use of the program during the COVID-19 pandemic. The results show that, among the key events, the largest decrease in average steps occurred after the lockdown started in Australia. The finding is consistent with the Fitbit report [5] stating that a reduction of 3% to 4% in steps was observed among the participants in Australia during the lockdown. Although the difference between days with the highest and lowest steps was less than 1500 steps, it has been shown that risk reductions in all-cause mortality are between 6% and 36% for every 1000 steps per day increase [18]. However, it is also worth noting that the decrease in steps was only for several months, and the physical activity level among the participants was already high with average daily steps greater than 9000, which are above the national average for Australia [19]. There also seemed to be a decrease in steps even before the lockdown. This may be because the first case of COVID-19 in Australia was reported at the end of January 2020 and the number of cases increased rapidly well before the lockdown in

March 2020. This was very prominently reported by the media, so it is likely that many people were already adjusting their behavior before they were imposed to do so by the government. Compared to many other countries that have seen much larger decreases in physical activity [6], the effect during the lockdown was small for Australia. This could be attributed to the fact that Australians were still allowed to exercise outdoors during the pandemic, whereas people from many other countries were not. In addition, at the time of data collection, the Australian Government's response to COVID-19, ranked third worldwide, was effective not only in keeping infection and death rates low but also in minimizing social disruption compared to many other countries [20]. As a result, people may have felt less worried and were willing to exercise outside. It is also likely that an increase in steps in April 2020 before the end of the lockdown indicated a partial return to normal life as restrictions eased.

The findings also indicate that technology-based (ie, web and app) physical activity promotion programs, such as the 10,000 Steps program, may play a significant role in minimizing the effect of the COVID-19 pandemic on physical activity. As demonstrated in this study, the number of newly registered users reached a record high during the pandemic, along with billions of steps logged monthly. The engagement with the 10,000 Steps program was much higher during the pandemic compared to earlier periods. Consistent with another study reporting an increase in interest in physical activity at the population level [8], our findings support the notion that people were actively searching for alternative ways to stay motivated to engage in physical activity during the pandemic. A possible explanation may be that people were more often choosing to go for a walk as a way to take a break from work or the restrictions of staying at home. It could also be that physical activity was used as a method to cope with stress and anxiety, as physical activity helps reduce stress and improve mental health [1]. A recent study also found that people who self-reported a decrease in physical activity during the pandemic were likely to experience higher stress and depression [10]. As technology-based physical activity programs are able to provide a social platform to support and encourage people to be more active, even when social distancing is mandated, their role is important, especially during distressing times.

In general, the trend in average steps was consistent across age groups and genders during the pandemic. However, the effect of the lockdown appeared to be larger for younger adults. It is likely due to differences in physical activity preferences between the age groups. As older adults are less likely to participate in team-based activities [21] and are more likely to be active at home or go for a walk around their neighborhood compared to using gyms and sporting facilities [22], the effect may be less severe compared to younger adults. In addition, studies have found that older adults were better at emotion regulation and more likely to use positive reappraisal [23,24] (ie, think positively in a negative situation) as a coping strategy [25], which may help them adjust and maintain their lifestyle behaviors, including physical activity in accordance with social isolation measures. It may also be due to the presence of children in younger adults' households, as studies have shown that parents are likely to be less active compared to nonparents [26,27]. The larger lockdown effect on men could be because men participate more often in competitive physical activities [28], which were more likely to be affected during the pandemic. However, the actual reasons for the observed differences are unclear and more research on this topic is needed.

The immediate effect of the lockdown on step counts was found for most states and territories, with the largest decrease of 7% in New South Wales where a majority of the cases were located in March 2020 [29]. Others with large step count decreases were Victoria, where the second highest number of cases were located, and Australian Capital Territory. Although the number of cases was the third highest in Queensland, the step count decrease was quite small. It is not clear what factors helped, but there was a sharp increase in the use of the 10,000 Steps program, which is based in Queensland. In addition, engagement activities, such as the Queensland Billion Steps Challenge, were implemented by both the government and local organizations. Queensland was also quick in closing the border with New South Wales right after the announcement of the lockdown.

This prospective study included a large number of participants across Australia. Although the main focus was to see the immediate changes in step counts due to COVID-19 events, using several years of data provided additional information on seasonal trends and, therefore, strengthened the results. Time series data also allow examination of both increases and decreases in steps around the key events. However, this study has several limitations. Firstly, many types of physical activity that are dependent on infrastructure that would have closed during the lockdown (eg, swimming pools) were not accounted for by only examining step counts. Secondly, the analysis did not account for differences in lockdown measures between states and territories. Finally, there is a possibility of selection bias, as participation was voluntary. However, the threat of selection bias to validity of this study is minimal due to the fact that our main objective was to see changes in steps over time during the pandemic. When the samples are similar at different time points, the findings will be valid. Furthermore, the sample was large; although a large sample does not mean it is a representative sample, this sample included people from different areas in all states and territories in Australia. Additionally, the 10,000 Steps program supports a variety of step tracking methods and allows both manual entry of steps tracked on any pedometer, activity tracker, or smartphone and automatic syncing of Fitbit and Garmin devices. As such, the risk of selection bias due to the need for an activity tracker or instalment of a specific app was likely low.

Conclusions

The COVID-19 pandemic had a negative effect on step counts among Australians across age groups and genders. However, the effect was relatively small even during the lockdown; in addition, physical activity levels quickly recovered after the lockdown. There was a significant increase in the use of the 10,000 Steps program during the pandemic, which might help minimize the negative effect of the pandemic and confirm the important role of technology-based physical activity programs during times of distress and lockdowns.

Abstract

Background: Since the COVID-19 outbreak was first reported, considerable attention has been drawn to mental health problems among college students.

Objective: We aimed to estimate the prevalence of anxiety and depressive symptoms among college students in different geographical areas of China during the early stage of the COVID-19 outbreak.

Methods: A nationwide cross-sectional survey was conducted among Chinese college students of 16 provinces or municipalities from February 4 to 12, 2020. A web-based survey was adopted to collect information from these college students, including demographics, perceived risk of infection, attitudes toward the epidemic and its control, and mental health status. Anxiety symptoms were assessed using the Generalized Anxiety Disorder scale, and depressive symptoms were assessed using the Patient Health Questionnaire. Chi-square test was used to compare the percentage of perceived risk of infection and attitude toward COVID-19 among college students in different geographic locations. Binary logistic models were used to identify associations between geographic locations and mental health problems after controlling for covariates.

Results: A total of 11,787 participants were analyzed in this study (response rate: 79.7%). The prevalence of anxiety and depressive symptoms among college students was 17.8% (95% CI 17.1%-18.5%) and 25.9% (95% CI 25.1%-26.7%), respectively. After controlling for covariates, current residence area in Wuhan city was found to have a positive association with anxiety symptoms (odds ratio [OR] 1.37, 95% CI 1.11-1.68) and depressive symptoms (OR 1.32, 95% CI 1.09-1.59). Similarly, college location in Wuhan city was found to have a positive association with anxiety symptoms (OR 1.20, 95% CI 1.07-1.35) and depressive symptoms (OR 1.22, 95% CI 1.10-1.36). History of residence in or travel to Wuhan city in the past month was also positively associated with anxiety symptoms (OR 1.62, 95% CI 1.46-1.80) and depressive symptoms (OR 1.48, 95% CI 1.35-1.63). Furthermore, the perceived risk of COVID-19 was higher among students whose college location and current residence area were in Wuhan city, and it was positively associated with anxiety and depressive symptoms.

Conclusions: During the COVID-19 pandemic, mental health problems among Chinese college students were widespread and geographically diverse. Our study results provide further insight for policymakers to develop targeted intervention strategies.

KEYWORDS

COVID-19 pandemic; college students; mental health problems; geographic location

Introduction

In December 2019, a new type of coronavirus named SARS-CoV-2 emerged in Wuhan, China [1]. This novel virus was found to cause a pneumonia-like respiratory infection called COVID-19; the disease rapidly spread all over China and turned into a pandemic, affecting most countries globally and putting the entire world on alert [2]. Because this is a novel disease, the preventive and treatment options were not clearly established at the beginning of the outbreak, imposing increased risk for mental health problems associated with COVID-19 [3]. The COVID-19 outbreak has also led to a major education crisis for children and adolescents. It is estimated that approximately 1.5 billion young people (ie, over 90% of all enrolled learners) worldwide were out of education [4], and more than 220 million children and adolescents in China were confined at home as a result of the COVID-19 outbreak [5]. Few studies have examined the effects of COVID-19 on young people, but studies on the general population have reported adverse mental health effects, including increased risks of anxiety, depression, general psychological distress, and posttraumatic stress disorder [6-8]. A recent study in China found that the general public's vicarious traumatization scores were significantly higher than those of front-line nurses [9]. Health professionals and the general public were concerned with the potential adverse effects of the COVID-19 pandemic on the mental health of college students [10]. These concerns are consistent with earlier studies that have reported higher rates of mental health problems among college students following other disease outbreaks, such as SARS [11]. However, not much is known about the mental health effects of large-scale disease outbreaks on college students. Thus far, a few previous studies have allowed us to clarify the factors associated with mental health in a large population of college students after the COVID-19 outbreak.

The Chinese Lunar New Year is the largest annual event of mass travel worldwide [12]. In the context of the COVID-19 outbreak, tracking the migratory flow of college students in China is especially important because almost all of them were in the run-up to the annual Chunyun mass migration since the start of the winter holidays. Spatiotemporal patterns can help detect existing spatially clustered characteristics and high-risk areas, which can lead to a better understanding of the disease epidemic in the spatiotemporal dimension, thus providing reliable information for decision-making of disease prevention and control [13]. A compelling spatial analysis has identified hotspots within and outside of Hubei Province in China [14]. Wuhan is a city with many immigrants, and thousands of people left Wuhan to go to other cities and provinces before the COVID-19 lockdown came into effect. During this time, college students were also headed home for the winter holidays [15].

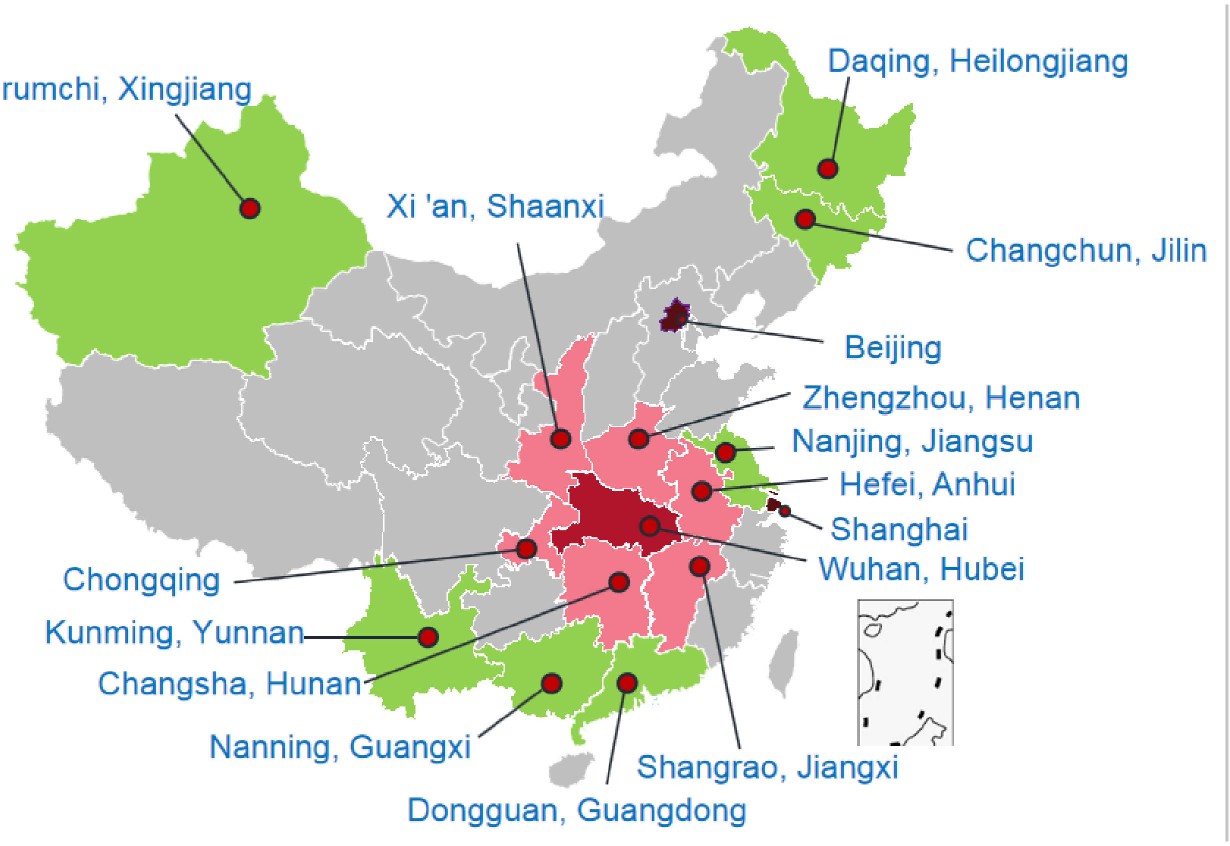
Therefore, we considered this specific population of college students in China to identify target locations for high risk of mental health problems. In this study, we aimed to estimate the prevalence of anxiety and depressive symptoms among college students in different geographical areas of China during the COVID-19 pandemic. It is essential to assess the spatial variability of mental health among Chinese college students during this pandemic, as it could provide useful insights to policymakers for targeted interventions.

Methods

Study Design and Participants

This nationwide, cross-sectional, web-based survey was conducted from February 4 to February 12, 2020. A 2-stage sampling strategy was used. In the first stage, based on the geographic location and cooperation intention, we selected the following 16 provinces or municipalities: Wuhan city, neighboring provinces of Hubei (Henan, Anhui, Jiangxi, Hunan, Chongqing, and Shanxi), first-tier cities (Beijing and Shanghai), and other areas (Jiangsu, Guangdong, Guangxi, Yunnan, Xingjiang, Heilongjiang, and Jilin) (Figure 1). A total of 4 universities in Wuhan, Hubei Province, and 15 universities in other areas or municipalities were randomly selected for the analysis. In the second stage, 100-120 students of each grade (in general, 5 years for medical students and 4 years for nonmedical students) of a faculty were randomly selected from each university; these participants were invited to complete the web-based survey though the Wenjuanxing platform [16]. In total, 14,789 students were selected to participate in this study.

Figure 1. Distribution of study sample based on geographic locations of 16 provinces or municipalities in China.



This study was approved by the Ethics Committee of Anhui Medical University. Electronic informed consent was obtained from all participants before the survey.

Measurements

Geographic Location

Participants were asked to report their college location and current residence area. College locations were divided into the following 4 groups according to the geographic location: Wuhan city (the epicenter of the outbreak), neighboring provinces of Hubei, first-tier cities, and other provinces. Similarly, current residence areas were divided into the following 4 groups according to the geographic location: Wuhan city, other cities in Hubei Province, neighboring provinces of Hubei, and other provinces. Participants were also asked about their history of residence in or travel to Wuhan in the past month via a single question (yes, no).

To further understand the degree to which the COVID-19 pandemic had affected this student population, we divided the participants into the following groups according to the number of confirmed COVID-19 cases in their current residence area: <200, 200-600, 601-1000, and >1000. For this, we referred to the province-wise updates from the World Health Organization’s COVID-19 situation reports [17].

Perceived Risk of Infection and Attitude Toward COVID-19

Perceived risk of infection and attitudes toward COVID-19 were evaluated by the following questions: (1) How likely do you think you are at risk of COVID-19 infection? (2) How likely do you think are your family members at risk of COVID-19 infection? The responses to these questions were assigned the following scores: 1 (much less likely), 2 (less likely), 3 (more likely), and 4 (much more likely). Cronbach α was .876.

Participants’ worries about themselves and community members contracting the infection were evaluated by the following questions: (1) Do you worry about contracting the infection yourself? (2) Do you worry about infection among your community members? The responses were assigned the following scores: 1 (not at all), 2 (only a little), 3 (somewhat worry), and 4 (quite a lot). Cronbach α was .787.

Participants’ attitudes toward the COVID-19 epidemic and its control were evaluated by the following questions: (1) What is your attitude toward the COVID-19 epidemic? The responses to this question were assigned the following scores: 1 (very optimistic), 2 (somehow optimistic), 3 (somehow pessimistic), and 4 (very pessimistic). (2) Do you think the COVID-19 epidemic is hard to control at its current stage? The responses to this question were assigned the following scores: 1 (don’t agree), 2 (don’t agree or disagree), and 3 (agree). Cronbach α was .442.

Mental Health Problems

Participants’ anxiety symptoms were assessed by the Chinese version of the Generalized Anxiety Disorder (GAD-7) scale [18]. Participants were asked to rate the frequency of anxiety symptoms they experienced during the last 2 weeks. The GAD-7 scale contained 7 items that were scored on a 4-point scale, with scores ranging from 0 (not at all), 1 (several days), 2 (more than half the days), and 3 (nearly every day). The total score ranged from 0 to 21, with higher scores indicating higher GAD symptoms. The total score was categorized as mild, moderate, or severe anxiety based on cutoff scores of 5-9, 10-14, and 15-21, respectively.

Depressive symptoms were assessed using the Chinese version of the Patient Health Questionnaire (PHQ-9) [19], which is a 9-item questionnaire designed to screen for depressive symptoms. This questionnaire evaluated the frequency of depressive symptoms experienced by the participants in the last 2 weeks. Participants rated individual items on a 4-point scale, with 0 (not at all), 1 (several days), 2 (more than half the days), and 3 (nearly every day). The total score ranged from 0 to 27, with higher scores indicating higher levels of depression. The total score was categorized as mild, moderate, and severe depressive symptoms based on cutoff scores of 5-9, 10-14, and 15-27, respectively.

Covariates

The following variables were included in the analysis as potential confounders: gender, age, and residence (urban and rural). Participants' physical activity levels were assessed by the question "During the past 7 days, on how many days were you physically active for a total of at least 60 minutes per day? (Add all the time you spend in any kind of physical activity that increased your heart rate and made you breathe hard some of the time.)" [20]. The responses ranged from 0 to 7 days, and a high level of physical activity was defined as at least 3 days of exercise per week. Nighttime sleep duration was assessed by the following questions: "During the past week, when have you usually gone to bed?" "During the past week, when have you usually woken up?" [21]. Screen time was assessed using the following question: "How many hours per day did you spend on the computer (including playing video games or computer games or using a computer for something else) and watching TV/video programs during the past 7 days?" We categorized screen time as <2 hours/day (h/d), 2-4 h/d, and >4 h/d [22-24]. We also examined screen time spent viewing or obtaining COVID-19 information, and categorized it as <0.5 h/d, 0.5-1 h/d, and >1 h/d.

Statistical Analyses

Categorical variables are presented as percentages (%) and frequencies (n). Continuous variables are presented as mean (SD) or median (IQR) values. Chi-square test was used to compare the percentages of perceived risk of infection and attitudes toward the COVID-19 pandemic among college students in different geographic locations. Binary logistic models were used to identify associations between geographic location and mental health problems after controlling for covariates. Variables that were potentially correlated with lifestyle during the COVID-19 pandemic and could cause a bias in the association with mental health, including gender, age, residence, nighttime sleep duration, physical activity, and screen time, were adjusted for in the regression models. We estimated the adjusted odds ratios (ORs) and 95% CIs of independent variables.

Data were analyzed using SPSS (version 23.0; IBM Corp). *P* values <.05 were considered statistically significant.

Results

Characteristics of the Study Sample

Survey responses from a total of 11,787 participants were analyzed in this study (response rate: 79.70%). The mean age of the study participants was 20.45 (SD 1.76) years, and 57.11% (6731/11,787) of all participants were female. Of all participants, 48.02% (5660/11,787) had a rural residence, 5.06% (597/11,787) reported they were currently residing in Wuhan, 41.46% (4887/11,787) attended a college located in Wuhan, and 26.52% (3126/11,787) had a history of residence in or travel to Wuhan in the past month. The prevalence of anxiety and depressive symptoms among the study participants was 17.80% (2098/11,787) and 25.90% (3053/11,787), respectively. Sample characteristics stratified by gender are shown in Table 1. The results of gender differences in risk perception are shown in the table in Multimedia Appendix 1. Our results showed that the high rate of perceived infection risk of participants themselves and their family members was more elevated among female participants than among male participants. Moreover, compared with male participants, female participants were more worried about themselves and their community members contracting the infection. The pessimistic attitude of female participants toward the COVID-19 epidemic was also higher than that observed among male participants. A larger proportion of female participants agreed that COVID-19 is difficult to control at the current stage. Prevalence of anxiety and depressive symptoms among college students with different demographic characteristics is shown in Multimedia Appendices 2 and 3, respectively.

[a] N/A: not applicable.

Participants whose current residence area and college were located in Wuhan had higher depressive and anxiety symptoms than those from other regions. Moreover, depressive and anxiety symptoms were more elevated in female participants than in male participants. Participants who had a history of residence in or travel to Wuhan in the past month also had higher depressive and anxiety symptoms than those without such history.

Differences Between Current Residence Area or College Location and Perceived Risk of Infection and Attitude Toward COVID-19

Perceived risk of infection and attitudes toward COVID-19 for participants in different current residence areas and college location groups are shown in Multimedia Appendices 4 and 5, respectively. The percentage of high perceived infection risk for individuals was higher among participants who were currently residing in Wuhan and whose college area was located in Wuhan (both *P*<.001). Likewise, the percentage of high perceived infection risk for family members was higher among participants who were currently residing in Wuhan and whose college area was located in Wuhan (both *P*<.001). The percentage of participants who worried very much about themselves and their community members contracting the infection was higher among those whose college and current residence was located in Wuhan (both *P*<.001). The percentage of optimistic attitude toward COVID-19 was the lowest among college students whose current residence and college was located in Wuhan compared to those in the other groups. The highest proportion of college students currently residing in Wuhan agreed with the statement “COVID-19 is hard to control at its current stage” (*P*<.001); nevertheless, a median proportion of college students whose college area was located in Wuhan agreed with this statement (*P*<.001).

Differences Between Perceived Risk of Infection and Attitude Toward COVID-19 and Mental Health

Overall, a strong gradient was observed between different levels of perceived infection risk for individuals themselves and for their family members with regard to the prevalence of anxiety and depression symptoms (Multimedia Appendices 6 and 7). Similarly, a strong gradient was also observed between different levels of worry about infection risk for individuals themselves and for their community members with regard to the prevalence of anxiety and depression symptoms (Multimedia Appendices 8 and 9). Furthermore, a gradient was observed between the different attitudes of college students toward the COVID-19 epidemic and its control and the prevalence of anxiety and depression symptoms (Multimedia Appendices 10 and 11).

Both anxiety and depression symptoms were more prevalent among college students who reported high perceived infection risk for themselves (χ^2_2=220.46 for anxiety, χ^2_2=131.79 for depression; both *P*<.001) and for their family members (χ^2_2=197.52 for anxiety, χ^2_2=136.06 for depression; both *P*<.001). The prevalence of anxiety and depression symptoms was the highest among college students who worried very much about themselves (χ^2_3=285.77 for anxiety, χ^2_3=186.10 for depression; both *P*<.001) and their community members (χ^2_3=178.46 for anxiety, χ^2_3=119.60 for depression; both *P*<.001) contracting the infection. The prevalence of anxiety and depression symptoms was the highest among college students who had a pessimistic attitude toward the COVID-19 epidemic (χ^2_3=444.61 for anxiety, χ^2_3=355.95 for depression; both *P*<.001) and its control (χ^2_2=154.02 for anxiety, χ^2_2=124.84 for depression; both *P*<.001).

Associations Between Geographic Location and Mental Health

Tables 2 and 3 show the estimated ORs for the associations between geographic location and the prevalence of anxiety and depression among Chinese college students. Most associations were evident in both crude and adjusted models.

Table 2. Associations between geographic location and the prevalence of anxiety symptoms among college students in China.

Geographic location	Value, n (%)	Crude odds ratio (95% CI)	Adjusted odds ratio (95% CI)[a]
Current residence area			
Wuhan	136 (22.8)	1.35 (1.10-1.65)*	1.37 (1.11-1.68)*

*$P<.01$.

**$P<.001$.

Compared with the college students currently residing in other provinces, those currently residing in Wuhan city were significantly more likely to be at risk for symptoms of anxiety (crude OR 1.35, 95% CI 1.10-1.65, *P*<.01; adjusted OR 1.37, 95% CI 1.11-1.68, *P*<.01) and depression (crude OR 1.35, 95% CI 1.12-1.62, *P*<.01; adjusted OR 1.32, 95% CI 1.09-1.59, *P*<.01). Similarly, compared with the students whose colleges were located in other provinces, those whose colleges were located in Wuhan had a significantly increased risk of anxiety (crude OR=1.18, 95% CI 1.05-1.33, *P*<.01; adjusted OR 1.20, 95% CI 1.07-1.35, *P*<.01) and depression (crude OR 1.26, 95% CI 1.14-1.40, *P*<.001; adjusted OR 1.22, 95% CI 1.10-1.36, *P*<.001). Furthermore, students who had a history of residence in or travel to Wuhan in the past month were significantly more likely to be at risk for symptoms of anxiety and depression than those without such history (anxiety: crude OR 1.65, 95% CI 1.49-1.82, *P*<.001; adjusted OR 1.62, 95% CI 1.46-1.80, *P*<.001; depression: crude OR 1.55, 95% CI 1.41-1.69, *P*<.001; adjusted OR 1.48, 95% CI 1.35-1.63, *P*<.001). All associations were evident in both crude and adjusted models (Tables 2 and 3).

Nevertheless, participants' currently living in areas with a median number (200-600, >1000) of confirmed COVID-19 cases were more likely to be at risk for both anxiety and depression symptoms compared with than were those currently living in areas with <200 confirmed cases; however, these associations were not statistically significant.

Discussion

Principal Findings

The COVID-19 crisis has caused significant public concern in China and around the world. Therefore, there is an urgent need to understand the psychological status of college students in different areas affected by the COVID-19 outbreak. To our knowledge, some studies have described the mental health status of Chinese college students during the COVID-19 epidemic [25,26], but these studies have not evaluated geographical location in detail. In this study, we adopted a web-based questionnaire to explore the association between mental health problems and geographic distribution. Our study provides important findings about the psychological well-being of college students across different geographical locations, which can help policymakers design targeted interventions in order to effectively improve the mental health status of these students.

We found that anxiety and depressive symptoms were positively associated with Wuhan-based geographic locations (ie, current residence area or college location) as well as history of residence in or travel to in Wuhan. Moreover, female students had a higher prevalence of anxiety and depression, which could be because women are considered to be more perceptual, emotional, relatively vulnerable to tension, and have a high incidence of depressive symptoms than men [27,28]. These findings implicate that intervention strategies should primarily focus on college students who studied, lived, or ever traveled to Wuhan city during the COVID-19 pandemic, so as to provide useful insights for policymakers for targeted intervention of COVID-19.

During the outbreak, college students were concerned about the possibility of being infected with COVID-19. In the present study, significant differences were observed between students' current residence area or college location and perceived risk of infection and attitude toward COVID-19. Similarly, de Zwart [29] revealed the relatively high perceived threat for SARS. Public perception of health risk plays a key role in adopting these actions, in people's feelings, and their daily habits [30]. Furthermore, our results revealed that the perceived risk of infection and attitudes toward COVID-19 were both associated with increased risks of anxiety and depressive symptoms. Similar to previous studies, increased worry about contracting infection and lower self-perceived health conditions were significantly associated with higher scores on the Self-Rating Anxiety Scale and Self-Rating Depression Scale [31]. Fear of the unknown increases anxiety levels among healthy individuals as well as those with preexisting mental health conditions [7]. As emotional responses will likely include extreme fear and uncertainty, this can further predict mental health consequences.

During the COVID-19 lockdown period, anxiety and depression among people substantially increased [8]. In the present study, 17.8% and 25.9% of respondents reported anxiety and depressive symptoms, respectively. One of the strengths of our study was that we used nationally representative data collected during the early stage of the COVID-19 outbreak in China and geographic location groups to explore mental health distribution. Currently, a large body of study has utilized web-based or mobile geographic information systems and mapping dashboards for tracking the COVID-19 epidemic [32,33]. The COVID-19 outbreak affected different locations such as Wuhan city or regions outside the Hubei Province, to varying levels [14]. A clear and comprehensive understanding of the effects of the COVID-19 epidemic on the mental health problems of college students residing and attending college across different geographic locations would effectively provide target prevention and control strategies.

We found that anxiety and depressive symptoms were positively associated with the current residence area and college locations based in Wuhan as well as with history of residence or travel to Wuhan. The evidence suggests that, in the early stages of the COVID-19 outbreak in Wuhan, rumors and misinformation were more prevalent in those areas and could cause anxiety and stress about the outbreak [34]. In particular, people who contracted the disease may be more vulnerable to the psychosocial effects than others [3]. Given that college students who were currently residing or attending college in Wuhan, as well as those who had a history of residence in or travel to Wuhan, likely had a higher risk of exposure to infection, there may be greater concern about infection. Moreover, college students residing in Wuhan during the outbreak may have experienced a shortage of personal protective equipment and had inadequate supplies, medical care, and medications during home confinement; all these factors would have likely increased the risks of mental health problems [3].

Our study mapped the effects of geographic location on spatial variability of mental health, and the findings would aid policymakers in developing targeted interventions. Recent studies among university studies during the COVID-19 pandemic have found similar results. For instance, Xin et al [35] reported that the prevalence of depression was 14.8%. Wang et al [36] demonstrated that the prevalence of anxiety and depressive symptoms was 7.7% and 12.2%, respectively. Another study conducted in Hubei Province among medical college students reported that 35.5% of the students experienced depression, and 22.1% experienced anxiety, and most students who were depressed or anxious had mild or moderate conditions [37]. Similar results were found in an American survey, wherein 71% of the participants reported increased stress and anxiety due to the COVID-19 outbreak [38]. The reason for these high levels of depression and anxiety could be attributed to the severity of the epidemic in the United States. These results show that the psychological condition of students during the epidemic cannot be ignored.

Strengths and Limitations

This study evaluated the effects of COVID-19 on mental health among the Chinese youth. The investigation is representative of youth in China during the COVID-19 outbreak, and a relatively high response rate was achieved. The large national sample provided enough statistical power to examine the geographic location and mental health status of the participants. Our results provide further insight into developing targeted intervention strategies, including particular efforts undertaken by vulnerable populations [39,40]. Further research is required to study the effectiveness of prevention and control strategies, such as web-based mental health services [41], to promote mental health among college students during the COVID-19 epidemic.

However, this study has some potential limitations. First, this is a cross-sectional study, so it is difficult to elucidate causal relationships accurately. Additional longitudinal studies are necessary in the future. Nevertheless, we conducted follow-up examinations every 3 months for the study participants, thus enabling further clarification of the causal relationship. Second, despite the convenience of rapid assessment, our web-based survey may have potential respondent bias.

Conclusions

Based on our findings, we can conclude that the geographic location of students' current residence area or college location had a positive association with anxiety and depressive symptoms if based in Wuhan, compared with other areas. Moreover, a history of residence in or travel to Wuhan was also positively associated with anxiety symptoms and depressive symptoms. Thus, based on the geographic location of the college location and current residence area, college students in Wuhan city had a higher risk perception toward COVID-19.

Acknowledgments

The authors would like to thank all participants involved in the study for their inputs. Abstract

Background: A reduction in the number of face-to-face medical examinations conducted for patients with noncommunicable diseases (NCDs) during the first wave of the COVID-19 pandemic has led to health care professionals quickly adopting different strategies to communicate with and monitor their patients. Such strategies include the increased use of digital health tools. However, patient preferences, privacy concerns, a lack of regulations, overregulation, and insufficient evidence on the efficacy of digital health tools may have hampered the potential positive benefits of using such tools to manage NCDs.

Objective: This viewpoint aims to discuss the views of an advisory board of patient and caregiver association members. Specifically, we aim to present this advisory board's view on the role of digital health tools in managing patients with NCDs during and after the COVID-19 pandemic, and to identify future directions based on patients' perspectives.

Methods: As an initiative under the NCD Partnership (PARTners in Ncds Engage foR building Strategies to improve Healthy ageing In Patients) model of Upjohn, a web-based advisory board of patient and caregiver advocates was held on July 28, 2020, to bring together key stakeholders from public and private sectors.

Results: The following key themes emerged: (1) technology developers should understand that the goals of patients may differ from those of health care professionals and other stakeholders; (2) patients, health care professionals, caregivers, and other end users need to be involved in the development of digital health tools at the earliest phase possible, to guarantee usability, efficacy, and adoption; (3) digital health tools must be better tailored to people with complex conditions, such as multimorbidity, older age, and cognitive or sensory impairment; and (4) some patients do not want or are unable to use digital health care tools, so adequate alternatives should always be available.

Conclusions: There was consensus that public-private partnership models, such as the Upjohn NCD Partnership, can be effective models that foster innovation by integrating multiple perspectives (eg, patients' perspectives) into the design, development, and implementation of digital and nondigital health tools, with the main overall objective of improving the life of patients with NCDs.

Introduction

During the COVID-19 pandemic, there has been a justifiable focus on communicable disease prevention and management, which aims to control the risk of infection and transmission. However, noncommunicable diseases (NCDs) are still highly prevalent conditions [1,2], especially in older persons. NCDs accounted for an estimated 71% of worldwide deaths in 2016 [3,4].

During the first wave of the COVID-19 pandemic in 2020, many nonurgent outpatient services were closed to patients with NCDs; appointments were cancelled or postponed to reduce the risk of infection for patients and health care personnel and ease the burden on national health care services. These infection control procedures will have relevant implications for short- and long-term health, disease management, and quality of life of patients with NCDs [5]. This may be especially relevant to patients with complex conditions or multimorbidity (ie, the presence of 2 or more chronic conditions) [6,7]. Such patients usually benefit from integrated care, which includes comprehensive, coordinated care from multidisciplinary experts in multiple sectors [8-10].

Digital health tools include various technologies that can enhance health and health service delivery. Digital health tools can range from instruments that improve communication between health care professionals (HCPs) and patients, such as telemedicine technology, to electronic health records, mobile apps for monitoring symptoms, and medication and appointment reminder systems [11-16]. Digital health tools have been used for a range of purposes during the COVID-19 pandemic, including telemedicine service provision; remote patient monitoring; digital communication between political leaders and scientific authorities; and digital data monitoring for analyzing COVID-19 spread, COVID-19 evolution, and people's perceptions [17,18]. However, most countries lack a regulatory framework to authorize, integrate, and reimburse telemedicine services, and there is large heterogeneity between countries [19].

Even before the COVID-19 pandemic, many have emphasized that digital health tools are important for the prevention and management of NCDs [20], as digital health tools play an essential role in integrated care [9,21], especially in managing multimorbidity [8-10,22], delivering precision medicine [23], and increasing medication adherence [24]. However, older patients are less likely to choose telemedicine visits over office visits than younger patients, and other factors, such as access to technology, also play a role in patients' preferences for service delivery modes [25]. Patients' engagement with digital health tools is affected by multiple factors, including individual motivations, personal life values, approaches for facilitating engagement and recruitment, and the quality of the tool [11].

Since the start of the pandemic, there has been a rapid surge in the use of telemedicine tools and digital health tools for addressing non–COVID-19 medical issues [26]. However, patient preferences, privacy concerns, and insufficient evidence on the efficacy of digital health tools may hamper the potential positive benefits of such tools in the management of NCDs. Since the start of the pandemic, research on the use of digital health tools has mostly focused on how these instruments can be used to screen and diagnose COVID-19 [18]. This raises important questions about how these tools will be used in the health care of patients with NCDs in the postpandemic era. Although evidence-based results on clinical efficacy, ease of use, and cost-effectiveness from the perspective of HCPs, health care institutions, and national health services are important, we must also consider the needs, abilities, and wishes of the patients and caregivers who will ultimately be using and benefiting from these tools. We need to know whether patients want to manage their NCDs with digital health tools in the future, and understand the aspects that should be considered as we move forward to the next stage of the pandemic.

The objective of this viewpoint is to present the perspective of patients with NCDs and caregivers, with regard to the use of digital health tools for the prevention and management of NCDs. This viewpoint does not present a scientific summary of published evidence. Instead, it focuses on the aspects that patients and caregivers deem important for NCD prevention and care, in the context of an advisory board. Our specific aims include (1) describing the evolving scope of digital health tools for NCDs in the advent of the COVID-19 pandemic, and discussing patients' opinions on how these tools can be better designed and developed; (2) outlining ways to increase patient and caregiver engagement to optimize digital health tools; (3) presenting the challenges that patient and caregiver organizations perceive to be barriers to the use of digital health tools; and (4) identifying research priorities for improving the future use of digital health tools in NCD management.

Methods

The content of this viewpoint summarizes the consensus discussion of an advisory board within the NCD Partnership (PARTners in Ncds Engage foR building Strategies to improve Healthy ageing In Patients), which is an initiative that brings together different stakeholders from public and private sectors, so that they can work together to find tools for increasing healthy aging and reducing the burden of NCDs. This initiative involves an institutional collaboration between Upjohn, a division of Pfizer, and the European Innovation Partnership on Active and Healthy Ageing. The NCD Partnership has been engaged in numerous activities, including the creation of several advisory boards that consist of policy makers, physicians, HCPs, researchers, patient and caregiver advocacy groups, patient empowerment organizations, and industry experts.

On July 28, 2020, Upjohn and the European Innovation Partnership on Active and Healthy Ageing organized a web-based advisory board that consisted of patient and caregiver advocacy group members and patient empowerment organizations. The EUPATI (European Patients' Academy on Therapeutic Innovation) Guidance for Patient Involvement in Medicines Research and Development: Health Technology Assessment [27] has suggested that consensus building excercises should be one of the patient involvement activities.

The NCD Partnership has been operating in the field of NCDs and healthy aging for more than 2 years, since 2018. Several advisory boards that consist of researchers, HCPs, and patient advocacy groups have already been created by the NCD Partnership (ie, in September 2018, September 2019, June 2020). Furthermore, the partners of the NCD Partnership have published several papers based on information that was provided in meetings. These papers formed the basis of the advisory board in this viewpoint.

The organizing committee consisted of an expert (AM) in personalized medicine, health care administration, and regulatory affairs; an epidemiologist (KP) with extensive research expertise in NCDs, multimorbidity, and aging disorders; and a physician (SD) with expertise in pharmaceutical medicine, digital initiative leadership, and partnerships for improving patient outcomes. Both AM and KP have extensive experience in the public sector with regard to chairing and conducting consensus meetings, preparing clinical guidelines, and working with researchers, HCPs, and advocacy groups.

In addition to the chairman (AM) and epidemiologist (KP) who led the consensus dialogue, the advisory board included 7 members from patient and caregiver organizations who were recognized by the organizing committee. We aimed to include a wide range of organizations with views on the different aspects of NCDs including caregiver involvement; patient empowerment; health literacy and patient education; patient rights; and specific priority NCD themes, such as aging, pain, and neurology.

In terms of this viewpoint's methodology, we first identified several themes from previous NCD Partnership advisory board meetings that reflected major barriers to NCD management for patients, including integrated care [21], health technology [20], and COVID-19–related changes to the management of risk factors and diseases in patients with NCDs [5]. Afterward, we prepared a draft of talking points based on these themes. This draft was sent to the members of the advisory board. Each member was given time to discuss with their organizations and obtain feedback from patients, caregivers, and other experts from their associations. We then organized individual web-based meetings with the organizing committee and each advisory board member. During these meetings, the advisory board member provided feedback on the talking points. They were asked to add, remove, or modify the discussion points based on comments from their organization, and identify priority areas for discussion. A new set of talking points was then drafted and sent out to advisory board participants before the final meeting. The final meeting was a 1-day, web-based event that lasted for 7 hours. This meeting included several scheduled breaks throughout the day to ensure that any advisory board members with health issues had ample time to rest or move around. AM acted as the chairperson, while the epidemiologist (KP) documented the views, disagreements, and areas of consensus. A qualitative discussion was conducted, and this continued until a consensus was reached. In case a consensus was not reached, a list of areas for future research was made, as reported in the Results section. The meeting was also recorded to allow the chairperson and epidemiologist to review all discussions and identify key themes and recommendations.

Results

Patients' and Caregivers' Perspectives of Digital Health Tools in NCD Management

Summary of Results

The results section of this viewpoint provides a summary of the consensus points that were agreed upon by the patient and caregiver organizations. These consensus points were related to the use of digital health tools for preventing and managing NCDs. We provide several patient and caregiver perspectives and present their opinions on how digital tools can be optimized during and after the COVID-19 pandemic to improve patient outcomes. The results section reflects the perspectives of the patients and caregivers that the advisory board participants represent.

Consensus Theme 1: The Evolving Scope of Digital Health Tools for NCDs in the Advent of the COVID-19 Pandemic, and Patient and Caregiver Perspectives on How These Tools Can Be Better Designed and Developed

The COVID-19 pandemic has prompted a rapid change in the use of digital health tools. The advisory board members felt that the pandemic has provided the opportunity for scaling up the development of these tools so that they can be used to manage both communicable diseases and NCDs. During the pandemic, there was a rise in the use of digital tools for increasing communication between HCPs and patients (eg, telemedicine and video consultation technologies). Digital health tools can be used as an alternative when nonurgent face-to-face consultations are cancelled. Furthermore, these tools can be used for COVID-19 symptom tracking and tracing. These changes may have a positive and negative impact on the future use of digital health tools in health care. During the consensus discussion, the patient and caregiver advocates felt that the pandemic may have triggered the opportunity for citizens to engage in the use of digital tools and participate in studies that collect data on health and NCD prevention. However, some people may be concerned about ethical and privacy issues. They may also be skeptical about replacing face-to-face health care with digital alternatives. There was consensus that digital health development should be part of an overall long-term strategy that advances in parallel with the greater investments that multiple clinical and nonclinical settings have put into medicine and integrated care. The COVID-19 pandemic is likely to result in the reconfiguration of care pathways in the short- and long-term future, and this reconfiguration may lead to a considerable increase in community- and home-based care, wherein digital tools can support patient management. In the following section, we discuss what roles patients and caregivers can play in the design and development of digital health tools, and whether tools used during the COVID-19 pandemic can play a part in the future management of NCDs.

The advisory board members proposed that a comprehensive range of digital health tools that take into account the whole life of an individual (ie, including the epigenetic life cycle) should be used. This includes an individual's preconception, birth, childhood, adulthood, and older age. These tools should also provide methods for primary prevention (eg, control of lifestyle and treatment of risk factors in healthy individuals), secondary prevention, tertiary prevention, and management of NCDs (eg, symptom management for people in a disease state). To prevent NCDs, digital health tools can include exercise monitors, fitness watches, sleep monitors, and apps that monitor lifestyles and NCD risk factors. Tools that focus on disease and symptom management can include a variety of individual-level instruments (eg, medication reminder systems, adherence monitoring systems, etc), organization-level instruments (eg, appointment scheduling systems, electronic health records, etc), or instruments that improve communication between HCPs and patients (eg, teleconsultation technologies, remote symptom monitoring technologies for blood pressure control, wearable glucose monitors, etc). Different individuals who are involved in the care process may be the target users of digital health tools. Such individuals include community nurses, pharmacists, and people who play an important role in patients' care outside of clinical settings [28]. The perspectives of patients and caregivers may differ depending on the goal of the digital health tool and the type of technology used. The advisory board members felt that it was important to identify the target users for each type of technology and have clear objectives for each tool. The profile of patients with NCDs can differ dramatically in terms of their characteristics and the type of disease or diseases that they have. For example, an oncological patient might have very different needs compared to a person with a neurological disease.

There was strong consensus that digital health tools should be used to enhance health care, rather than transition from nondigital NCD management to fully digital NCD management. Although HCPs and patients with NCDs do not usually have the option to manage NCDs through face-to-face consultations during pandemic-related lockdowns and periods of shielding or quarantine, it is important to identify which digital health tools provide the best solutions for patients and HCPs, and ensure that such tools do not replace better alternatives in nonpandemic times. Appropriate digital health tools might differ depending on situational changes, and people need to have a clear motivation for using digital tools instead of nondigital tools. For example, during the COVID-19 pandemic, patients have clearly benefited from teleconsultations because they minimize the contact between patients and HCPs and reduce the risk of contracting SARS-CoV-2. However, many of the advisory board members emphasized that some individuals want face-to-face contact with HCPs once social distancing measures have eased because they miss human contact. This may be relevant to specific patient groups who prefer nondigital contact with HCPs. On the other hand, some patients, such as those with certain psychiatric disorders, may prefer to receive remote medical care in a home setting.

Consensus Theme 2: Methods for Increasing Patient and Caregiver Engagement to Optimize Digital Health Tools

The advisory board members agreed that digital health tools need to demonstrate a clear benefit for patients, to increase their engagement with these tools. If individuals cannot perceive the personal advantages of using a specific tool, it is less likely that they will use it. On the other hand, institutions have analytic tools that can assess the cost-effectiveness of adopting innovative tools and predict the socioeconomic impact of technological solutions. The patient and caregiver advocates emphasized that outcomes need to be meaningful to the patient and take into account individual aspirations. Further, there needs to be clear definitions for what a digital health solution aims to do. For example, a tool can be designed to improve the frequency of communication between HCPs and patients, prevent disease onset, improve adherence to therapies, manage multimorbidity, or help caregivers. During the COVID-19 pandemic, the purpose of digital health tools has mainly been to increase communication between patients and HCPs. However, there are many different goals that can be achieved via digital health tools (eg, symptom monitoring, health tracking via biosensors, risk factor control, and medication adherence), and some of these goals may be important to other end users, such as caregivers, HCPs, or health care systems. Therefore, digital health tool developers should understand that the goals of patients may differ from those of HCPs and other stakeholders. Outcomes that may be deemed more relevant from an HCP perspective (eg, controlling symptoms, increasing medication adherence, etc) might not be as relevant from a patient perspective, in terms of quality of life and other aspects (eg, patients are often more interested in concrete goals, such as visiting grandchildren, being able to go to a concert, gardening, etc). If the HCP perspective is not in line with the end user perspective, any developed digital health tools are likely to be unsuccessful.

The advisory board members felt that HCPs, caregivers, and other end users need to be involved with the development of digital health tools at the earliest phase possible, to increase the chances of developing technologies that people are motivated to use. These technologies should also have a high impact on patient outcomes. Ideally, the involvement of end users should occur before the implementation phase. Carefully designing and developing digital health tools will hopefully improve the life of patients and caregivers by helping them achieve meaningful goals that have an impact on their quality of life.

However, even if better-designed tools become available, this does not guarantee that they will be widely used.

Patients' engagement with digital health tools is affected by multiple factors, including individual motivations and personal life values. However, the advisory board members stressed that during the COVID-19 pandemic, many patients with NCDs have not had many viable alternatives to routine medical care; patients have no choice but to use telemedicine tools. Although telemedicine techniques are essential for helping HCPs maintain contact with patients with NCDs during periods of social distancing and lockdown, there should be a clear discussion and assessment of which digital health tools will be best used in the future management of patients with NCDs, and whether such tools are able to adequately replace or enhance nondigital health care techniques. Research, product development, and training must focus on individuals who will ultimately benefit from digital health tools as well as methods for improving tool usability (ie, improving user interfaces to facilitate adoption).

There was an overall consensus for improving potential users' engagement with digital health tool by developing instruments that focus on the positive aspects of a tool, instead of just the negative aspects (eg, using language such as "prevention and health" rather than "disease and symptoms"). Technologies that monitor changes in symptoms may not provide impactful incentives that adequately engage patients. Such technologies even run the risk of demotivating individuals during periods of NCD progression and symptom deterioration. Thus, digital health tools should have distinct purposes based on target users and their goals. For example, sports watches should be promoted as preventative tools for healthy individuals who want to monitor their fitness and reduce the risk of developing a future NCD, whereas people who already have NCDs might become distressed from receiving continuous feedback on their health data. Therefore, people with NCDs might better engage with tools that focus on more concrete changes that are relevant to their needs. Patients with NCDs are often motivated by specific and personalized goals, such as being able to independently manage their everyday life.

The advisory board members suggested that it is challenging to have individuals engage with digital health tools over long periods of time. People are often more motivated to use health-related technology when they receive a new diagnosis or experience symptoms. However, when their symptoms improve, the urge to use digital health tools can decrease. Thus, in addition to increasing new users' engagement with digital health tools, it is important to find methods for increasing motivation in people who have recovered or have not experienced severe disease symptoms, to prevent reoccurrence.

Increasing patients' engagement with digital health tools can also be achieved by designing or adapting digital health tools to be more user-friendly, and by focusing on the specific limitations (ie, physical, functional, and cognitive limitations) that patients with NCDs may experience. It is imperative to develop strategies that limit the time and effort needed to input data, so that simpler, more time-efficient tools can be created. It is also essential to tailor digital health tools to individuals with limited experience of technology (eg, older persons), and to adapt technologies so that they can be better used by people with specific needs, such as those with cognitive or sensory impairment.

Many people with NCDs, especially those with multimorbidity, are older individuals. The advisory board felt that age is an important factor to consider, because older individuals may be less likely to use digital health tools than younger people, and specific strategies are needed to engage older individuals. For example, isolated older persons who live in remote areas might not have access to technology or may not use the internet. The patient and caregiver advocates agreed that digital health approaches must be sensitive to the needs and wants of older people. Furthermore, the advisory board members questioned whether HCPs should continue to have patients engage with nondigital methods, or try to change the situation by providing patients with tools, technology, or training for using new digital health care tools. There will always be a proportion of the population who will not want or will not be able to use a digital health care solution. Therefore, there should always be adequate alternatives available to those who want them.

Consensus Theme 3: Challenges That Patient and Caregiver Organizations Perceive to Be Barriers to the Use of Digital Health Tools

The advisory board members discussed how to best use digital health tools in the prevention and management of NCDs in the short- and long-term future. When developing innovative solutions, there need to be clear outcomes and benefits for all patients and stakeholders. There was concern that the rapid development of digital health tools might not necessarily result in the best care of patients. Furthermore, whether patients and HCPs like using digital health tools, and whether they prefer digital health tools over nondigital alternatives still needs to be established. Patient advocacy organizations can help to improve knowledge by investigating patients' motivations for using digital health tools. For example, Pain Alliance Europe [29] conducted a web-based survey in 2020 to collect information on the use of eHealth (ie, the use of information and communication technologies for health purposes) and mobile health (mHealth; ie, the use of mobile devices for medical and public health practices) services. Data were collected from 1789 patients with chronic pain from 28 European countries. The responses showed that 46.28% (827/1787) of individuals did not use eHealth or mHealth services. The use of such services varied between different countries and age groups; the frequency of a lack of use was generally higher in older age groups (ie, >50 years) than in younger age groups. One of the main reasons that patients did not use eHealth or mHealth services was because they did not know about them (422/779, 54.17%). Additionally, 16.17% (126/779) of participants did not use such services because they did not see how these services would benefit them as an individual. The most common reason for using eHealth and mHealth services was because patients could use them to self-manage their conditions. With regard to the patients who did use eHealth or mHealth services, almost half (317/472, 48.84%) did not share their health data with anyone, while 9.86% (64/472) of patients shared data with their primary care physician. Future surveys that evaluate patient preferences, motivations, and patterns of use can help identify barriers to the use of digital health tools and different patterns that are based on the types of NCDs and symptoms.

Another major concern of the advisory board members was whether the use of digital health tools in health care will lead to inequalities among patients. Nondigital alternatives are needed for people who are unwilling or unable to use digital health technologies, and specific groups (eg, older persons, migrants, and people with cognitive or sensory impairment) should not be disadvantaged if they do not use digital health tools. Inequalities among patients may be relevant to different aspects of digital health tool use, including access to technology, training, digital health literacy, and motivation to use them. Many individuals have expressed concerns about data privacy and who their information will be shared with (eg, insurance companies, banks, or employers). It is unlikely that patients will fully embrace digital health care tools until privacy concerns are adequately addressed.

Consensus Theme 4: Research Priorities for Improving the Use of Digital Health Tools in Future NCD Management

The advisory board members agreed that before digital health tools are used on a wider scale, high-quality research is needed to investigate how effective they are in the prevention and management of NCDs during the COVID-19 pandemic era and beyond. The patient and caregiver advocates devised several concrete research questions that should be prioritized. The questions about the individual patients' characteristics, needs, and wants, and the questions about how digital health tools will improve patient outcomes and quality of life are particularly important. Specific research objectives are proposed in Textbox 1. The advisory board members were also concerned about the amount of current evidence that is based on clinical outcomes that have been defined and assessed by HCPs, as there is often a lack of patient and caregiver perspectives in the literature. Research should clarify the distinctions between digital health tools that are developed for healthy people (eg, digital health tools that help prevent disease in the long term) and those developed for patients (eg, digital health tools that improve patient outcomes via symptom monitoring or increasing drug adherence). A key topic for research is determining whether motivations for using digital health tools differ among patients with different diseases or characteristics. For example, if the goal is to increase physical activity levels, digital health tool developers need to know which people are driven by face-to-face interventions and which people prefer using wearable devices. We also need to build registries to identify biomarkers and risk factors for so-called "unpreventable diseases." Digital health tools may help with gathering and analyzing data on a wider scale. It is also vital to develop and design health technologies while carefully considering the European Charter of Patients' Rights [30].

Textbox 1. Research questions on digital health tools in noncommunicable disease management, as suggested by patient and caregiver organizations on the advisory board.

Research questions

- How did patients and health care professionals view the use of telemedicine during the first wave of the COVID-19 pandemic? Did these tools have a positive impact on patient management and symptom control in the short and long term?
- How do patients and health care professionals feel about teleconsultations? Do patient outcomes differ depending on whether care is provided through remote telemedicine tools versus face-to-face methods? Are there specific diseases that these solutions work better for (eg, people with social anxiety might prefer teleconsultations)?
- Which type of digital health tools have a greater impact on the outcomes of individuals and is it always a positive impact?
- Do patients and health care professionals want to continue using telemedicine and other digital health tools after the COVID-19 pandemic, and if so, which ones?
- Which demographic groups are more likely to use digital health tools and how can the other groups be encouraged to use tools more frequently?
- How effective is technology in increasing behavioral change? Do changes in behavior affect clinical outcomes or help patients achieve meaningful goals?
- Which clinical changes have an effect on a patient's quality of life and how can health care professionals better assess what patients' individualized goals are?
- Is quality of life improved by better medication adherence or do changes such as symptom control or psychological support have a bigger effect? Do these differ based on disease, age, gender, and other characteristics?
- Can single digital health tools be adapted to the specific goals of individual patients?
- What motivates individual people to use digital health tools? Does motivation differ based on disease type and other patient characteristics?

Discussion

In conclusion, the COVID-19 pandemic has instigated a rapid increase in the use of digital health tools, and has highlighted the need for developing better tools that are adequately suited to the future needs of both HCPs and patients. It is still unclear how the COVID-19 pandemic will develop; it seems likely that we will face new outbreaks and repeated lockdowns that will result in a renewed disruption of NCD health services and management. Digital health tools can help with providing alternatives for nonurgent, face-to-face medical and care services during lockdown periods. However, digital health tools can also be used to further enhance NCD prevention and management by integrating them into health care services during nonpandemic times. Furthermore, patients' and caregivers' opinions are essential for driving the development of effective tools with the maximum potential impact for end users. Patient and caregiver advocacy groups, citizen networks, and empowerment organizations need to be better integrated into all phases of digital health tool development. This will ensure that meaningful patient and public involvement occurs. Concrete goals need to be set for increasing patients', caregivers', and HCPs' digital literacy. We also need to build and enhance well-connected infrastructures that allow for equitable access to digital health tools. Current regulatory and reimbursement frameworks also need to be reviewed so that they can be adapted to the changing health care pathways that are likely to be increasingly supported by future digital health tools.

We need to clarify how to facilitate patient and caregiver association involvement in the research, development, design, and innovation of care processes and digital health care tools. Our viewpoint highlights the importance of public-private partnership models (eg, the NCD Partnership) and other initiatives (eg, the EUPATI [27], the Partners Forum [31], and the NCD Alliance [32]) in fostering innovation to achieve meaningful goals. The NCD Partnership is an initiative that aims to create a platform for debate and facilitate the collaboration of policy makers (eg, the European Commission), HCPs, industry experts, researchers, patients, and caregivers, by creating advisory boards, implementing collaborative research projects, and conducting other activities. It has been emphasized that successful plans for addressing NCDs require international-level, national-level, and local-level partnerships among national governments, private sectors, and civil societies, and the involvement of a wide range of key actors, including patients and their families [33]. Other multistakeholder partnerships, such as the EUPATI, have emphasized the importance of patient involvement in health technology assessment [27], and have suggested that consensus-building exercises can be used to improve patient involvement. Strengthening the collaboration between public and private organizations that have a strong involvement in civic and patient associations (ie, in terms of health literacy and digital health literacy) can help increase people's ability to obtain, read, understand, and use information that relates to digital technologies. By bringing together multiple stakeholders, including patients, into the design, development, and implementation of digital health tools, we can make advancements that will help align the goals of all partners who share an overall objective of improving the life of patients with NCDs.

Conflicts of Interest

VC is employed by Pfizer Upjohn and DD, MCY, and SD are former employees of Pfizer Upjohn. VC, DD, MCY, and SD are also Pfizer stockholders. AM, KP, NHRF, IK, MS, AV, JVG, MV, and DW have no conflicts of interest to declare.

Abstract

Background: Continuous in-home monitoring of older adults can provide rich and sensitive data capturing subtle behavioral and cognitive changes. Our previous work has identified multiple metrics that describe meaningful trends in daily activities over time. The continuous, multidomain nature of this technology may also serve to inform caregivers of the need for higher levels of care to maintain the health and safety of at-risk older adults. Accordingly, care decisions can be based on objective, systematically assessed real-time data.

Objective: This study deployed a suite of in-home monitoring technologies to detect changing levels of care needs in residents of independent living units in 7 retirement communities and to assess the efficacy of computer-based tools in informing decisions regarding care transitions.

Methods: Continuous activity data were presented via an interactive, web-based tool to the staff identified in each facility who were involved in decisions regarding transitions in care among residents. Comparisons were planned between outcomes for residents whose data were shared and those whose data were not made available to the staff. Staff use of the data dashboard was monitored throughout the study, and exit interviews with the staff were conducted to explicate staff interaction with the data platform. Residents were sent weekly self-report questionnaires to document any health- or care-related changes.

Results: During the study period, 30 of the 95 residents (32%) reported at least one incidence of new or increased provision of care; 6 residents made a permanent move to a higher level of care within their communities. Despite initial enthusiasm and an iterative process of refinement of measures and modes of data presentation based on staff input, actual inspection and therefore the use of resident data were well below expectation. In total, 11 of the 25 staff participants (44%) logged in to the activity dashboard throughout the study. Survey data and in-depth interviews provided insight into the mismatch between intended and actual use.

Conclusions: Most continuous in-home monitoring technology acceptance models focus on perceived usefulness and ease of use and equate the intent to use technology with actual use. Our experience suggests otherwise. We found that multiple intervening variables exist between perceived usefulness, intent to use, and actual use. Ethical, institutional, and social factors are considered in their roles as determinants of use.

KEYWORDS

technology; remote sensing technology; care transition

Introduction

Although factors associated with older adults' moves to residential facilities have been well described [1-4], our understanding of the reasons for changes in the level of care in persons who live in continuing care retirement communities (CCRCs) is limited. However, there appears to be some overlap with transitions from independent community living. Increased confusion, loss of mobility, medication nonadherence, and reduced socialization have been identified as predictors of movement to higher levels of care in a CCRC [5-8].

A delay in identification of increased dependence or inability to perform routine self-care activities can result in costly and potentially dangerous outcomes for at-risk residents. Typically, decisions about care needs and transitions in the levels of care for older adults living in CCRCs rely on communication and coordination among professional staff members. Ideally, these decisions are based on the evaluations of relevant health and behavioral changes. As Couture et al [9] have argued, the decision-making process is best accomplished by input from all stakeholders across health care professions as well as from family members and the residents themselves. Georgiou et al [10] identified barriers to optimal communication in residential care facilities, which may have a negative impact on the provision of quality care related to efficient and timely transitions to different levels of care. Another challenge to judicious care transitions is the relative inability to detect changes in a resident's care needs before an acute event occurs.

It has been noted that policies and procedures may not be suitable for efficient and timely information transfer. Kelsey et al [5] reported that policies for transfer from one level of care to another vary across facilities, ranging from a multidisciplinary team approach to decision making by a facility manager or administrator. They recommend that future research attention be paid to the ultimate appropriateness of resident transfers to higher levels of care. In the long term, codification of procedures and identification of factors contributing to moves within a residential community can serve to reduce resistance and misunderstanding and may have the potential to enhance safety and prolong independence in at-risk older adults.

A lack of formalized protocols or objective behavioral markers to guide the process may contribute to the uncertainty and divergent views associated with the determination of residents' needs for transition from independent to more assisted living within a continuing care setting. One way to compile objective, systematically assessed activity data is through continuous monitoring technologies. Demiris and Thompson [11] have cited the value of in-home activity monitoring technologies in delivering large, individually anchored data sets that are *useful, meaningful, and actionable*.

Systems that improve our ability to unobtrusively monitor important health changes because of chronic disease and aging could allow timely intervention that prevents avoidable loss of independence. Continuous collection of health and activity information in the home can enable early identification of clinically significant changes. Our experience in examining the feasibility of deploying a comprehensive, ubiquitous sensing platform in the homes of older adults has been reported previously [12,13]. ORCATECH (Oregon Center for Aging & Technology) research has demonstrated the sensitivity of unobtrusive in-home technology to detect early changes in medication management capacity [14,15], patterns of mobility [16-18], nighttime sleep behaviors [19], computer use [20,21], and driving [22]. Such technologies can provide important information in guiding decisions regarding increased care needs. We aimed to test the hypothesis that providing objective and continuous data from home-based technologies to the care teams in retirement communities will result in fewer transitions to higher levels of care through early identification of behavioral or activity changes that lead to increased in-home assistance.

In this paper, we report on the results of Ambient Independence Measures for Guiding Care Transitions (AIMS), a study that provided designated staff at 7 continuing care residential communities with access to an automated, continuous data monitoring platform via a web-based dashboard that collected residents' behavioral and physiological sensor-based independence metrics. Owing to low use of data by the staff, the trial was not able to adequately evaluate the primary hypothesis that providing these data will result in fewer transitions to higher levels of care and increase in-home assistance because of early identification of potential problems. We describe the procedures implemented to maintain staff engagement and consider the challenges of new technology adoption in residential facilities. Using exit interviews with the staff, we examined the reasons for the low use of the data to recommend how studies of home monitoring of health and activity can be improved.

Methods

Overview

Before initiating the trial, focus group sessions were conducted with care transition teams at the participating retirement communities to better understand their routine process of making decisions about when residents need to transition to a higher level of care and to receive feedback on the proposed AIMS data provision interface. Their recommendations were incorporated into the final dashboard interface where feasible. Residents were then monitored for 3 years, with behavior and activity data supplied to identified staff for half the study residents.

Recruitment

Older Adult Participants

Individuals were recruited from existing registries of volunteers for research residing in one of 7 retirement communities in the Portland metropolitan area and during presentations given at these communities about the project. These residential facilities participated in previous and ongoing research about technology and aging. Demographic data were collected at the time of enrollment in this study or other ORCATECH studies. Participants were aged 75 years or older, independently living in an apartment that was larger than one room, living alone, not demented, and of average health for their age (ie, without a medical illness that would limit physical participation or possibly lead to death over the next 36 months). As part of their participation in this study, the residents agreed to have their in-home activity data shared with their facility staff and were required to have internet service and to be computer users. The cohort was allocated to having the staff view their in-home activity via the web-based dashboard versus no viewing, using simple randomization (computer-generated assignment) at a 1:1 ratio, with an enrollment goal of 50 residents per group. The observation period for the study was 3 years.

Resident participants were instructed to live their lives without any specific health or activity intervention. They replied once a week to an email that directly queried them regarding health or activity change (mood, pain, loneliness, falls, hospital visits, visitors, and limited activity due to health) as well as the need for new or additional care.

Staff Participants

A total of 25 staff members at these facilities were self-identified as participants in decision making around residents' transitions in levels of care. They were recruited to this study during regularly scheduled staff meetings. Staff were aged between 21 and 66 years (mean 39.6, SD 10.4 years) and were employed at their present facility for an average of 10 years (range 2 weeks to 16 years). Staff levels of education ranged from high school graduate to master's degree; a majority (17/25, 68%) had obtained at least a college degree. Their job titles varied and included directors, nurses, social workers, and resident care coordinators.

Monitoring Platform

The details of the home technology system have been described previously [12,13]. In brief, sensors and other in-home technologies are deployed to continuously monitor daily activities. In response to specific queries from the research team regarding the dashboard content and interface, the staff made multiple concrete suggestions on all aspects, ranging from how to better navigate the site to changing the symbols used to represent alerts for changes in activity status. On the basis of the input from the care teams, a study protocol was finalized, which focused on home-based sensors and devices whose data were perceived as indicating that major functions had changed and thus could influence independent living decisions. The selected metrics included mobility, physiological health, nighttime behaviors, medication adherence, socialization, cognitive function, and self-reported health changes via a web-based weekly health form (Table 1).

Table 1. Ambient Independence Measures for Guiding Care Transitions study metrics and devices.

Core functions	Measures	Sensors or devices used
Physical capacity and mobility	Total daily activity, number of room transitions, typing speed, time out of home	PIR[a] motion sensors and contact sensors, computer use metrics (eg, keyboard trigrams)
Walking speed	Median weekly walking speed from multiple daily walks	PIR motion sensor line
Sleep and nighttime behavior	Time of awakening in the morning, time spent in bed at night, wake after sleep onset, times up at night, sleep latency	PIR motion sensors
Physiologic health	Daily BMI, morning pulse	Bioimpedance scale
Medication adherence	Percentage of doses missed in a 7-day period relative to prescribed schedule	MedTracker electronic pillbox
Socialization and engagement	Time out of home, time alone, phone call patterns, online computer activity (email and social networking sites)	PIR motion sensors, contact sensors, personal computer, phone monitors
Cognitive function	Time to complete online tasks, mouse movements, prospective memory for medication	Personal computer or tablet, MedTracker
Health and life events	Online self-report: emergency room, doctor, hospital visits, home visitors, mood, pain, loneliness, falls, injuries, change in home space, home assistance received, change in medications	Personal computer or tablet

[a] PIR: passive infrared.

Resident homes were installed with a sensor platform consisting of passive infrared motion and contact sensors, MedTrackers, weight scales, and software to capture all metrics as well as residents' computer use. A web-based reporting tool was developed to track these data, identify outlying data and trends, and provide staff with access to views of these data on a variety of timescales in a dashboard format that was available to the participating facilities' care transition teams. Figure 1 presents an example of a dashboard data summary for a single resident across various metrics over time. The dashboard interface was designed to be interactive, allowing for the manipulation of time scale, activity, and residents of interest. It also provided alerts to the staff for behaviors and activities that fell outside the range of normal for any particular resident. The basic approach for alerts was to develop a baseline model of typical measures for each individual over multiple weeks and monitor these measures on a regular basis (eg, weekly) for trends away from the norm. Alerts were embedded in data summaries for individual behaviors and activities. Figure 2 depicts a sample resident's summary graphic, where outlying behaviors are represented by an alert (!) and green checkmarks indicate the usual behavior *for that resident*.

Figure 1. Sample dashboard display (screenshot) of continuously assessed in-home activity metrics in Ambient Independence Measures for Guiding Care Transitions (AIMS) residents. The display, showing data at the individual level, can be customized by the user to show higher-level summaries, single metrics, numerical detail, and different windows of time. In this custom view, multiple metrics are displayed (eg, time out of home, physiologic measures, sleep measures, bathroom trips). The gray shading indicates preset ranges.

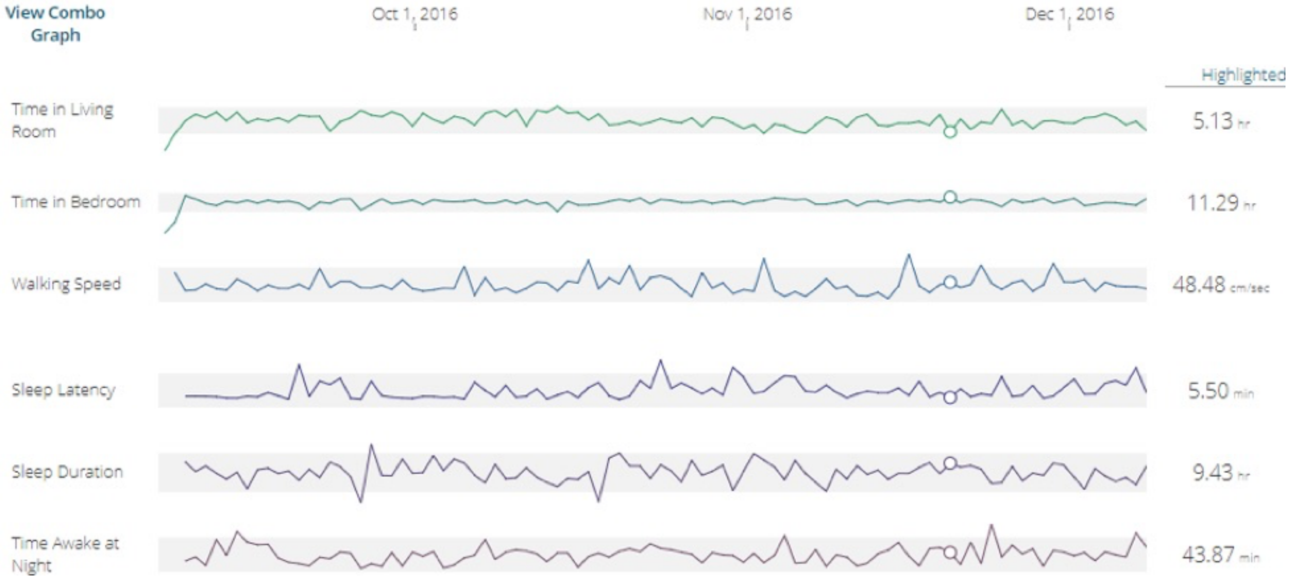

Figure 2. Sample dashboard display of residents' summary data. Exclamation points indicate departure from the usual level of behavior or activity for each resident (Temperature and Carbon Dioxide refer to environmental metrics and were not included in this study).

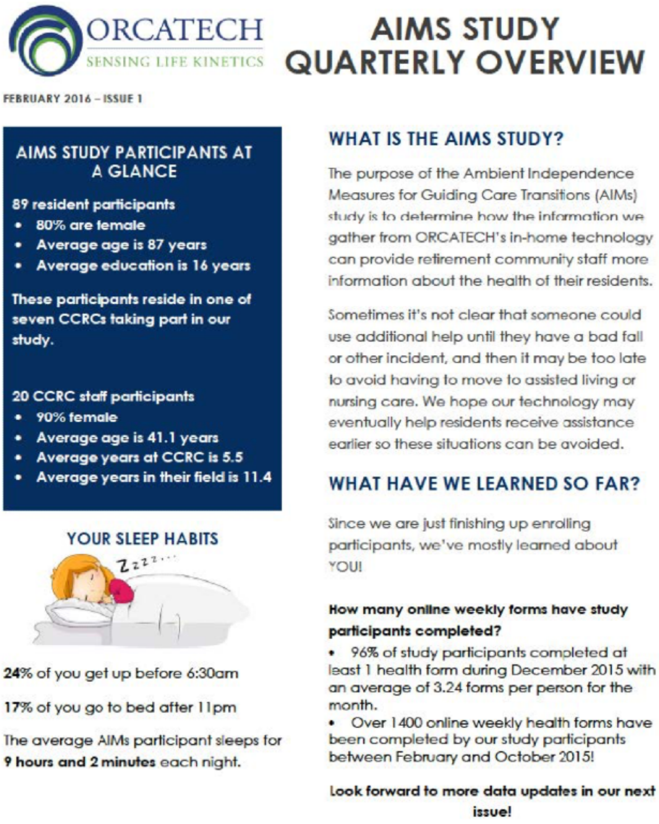
Staff Training and Engagement

Facility staff who had been identified as part of the transition assessment team and were willing to participate in the study were scheduled for 1-hour training sessions by AIMS study staff. Each staff member also received a printed dashboard user guide with detailed instructions on the use of the dashboard and its functionalities in terms of resident activity categories, data summaries, and useful comparisons across activities and time frames. Contact information for additional help was included, and technicians returned to sites to provide additional training as needed. During the study period, minimal additional training was requested; our technician made 2 additional visits to facilities and provided occasional help by telephone. These data are not tabulated.

To maintain engagement with the project, we mailed quarterly newsletters to residents and staff participants (Figure 3).

Newsletters contained study updates regarding recruitment and participation, illustrative dashboard screenshots and data summaries, and *fun facts* based on data collected. For example, one newsletter presented data summarizing the sleep habits of participating residents. Newsletters to staff were accompanied by nominal gift cards to express appreciation.

Figure 3. Sample page from the quarterly newsletter mailed to Ambient Independence Measures for Guiding Care Transitions (AIMS) study participants and staff. Study enrollment at the time of this newsletter was 89 residents and 20 staff.



ORCATECH
SENSING LIFE KINETICS

AIMS STUDY
QUARTERLY OVERVIEW

FEBRUARY 2016 – ISSUE 1

AIMS STUDY PARTICIPANTS AT A GLANCE

89 resident participants
- **80% are female**
- **Average age is 87 years**
- **Average education is 16 years**

These participants reside in one of seven CCRCs taking part in our study.

20 CCRC staff participants
- **90% female**
- **Average age is 41.1 years**
- **Average years at CCRC is 5.5**
- **Average years in their field is 11.4**

YOUR SLEEP HABITS

24% of you get up before 6:30am

17% of you go to bed after 11pm

The average AIMs participant sleeps for **9 hours and 2 minutes** each night.

WHAT IS THE AIMS STUDY?

The purpose of the Ambient Independence Measures for Guiding Care Transitions (AIMs) study is to determine how the information we gather from ORCATECH's in-home technology can provide retirement community staff more information about the health of their residents.

Sometimes it's not clear that someone could use additional help until they have a bad fall or other incident, and then it may be too late to avoid having to move to assisted living or nursing care. We hope our technology may eventually help residents receive assistance earlier so these situations can be avoided.

WHAT HAVE WE LEARNED SO FAR?

Since we are just finishing up enrolling participants, we've mostly learned about YOU!

How many online weekly forms have study participants completed?

- 96% of study participants completed at least 1 health form during December 2015 with an average of 3.24 forms per person for the month.
- Over 1400 online weekly health forms have been completed by our study participants between February and October 2015!

Look forward to more data updates in our next issue!

Data Collection and Analysis

For the duration of the study, dashboard access metrics were tracked, including the number of log-ins, average time spent on each dashboard page, and number of page views by each staff member.

Staff were emailed monthly surveys querying their use of the AIMS dashboard. They were asked whether they had looked at the dashboard in the last month and whether the dashboard was used in discussions about any residents. If they reported not having used the dashboard, they were asked to provide a reason. All surveys ended with an open request for feedback about the web-based activity dashboard. Midway through the study, in an effort to reengage, staff participants were sent a new survey with sample data illustrating acute and subtle changes in the behavior of one study resident. The staff responded to questions regarding the management of alerts and subsequent actions. For example, they were asked to identify preferred methods for the transmission of event reports, whether by dashboard alerts, emails, or other formats. Possible time frames for alerts, follow-up actions, and data interpretations were also probed.

At the end of the 36-month data collection period of the study, interviews with staff participants were held at 2 facilities jointly by 2 authors (KW and J Kaye) to discuss actual dashboard use among staff, study-related workload, and any other factors related to their use of the dashboard over the course of the study. The interviews were open ended and intended to elucidate barriers and opportunities for improving staff engagement in future studies (Multimedia Appendix 1).

Descriptive data for participating residents were collected at baseline. The rest of the data presented here were collected via web-based surveys and in-person interviews. Owing to small numbers, quantitative analyses of staff responses were not deemed appropriate.

Human Subjects' Protections

The protocol was approved by the Oregon Health & Science University Institutional Review Board (IRB#9944). Written informed consent was obtained from all participants before their inclusion in the study. The older adult residents did not receive compensation for study participation; the staff received nominal gift cards with newsletter mailings.

Results

Participants

A total of 95 older adult residents from 7 residential facilities in the Portland, Oregon, metro area were recruited and enrolled into the AIMS cohort (Table 2). They were 80% (76/95) female, with a mean age of 86.4 years (range 70-105 years) and Mini-Mental State Examination score of 28.7 (range 21-30). Overall, 10 participants had a Clinical Dementia Rating score of 0.5, consistent with mild cognitive impairment. Between enrollment and the data collection period, 4 participants withdrew; of the remaining 91 participants, 44 were assigned to the *viewable data* group and 47 to the *nonviewable data* group.

During data collection from December 2014 to December 2017, 6% (6/95) AIMS participants made a permanent move from independent living to assisted living or to a health care center. In addition, 32% (30/95) participants answered “yes” at least once to the weekly question regarding new care provision. The most commonly reported forms of assistance were medication management (n=22) and help with bathing, dressing, and grooming (n=19). Most of the additional assistance was provided by facility staff (n=20), whereas a minority received assistance from family or privately hired caregivers.

Table 2. Baseline demographic and clinical characteristics (N=95).

Variable	Value
Age (years), mean (SD)	86.4 (7.4)
Female, n (%)	76 (80)
Education (years), mean (SD)	15.9 (2.4)
Mini-Mental State Examination, mean (SD)	28.7 (1.6)
Cognitively impaired, n (%)	10 (11)
Geriatric Depression Scale, mean (SD)	1.1 (1.9)
Functional Assessment Questionnaire, mean (SD)	1.0 (3.3)
Cumulative Illness Rating Scale, mean (SD)	20.6 (2.6)

Staff Engagement

During the 3 years of study, 11 of the 25 consented staff members logged in at least once to the activity dashboard (Table 3). All facilities were represented by at least one staff member. The number of unique log-ins to the dashboard per facility ranged from 1 to 9. Staff *page views*, that is, the number of pages of data looked at per staff member, ranged from 4 to 211 over the duration of data collection. It is clear that some staff were more engaged than others; at facility #7, 1 of 5 participating staff members logged in during the course of the study, but that staff member had 211 page views. In the 4 facilities where more than one staff member viewed the dashboard, there was consistent overlap in the residents viewed. For example, in one facility, 2 staff members viewed the same 3 residents’ data. Some residents merited multiple page views. Of the 6 residents who actually transitioned to a higher level of care during the study period, 4 had been randomly assigned to the group where monitored data were shared with staff; only 2 of these transitioned residents’ data were viewed by the staff before their transitions.

Monthly surveys were discontinued because of a low response rate. Across the 5 monthly email surveys, a total of 81 invitations to respond were sent to the staff. A total of 25 completed surveys were returned. Of the 25 surveys, in 12 instances, staff members indicated that they had looked at the web-based AIMS dashboard in the past month. Survey responses of those who had not used the dashboard in the past month (n=13) indicated that they forgot to use the dashboard (7/13, 54%), they did not need to use it because of their role in the organization (4/13, 30%), or they were unable to get onto the dashboard system because they forgot their password (2/13, 15%). Of the 12 instances where the staff indicated they had looked at the web-based AIMS dashboard, none had used the information from the dashboard as a part of a discussion about a resident they viewed.

Of the 25 eligible staff participants, 5 responded to the midstudy survey, which included sample data designed to reengage staff participants, emailed in January 2017. They generally endorsed a preference for controlling the frequency of initial alerts and follow-up reminders. Although 4 of the 5 respondents judged alerts to acute changes to be useful, only 2 respondents felt the same for alerts regarding subtle changes or trends. In open text, they explained that subtle changes in behavior were not likely to affect the overall function or well-being and were not *acute enough* to warrant their involvement. One respondent elaborated:

> *There is a fine line between monitoring someone’s independent lives and knowing when to interfere for safety reasons...It is hard to know when to involve a care team without being too Orwellian. I would likely wait a month and then have a bit more data to take to a team meeting to assess the subtle changes collectively.*

At the end of the data collection period, 6 staff participants at 2 facilities were interviewed by 2 authors (KW and J Kaye). Interviews ranged from 1 to 1.5 hours. Feedback regarding barriers to the use of the AIMS dashboard and the data presented fell into 2 general categories.

Table 3. Staff engagement with the data dashboard.

Site	Number of participants consented	Dashboard use		
		Total number of participants logged	Total number of unique log-ins	Total page views
1	5	2	3	121
2	3	2	6	57
3	2	2	2	51
4	3	2	9	88
5	4	1	1	17
6	3	1	2	40
7	5	1	4	211

Practical Issues and Barriers

Technical difficulties with the use of dashboard at the beginning of the study proved to be dissuasive for some staff members:

> *We had difficulty logging into the system in the beginning.*

The infrequency of use exacerbated the log-in challenges because of continued unfamiliarity with the system. Furthermore, multiple staff noted that once they did access the site, the residents of interest to them in terms of changing care needs were not always study participants (because a minority of the residents they were overseeing were in the study at their site), making it less likely that they would re-enter the site. At the same time, the staff felt inundated by data in general and lacked the time to adequately review and interpret dashboard metrics. More than one staff commented that the study required a designated staff member to monitor data. Alternatively, one staff member suggested that if alerts were triaged to appropriate staff, they would all receive fewer irrelevant emails and alerts. Another staff member added that it would be critical for the system's effectiveness that staff only receive alerts relevant to their position, "then if you get an alert you know it was meant for you." The frequency of alerts and potential false alarms were naturally of concern in relation to time management for already overextended care providers.

Other feedback related to specific behaviors was monitored by the AIMS project. Despite initial enthusiasm about the areas of interest (eg, sleep, medication adherence, socialization), the staff subsequently recognized additional behaviors as more relevant to their decision making, such as disruptive behaviors or missing meals or appointments. At the same time, others appreciated receiving *real-time data* on metrics such as weight and sleep duration. They did acknowledge that although the residents were excited to be part of a research program, the staff felt they needed more experience with possible outcomes to see the benefits of behavior monitoring. In general, the staff struggled with the challenge of responding to acute events versus detecting trends and patterns of behavioral decline and determining how to integrate such monitoring into their daily schedules. Ultimately, some saw these data as potentially helpful in developing a model for transition, allowing them to be more proactive and less reactive.

Professional Bias and Ethical Concerns

One interviewee acknowledged that she had biases from the beginning, in that her training as a counselor led her to be more intuitive than data driven in her decision making. Others noted their strong inclination to use the data as objective support for their own subjective perceptions of care needs.

A second concern was related to the inherent conflict between resident autonomy and safety. Multiple staff members voiced this sentiment, citing the necessary compromise between letting a resident "do what they want" even if that were to include risky behavior. However, the installation of monitoring technology raised the issue of risk management for some, in that knowledge of potentially unsafe behavior would require a decision regarding the appropriate staff response. Patient autonomy and privacy were referenced in a question posed by a director of nursing services: "How paternalistic do you want your environment to be?" An intrinsic tension between residents' desire for control and their general willingness to share monitoring data was reflected in staff efforts to provide optimal care while respecting self-determination.

Discussion

Principal Findings

We report the results of developing and implementing an automated, continuous data monitoring platform that presented CCRC residents' daily activity data on a regular basis to professional staff charged with decisions about care transitions. Our goal was to assess whether these activity metrics meaningfully contributed to this decision-making process and to test their contribution by examining in a randomized controlled trial framework whether those metrics might inform decisions regarding transitions to higher levels of care by providing early and actionable data on changes in behavior and activity.

During the 3 years of study monitoring, only 6 participants transitioned to a higher level of residential care. This number was lower than anticipated and may reflect a growing trend toward engaging additional in-home assistance instead. A total of 30 participants reported needing new in-home assistance during the study, ranging from medication management to assistance with bathing. The low rate of transitions may have contributed to the underutilization of the monitoring data dashboard by facility care staff.

Although initial acceptance of the project was enthusiastic, with the staff in 7 facilities committing to regular utilization of the data dashboard, this enthusiasm failed to carry over into implementation. The staff used the dashboard sporadically, and those who did identified several limitations to use, ranging from technology challenges to ethical concerns.

Comparisons With Previous Work

Previous work on the adoption of technology by health care professionals has used various iterations of the Technology Acceptance Model (TAM) [23]. This model postulates that the intention to use technology is predicated on attitudes that are mediated by the perceived attributes of the technology. The two most important attributes in explaining acceptance and use of technology have been proposed to be perceived usefulness and perceived ease of use [24]. Modified technology acceptance models have added subjective norms and facilitator conditions as determinants of intent to use [25].

Although all models have been shown to have some explanatory power, research applications have typically incorporated *behavioral intention to use* rather than actual use. Few studies include measures of actual technology use, relying instead on measures of behavioral intent. Our experience in this project suggests that despite perceived usefulness at baseline and attempts to accommodate users' needs to achieve perceived ease of use, actual technology use can still be lower than predicted by indicators of intent to use.

TAMs have been applied to the identification of barriers to adoption by health care providers. Organizational factors such as administrative leadership and support, including additional time allotment and clear incentives, adequate resources for training and ongoing technical support, and organizational planning for implementation have been cited as important barriers [26-29]. Technical impediments include malfunctioning or unreliable equipment and devices and lack of coordination or complementarity with existing procedures. Failure to include potential end users in the design and planning of technology applications has also been cited as an impediment to adoption [27,30]. In addition, the ability of users to exert control over the technology's behavior has been cited as an important motivator in the adoption of a new technology [31]. Sabrowski and Kollak [32] describe the *domestication* of technology as a process whereby the system or device is integrated and adapted to the user's needs and environment. They postulate that until care professionals view a technology as integral to an improvement in the delivery of care, they will be resistant to adoption. Finally, human factors connected to attitudes and previous experiences with technology can have enormous influence. Lack of knowledge or familiarity with a device or system can diminish both perceived usefulness and ease of use. Furthermore, for health care providers seeking to maximize the quality of life for a medically fragile population, concerns about loss of human contact can foster negative attitudes toward technology. Savenstedt et al [33] identified themes elicited from interviews with professional caregivers of older adults. Technology applications were seen as both an aid and a threat to not only humane care but also to their roles as caregivers. They cited the loss of immediate contact and involvement with their care recipients as a potential consequence of technology applications. The authors suggest that these inherent conflicts foster resistance to change despite outward acceptance.

Limitations and Lessons Learned

We found sporadic adoption of a new monitoring technology by professional staff. Despite initial enthusiasm and ongoing efforts to engage the participating staff in 7 residential care communities, the goal of this study, that is, to analyze the impact of technology-based data on decision making around transitions in care, was not achieved. Previous research has described organizational, personal, and technological characteristics and contexts that may facilitate or impede the adoption of health technologies [29,34-37]. Feedback from our staff participants was consistent with these barriers to technology use.

Organizational Barriers to Use

Organizational factors such as clearly communicated expectations and possible study outcomes, continuous monitoring of technical support needs of the staff, and recognition of time commitments may have been inadequately addressed. A consistent recommendation has been the early inclusion of end users in design and implementation. Although our initial focus groups elicited some preferences and priorities, a longer run-in iterative process might have reduced the gap between our efforts at participatory design and the reality of the final implementation. Although some staff members recommend identifying a *champion* or *super-user* at each facility to provide onsite, continuous support and motivation to engage with the platform [37], we found few staff members who self-identified as such. Other organizational factors, although beyond the scope of this project, should be considered moving forward. A unified commitment to the implementation of new technologies by the administration, staff, and residents is required and must include the provision of adequate time for staff education and training, recognition of professional autonomy, and ongoing identification of potential barriers.

Personal and Professional Barriers to Use

Personal and professional traits related to technology adoption include experience with technology, peer attitudes, staff engagement, and professional satisfaction [29,34]. Although initial training was provided to all staff in dashboard use and features, additional active ongoing technical support might have increased engagement. Perceived usefulness may have been diminished because of lack of concordance between resident research participants and particular residents of interest (who were not monitored in the study) to the transition teams.

The staff expressed ethical concerns related to the quality of care and privacy. Previously, unexamined conflicted attitudes toward monitoring technology surfaced only after actual engagement with the system. A more detailed discussion of the implications and possible outcomes of staff participation in a continuous monitoring study before implementation might have mitigated ethical apprehensions. An increase in staff workload or change in procedure, without adequate motivation and explanation, cannot be expected to be enthusiastically adopted.

In the future, identification of intrinsic and extrinsic motivators, adequate and sustained training, and a realistic understanding of the goals of the study must be an integral part of research in technology adoption.

Technical Barriers to Use

Finally, issues with the technology itself may have presented barriers to implementation. Technical issues such as failed passwords and initial platform malfunctions, while infrequent, led to some early negative interactions, which proved to be difficult to overcome. In addition to the initial discussion of needs with end users, further refinement of the platform might have enhanced sustained participation. However, the refinement of protocols must be balanced with the time and resources needed to implement a program, acknowledging that staff turnover can attenuate involvement over time.

The original premise of our intervention was that a less obtrusive, information-on-demand approach would be least disruptive to workflows. However, at least initially, sending notifications of changes in resident behavior rather than relying on the staff to engage and retrieve data from a novel and unfamiliar source might have increased their understanding of the utility of the technology and its relevance to their daily practice. Providing actionable, customized information on residents at risk would demonstrate the potential benefits of continuous monitoring over standard procedures regarding transitions in care.

Conclusions

The limitations of previous work describing the intent to use technology without the inclusion of actual use as the final outcome are demonstrated by our findings. Initial enthusiasm and support for in-home, continuous monitoring of activity and behavior was established among the staff of 7 continuing care residential communities. Nevertheless, multiple factors, whether technical, personal, or institutional, intervened between intent and use. Future research examining technology adoption cannot ignore this crucial outcome measure if widespread acceptance and implementation of health care technologies are to be advanced. Finally, and perhaps most importantly, future work should examine whether a culture change toward proactive intervention to prevent or safely delay unwanted care transitions, rather than using technology for emergency response and acute situational management, will achieve wider use of technologies across residential care communities and related settings.

Conflicts of Interest

None declared.
