Abstract

Background: Online health communities (OHCs) have increasingly gained traction with patients, caregivers, and supporters globally. Chinese OHCs are no exception. However, user-generated content (UGC) and the associated user behaviors in Chinese OHCs are largely underexplored and rarely analyzed systematically, forfeiting valuable opportunities for optimizing treatment design and care delivery with insights gained from OHCs.

Objective: This study aimed to reveal both the shared and distinct characteristics of 2 popular OHCs in China by systematically and comprehensively analyzing their UGC and the associated user behaviors.

Methods: We concentrated on studying the lung cancer forum (LCF) and breast cancer forum (BCF) on Mijian, and the diabetes consultation forum (DCF) on Sweet Home, because of the importance of the 3 diseases among Chinese patients and their prevalence on Chinese OHCs in general. Our analysis explored the key user activities, small-world effect, and scale-free characteristics of each social network. We examined the UGC of these forums comprehensively and adopted the weighted knowledge network technique to discover salient topics and latent relations among these topics on each forum. Finally, we discussed the public health implications of our analysis findings.

Results: Our analysis showed that the number of reads per thread on each forum followed gamma distribution (H_L=0, H_B=0, and H_D=0); the number of replies on each forum followed exponential distribution (adjusted R_L^2=0.946, adjusted R_B^2=0.958, and adjusted R_D^2=0.971); and the number of threads a user is involved with (adjusted R_L^2=0.978, adjusted R_B^2=0.964, and adjusted R_D^2=0.970), the number of followers of a user (adjusted R_L^2=0.989, adjusted R_B^2=0.962, and adjusted R_D^2=0.990), and a user's degrees (adjusted R_L^2=0.997, adjusted R_B^2=0.994, and adjusted R_D^2=0.968) all followed power-law distribution. The study further revealed that users are generally more active during weekdays, as commonly witnessed in all 3 forums. In particular, the LCF and DCF exhibited high temporal similarity (ρ=0.927; P<.001) in terms of the relative thread posting frequencies during each hour of the day. Besides, the study showed that all 3 forums exhibited the small-world effect (mean σ_L=517.15, mean σ_B=275.23, and mean σ_D=525.18) and scale-free characteristics, while the global clustering coefficients were lower than those of counterpart international OHCs. The study also discovered several hot topics commonly shared among the 3 disease forums, such as disease treatment, disease examination, and diagnosis. In particular, the study found that after the outbreak of COVID-19, users on the LCF and BCF were much more likely to bring up COVID-19–related issues while discussing their medical issues.

Conclusions: UGC and related online user behaviors in Chinese OHCs can be leveraged as important sources of information to gain insights regarding individual and population health conditions. Effective and timely mining and utilization of such content can continuously provide valuable firsthand clues for enhancing the situational awareness of health providers and policymakers.

Introduction

Background

An online community is a social group created by internet users for a variety of purposes and interests. The rapid development of the "internet plus" [1] technology has further promoted the value of online communities in recent years. In the meanwhile, the health consciousness of populations and their motivation for better self-health management have been steadily growing. Propelled by the strong desire to mitigate the information asymmetry between doctors and patients pervasive in traditional health care communications, patients have gained a new way to share their disease situation and receive needed health care advice through online health communities (OHCs). For example, a continuously rising number of patients and their relatives continually participate in OHCs, actively share their treatment experiences, and openly express their personal opinions and feelings on various issues encountered during treatment or the whole care journey. The value of OHCs for exchanging emotional communications and delivering social support for patients and their families has also been widely recognized [2]. At present, an increasing multitude of user-generated content (UGC) and associated online user behaviors are becoming available on OHCs. The US Office of the National Coordinator for Health Information Technology defines patient-generated health data as health-related data created, recorded, or gathered by or from patients (or family members or other caregivers) to help address a health concern [3]. The Chinese National Health Commission publicly released an Action Plan for the Further Improvement of Medical Services (2018-2020), which emphasizes the role of patient organizations in knowledge sharing, whole-course disease management, rehabilitation support, drug development, and clinical trials [4]. However, such UGC in Chinese OHCs and their associated user behaviors are often underexplored and rarely analyzed systematically, thus losing valuable clues and evidence for improving treatment design and patient care.

Status of Research Concerning OHCs

A number of OHCs exist, providing users with diverse and fluent ways to exchange information, share experiences, seek answers, and receive support. PatientsLikeMe is the first and also the largest social network platform in the world dedicated to patients. By 2018, more than 650,000 users had communicated and shared their health information over the platform, with more than 2900 diseases involved [5]. MyHealthTeams [6] is a social network for people living with chronic diseases, which aims to provide mutual aids for its participants, and has gathered more than 2 million users spread over 33 online disease platforms. Several OHCs, such as Breastcancer [7] and BecomeAnEX [8], are also popular among patients. In China, Manyoubang [9] provides an interactive OHC for patients with chronic diseases, which has more than 22 subforums. Yi Xiang Network [10] is the largest case sharing website in China, providing services, such as case upload, communications, and mutual assistance, for patients. Mijian [11] is the largest interactive OHC for patients in China at the time of writing this manuscript, which integrates multiple single disease forums with interactive question and answer functions. Other OHCs in China, such as Sweet Home [12] and Lymphoma Home [13], mainly focus on servicing patients with chronic conditions. Meanwhile, in some general-purpose Chinese online forums (eg, Tianya [14], Tieba [15], and Zhihu [16]), there are also subforums specifically dedicated to disease-centric discussions.

Since the emergence of versatile OHCs, scholars have attempted to analyze these virtual communities from various perspectives. For example, Smailhodzic et al [17] conducted a literature review covering 22 articles, according to which, patients' use of social media were classified into the following 6 categories: emotional, information, esteem, network support, social comparison, and emotional expression. Dongxiang [18] overviewed OHCs in China from 3 perspectives, including their UGC, and the characteristics of participants and underlying online communities. Wu et al [19] summarized research hotspots concerning OHCs and the evolution of OHCs, as well as the key analysis methods for OHCs. To reveal factors that may motivate knowledge sharing in OHCs, scholars utilized text mining to better understand and predict user participation [20,21]. Fernandes et al [22] adopted a netnography method to analyze the positive impact of OHCs on the prognosis of diabetes. Li [23] utilized the structural equation model to study factors affecting individual patient's willingness to share medical information. Scholars also studied the distribution of health topics according to questions and answers on OHCs using machine learning approaches [24-27]. In addition, scholars utilized social network analysis methods to analyze knowledge exchange behaviors among users in OHCs by constructing and examining underlying knowledge-sharing networks [28-33].

Overall, existing research on OHCs has mainly focused on uncovering users' motivation for participating in the OHCs, discussing factors affecting users' online knowledge-sharing behaviors, and mining UGC in OHCs. For Chinese OHCs, existing research primarily concentrates on examining small-scale single-disease forums. In comparison with peer international studies, both the breadth and depth of current analysis regarding Chinese OHCs are much more limited, calling for expanded efforts to broaden the understanding and strengthen preliminary findings produced through existing studies. To meet the demand and fill the gap, this study comprehensively examined 3 representative disease forums hosted on the 2 most popular Chinese OHCs. The large-scale evaluation reveals both the shared traits and distinct characteristics of user behaviors and UGC on these forums to shed light on understanding user behaviors and UGC on Chinese OHCs in general.

Objectives

Given the popularity and proliferation of OHCs, understanding multifaceted patient experiences reflected from UGC in these forums and related user behaviors can provide many valuable

insights for enhancing public health awareness and improving the quality of the care delivered. Comprehensive and in-depth analysis of such user content and behaviors can also help optimize the design and management of OHCs from a software engineering perspective, as well as the design and development of better community-based knowledge services at large. Driven by the above anticipated benefits, this study performed an in-depth analysis on UGC and related online user behaviors in 3 large-scale OHCs in China. We utilized a variety of social network analysis methods and constructed a knowledge-sharing network for each OHC to study the evolution of OHCs, discover characteristics of user behaviors, uncover salient topics and their relations in each of the virtual communities, and reveal common traits and distinct characteristics in the 3 OHCs examined. Through these case analyses, we also aimed to offer insights regarding user behaviors and UGC in Chinese OHCs in general.

Methods

Data Collection

Two influential OHCs in China, Mijian and Sweet Home, were selected for analysis in this study. Mijian was selected for analysis in this study because it is the largest OHC for patients in China at present. The site targets to serve patients diagnosed with chronic, severe, or rare diseases, aiming to help relieve their psychological stresses, learn disease-related health knowledge, and effectively acquire medical resources. Sweet Home was selected for analysis in this study because it is the largest OHC in China for patients with diabetes. The site offers categorized forums for medical consultation, service guidance, and emotional expression. Through the site, patients with diabetes can not only discuss their medical conditions, but also connect and communicate remotely with other patients across the country. Regarding the 2 focus OHCs identified in this study, our analysis concentrated on examining the lung cancer forum (LCF) and breast cancer forum (BCF) on Mijian, and the diabetes consultation forum (DCF) on Sweet Home in particular because of their predominant popularity among users of the 2 OHCs and the significance of the 3 diseases for the well-being of Chinese patients and the population as a whole given that breast cancer and lung cancer represent the 2 leading chronic noncommunicable diseases in the world and China has the largest number of patients with diabetes globally [34,35].

In a disease forum, a single conversation is referred to as a "thread" (ie, a topic). Users can respond to another person's thread, which is referred to as a "reply." Thus, a post made by a user on a forum can either be an original thread created by the user or a reply to another user's thread [36]. We crawled all threads on the 3 focus disease forums from their respective forum establishment dates (LCF: November 15, 2013; BCF: August 25, 2015; DCF: September 1, 2005) to October 20, 2020. Once a post was crawled, we also obtained its ID, posting time, number of reads, and number of replies. We then performed a series of data cleaning operations, including filtering posts automatically created by chatbots on these forums and deleting missing data. Table 1 presents key statistics of the acquired online data sets in comparison with those of data sets used in peer studies [20,24,26,28,30,37,38], which shows that the scale of the current analysis significantly transcends that of all prior efforts.

Table 1. Comparison between experimental data sets analyzed in this study and the counterpart data sets in peer studies.

Study	Website	Forum	Number of threads	Number of users	Number of replies
Present study	Mijian [11]	Lung cancer forum	37,090	22,610	254,687

Social Network Analysis

A social network is a social structure made up of a set of social actors (such as individuals and organizations), sets of dyadic ties, and other social interactions between actors [41]. Social network analysis can help identify community structures at the network level, as well as individual behaviors at the single-user level. Since a user could be both a thread author and a reply author, this study adopted a directed network structure to model the community network. In such a directed network, each edge

of the network is directional, where the in-degree of a node refers to the number of directed edges ending with the node. Conversely, the out-degree of a node is the number of directed edges starting from the node. The total degree of a node is the total number of its network neighbors irrespective of the tie direction (ie, the sum of its in-degree and out-degree).

We conducted a topological analysis for complex networks [41] to explore the structural characteristics of each forum. Our analysis was carried out in 2 steps. First, we explored the small-world effect of each social network. We took the path length between 2 nodes as the minimum number of edges connecting these nodes in the network. The average path length, also known as characteristic path length, is defined as the average number of steps along the shortest paths for all possible pairs of network nodes. Let d_{ij} denote the shortest distance between 2 nodes i and j in the network. Assume that $d_{ij}=0$ if $i=j$ or j cannot be reached from i. Then, the average path length L is as follows:

where N is the number of network nodes. The clustering coefficient of a network measures the degree of node clustering in the network. Assume a node k has n adjacent neighboring nodes (N_1, N_2, …, N_n). If 2 nodes i and j are connected with a link, the directed link is denoted as e_{ij}. The local clustering coefficient of the node k is defined as follows:

Assume the entire network has K nodes in total. The average clustering coefficient of the network is the mean of the clustering coefficients of all its nodes, that is,

The small-world effect, also known as the 6 degrees of separation, is the idea that all strangers can be related through 6 or fewer people [42]. Watts et al proposed a small-world network model (WS model) [43], in which a small-world network is characterized by a small average path length and a high clustering coefficient. As a general method for quantifying the small-world effect of a network, the network can be measured by comparing its clustering coefficient and average path length with those of an equivalent Erdös–Rényi (ER) random network that has the same number of nodes and edges [44]. To construct such an equivalent random network, we employed the following generative procedure: Let N and M be the number of nodes and edges expected of the network to be generated, respectively. The network is initialized to have N unconnected nodes. At each step, we randomly selected and linked a pair of nodes not currently connected in the network. We repeated the above step until all M edges were added into the network. Given the random network generated, σ can be calculated as follows:

where  is the average clustering coefficient of the network, L is the average path length of the network, C_r is the average clustering coefficient of the equivalent ER random network, and L_r is the average path length of the equivalent ER random network. If $\sigma>1$ (eg, ), the network is considered a small-world network [44], in which case, it is assumed that knowledge can be spread efficiently and rapidly in the community represented by the network.

Second, we explored the scale-free property of social networks. Scale-free property is a structural characteristic concerning a network as introduced by Barabási et al [45]. Across scientific domains and classes of networks, it is common to encounter the claim that most or all real-world networks are scale free. Generally, a network is deemed scale free if the fraction of nodes with degree k follows a power-law distribution $P(k)=c\times k^{-r}$, where $r>1$. The property mainly comprises the following 2 aspects. First, the distribution of nodes follows a power-law distribution, where most nodes have few links, while a small fraction of nodes has a large number of links. In a power-law distribution, the probability that a node has degree k follows the distribution equation $P(k)=c\times k^{-r}$, where c and r are network-specific constants. It is generally believed that if the degree of nodes in a network follows a power-law distribution, the network is a scale-free network. Second, during a network growth process, new nodes preferentially establish relations with well-connected nodes. The scale-free network model is also commonly referred to as the B-A model [45].

Weighted Knowledge Network

Topic analysis techniques can be leveraged to extract conceptual topics, determine their types, and analyze their internal structures latent in a large text corpus. In this study, we analyzed health topics on OHCs to identify hot topics and the salient health information needs of their users.

We executed the topic analysis in 2 steps. First, we extracted key phrases among UGC according to point-wise mutual information (PMI), as well as the left and right information entropy, with which the co-occurrence relationship between words can be efficiently found. In this step, mutual information is mainly used to measure the degree of correlation between 2 signals according to information theory [46], which is repurposed to measure the degree of interdependence between 2 variables. In natural language processing (NLP), PMI is used to calculate the degree of correlation between 2 words, so that the co-occurrence of words can be found from a statistical perspective to examine whether any semantic correlation or thematic correlation exists between a pair of words. The PMI of 2 adjacent words x and y is computed as follows:

where $p(x)$ is the probability of word x appearing in all threads, that is, $p(x)$=the number of occurrences of word x / the total number of words in all threads; $p(y)$ is the probability of word y appearing in all threads, that is, $p(y)$=the number of occurrences of word y / the total number of words in all threads; and $p(x,y)$ is the joint probability of x and y, which is the

probability that 2 words (x,y) appear adjacent to each other in the text. A higher PMI of x and y is associated with higher internal aggregation and greater possibility of the 2 words forming a phrase. Conversely, those 2 words are more likely to have phrasal boundaries.

Entropy is an uncertainty measure associated with a random variable. A higher entropy is associated with greater underlying information content and hence higher uncertainty [47]. In NLP, the left and right entropy of the word W are defined as follows:

where E_L and E_R are the left entropy and right entropy of the word W, respectively; A and B represent the sets of all words appearing to the left and right of W, respectively; and a and b represent the words appearing immediately on the left and right sides of W, respectively. Greater left or right entropy is associated with a higher degree of freedom of the word, which indicates more abundant choices for a target word surrounding the given word W.

Second, we treated a keyword as a node and the co-occurrence relationship between a pair of keywords as an edge to construct a weighted knowledge network (WKN) [37,48]. In the process, we also assigned weights to the nodes and edges according to weights of the corresponding keywords and the relationship strength between the corresponding key phrases. The WKN integrated and modeled fragmentation knowledge of the thematic content, which can be used to effectively discover the internal relationships and overall characteristics of a knowledge network. More specifically, we summed the PMI value of the left entropy and right entropy calculated above, which was used as a measure of 2 words as a phrase. We then extracted key phrases in each post and their respective weights where the frequency of a key phrase is used as the weight of the key phrase. We define E as the keywords co-occurrence set and $Q(E)$ as the weight set associated with E, as follows:

In the above equations, if keywords k_i and k_j formulate a key phrase, as indicated by a co-occurrence relationship between them in the WKN, then e_{ij}=1; otherwise, e_{ij}=0. $q(e_{ij})$ is the weight of e_{ij}. $q(e_{ij})=n(e_{ij})/N$, where $n(e_{ij})$ is the number of occurrences of a key phrase in all phrases and N is the total number of all phrases. Next, all detected key phrases were organized as a keywords set K, for which an associated keyword weight set $Q(K)$ was introduced as follows:

where k_i is a keyword and $q(k_i)$ is its weight. $q(k_i)=m(k_i)/M$, where $m(k_i)$ is the number of occurrences of a keyword k_i in the 200 key phrases and M is the total number of all keywords in the 200 key phrases.

Now, we can define a WKN model for the concerned OHC as follows:

According to the constructed WKN model, the results can be displayed by social network visualization tools.

Results

Descriptive Statistics

Table 2 presents descriptive statistics of the OHC data analyzed in this study where extreme outliers were removed during the preprocessing. In terms of the number of reads and replies per thread, the data distribution was severely nonuniform. In other words, most of the threads had fewer reads and replies, and only a few threads got a large number of reads and replies, which meant that most users preferentially read the threads that had received a larger number of replies, thus resulting in the polarization. The SD is a measure of the amount of variation or dispersion of a set of numbers, which is also affected by the volume of data analyzed. The coefficient of variation is a statistical measure of the dispersion of data points around the mean of a data series. The coefficient of variation of the general normal distribution is less than 1. Considering the large coefficient of variation for each attribute listed in Table 2 and according to the skewness of the frequency distribution graph (SK_L=35.41, SK_B=25.65, and SK_D=12.45), we concluded that none of them follows a normal distribution.

Table 2. Statistical characteristics of the 3 data sets analyzed in this study.

[a]CV: coefficient of variation; CV=SD/mean.

Next, we plotted the frequency distribution of the number of reads per thread in each forum, as shown in Figure 1. We also adopted the K-S test (H_L=0, H_B=0, and H_D=0), from whose results we can determine that the number of reads per thread follows the gamma distribution [49]. When we plotted the frequency distribution of the number of replies per thread, we found that they exhibited an obvious long-tail phenomenon, which suggests that the number of replies per thread follows the power-law distribution. We further found that the log-log distribution of the number of replies per thread was noticeably curved, as shown in Figure 2, according to which we determined that the number of replies per thread follows an exponential distribution. The values of all fitted exponential curves were above 0.94 (=0.946, =0.958, and =0.971). Through similar analysis procedures, we further found that both the number of threads a user is involved with (=0.978, >=0.964, and =0.970) and the number of followers of a user (>=0.989, =0.962, and =0.990) followed the power-law distribution, and the values of all fitted power-law curves were above 0.96.

Figure 1. The distribution of the number of reads per thread in each of the forums (lung cancer, breast cancer, and diabetes consultation). For better visualization, the horizontal axis only shows the number of reads per thread up till 5000, since such threads hardly exist.

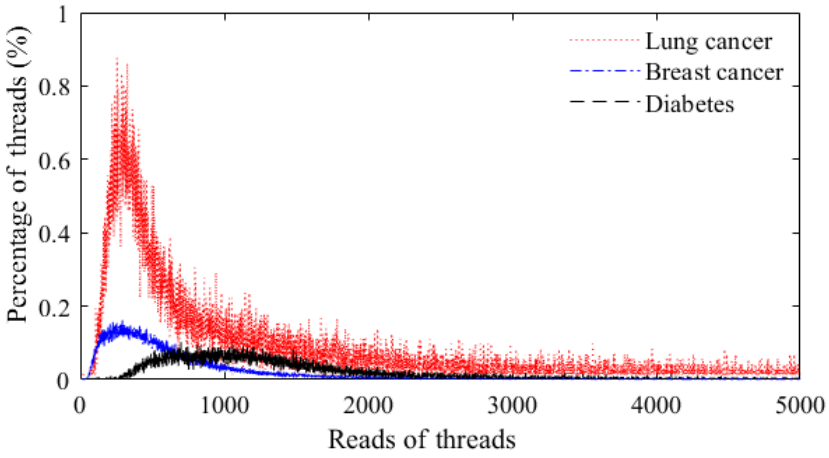

Figure 2. The log-log distribution of the number of replies per thread in each of the forums (lung cancer, breast cancer, and diabetes consultation).

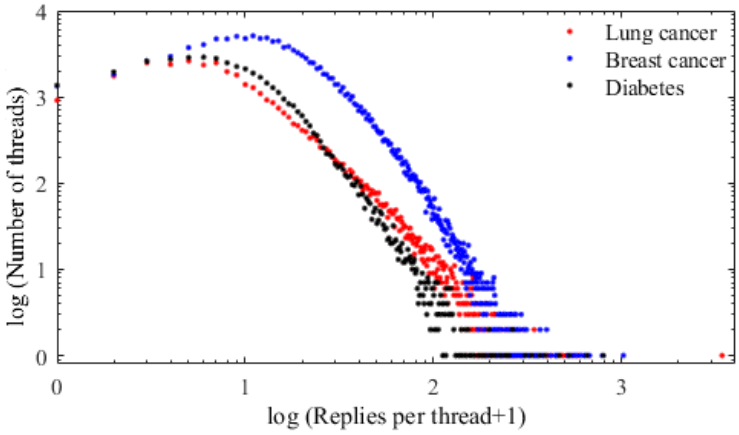

User Activities

We explored key user activities on each forum. To understand user stickiness in a community, we analyzed online user activities. Community managers can adopt different strategies and incentives to improve their user experiences based on the behaviors of these users. Figure 3 shows the percentage of all posts (threads plus replies) created on each day of the week. These forums had similar trends, especially between the LCF and DCF. Besides, most online question and answer communities or vertical knowledge sharing communities are more active on weekdays than weekends, presumably due to users' conscious work-life balance choices. By counting the frequency of posting for each day of the week by month and drawing a box plot, it can also be seen that users in the LCF and DCF post more frequently during the week and are more active during the week than on the weekend (Multimedia Appendix 1). The same conclusion was found in nononline health communities such as the DISboards [36,50] and Tianya community [15,51].

Figure 3. Percentage of all posts on each day of the week.

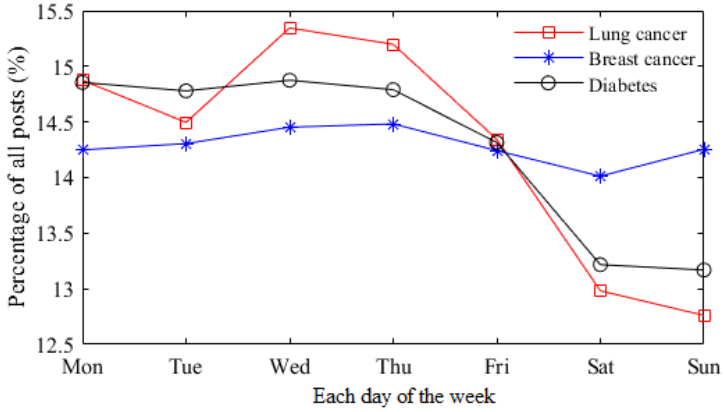

Figure 4 shows the percentage of threads and replies created at each hour of the day. In each forum, the number of posted threads and replies increased significantly from 4 AM. In terms of the posting time of each thread, the number of posted threads in the BCF had a peak around 8 AM, which declined in the middle of the day, followed by a second peak around 9 PM. Both the LCF and DCF showed 3 peak posting moments at around 10 AM, 4 PM, and 9 PM, with their least active posting moment at around 6 PM. Furthermore, there was high similarity (ρ=0.927; P<.001) between the LCF and DCF in terms of the relative thread posting frequencies during each hour of the day. The numbers of posted threads among the 3 disease forums around 12 PM and 6 PM were less than those at other moments in the day, presumably due to the common lunch and dinner hours observed for the 2 moments of the day. Most users became active from 7 PM after dinner, and activity peaked again at 9 PM, after which the number of posted threads gradually declined as it approached bedtime. We also found that the number of posted threads in the LCF and DCF peaked around 2 or 3 hours before the Chinese mealtime (12 PM and 6 PM), likely because diabetic patients pay more attention to their diet to control blood glucose. Similarly, lung cancer affects the digestive function of patients, which may cause decreased appetite. Especially in the advanced stage of lung cancer, it is indispensable to control and adjust the diet. Therefore, most users consulted about diet in advance, leading to a significantly increased number of posted threads. Due to the different dietary behaviors of breast cancer patients and those of patients with the other 2 diseases, the active posting periods of the BCF were different from those of the other 2 forums. In terms of the posting time of replies, we found that the relative frequencies of posting for threads and replies during each hour of the day were highly positively correlated in each forum. Table 3 shows the Spearman correlation test results. Similarly, the least numbers of replies were posted at around 12 PM and 6 PM, and this was also due to their overlap with common mealtimes.

Figure 4. Percentage of threads (A) and replies (B) at each hour of the day.

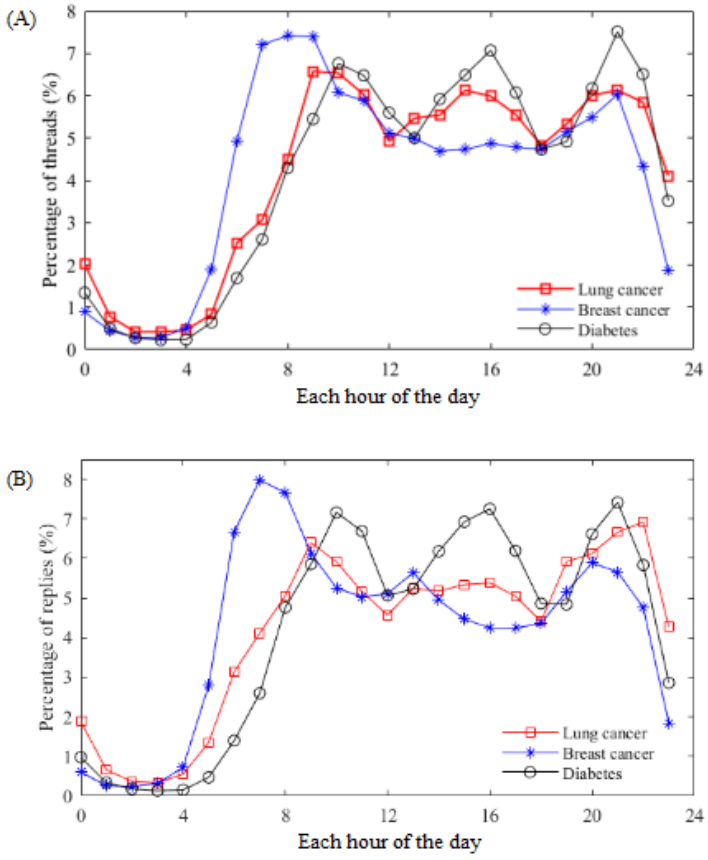

Table 3. Spearman rank correlation coefficients of the relative frequencies of posting for threads and replies during each hour of the day in each forum.

Forum	ρ	*P* value
Lung cancer forum	0.911	<.001[a]
Breast cancer forum	0.914	<.001[a]
Diabetes consultation forum	0.976	<.001[a]

[a]Significantly correlated using the significance level of .01 (2-tailed test).

Social Network Structure

The social network structure graph visually presents the node relationship matrix of the network [41]. Table 4 shows the characteristics of the aggregated social network based on users' reply postings on each forum. In the structure graph, each node represents a user in the community, and edges are directed links formed by replies between users. The average clustering coefficient of all 3 forums was lower than those of Facebook (0.519), Flickr (0.313), and LiveJournal (0.330) [52]. A higher global clustering coefficient indicates that there was a closer connection between users where friends tend to find each other through their mutual friends [36]. In a network, user degree is the sum of out-degree and in-degree of a user. In our data set, all users had at least one thread due to the crawling strategy used at the time of data acquisition. In the LCF, 39.7% (8968/22,610) of users had a user degree of 1; in other words, more than 39% of users only had a post. In the BCF, 51.4% (15,886/30,901) of users had a user degree of 1, and in the DCF, 24.7% (6604/26,751) of users had a user degree of 1. Most users had a relatively lower degree, while only a few users had higher degrees. Figure 5 shows the user degree distribution in each forum, from which we visually noticed that the degree distribution of each forum follows the power-law distribution. To quantitatively verify this finding, we treated the number of user degrees as an independent variable and the number of users as a dependent variable to fit a power-law curve. The resulting fitted curves were $y=3.571x^{-1.330}$ (R^2=0.9976) for the LCF, $y=3.253x^{-1.056}$ (R^2=0.9946) for the BCF, and $y=3.873x^{-1.445}$ (R^2=0.9683) for the DCF. The fitting degree of the power-law curves for each forum was nearly perfect, indicating that the distribution of user degrees on each forum follows the power-law distribution and $r>1$, which further shows that the underlying social network is a typical scale-free network. Many studies have reached the same conclusions that other OHCs [20,29,53], such as Facebook [52] and Weibo [54], are also typical scale-free networks. We additionally calculated the average clustering coefficient and the average path length of

the equivalent ER random networks for each forum. We randomly generated 50 sets of equivalent ER random networks, calculated σ according to equation (4), and calculated the mean value of 50 sets of σ as the final judgment coefficient. The final calculation results showed that all were far greater than 1 (=517.15, SD_L=13.31; =275.23, SD_B=13.02; and =525.18, SD_D=14.38), demonstrating that all 3 forums exhibited the small-world effect.

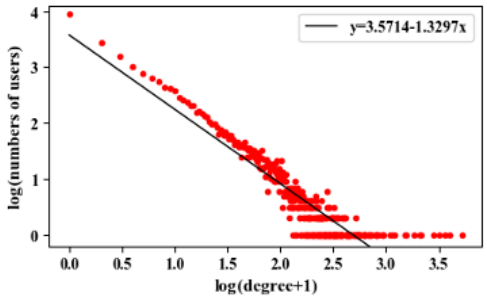
Table 4. Characteristics of each aggregated social network.

Characteristic	Lung cancer forum	Breast cancer forum	Diabetes consultation forum
Number of nodes	22,610	31,909	26,751
Number of edges	183,175	739,620	223,077
Average node degree	8.10	23.179	8.34
Network diameter	10	8	11
Average clustering coefficient	0.130	0.179	0.130
Average path length	3.494	3.011	3.967
Percentage of high-degree users[a]	3.1% (697/22,610)	9.1% (2906/31,909)	2.6% (697/26,751)
Percentage of low-degree users[b]	66.6% (15,050/22,610)	67.0% (21,382/31,909)	49.3% (13,057/26,751)

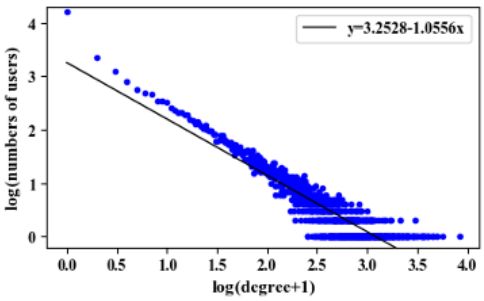
[a]Percentage of users with degrees higher than or equal to 100.

[b]Percentage of users with degrees lower than or equal to 5.

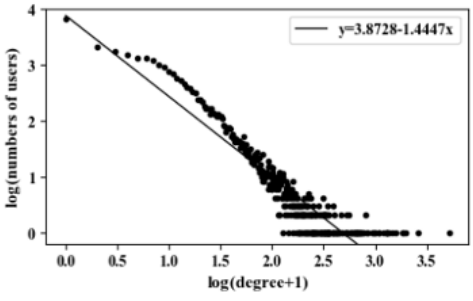
Figure 5. The total degree distribution of users for each of the aggregated social networks. (A) Lung cancer forum (LCF); (B) Breast cancer forum (BCF); (C) Diabetes consultation forum (DCF).



(A) LCF: y=3.5714-1.3297x



(B) BCF: y=3.2528-1.0556x



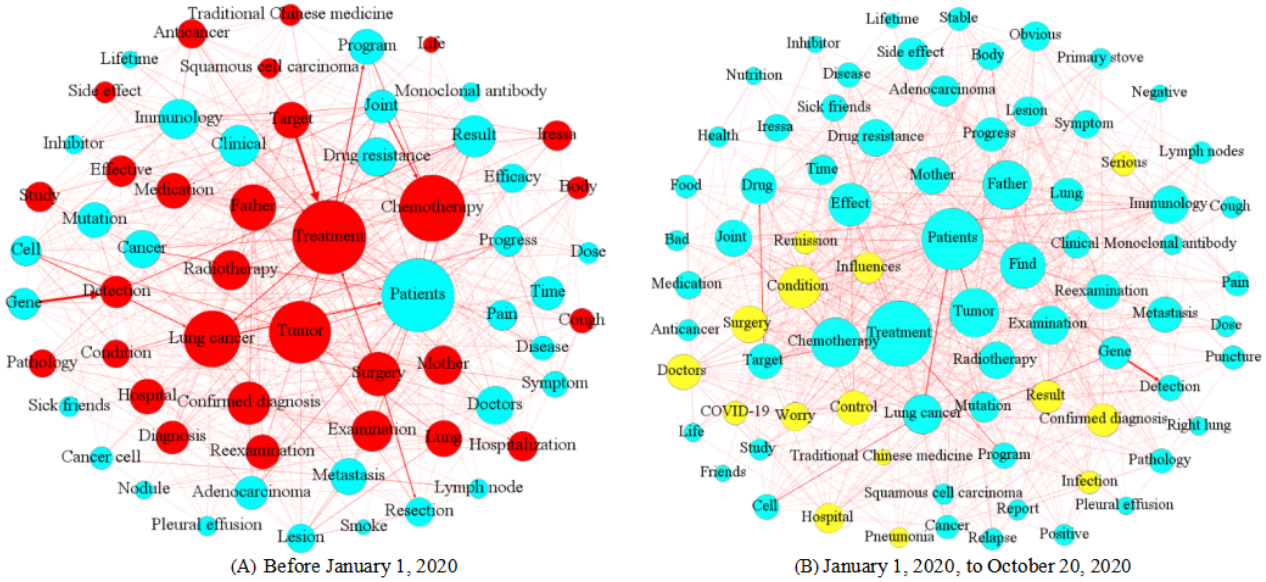
(C) DCF: y=3.8728-1.4447x

Next, we analyzed the dynamic evolution characteristics of the 3 social networks from their initial establishment days (LCF: November 15, 2013; BCF: August 25, 2015; DCF: September 1, 2005) to 2020 (Multimedia Appendix 2). The results indicated that the numbers of nodes and edges increased yearly since the creation of the LCF. With the development of the community, the number of users was gradually increasing accompanied by more active user behaviors. Since the establishment of the BCF in 2015, its number of nodes has been increasing yearly, indicating that new users constantly join the forum. In the meanwhile, the number of edges in the network increased in the beginning and reached a peak in 2017, and then declined afterwards. Such a trend line shows that the disease forum reached its most active period in 2017. Since the creation of the DCF back in 2005, the numbers of nodes and edges of the forum had been steadily increasing until its peak in 2015, after which the activity of the community continuously declined, in particular between 2018 and 2019. The "sleeping rate" or "loss rate" of users in the forum was noticeable. More concretely, the number of nodes active in 2019 was 21% (943/4510) of that in 2015, while the number of edges active in 2019 was only 5% (2731/55,741) of that in 2015, and both statistics indicate an apparent recession phase of the forum.

Analyzing UGC Using WKNs

Due to the COVID-19 outbreak in 2020 and its likely impact on user behaviors on OHCs, we divided our observation window into 2 periods (one before January 1, 2020, and another afterwards). By comparing user behaviors between these 2 periods, we analyzed whether the UGC changed notably due to the disease outbreak. We extracted the first 200 key phrases from the UGC of each of the 3 forums. In the preprocessing, we first filtered away keywords with no factual information according to peer literature, as well as merged synonym keywords [25,37]. For each forum, we subsequently constructed its corresponding WKN according to the construction method of the WKN model discussed above. Figures 6-8 show the resulting WKNs for each forum (Multimedia Appendix 3 for the detailed pictures). A larger node of a keyword in the WKN is associated with a greater weight of the keyword, implying more attention received by the keyword. Applying the criterion, we detected significant keywords in each forum, for example, the keywords "treatment" and "chemotherapy" in the LCF, according to Figure 6A. A darker color of the connection link between 2 keywords was associated with a higher co-occurrence frequency between these keywords. For example, the keyword "target" most frequently co-occurs with the keyword "treatment" in the LCF; thus, the connection link between these nodes has the darkest color in the forum's corresponding WKN as shown in Figure 6A. The dense connection of a keyword indicates that the keyword co-appears with many other keywords in a sentence, for example, the keywords "treatment" and "patients" in the LCF, according to Figure 6A.

Figure 6. Two separate weighted knowledge networks constructed for the lung cancer forum for the analysis phases (A) November 15, 2013, to January 1, 2020, and (B) January 1, 2020, to October 20, 2020.



There were 8 major categories of theme feature classification strategies, namely, "etiology and pathological knowledge," "diagnosis and examination," "treatment," "disease management," "complications," "social life," "disease prevention," and "education and research," based on the classification of OHC information in PubMed literature [55]. According to these 8 classification strategies, the classification categories of the keywords of the 3 disease forums were judged, and the topic distribution was macroclassified, so as to determine the hot topics discussed in the content more clearly and quickly. There were 400 keywords in the 200 key phrases. In the LCF, the topic "disease treatment" (145/400, 36.3%) included keywords such as "treatment" and "chemotherapy;" the topic "examination and diagnosis" (118/400, 29.5%) included keywords such as "examination," "confirmed diagnosis," and "detection;" and the topic "social life" (38/400, 9.5%) included keywords such as "sick friends" and "life." In the BCF, the topic "disease treatment" (128/400, 32.0%) included keywords such as "treatment" and "chemotherapy;" the topic "examination and diagnosis" (119/400, 29.8%) included keywords such as "examination" and "confirmed diagnosis;" and the topic "social life" (58/400, 14.5%) included keywords such as "sisters,"

"foods," and "sport." In the DCF, the topic "disease treatment" (155/400, 38.8%) included keywords such as "control," "treatment," and "injection;" the topic "examination and diagnosis" (115/400, 28.8%) included keywords such as "examination," "confirmed diagnosis," and "hyperglycemia;" and the topic "social life" (31/400, 7.8%) included keywords such as "foods," "sport," and "sick friends." It can be concluded that the 3 forums had "disease treatment," "examination and diagnosis," and "social life" themes. However, we noticed that topics related to disease prevention were rarely discussed in all 3 forums. Table 5 shows the top 10 keywords appearing in each forum, which primarily focused on disease treatment and diagnosis. Given the fact that target users of Mijian are patients after diagnosis, users of the forum tend to discuss topics on disease treatment and examination more frequently. More specifically, in both forums on Mijian (LCF and BCF) users generally paid more attention to topics on disease reexamination, metastasis, recurrence, anticancer drugs, and drug side effects. In both the BCF and DCF, users paid more attention to topics on healthy diet, exercise, and disease management.

Table 5. Top 10 keywords in each of the 3 forums.

Period	Lung cancer forum top keywords	Breast cancer forum top keywords	Diabetes consultation forum top keywords
Before January 1, 2020	Treatment, patients, chemotherapy, tumor, lung cancer, father, mother, confirmed diagnosis, surgery, and examination	Breast cancer, patients, treatment, tumor, chemotherapy, cancer, surgery, influences, examination, and metastasis	Blood glucose, control, insulin, fasting, treatment, normal, examination, diabetes, patients, and detection
January 1, 2020, to October 20, 2020	Treatment, patients, chemotherapy, tumor, find, father, effect, mother, lung cancer, and condition	Breast cancer, patients, treatment, tumor, chemotherapy, find, influences, increase, surgery, and examination	Blood glucose, control, insulin, fasting, treatment, normal, examination, diabetes, patients, and detection

According to Figure 6A, hot topics on the LCF before January 1, 2020, mainly concentrated on lung cancer treatment, examination and diagnosis, and social life. The most salient topic on the LCF was disease treatment, because this topic had the greatest weight. This category mainly focused on topics including keywords such as "lung cancer treatment," "chemotherapy," "surgical treatment," "drug treatment," and "treatment effect." The most relevant topics for treatment were examination and diagnosis, including keywords such as "lung pain" and "cough symptoms," indicating that users discussed examination and diagnostic contents, as well as the treatment of lung cancer. Ego networks consist of a focal node known as the ego, and the nodes to whom the ego is directly connected to, called alters, with edges showing links between the ego and altars or between altars. Each alter in an ego network can have its own ego network, and all ego networks combine to form the social network. The red nodes in Figure 6A formulate 2 ego networks for the keywords "father" and "mother." We found co-occurrence relationships among the keywords "mother," "father," "confirmed diagnosis," "reexamination," and "surgery," and they appeared in the same thread, implying that many users were probably children who consulted and communicated online health information for their parents. In the BCF, the hot topics before January 1, 2020, mainly focused on factors such as breast cancer treatment, social life, examination and diagnosis, and disease management, as shown in Figure 7A, and users mainly focused on breast cancer treatment and chemotherapy, such as endocrine therapy and treatment effects. The green nodes in Figure 7A formulate an ego network for the keyword "children." We found the keywords related to "result," and "health" was associated with "children." Due to the particularity of breast cancer, patients considered some special factors such as the health status of the next generation. Different node colors were used to more clearly distinguish the ego network of a particular keyword. Since the ego networks of other nodes do not have obvious characteristic results, only the ego networks of nodes with characteristic results are discussed in the paper. In the DCF (Figure 8), the UGC mainly concentrated on topics like diabetes control and management, disease treatment, examination and diagnosis, and social life, including keywords such as "blood glucose control" and "diet control." Meantime, the examination and diagnosis of diabetes were mostly related to disease management. In Figures 6B and 7B, yellow nodes formulate the ego network for the keyword "COVID-19," relating to keywords such as "infection," "remission," "confirmed diagnosis," and "influences." Cancer patients represent one of the susceptible populations of COVID-19, who are more vulnerable to COVID-19 complications [56] and prone to experience severe events on exposure to COVID-19, such as admission to an intensive care unit or death. Thus, they should pay more attention to self-protection and social distancing. Since 2020, both in the LCF and BCF, users tended to mention COVID-19–related matters while discussing their medical issues. Meanwhile, the relative mention frequencies of other key topics did not change noticeably. Given that there were only a few threads (only 130 threads) posted on the DCF after 2020, no clear thematic change was observed to draw any qualitative conclusions regarding the response of its participants to COVID-19. Thus, no distinction was made.

Figure 7. Two separate weighted knowledge networks constructed for the breast cancer forum for the analysis phases (A) August 25, 2015, to January 1, 2020, and (B) January 1, 2020, to October 20, 2020.

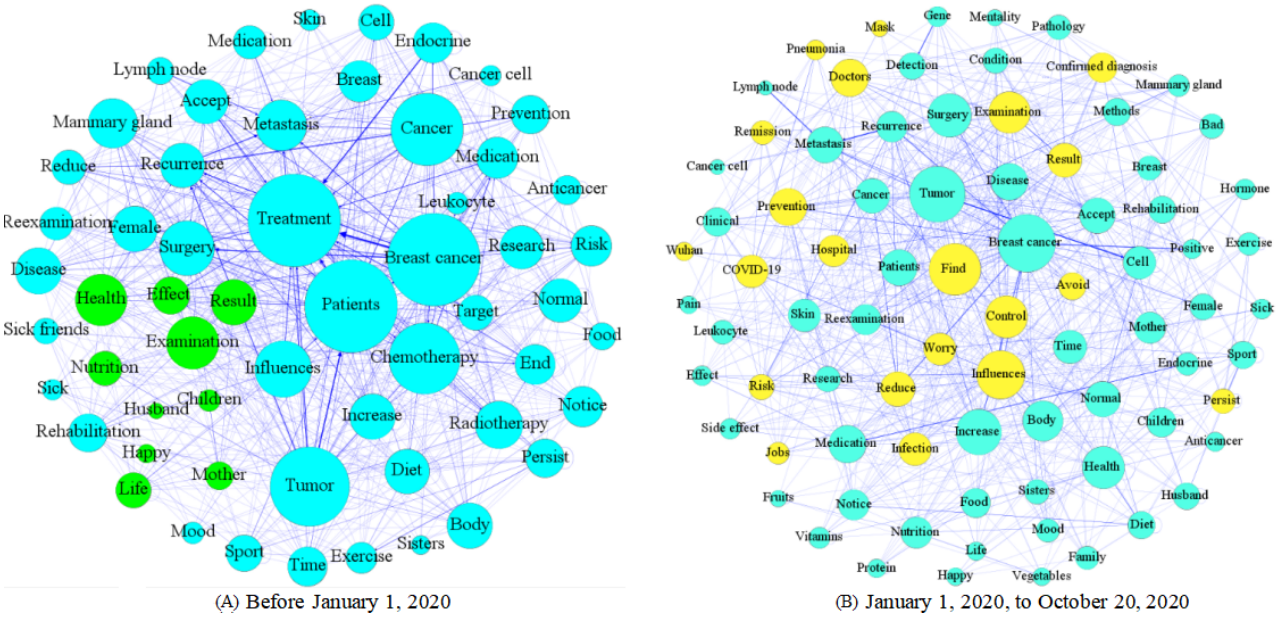


Figure 8. The weighted knowledge network constructed for the diabetes consultation forum during its full duration (September 1, 2005, to October 20, 2020).

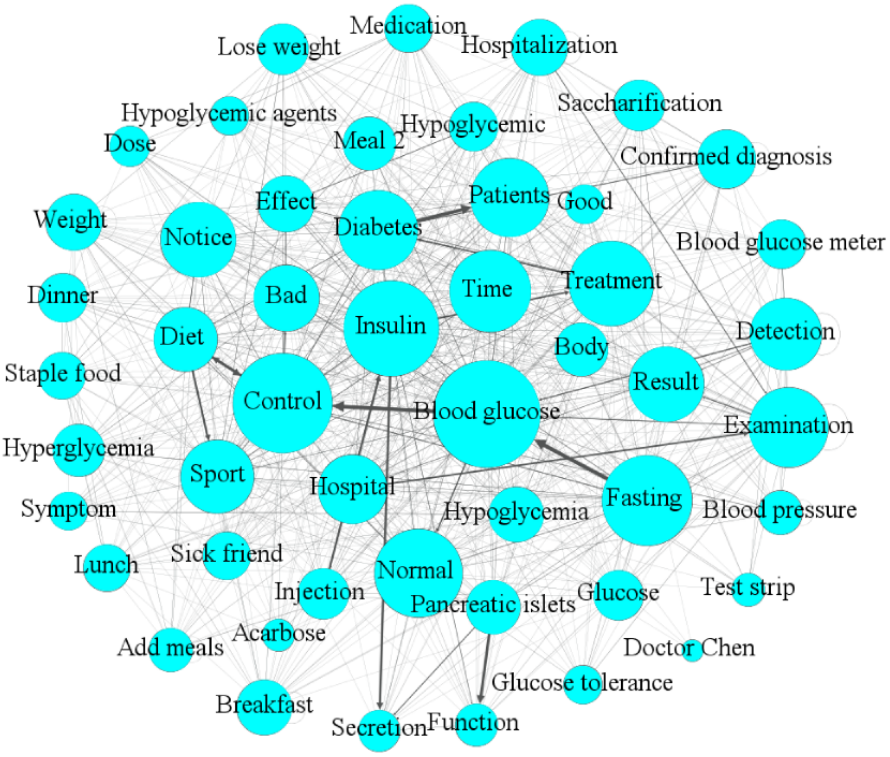

Discussion

Principal Findings

This study carried out an in-depth analysis of the UGC and related online user behaviors of 3 large-scale OHCs in China. We utilized a variety of social network analysis methods and constructed a knowledge-sharing network for each OHC to study the evolution laws of the corresponding online community, discover characteristics of user behaviors, and uncover salient topics and their relations shared in the virtual community.

Since the existing research conducted on OHCs in China only examined a small-scale single disease forum, as shown in Table 1, that is, the number of data sets was less than 2000 threads and less than 10,000 replies [28,30,37,38], the scale was significantly smaller than that of analyses performed in Western countries [20,24,26], which severely undermines the reliability and comprehensiveness of the analysis findings. To meet the demand and fill the gap, we conducted thorough and extensive research on 3 representative disease forums selected from the 2 most popular Chinese OHCs. Over 80,000 users, 190,000 threads, and more than 2.8 million replies were crawled to reveal

the common traits and unique characteristics of user behaviors and UGC in these forums, which can better support our findings and represent the overall characteristics of OHCs in China. The results are discussed in detail below.

First, we found that the data of these 3 disease forums were polarized, and the underlying data distributions were certainly nonuniform. In these disease forums, the number of reads per thread followed gamma distribution (H_L=0, H_B=0, and H_D=0), and the number of replies per thread followed exponential distribution (=0.946, =0.958, and =0.971). However, the number of threads a user is involved with (=0.978, =0.964, and =0.970) and the number of followers of a user (=0.989, =0.962, and =0.990) both followed power-law distribution.

Second, users were more active during the weekdays than on weekends. The thread posting frequencies and reply frequencies in the abovementioned 3 forums had highly positive correlations between each other during each hour of the day. In particular, the LCF and DCF exhibited high temporal similarity (ρ=0.927; P<.001) in terms of the thread posting frequencies during each hour of the day. The numbers of threads and replies increased significantly from 4 AM, and the number of posted threads was relatively small in each forum around 12 PM and 6 PM. Because both lung cancer patients and diabetes patients need to pay attention to their diets, the number of posted threads in the LCF and DCF had a crest around 2 or 3 hours before the Chinese mealtime (12 PM and 6 PM).

Besides, the study showed that all 3 forums had the small-world effect (=517.15, SD_L=13.31, =275.23, SD_B=13.02, and =525.18, SD_D=14.38) and scale-free characteristics, and the user degrees followed the power-law distribution (=0.997, =0.994, and =0.968), while their global clustering coefficients were lower than those of international peer OHCs. According to the dynamic trends of the community networks, it was demonstrated that the LCF was still in the developing stage, the BCF needed to stimulate the activity of "zombie users," and the DCF needed to attract more new users and improve the retention rate of users.

Finally, we found that several hot topics were commonly shared among the abovementioned 3 disease forums, such as disease treatment, disease examination, diagnosis, and social life. The most relevant topics for treatment were examination and diagnosis, and many children consulted related information for their parents in the LCF. In the BCF, users paid more attention to the next generation's health, while in the DCF, users paid more attention to the detection of blood glucose and diet control. Furthermore, we noticed that in both the LCF and BCF, users tended to mention COVID-19–related matters while discussing their medical issues after the outbreak of the disease in 2020.

Limitations

There are few limitations in this paper. On one hand, although 2 influential OHCs in China (Mijian and Sweet Home) were selected for analysis in this study, the analysis results cannot be extended to all Chinese OHCs. On the other hand, this paper only focused on the characteristics of the overall social network structure, which did not distinguish the strong and weak connections between users and user roles. At the same time, this study only analyzed the topic content of 1 user, which did not consider replies or the topic type of a thread. Therefore, subsequent research should try to add weights to the connection edges between users to study the influence of users in social networks, or study the theme changes in different periods.

Conclusions

Our findings shed light on the basic characteristics of social networks, user behaviors, and UGC in Chinese OHCs. UGC in OHCs and related online user behaviors can be leveraged as an important source of information to gain insights on individual and population health conditions, which can be beneficial for users to understand hot topics in different forums and gain knowledge of health management. Despite the fact that OHCs are developing in China, it is indispensable to take measures to improve the retention rate and activity of users, increase user stickiness, analyze user behavior, and mine forum content themes. It is important to better mine potential content to provide users with useful information and knowledge. In conclusion, our research not only contributes to the understanding of the different characteristics of OHCs, but also helps to discover the salient topics and latent relations among these topics in each forum. Hence, effective, timely, and consistent mining and utilization of content can provide more valuable evidence for health providers and policymakers.

Abstract

Background: Medical blogs have become valuable information sources for patients and caregivers. Most research has focused on patients' creation of blogs as therapy. But we know less about how these blogs affect their readers and what format of information influences readers to take preventative health actions.

Objective: This study aimed to identify how reading patient medical blogs influences readers' perceived health risk and their intentions to engage in preventative health actions. Further, we aimed to examine the format of the medical blog and the reader's response.

Methods: We surveyed 99 university participants and a general-population, online panel of 167 participants. Both studies randomly assigned participants to conditions and measured blog evaluation, intentions for preventative health action, and evaluation of health risk and beliefs, and allowed open-ended comments. The second study used a different sample and added a control condition. A third study used a convenience sample of blog readers to evaluate the link between reading medical blogs and taking preventative health action.

Results: Across 3 studies, participants indicated a desire to take future preventative health action after reading patient blogs. Studies 1 and 2 used experimental scenario-based designs, while Study 3 employed a qualitative design with real blog readers. The 2 experimental studies showed that the type of blog impacted intentions to engage in future preventative health actions (Study 1: $F_{2,96}$=6.08, P=.003; Study 2: $F_{3,166}$=2.59, P=.06), with a statistical blog being most effective in both studies and a personal narrative blog showing similar effectiveness in Study 2, contrary to some prior research. The readers' perceptions of their own health risk did not impact the relationship between the blog type and health intentions. In contrast, in one study, participants' judgments about the barriers they might face to accessing care improved the fit of the model ($F_{2,95}$=13.57, P<.001). In Study 3's sample of medical blog readers, 53% (24/45) reported taking preventative health action after reading a health blog, including performing a self-check, asking a doctor about their health risk, or requesting a screening test. Additionally, these readers expressed that they read the blogs to follow the author (patient) and to learn general health information. All studies demonstrated the blogs were somewhat sad and emotional but also informative and well-written. They noted that the blogs made them appreciate life more and motivated them to consider taking some action regarding their health.

Conclusions: Reading patient blogs influences intentions to take future health actions. However, blog formats show different efficacy, and the readers' disease risk perceptions do not. Physicians, medical practitioners, and health organizations may find it useful to curate or promote selected medical blogs to influence patient behavior.

KEYWORDS

health blogs; patient blogs; preventative care; cancer; caregivers; perceived risk

Introduction

Background

Patients and caregivers rely on online blogs, social media posts, or online health communities to share information about their illness, treatment paths, or feelings about their condition [1]. Some share with a small circle of friends and family, while others make their blog posts public and shareable with a worldwide audience. Many studies have shown the therapeutic power that writing has for patients [2,3]. Some cancer organizations now even offer writing classes and activities for survivors [4], and many health care providers are writing blogs as well [5,6]. Comparatively less research has focused on the blog readers, however.

Over the years, the web has become more interactive and "participatory" with many peer-to-peer communication forms, such as social media, blogs, and wikis, making up much of what we do online [7]. Softwarefindr estimated there were over 505 million blogs online [8] in 2018. As of 2020, internet users create new posts every 0.5 seconds, while 77% of them say they read blogs regularly [9]. Though lifestyle topics are among the most popular categories [10], personal health and illness-related blogs have proliferated as many people go to the internet as their first source of health-related information [11].

As the Pew Internet Project explains, "peer-to-peer health care acknowledges that patients and caregivers know things—about themselves, about each other, about treatments—and they want to share what they know to help other people." We have a natural tendency to want to both seek and share information about our health, and technological advances have made this easier than ever [12]. The internet allows community interactions between individuals, including patients and caregivers, and it can be a resource for individuals to discover health information. Further, it has facilitated access to health information and emotional support [13,14]. Social media conversations also have proven effective in improving patient knowledge of their conditions and reducing anxiety [14], but research has demonstrated that individuals are more likely to consume social content instead of creating it [15]. In fact, while the internet has become more participatory, a relatively smaller group of "power users" contribute more than the average user [15].

Researchers studying cancer patient bloggers found that writing their own and reading other patients' stories affected these patients' perceptions of their illnesses and prognoses [16]. These cancer patients kept blogs to be remembered after their death, to release negative emotions and frustrations, and to share information about their experience with others, especially other patients. Additional research found that patients explore other patients' experiences, find community and belonging, and gain a sense of hope by reading and following survivor stories on social media [17-19]. A study of 5 women experiencing depression reported similar results, finding that the blogs helped the writers stave off feelings of seclusion, find community, and form bonds with readers [20]. Moreover, the author coined the term "narrative sandbox" to refer to these blogs as a "protected virtual space that allows bloggers to temporarily and experimentally add or remove different sections from their narrative" [20]. As such, these narratives are dynamic and changeable, with the blog readers becoming "active participants in the writing and rewriting of bloggers' depression narratives" [20].

Caregivers—usually parents of ill children, adult children caring for aging parents, or the patient's spouse—write many health blogs as well, and studies of cancer caregiving report the key motivations: "to report, explain, express, reflect, archive and advocate" [21]. Thus, these parent blogs provide information to readers by reporting events and explanations of medical terms while also expressing feelings, emotions, and reflections about events. A study of blogs by caregivers of dementia patients found similar themes, including social support and engagement, gathering and sharing information, reminiscing and building legacies, and altruism [22]. Just as the parents of children with cancer often have to advocate for their children, the family members of patients with dementia often feel drawn to activism and want to advocate for others. Some researchers argue that blogs about the end of life are understudied. In her analysis of 3 late-stage cancer blogs, Andersson [23] posits that the blogs provide useful language around illness, death, and dying, which in turn produces emotional responses in the reader. However, the paper also recognized the deficiencies in our language and feelings of powerlessness. The paper noted that the blogs often feature narratives of struggle and fighting the disease, positive thinking, and even magical thinking, but little direct discussion of death. This lack of adequate language for discussing death creates a meaningful bond between the writer and the reader in their "shared ineffability" or an inability to properly express their thoughts and feelings about death.

Blog Readers and Health Beliefs

We have seen that blogs about a treatment plan can enhance patient-provider relationships [24], and participation in online groups can help empower patients and counteract isolation [25]. Yet, researchers know comparatively less about the influence of these blogs on their readers. Much of the literature on reading medical blogs refers to medical students as the readers and how these blogs enhance medical education [26,27]. Although that is indeed a worthwhile goal, medical students are not the target of the present research.

One survey of cancer blog users identified 3 different clusters [28] that varied by their motivations for reading blogs, and one segment had the most behavioral change (seeking changes in care) due to the blogs. However, 59.29% of their sample were cancer patients, 31.86% were family or friends of cancer patients, and the remaining 6.19% were medical professionals, and this study did not explicitly differentiate between the characteristics of the blog content or between blog users who were the writers and those who were readers.

A study that explicitly studied blog readers found 4 reasons for reading blogs and linked these to 3 behavioral outcomes [29]. The 4 motivations for reading blogs included "affective exchange, information search, entertainment, and getting on the bandwagon," while outcomes included changing readers' opinions, reader-writer interaction, and spread of word-of-mouth communications to others. Thus, given that reading blogs can change one's opinions and motivate some actions, it is

reasonable to conclude that readers might seek to monitor their health or take preventative action upon reading an illness blog.

Some characteristics of an illness blog may produce greater behavioral change than others. According to the Stanford Encyclopedia of Philosophy, Aristotle presented 3 means to persuasion: the character or credibility of the speaker (*ethos*), the emotional response of the listener (*pathos*), or the argument itself (*logos*) [30]. In addition, Cialdini [31] proposed that people employ decisional heuristics, or shortcuts, to deal with the volume of information they encounter. One such heuristic is similarity, in which people trust and believe those they deem to be like themselves [32]. Past research also has associated social proof, another persuasion tool in which we follow what we see others doing, with persuasion and conforming to established norms [33]. Similarly, other persuasion tools of commitment and consistency by Resnik and Cialdini [33] have also been associated with compliance in behavior.

This research is interested in patient blogs rather than those written by medical professionals. Thus, we did not investigate the writer's credibility (ethos) due to specialized knowledge or expertise. Instead, the study considers the blog's emotional response (pathos) through a personal narrative, which may demonstrate similarity or social proof to the reader, and objective data in the form of cancer statistics (logos), which may be an indication of disease risk.

Past research found that personal stories (narratives) increased both the perceived risk of infection with the hepatitis B virus and the intention to vaccinate more than statistical evidence [34]. This research suggested that personal narratives are less prone to counterarguing or discounting by the reader, as messages inconsistent with one's prior beliefs have been shown to be [35]. Thus, the researchers proposed: "narratives are hence expected to be superior in conveying personal health risks than statistical evidence" [35]. Similar work found statistical data were less persuasive in an alcohol education message [36], while other research found anticipated emotions more strongly predicted influenza vaccination than perceived risk [37]. The presentation of objective information caused people to rely on a peripheral cue—the expertise of the source—"so that an expert communicator induced greater persuasion than did a source with lower expertise" [38]. Readers would not be likely to consider a patient to be an expert source, and thus, perhaps, patient blogs might be less persuasive when written with statistical data than when written as a personal story.

Objective

While researchers have explored patient use of writing, we know less about the readers of these writings, and these studies aimed to fill this gap. The research's primary objective was to determine whether medical blog readers intend to take some health action specifically after reading a health blog (objective 1).

Specifically, we posited that blog type will significantly affect intentions to take some personal health action, with a *personal narrative* eliciting higher intentions than a blog with *statistical data*. Thus, the secondary objective was to determine specific characteristics of the most likely blogs to produce these health changes (objective 2). The final objective was to determine whether the blog reader's perceived health risk will mediate the effect of blog type on behavioral intentions (objective 3). That is, do readers believe themselves to be at higher risk after reading a health blog and then take some preventative action? To explore the 3 objectives, we employed a combination of quantitative and qualitative methods across 3 studies.

Methods

Study Design

All research was conducted in the United States using Qualtrics XM survey software to randomize treatment conditions for Studies 1 and 2. Study 3 was a qualitative survey with no treatment conditions.

Studies 1 and 2

The first study was a single-factor design with 3 levels of medical blog types. This study presented participants with 1 of 3 cancer blog excerpts—a personal narrative (story), a blog with statistical data about disease prevalence, and a more general cancer blog. The second study replicated those 3 conditions with a different sample population and added a control condition (with no blog excerpt).

Study 3

A third study of real blog readers provided some external validity and assessed actual preventative health actions taken (rather than hypothetical, intended actions) after reading a patient blog. This study utilized a qualitative survey with no intervention or experimental conditions.

Participants

Study 1

The participants were 99 students in an academic research subject pool at a large southeastern public university. The student participants received a few extra credit points in a college class in exchange for participating in the study. Potential participants saw a brief description of the study posted using SONA research panel software, where they could decide which studies they wished to complete. The completion rate was 97.1% (99/102) of the sample, while the remaining 2.9% (3/102) abandoned the online survey without answering any questions and thus were dropped from the final sample. The sample had an average age of 24.5 years and was 53% (53/99) female.

Study 2

Study 2 used a sample from the Amazon Mechanical Turk (MTurk) panel who were over 18 years old. Amazon workers have their choice of which studies they wish to complete and when. Participants included 167 Amazon master MTurk workers (past participants who have provided quality responses to other researchers) who received a US $2 payment for participation. An additional 22 participants began the survey and read the online consent form but answered no other questions; they were thus dropped from the final dataset, resulting in an 88.4% (167/189) participation rate. Respondents were 56.4% (94/167) female with an average age of 44.8 years.

Study 3

Participants were a convenience sample of actual medical blog readers recruited through posts to the authors' social media, which were then reposted or forwarded in a snowball sample. Although 59 participants began the survey, 8 participants said they had not read any medical blogs, and 3 participants were not sure or did not respond to the question. An additional 3 participants responded that they had read a medical blog but did not answer any further questions. Thus, the final sample contained responses from 45 participants. Table 1 summarizes the sampling, recruitment, and analysis methods employed in the 3 studies.

Table 1. Summary of participants in the 3 studies that focused on blog intention investigations.

Characteristics	Study 1 (n=99)	Study 2 (n=167)	Study 3 (n=45)
Type of sample	University research panel	Amazon MTurk master respondent panel	Convenience and snowball sample of medical blog readers
Average age (years), mean (range)	24.5 (18-46)	44.8 (21-76)	Not collected
Location	Southwestern US research university	United States	United States
Research tools	Qualtrics XM Survey Software	Qualtrics XM Survey Software	Qualtrics XM Survey Software
Development of tools	Adaptation of existing scales and creation of blog posts	Adaptation of existing scales and creation of blog posts	Blog evaluation scales repeated from studies 1 & 2 and additional questions
Prior relationship with researcher	Primarily no (4 of the 99 were enrolled in the researcher's course)	No	Some—convenience snowball sample
Blinded	No—identifying information collected in a separate file from participant response data, per institution IRB[a] guidelines	Yes	Yes
Statistical analysis			
Quantitative data	One-way ANOVA[b] (SPSS)	One-way ANOVA, stepwise regression (SPSS)	Simple means and % reported
Qualitative data	Hand coding of open-ended responses	Hand coding of open-ended responses	No coding—qualitative responses reviewed and summarized
Female, n (%)	53 (53.3)	94 (56.4)	Not collected
Education	Current undergraduate students	Not provided by panel	Not collected
Recruitment	University research panel software: Sona Systems	Posted on Amazon MTurk[c] open studies to eligible panelists	Recruitment via social media and snowball sample
Percentage of original sample that completed the study, %	97.1[d]	88.4[e]	76.3[f]

[f]N=59.

Intervention and Instruments

Study 1

Survey instruments were developed primarily by adapting existing materials and scales. The researchers adapted the blog posts used in Studies 1 and 2 from a publicly available, widely shared blog post about someone with skin cancer. This public blog excerpt was adapted and revised to create the 3 conditions (cancer statistics added to create that condition, for example). All blog posts were similar in total word length and readability. The Qualtrics survey software randomly assigned participants to 1 of 3 experimental conditions (for Study 1), which differed only in which blog post was presented to participants. The 3 blog types were a personal narrative (focused exclusively on a patient's personal story), a general cancer story, and a third statistics condition (that incorporated data and statistics about melanoma, rather than a personal story). All sample blog posts featured the same photo of a young woman and were approximately the same length.

After first reading the informed consent form and consenting to participate, subjects saw the sample blog post and answered an open-ended question asking their thoughts about the blog. This open-ended question was followed by an evaluation of the blog itself in terms of readability, informativeness, and interest on 7-point bipolar scales (all specific scale items and instruments are included in Multimedia Appendix 1).

Next, participants indicated how likely they were to engage in several preventative health actions (see a doctor for a skin check, monitor your skin yourself for any changes, use sunscreen daily, use sunscreen when going to the beach, or ask a doctor about cancer risk) on 7-point scales (from 1 = not at all likely to 7 = extremely likely). Then, respondents completed health beliefs model scales [39]; scales were reworded only to relate to skin cancer or skin checks rather than vaccination. These scales comprised measures of perceived barriers to seeking care, perceived benefits of skin checks, perceived susceptibility to skin cancer, and perceived severity of the effects of skin cancer. Although not intended to be predictive, we included these scales to explore potential relationships between constructs.

Finally, participants completed locus of control (loc) scales measuring internal, external-other (in which powerful others control events), and external-chance (in which events are due to fate or luck) loci of control [39]. The survey concluded with a few personal health questions (whether they used sunscreen and how often, whether they have ever had a skin check with a dermatologist, and whether they had a prior diagnosis of skin cancer). On average, participants spent 652.85 seconds (nearly 11 minutes) on the survey.

Study 2

Study 2 was conducted to replicate the significant effects found in Study 1 with a larger, general adult (nonstudent) sample population. Moreover, we added a control condition in which participants responded to the health intention, health beliefs, and locus of control measures but were not shown any blog post. Thus, for this study, the Qualtrics software randomly assigned participants either to 1 of the 3 blog-type conditions or to the no blog condition.

All study manipulations and measures were identical to those of Study 1, except for the addition of the control condition. In the control condition, instead of presenting a blog sample, we asked participants where they usually get their health information and their evaluations of that source. This design kept the survey to a similar length and provided participants a task to complete before answering the health intention measures. On average, respondents spent 618.17 seconds (10.3 minutes) on the survey.

Study 3

The first 2 studies were hypothetical, scenario-based designs. Thus, we also conducted a concise survey of real blog readers to explore our research objectives and assess the effect of medical blogs on actual preventative behaviors (rather than intentions). After asking respondents to think about a medical blog that they had read or followed, the survey asked who wrote the blog they read, whether they took any personal health-related actions after reading the blog, and if so, what actions. Next, the survey asked their reasons for reading the blog, what they liked or did not like about reading the blog, and for an evaluation of the blog writing itself. The researchers developed all measures for this study. These respondents completed the 7-question survey in an average of 212.9 seconds (3.55 minutes).

Statistical Analysis

We analyzed the quantitative scale data in Studies 1 and 2 with one-way analyses of variance (ANOVAs) and a simple regression model using SPSS version 26. Study 3 did not include an intervention; thus, the only quantitative data reported for that study were descriptive means and percentages.

The qualitative data from Studies 1 and 2 were analyzed through a coding process. First, researchers developed a list of codes for the open-ended, written evaluations of the blog posts based upon prior literature and an initial review of a sample of responses. All thought listings were downloaded to a spreadsheet and separated by respondent. Next, 2 coders, blind to both experimental condition and research objectives, independently coded all responses manually in the spreadsheet. Across the data from Studies 1 and 2, there was nearly 70% agreement (69.3%) between the 2 coders with a κ value of 0.63 [40]. This was deemed a sufficiently strong level of agreement, and a third coder resolved discrepancies.

Ethics

All studies were approved by the Social and Behavioral Sciences Institutional Review Board (IRB) at a large, public university in the southeastern United States (IRB 20-0088). Participants for all studies completed an online consent form prior to beginning the study and were free to omit any questions or leave the study at any time.

Study 1 was not blinded, as participant information was required for awarding the compensation (of the extra class credit). However, in accordance with the university's IRB guidelines, the identifying information was saved to a separate file and not connected with the experimental responses. Studies 2 and 3 were blinded. Amazon MTurk (used for Study 2) provides only a user ID, and participant identities are not revealed to researchers. The final qualitative survey (Study 3) used Qualtrics anonymous response settings and did not capture any identifying information.

Results

Study 1

The blog excerpts were rated overall as being easy to read (mean 5.84, SD 1.61), easy to understand (mean 6.29, SD 1.07), well-written (mean 6.02, SD 1.34), informative (mean 5.64, SD 1.31), emotional (mean 6.16, SD 1.07), and interesting (mean 5.82, SD 1.37). Importantly, these evaluations did not differ between the 3 blog conditions (all $F_{2,98}$ values <1.3, P>.30 for one-way ANOVAs). That is, the different blog types were judged to be equally informative, easy to read, and emotional. Thus, any significant effects of blog type on the health intentions could not be attributed to these characteristics. Table 2 summarizes the individual means for the evaluation of the blog posts, as well as the behavioral intentions.

Table 2. Study 1 blog evaluations and behavioral intentions.

Characteristics	Blog type			Overall (N=99), mean (SD)
	Personal (n=34), mean (SD)	General (n=38), mean (SD)	Statistics (n=27), mean (SD)	
Blog evaluation				
Easy to read	5.76 (1.58)	5.92 (1.60)	5.81 (1.71)	5.84 (1.61)
Easy to understand	6.32 (1.01)	6.18 (1.21)	6.41 (0.97)	6.29 (1.07)
Well-written	6.06 (1.41)	5.97 (1.33)	6.04 (1.32)	6.02 (1.34)
Informative	5.50 (1.33)	5.68 (1.25)	5.74 (1.16)	5.64 (1.31)
Emotional	6.26 (1.05)	6.26 (1.01)	5.89 (1.16)	6.16 (1.07)
Interesting	5.59 (1.44)	6.00 (1.21)	5.85 (1.49)	5.82 (1.37)
Behavioral intention				
Skin check by a doctor	4.26 (1.83)	4.55 (1.75)	5.04 (1.85)	4.59 (1.81)
Skin self-check	5.29 (1.43)	5.71 (1.43)	6.30 (0.869)	5.73 (1.35)
Sunscreen daily	4.15 (2.05)	4.47 (2.19)	5.30 (2.15)	4.59 (2.16)
Sunscreen at beach	5.85 (1.87)	6.18 (1.45)	6.70 (0.669)	6.21 (1.49)
Asked a doctor about skin cancer risk	4.58 (1.82)	4.84 (1.94)	6.11 (0.974)	5.10 (1.79)

Next, we examined whether blog type affected the readers' health intentions. First, the set of health intention measures proved to be reliable as one scale (Cronbach α=.79), with an overall mean of 26.2 (SD 6.4). The effect of blog type on health intentions surrounding skin cancer prevention was significant ($F_{2,96}$=6.08, *P*=.003). However, the direction was not as predicted, as both patient blog types (personal: mean 23.97, SD 1.26; general: mean 25.76, SD 6.10) elicited lower intentions to take preventative health action than did the blog that presented statistics without a personal story (mean 29.44, SD 4.54; *P*=.001, *P*=.02, respectively). Table 2 summarizes the means of the individual health intention measures for all conditions.

On the individual health intention measures, we observed significant differences between blog conditions only for self-monitoring of one's skin ($F_{2,98}$=4.47, *P*=.01) and asking a doctor about one's cancer risk ($F_{2,97}$=6.9, *P*=.002). On both measures, the blog with statistics led to greater preventative health intentions than either of the other 2 blog conditions (personal narrative and general cancer–related.) The 2 measures about using sunscreen demonstrated *P* values of .11 and .08, respectively, while the first measure about seeing a doctor for a skin check did not differ between blog conditions (*P*=.26).

The third research proposition was that blog type would influence health beliefs. First, we assessed the reliability of all health beliefs subscales, including the perceived barriers to accessing health care (Cronbach α=.63), perceived susceptibility (Cronbach α=.68), and perceived severity subscales (Cronbach α=.69; the perceived benefit of getting a skin check was a single-item measure, not a multi-item scale). However, the reliability of the perceived barriers scale was higher (Cronbach α=.65) without the second item ("a skin check could have unpleasant side effects"), and the reliability of the perceived severity subscale was higher without the first item ("skin cancer may lead to serious health problems"; α=.712 without that item). Thus, the final reported scales did not include those items. Moreover, the external-others locus of control scale was used in full (α=.78), while both the internal loc and external-chance loc scales had greater reliability if some items were dropped (α_s=.78 for resulting scales; internal loc removed the first 2 items, and chance loc removed the third item); thus, the reduced scale means are reported in the following sections. Table 3 summarizes the health belief subscales and locus of control scales (described in subsequent sections), and all scale items are listed in Multimedia Appendix 1.

Table 3. Study 1 locus of control.

Locus of control (LOC)	Blog type			Overall, mean (SD)	Number of items
	Personal, mean (SD)	General, mean (SD)	Statistics, mean (SD)		
Perceived barriers	14.06 (5.18)	12.46 (3.97)	11.08 (4.12)	12.62 (4.57)	4
Perceived benefits	5.19 (1.38)	5.32 (1.44)	5.85 (1.32)	5.42 (1.398)	1
Perceived susceptibility	8.75 (3.99)	8.76 (3.23)	9.96 (4.38)	9.09 (3.83)	3
Perceived severity	17.24 (5.84)	18.53 (5.49)	20.00 (6.08)	18.50 (5.81)	5
Internal LOC	18.70 (4.77)	18.84 (4.68)	18.81 (4.21)	18.79 (4.54)	4
Powerful others LOC	24.39 (7.21)	24.79 (6.64)	25.52 (5.08)	24.86 (6.41)	6
Chance LOC	13.91 (6.23)	15.03 (5.88)	14.52 (4.53)	14.51 (5.63)	5

Neither the perceived susceptibility to skin cancer ($F_{2,96}$ =.965 P=.38) nor the perceived severity subscales ($F_{2,97}$=1.7, P=.19) varied by blog condition. The perceived benefits of skin checks also did not differ by condition. However, perceived barriers to screening did significantly differ by blog condition ($F_{2,96}$=3.373, P=.04), with the personal narrative showing greater barriers than the statistics blog. We did not predict a priori any effects of blog condition on internal, powerful others or chance locus of control, and none were found (all F values <1, all P>.70).

Given that the perceived barriers to accessing care differed by blog type, we incorporated that scale alone into a regression model. A simple linear regression analysis regressing both blog type and perceived barriers to care onto the health intentions scale yielded an overall model that was significant ($F_{2,95}$=13.57, P<.001), as well as both variables that were significant (β_{blog}=.227, t_{92}=2.38, P=.02; $\beta_{perbarrier}$=–.36, t_{92}=–3.74, P<.001). Thus, adding the perceived barriers to care does not eliminate the effect of blog type on health intentions. Moreover, retaining the blog type in the regression model improved the model R^2 from .179 to .226 (Table 4).

Table 4. Regression analysis results.

Model factor	Estimate	SE	95% CI LL[a]	95% CI UL[b]	P value
(Constant)	10.951	2.679	5.630	16.271	<.001
PerBarScale	0.510	0.136	0.240	0.781	<.001
Blog version	–1.859	0.780	–3.409	–0.310	.02

[a]LL: lower limit.

[b]UL: upper limit.

Next, we turned our attention to the analysis of the open-ended question about the blog. The codes used for this qualitative analysis are shown in Table 5, along with sample responses and the number of responses coded into each category. The most-reported codes for the Study 1 sample were sadness/sympathy/empathy (code 1), makes one appreciate life more (code 7), informative (code 4), well-written (code 5), and makes one think of someone with cancer (code 8).

Table 5. Coding of open-ended responses and sample respondent statements in Study 1.

Open-ended question code category	Sample statements	Number of responses
1. Sadness/sympathy/empathy	I feel saddened by the writer's situation and an urge to help by any means necessary.	17
2. Feel guilty (eg, to be alive and well when others are not)	I feel guilty that I do not appreciate my life enough.	1
3. Feel worried/concerned for oneself	I feel nervous when I think about this sort of thing happening.	0
4. Informative	I think that it is informative about the feelings of people with cancer, which is something that you do not hear about often.	11
5. Well-written	I think that Natalie is an excellent writer who is expressing her true feelings about having cancer.	9
6. Motivates behavior (eg, will make an appointment, do a skin check)	After reading this, I really felt like I want to go and do my annuals, which is pending.	2
7. Makes you appreciate life more	That life is a gift. And we need to leave it with meaning and love what we do. Be thankful.	13
8. Thought of someone with cancer	I'm thinking of all of the people that I know who have had cancer. I have lost so many family members to cancer.	9
9. Did not want to read/would not read	I immediately wanted to close the page when I saw the topic. I feel sick to my stomach. This is not a topic I would ever want to read about.	4
10. No new information/heard it all before	There are many blogs like that, and I have heard many similar ones.	2

The distribution of codes across the 3 blog versions was also significantly different ($X^2_{16,68}$=28.54, P=.03). Both personal blog types elicited great feelings of sadness and sympathy (code 1), with the personal narrative blog also being considered well-written (code 5) and the general blog making readers appreciate their own life more (code 7). Participants most often cited the statistics blog as being informative (code 4). Notably, 3% (2 out of the 68 who provided a response to the open-ended question) stated, without prompting, that the blog made them intend to take some personal medical action.

Study 2

In this sample, the blog excerpts were again rated overall as being easy to read (mean 6.28, SD 1.17), easy to understand (mean 6.65, SD 0.724), well-written (mean 6.10, SD 1.28), informative (mean 5.47, SD 1.43), emotional (mean 5.91, SD 1.26), and interesting (mean 5.64, SD 1.62). There were few differences in these evaluations across the 3 blog types, except for how understandable ($F_{2,123}$=3.45, P=.04) and emotional ($F_{2,123}$=3.40, P=.04) the blogs were. The blog with the very personal story was rated more understandable than the general blog (P=.01), and the personal story was rated more emotional than the statistics-focused version (P=.01). Table 6 summarizes the evaluations of the blog posts.

Table 6. Study 2 blog evaluations.

Characteristic	Blog type			Overall (N=167), mean (SD)
	Personal (n=42), mean (SD)	General (n=41), mean (SD)	Statistics (n=41), mean (SD)	
Easy to read	6.14 (1.42)	6.12 (1.21)	6.59 (0.706)	6.28 (1.17)
Easy to understand	6.81 (0.505)	6.41 (0.974)	6.71 (0.559)	6.65 (0.724)
Well-written	6.26 (1.27)	5.85 (1.30)	6.17 (1.26)	6.10 (1.28)
Informative	5.38 (1.58)	5.24 (1.46)	5.78 (1.22)	5.47 (1.43)
Emotional	6.19 (1.37)	6.02 (1.24)	5.51 (1.08)	5.91 (1.26)
Interesting	5.76 (1.57)	5.56 (1.67)	5.59 (1.63)	5.64 (1.62)

Next, we turned our attention to the primary research objectives—does reading a personal illness blog affect the reader's own health intentions (objective 1)? Specifically, is there an effect of the blog type on these health intentions (objective 2)? First, the set of health intention measures proved to be reliable as a scale (Cronbach α=.80), with an overall mean of 24.48 (SD 6.94). The experimental condition's effect on health intentions was not significant in the overall ANOVA ($F_{3,166}$=2.59, P=.06). However, looking at the planned comparisons revealed that all blog conditions led to higher health intentions than the control (no blog) condition, but there were no significant differences between the 3 experimental blog conditions. Specifically, the personal (mean 25.21, SD 6.64; P=.03) and statistical (mean 25.95, SD 6.81; P=.01) blog versions led to higher overall health intentions than did the no blog control (mean 22.02, SD 7.27) condition. The general blog

(mean 24.49, SD 6.84) condition did not significantly differ from either the control or the other blog conditions.

One-way ANOVAs conducted on the individual health intention measures showed a significant difference existed only for daily sunscreen use ($F_{3,166}$=4.39, P=.005), with the only other noteworthy comparison observed for getting a skin check by a doctor ($F_{3,166}$=2.06, P=.11). Post hoc tests showed that, for daily sunscreen usage, all blog conditions indicated greater intentions than the no blog condition (P=.002, P=.004, and P=.005, respectively), while both the personal story and statistics blog versions led to greater intentions to get one's skin checked by a doctor than the no blog condition (P=.04 and P=.03, respectively). Table 7 summarizes the health intention measures by experimental condition.

Table 7. Study 2 behavioral intentions.

Characteristic	Control (no blog), mean (SD)	Blog type			Overall (N=167), mean (SD)
		Personal (n=42), mean (SD)	General (n=41), mean (SD)	Statistics (n=41), mean (SD)	
Skin check by a doctor	3.42 (2.04)	4.33 (2.09)	3.88 (2.05)	4.39 (2.02)	4.00 (2.07)
Skin self-check	5.65 (1.36)	5.74 (1.74)	5.71 (1.33)	5.95 (1.52)	5.76 (1.49)
Sunscreen daily	3.28 (2.33)	4.69 (2.12)	4.61 (2.02)	4.56 (1.86)	4.28 (2.16)
Sunscreen at beach	5.95 (1.75)	6.33 (1.41)	5.93 (1.88)	6.54 (1.31)	6.19 (1.61)
Ask a doctor about skin cancer risk	3.81 (1.92)	4.12 (1.82)	4.37 (1.91)	4.51 (2.03)	4.20 (1.92)

As we did collect demographic data on age and gender in this study, we also evaluated whether either variable affected the behavioral intentions, and they did not. The average response by men (mean 23.91, SD 6.71) on the health intentions scale did not significantly differ from that of the female-identifying respondents (mean 25.11, SD 7.00; t_{158}=1.1; P=.27), nor were there any gender differences on any of the specific items (all P values >.13). A regression of age on behavioral intention also was not significant ($F_{2,161}$=1.3, P=.28).

Respondents in this study also completed the health beliefs and locus of control scales, which we used to consider our third research objective about readers' perceived risk. Although there is some criticism of how the Cronbach α statistic is used and disagreement as to what constitutes an acceptable reliability, values above .6 or .7 are frequently reported as acceptable [41].

All scales here demonstrated Cronbach α>.62: perceived barriers (Cronbach α=.79), perceived susceptibility (Cronbach α=.63), perceived severity (Cronbach α=.63), internal locus of control (Cronbach α=.77), external-other locus of control (Cronbach α=.82), and external-chance locus of control (Cronbach α=.84). Moreover, there were no differences on any of these scales by experimental condition (all F<1.2, P>.20). This implies that neither the reading of a blog (versus no blog) nor the different types of blogs affected any of the respondents' health beliefs or their loci of control. Post hoc comparisons did, however, reveal a significant difference in evaluations of external-chance locus of control between the statistics blog (mean 16, SD 6.24) and the no blog (control) condition (mean 19.12, SD 6.41; P=.04); no other differences emerged. Table 8 summarizes these results.

Table 8. Study 2 locus of control.

Locus of control (LOC)	Control	Blog type			Overall (N=167), mean (SD)	Number of items
		Personal (n=42), mean (SD)	General (n=41), mean (SD)	Statistics (n=41), mean (SD)		
Perceived barriers	17.1 (6.78)	15.9 (6.07)	16.32 (7.57)	14.68 (5.88)	16.01 (6.61)	5
Perceived benefits	5.52 (1.04)	5.74 (1.15)	5.44 (1.34)	5.88 (1.05)	5.64 (1.16)	1
Perceived susceptibility	9.62 (3.86)	10.10 (3.68)	9.83 (3.73)	10.17 (4.02)	9.93 (3.68)	3
Perceived severity	24.30 (5.64)	24.60 (5.07)	23.55 (5.55)	23.73 (4.98)	24.05 (5.28)	6
Internal LOC	28.88 (4.89)	28.64 (6.00)	29.60 (5.90)	28.93 (5.09)	29.00 (5.46)	6
Powerful others LOC	23.56 (7.11)	24.36 (6.23)	23.29 (7.14)	23.93 (6.63)	23.79 (6.73)	6
Chance LOC	19.12 (6.44)	18.31 (6.92)	17.66 (7.66)	16.00 (6.24)	17.78 (6.87)	6

The number of open-ended thoughts coded into each category for Study 2 are summarized in Table 9. Overall, the most common evaluations were feelings of sadness/sympathy, that the blog was informative, it made them think of someone they know, and that there was no new information presented. Comparing across conditions, we see that the most common responses again varied by blog type ($X^2_{16,121}$=35.49, P=.003). For the 2 personal blog versions, the top codes were for expressions of sadness/sympathy/empathy (code 1) and thinking of someone they knew with cancer (code 8). The blog with

statistics evoked far different responses, with informative (code 4), well-written (code 5), and motivates behavior (code 6) being the most reported. Across the 3 blog types, 5 responses explicitly expressed worry for oneself, and 8 expressed an intent to be proactive regarding their health (scheduling a doctor's appointment or getting a skin check, for example.) Thus, without prompting, nearly 11% (13/124, 10.5%) expressed concern about or desire to act regarding their health because of reading one sample blog entry.

Table 9. Coding of Study 2 open-ended responses.

Open-ended question code category	Number of responses
1. Sadness/sympathy/empathy	41
2. Feel guilty (eg, to be alive and well when others are not)	0
3. Feel worried/concerned for oneself	5
4. Informative	22
5. Well-written	15
6. Motivates behavior (eg, will make an appointment, do a skin check)	8
7. Makes you appreciate life more	1
8. Thought of someone with cancer	18
9. Did not want to read/would not read	3
10. No new information/heard it all before	18

Study 3

This nonexperimental study surveyed actual self-described readers of real medical blogs. Most of the blogs read by our study participants were written by patients (27/45, 60%), followed by the patient's spouse or caregiver (7/45, 16%), a medical professional (6/45, 13%), or the patient's parent (5/45, 11%). The participants read the blogs for various reasons, chiefly to stay up to date with their friend or family member's condition (23/45, 51%) and to provide support for their friend (21/45, 47%). Many also read the blogs to gain information about a health condition more generally (11/45, 24%) or to learn information that may be pertinent for their own health (11/45, 24%). Percentages sum to more than 100% because they were able to select more than one reason. They found the blogs easy to read (mean 6.34, SD 1.14), easy to understand (mean 6.25, SD 1.19), well-written (mean 6.13, SD 1.50), informative (mean 6.23, SD 1.38), and interesting (mean 6.24, SD 1.87). Blogs were also considered somewhat emotional (mean 4.97, SD 0.83; all measured on 1 to 7 Likert-type scales).

The central research question for this study (and the paper's first research objective) was whether readers took any personal health action or changed any behaviors based upon reading the blog, and, indeed, 24 respondents (24/45, 53%) reported doing so. These responses are summarized in Table 10. Of participants who reported taking action, 29% (7/24) scheduled a doctor's appointment, while others reported requesting a cancer or other health screening (7/24, 29%); performing a self-exam, such as a skin or a breast check (5/24, 21%); or asking a doctor about their own risk (4/24, 17%). Additionally, 54% (13/24) reported making other health changes, including taking supplements, making lifestyle modifications, purchasing cancer insurance, doing additional research, or making donations to disease research.

Table 10. Preventative health actions taken by participants in Study 3 (n=45).

Preventative health action taken	Responses, n (%)
Scheduled a doctor's appointment	7 (16)
Requested cancer or other health screening	7 (16)
Performed a self-exam	5 (11)
Asked a doctor about their own health risk	4 (9)
Other (made other health or lifestyle changes)	13 (29)

Participants cited being able to stay updated, especially without having to impose on their friend or family member for continued updates, as the greatest motivator for reading the medical blog. Additional motivations included learning specific ways they could support the person, feeling connected to the person, and hearing positive news when that was shared. Several also cited that the blog writer was very transparent, real, and open, which they appreciated, or used humor. Comments also corroborated prior findings about the use of medical statistics, with others citing how the writer explained detailed scientific information so that it was understandable for readers, sometimes prompting them to do additional research. Several participants with health challenges also said reading the blogs provided some relief to know that others were going through the same things and helped confirm their own treatment choices. Most said there was nothing they did not like or found difficult about reading the

blogs, but 24% (11/45) of participants described the experience as very emotional or sad to read, notably if the person's condition deteriorated or a treatment was unsuccessful. Those participants appreciated the blog and found it worthwhile to read, despite being sad or emotional at times. Interestingly, a few mentioned that the information was not always correct or that they would take it more as a suggestion for lifestyle modification or a reason to do more research, rather than as medical advice.

Discussion

Principal Findings

We conducted 2 scenario-based, experimental studies with different sample populations and 1 qualitative survey of real blog readers to explore the research objectives. All 3 studies confirmed the first research objective, that reading medical blogs was associated with intentions to take preventative health actions, though each study contributed unique findings. Studies 1 and 2 examined the specific characteristics of blogs that led to greater health intentions (objective 2), but neither perceived risk nor severity of skin cancer mediated these effects (objective 3). Study 3 confirmed the first objective with real, rather than intended, behaviors.

Study 1

This study confirmed that blog type significantly affects intentions to take preventative health action. We predicted that people would be motivated to take health actions upon reading a medical blog and that a highly personalized blog would produce the greatest health intentions. However, we discovered the reverse—the blog with melanoma statistics produced the most significant intention to take preventative health action, higher than either of the other blog conditions, which did not differ. Moreover, the statistics blog also yielded the lowest perceived barriers to accessing care compared with the other blog types. Including both blog type and perceived barriers to accessing care improved the predictive ability of the regression model on health intentions. Thus, blog type significantly affected perceived barriers, which impacted health intentions, but blog type's direct effect on behavioral intentions retained its significance. We conclude that medical blogs can produce intentions to engage in protective health behaviors, partially through an effect on perceived barriers to care.

Study 2

Study 2 corroborates and extends the findings of Study 1 by demonstrating that reading a medical blog excerpt led to greater intentions to take preventative health actions compared with a baseline (from a control condition in which participants did not read a blog entry), and this was true for all the blog versions we tested. Further, both a highly personal blog and a statistical blog led to greater personal health intentions than the control condition. In contrast, the more general cancer blog produced a moderate level of health intention that was not statistically different from either the control or the other blog conditions.

However, there were no differences by blog type on any of the health beliefs. Thus, perceived health risk—either susceptibility or severity—again did not mediate the effect of blog type on personal health intentions. Also, blog type and blog reading, in general, did not affect perceptions of either the barriers to or the benefits of skin checks. Interestingly, the statistics-oriented blog did reduce estimates of locus of control attributed to chance.

Study 3

The final study assessed whether reading medical blogs induced their readers to take any preventative health action in a real-world survey rather than a hypothetical scenario. For a majority of the respondents, it did. While the respondents primarily read the blogs in order to keep up to date with the patient's condition and provide support, they also found the writing emotional and informative, and many readers took personal health action as a result of reading the blogs. Reading medical blogs inspired people in many ways; they made medical appointments or requested health screenings, conducted additional research on their own, made donations to organizations, or made other lifestyle changes.

General Discussion

Researchers have long known medical blogs have demonstrable patient benefits, but less was known about the impact on their readers. The top intended health actions across our studies included skin checks and consulting with a physician about cancer risk, both of which are important preventative health actions that can help ensure that a skin cancer is caught early in a more treatable stage [42]. Furthermore, while our first 2 studies measured hypothetical health intentions, much past literature incorporating Ajzen's Theory of Planned Behavior [43] to health care has found intentions to be predictive of behaviors such as attending health screenings, engaging in healthy eating, or participating in regular physical exercise [44-46]. Thus, the increased intentions are likely to translate into actions, and Study 3 provides some support for that conjecture.

Some of our results also ran counter to predictions. The blog readers in our studies demonstrated a higher propensity to take preventative health actions when blog posts focused on statistics rather than personal stories. Whereas some prior literature showed personal stories to be most persuasive [34], our Study 1 found the statistics-oriented blog to be the most effective, and Study 2 found it to be as persuasive as the personal narrative. Because cancer can be scary and overwhelming to contemplate, there is a natural tendency to believe that cancer patients might have had either genetic or environmental reasons for their cancer diagnosis [47], to distance oneself from the situation and downplay one's own personal risk. Accordingly, it is possible that a personal story feels more specific to the writer and less relatable to the reader. In the past, people even avoided those with cancer out of fear they might "catch" the disease themselves [48]. This reduced relatability could minimize Cialdini's [49] similarity persuasion tool of the personal narrative. If one feels that the patient's story is unique and personal, then the reader may feel sadness and sympathy for the patient (as many of our participants in all 3 studies did) but may not feel motivated to take personal action because they read the story. And in fact, almost 47% of our Study 3

respondents said they did not engage in any preventative health actions after reading the blog.

In retrospect, perhaps the statistical blog increased the social proof aspect of persuasion by illuminating for our study participants that the condition is more widespread than they may have thought [31]. Providing some additional support for this conjecture, Study 1 results showed that the statistics blog reduced perceived barriers to screening compared with the personal story blog. Further, Study 2 showed that the statistics blog reduced the locus of control attributed to chance. Things that occur due to chance or fate, by definition, cannot be prevented by one's own actions. This effect could play a role in increasing one's intention to take personal preventative action if the perceived portion of cancer risk due to chance or fate is reduced. Perceived behavioral control—or one's belief in their ability to perform a behavior—is a central tenet in the Theory of Planned Behavior and has been found to be an important driver of intentions in health care [50]. The prospect of these potential mechanisms deserves further research to clarify our understanding.

We further explored whether the blog post conditions would differ significantly from a control (baseline) condition without any blog post. Indeed, all blog types we studied (general, statistics-focused, and a personal story) demonstrated greater health intentions as compared with the condition with no blog. Specifically, the personal story and statistics-focused blogs were associated with intention to use sunscreen, while all 3 blog types were associated with greater intent to schedule a medical visit for a skin check compared with the control condition. In our real-world follow-up study, we found that the desire to stay up to date on a patient's condition or find general information motivated survey participants to read medical blogs. As a result of reading these patient posts, more than 53% of respondents indicated that they took a preventative medical action (skin checks, doctor appointments) or other health-related behavior (additional research, insurance purchase, starting supplements). Remarkably, none of the blogs impacted perceived severity of or susceptibility to disease. Thus, perhaps even those readers who may believe they are at low risk might benefit from reading health blogs and be spurred to act.

Limitations

Limitations of this research relate to natural concessions made in sampling. The first study used a research panel at a major research university, while the second study used a panel from MTurk. Thus, neither sample may be representative of US adults more generally. Nonetheless, both samples included a diverse age range and, despite skewing a bit more female, at least 44% male-identifying respondents. For the sake of parsimony and because we did not have specific research objectives about age or gender, Study 3 did not collect this or any other demographic data. Thus, we cannot compare the results from that study to prior literature that examined these variables. Further, we did not collect educational data for the second or third studies.

Despite limitations inherent with any panel, both experimental studies provided convergent findings and extended our understanding of the efficacy of different blog presentations compared with one another and compared with a baseline without blog content. We designed the final study to understand blog readers' actual preventative health actions and to increase the robustness of qualitative insights.

The third study used a relatively small convenience sample with snowball sampling to provide insights into real actions resulting from reading patient health blogs. Although qualitative research often precedes quantitative efforts, the first 2 experimental studies' findings piqued the researchers' curiosity to explore the research objectives further and gain additional insights with a sample of readers of nonhypothetical medical blogs. Moreover, while we could have included many other variables, we kept the Study 3 survey purposefully short to reduce the burden on participants who received no compensation for participating. This study nonetheless provides an important step in helping to make a connection between blog reading and personal preventative health actions.

Next, this research inquiry looked at specific outcomes related to skin cancer. It is possible that the most influential blog style may differ when investigating other conditions, such as healthy behaviors postbariatric surgery or prevention of the spread of infectious viruses such as COVID-19. We anticipate that a relationship between reading health blogs and intended health actions would exist, but the presentation style and influence of perceived risk might be different. Additionally, these studies are among the first of which we are aware to investigate the impact of reading patient blogs by social media participants. Patients frequently turn to social media and online communities for medical information and advice [51,52]; future research is needed to explore additional predictors and outcomes in this area.

Conclusions

Blogs from patients undergoing health care treatments have become quite common. This article corroborates that, despite the emotional connection driven by personal story blogs, posts focusing on statistics related to the condition may be more effective at driving readers' preventative health intentions. This increased intention to perform preventative health action occurs regardless of the reader's perception of risk. Further, the current research clarifies that blog posts in general, regardless of format, are more effective at driving some preventative health intentions compared with merely thinking about where one gets health information. This finding indicates that reading patient-created content may be beneficial regardless of the reader's own risk for the health condition. Reading patient blogs may also impact perceived barriers to accessing care or perceptions of the part of our health risks that may be within our control (and not attributable to chance), leading to greater intentions to take preventative health actions. Finally, we gained insight that reading blogs, particularly those written by patients, were motivated primarily by a desire to support the patient, keep up with the patient, and learn more about the patient's condition. Some readers did indicate that they did further research and did not take blog information at face value, but a majority reported engaging in protective health action due to their blog reading.

Although much research exists on the benefits of patients' writing and journaling during health care treatment, the present research provides a foundation for future studies on patient and

health outcomes from reading health blogs. As people seek information online about medical conditions and preventative options, patient-generated content will appear between content created by and for medical professionals; health care practitioners cannot assume patients will only read edited content from medical professionals. Understanding what type of content presentation is most effective in encouraging positive health actions may guide health care providers, patient coordinators, and patient therapists to guide recommended content styles with the greatest impact. In the case of the present studies, the use of informative statistics was the most effective in driving these intentions. This research could also inspire future studies in other health specialties to understand how these results may generalize across medical conditions and treatments.

Acknowledgments

The authors acknowledge the readers of the first author's own "ProfessorMom" CarePages breast cancer blog and the PostHope blog of Shannon B Rinaldo, PhD (1973-2020), which documented her 5-year treatment at MD Anderson for glioblastoma IV, as inspiring and informing this research. They also thank Sphurti Sewak and Nuket Serin for their research assistance with coding the qualitative responses and reviewers AX, AY, and AN for their helpful comments on the manuscript.

Abstract

Background: There is a pressing need for digital tools that can leverage big data to help clinicians select effective antibiotic treatments in the absence of timely susceptibility data. Clinical presentation and local epidemiology can inform therapy selection to balance the risk of antimicrobial resistance and patient risk. However, data and clinical expertise must be appropriately integrated into clinical workflows.

Objective: The aim of this study is to leverage available data in electronic health records, to develop a data-driven, user-centered, clinical decision support system to navigate patient safety and population health.

Methods: We analyzed 5 years of susceptibility testing (1,078,510 isolates) and patient data (30,761 patients) across a large academic medical center. After curating the data according to the Clinical and Laboratory Standards Institute guidelines, we analyzed and visualized the impact of risk factors on clinical outcomes. On the basis of this data-driven understanding, we developed a probabilistic algorithm that maps these data to individual cases and implemented iBiogram, a prototype digital empiric antimicrobial clinical decision support system, which we evaluated against actual prescribing outcomes.

Results: We determined patient-specific factors across syndromes and contexts and identified relevant local patterns of antimicrobial resistance by clinical syndrome. Mortality and length of stay differed significantly depending on these factors and could be used to generate heuristic targets for an acceptable risk of underprescription. Combined with the developed *remaining risk* algorithm, these factors can be used to inform clinicians' reasoning. A retrospective comparison of the iBiogram-suggested therapies versus the actual prescription by physicians showed similar performance for low-risk diseases such as urinary tract infections, whereas iBiogram recognized risk and recommended more appropriate coverage in high mortality conditions such as sepsis.

Conclusions: The application of such data-driven, patient-centered tools may guide empirical prescription for clinicians to balance morbidity and mortality with antimicrobial stewardship.

Introduction

Background

Antibiotic-resistant infections are widespread in the United States and across the globe and are an urgent threat to human health [1,2]. In the United States, over 2.8 million resistant infections occur each year, leading to delayed or ineffective therapy, longer hospital stays, and increased risk of death [1]. Patients who receive early empiric therapy that matches the in vitro susceptibility of their infection are up to 12 times more likely to survive (30-day crude mortality) [3], have shorter length of stays (LOSs) [4], and less long-term sequelae [5]. At the same time, overuse and prescription of overly broad antibiotics increases the risk of antimicrobial resistance (AMR), creating a positive feedback loop between behavior and ecological response, perpetuating a vexing health dilemma that spans sociobehavioral, ecological, and technical dimensions [6]. Increased antibiotic use in response to the COVID-19 pandemic exemplifies this complexity with the potential to further amplify the risk of AMR [7,8].

To combat the global AMR crisis today, leading agencies (eg, World Health Organization, Infectious Disease Society of America, Centers for Disease Control and Prevention, Agency for Healthcare Research and Quality, and the Clinical and Laboratory Standards Institute) have recommended that health care institutions produce and distribute locally derived antibiograms to clinicians, primarily as part of antimicrobial stewardship efforts [9,10]. Antibiograms have traditionally been high-level printed tabular summaries of local resistance patterns within an institution. These tables do not account for many factors known to influence antimicrobial susceptibility [11,12], even though such data are available in the electronic health record (EHR).

Recent machine learning reports demonstrated that EHR data can predict susceptibility, although generally for single disease types [13-15]. For instance, Yelin et al [13] used a data set of over 700,000 community-onset urinary tract infections (UTIs) to show that the use of prior antibiotics predicts AMR. The underlying machine learning techniques require large data sets and are therefore best suited for common infections, such as uncomplicated UTIs [13,15]. Different approaches are needed for smaller data sets, for example, to understand the influence of rare patient-specific factors or local susceptibility patterns.

Few hospitals have incorporated patient-specific and epidemiologic information into traditional antibiograms [16] or clinical decision support systems (CDSSs) [17-19]. Unit-specific or syndrome-specific antibiograms have been developed [20-22]. Visual analytics software have been studied as a tool for integrating data within an EHR on patient risk factors with isolate-specific susceptibilities [23]. The TREAT system is one of the most comprehensive and well-documented diagnostic and antimicrobial decision support tools [24,25]. TREAT uses a sophisticated causal probabilistic network [24] that hybridizes expert knowledge with heuristics and local antibiotic susceptibility data. In a multinational randomized controlled trial in 2013, TREAT use for inpatients led to a decreased LOS (1 day) but did not show mortality benefits when all variables were accounted for [25].

Reviews of clinical decision systems for antimicrobial management [17-19] found a paucity of evidence that these systems reduce mortality and morbidity when incorporated into daily clinical workflow, an unnatural segregation of outpatient and inpatient approaches, and a lack of systematic engagement with stakeholders about needs and workflow integration for support systems. A recent survey showed that only 44% of medical residents knew how to access the local antibiogram and preferred web-based resources such as UpToDate or the Sanford Guide [26]. These web-based treatment guidelines are not tailored to a specific health care environment as local antibiograms, but they are more accessible and provide explicit guidance for a case at hand. Thus, decades after the first digital innovations, the traditional antibiogram, with all its limitations, is still the most common AMR tool in use today.

Objectives

In this study, we introduce iBiogram as a digital CDSS for data-driven antimicrobial selection in the absence of definitive antibiotic susceptibilities. iBiogram addresses the limitations discussed above by examining infectious disease decision support as a complex sociotechnical problem [6,27]. Physicians and CDSS have to work together to complement the understanding of a specific case with guidance about the local epidemiology, likelihood of resistance, and associated risk of failure. Shared representations between algorithms and people are the key to blending the best qualities of expert knowledge and digital tools for efficient human technology teamwork in such cases [28]. Shared representations establish a common language to translate between clinical expertise and machine inference to enable efficient human-machine collaboration. To this end, we explored diverse patient information and antimicrobial testing results, presented new visualizations of insights generated from these data, and share the results of evaluating a new prototype and risk-based metric compared with historic provider behavior.

Methods

Overview

We systematically evaluated a comprehensive clinical data set that crossed ambulatory and hospital settings and contained antimicrobial testing, clinical context, and patient factors. We then identified local factors influencing microbial prevalence and AMR, their impact on mortality, and how they combine to influence the success of antibiotic treatments. Finally, we developed and tested a decision support tool that may be used in both low-risk ambulatory settings where overprescriptions likely dominate and inpatient settings where the risks and benefits of early and accurate empiric therapy are the greatest.

Data Source and Analysis

We analyzed 5 years of antibiotic susceptibility isolate testing data and related deidentified patient information from the University of California San Diego Health Sciences (UCSDHS). The study was reviewed and approved by the University of California San Diego Human Research Protections Program

(Institution Review Board #161853). Positive bacterial cultures with susceptibility results between May 2011 and November 2016 were included. Contents included identified pathogens; their susceptibility to tested antibiotics; diagnostic information from before, during, and after the ordering of cultures; any medications prescribed before and throughout their visit; the problem list at the time of order; and general demographic information.

We processed the data before analysis by removing repeat susceptibility tests according to the Clinical and Laboratory Standards Institute guidelines [9]. Suppressed antibiotics and supplemental tests performed after cultures returned were not considered for the purposes of this study. The International Classification of Diseases-10 (ICD-10) codes at order and at discharge were mapped to syndromes and prevalent comorbidities; for example, sepsis was defined as a positive blood culture and a corresponding ICD-10 code. An overview of the mapping is provided in Multimedia Appendix 1.

We studied the influence of time, demographics, assigned syndromes, medications, and comorbidities on the resulting distribution of causal bacteria, their susceptibility, and clinical outcomes. Logistic regression was used to calculate the odds ratios (OR) adjusted for age and sex, and the results were filtered by significance ($P<.05$). The influence of ineffective therapy on clinical outcomes was assessed between syndrome-factor combinations. Critical combinations were identified by evaluating changes in 7-day all-cause mortality and median LOS for prescribed treatments.

The impact of factors and comorbidities on the resulting distribution of causal bacteria, their susceptibility, and mortality were analyzed using the Python statsmodels package implementation of logistic regression adjusted for age and sex to account for significant differences in syndrome types and commonly occurring organisms, for example, higher rates of UTI and gram-negative bacteria in women. Age was modeled as a categorical variable (0-14, 15-24, 25-44, 45-64, and ≥65). The impact of age and sex was evaluated by controlling for each other. The change in LOS was analyzed using the Mann-Whitney *U* test from the scipy package. The effect size in days was calculated as the difference in medians to account for skewed distribution.

Algorithm and iBiogram Decision Support Platform Development

To analyze and communicate the impact of risk factors for specific cases, we developed the remaining risk metric as a shared representation [28]. The risk of ineffective empiric antibiotic therapy was calculated as the sum of the individual resistance probabilities of each possible causal agent r_i weighted by the probability of that causal agent a_i. With n referring to the number of possible causal agents:

The remaining risk of combination therapy was calculated by selecting the minimal r_i of all therapy antibiotics. The result was a prevalence-weighted multiantibiotic antibiogram that we refer to as iBiogram. We then developed a web-based prototype of the iBiogram where all statistically significant factors may be coselected to generate a patient-centric antibiogram, as well as a recommended set of antibiotics with the best coverage for predicted organisms.

The iBiogram algorithm draws antibiotics from a knowledge base that maps antibiotics to syndromes. Antibiotics are additionally filtered by the available test data for the selected scenario to prevent inflated rankings caused by a few or, in the worst case, a single antibiotic susceptibility isolate test. All possible antibiotic combinations were generated and ranked based on the remaining subset of antibiotics. Sepsis is currently the only syndrome that allows the combination of three antibiotics with amikacin and gentamicin reserved as the third drug.

Evaluation

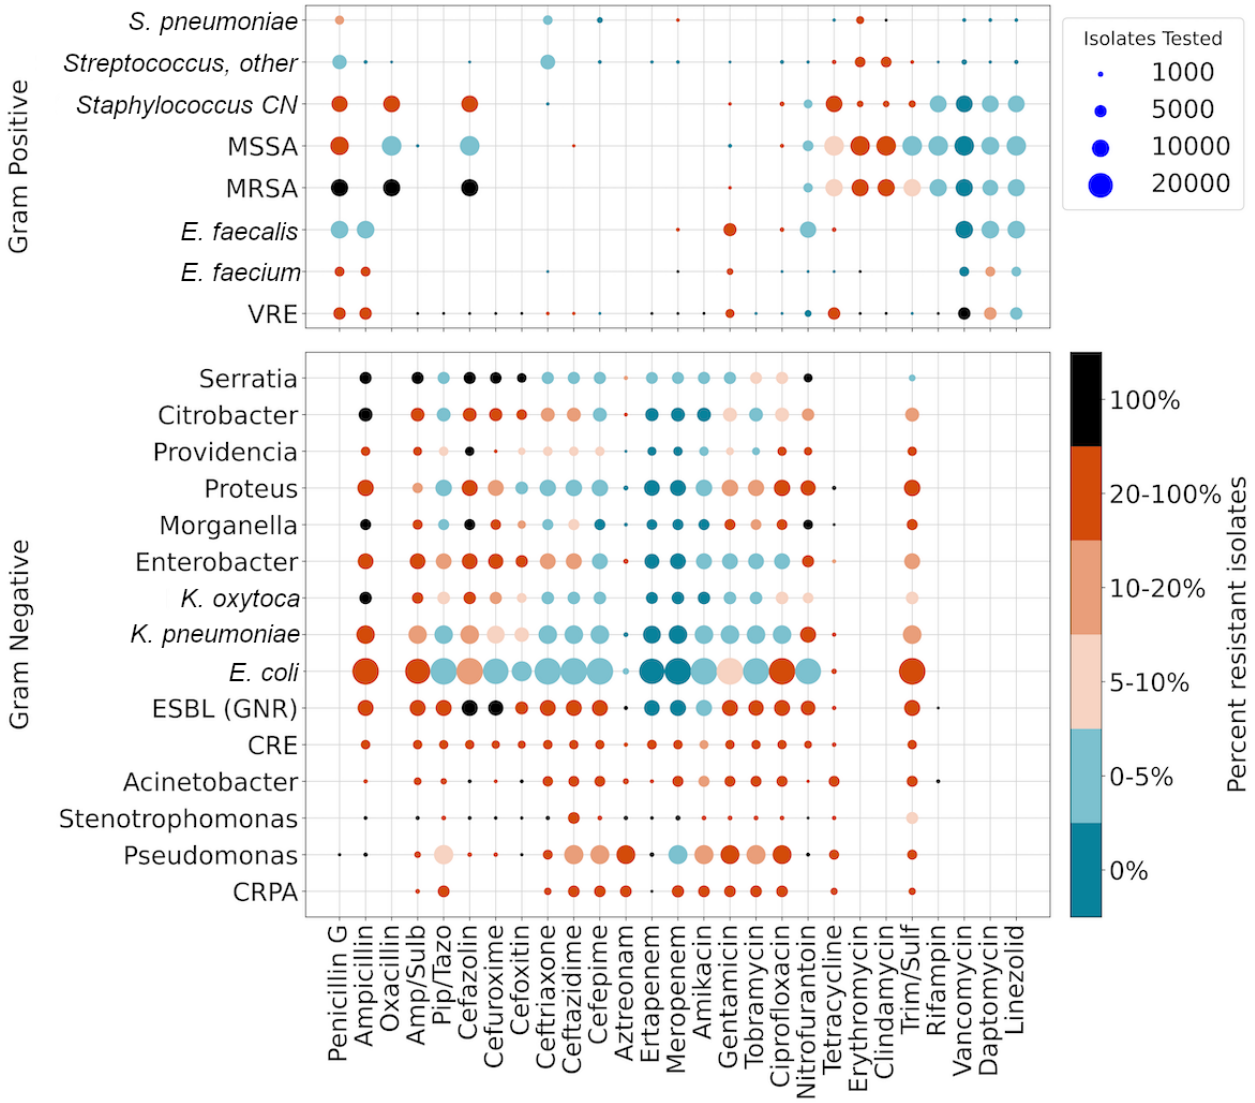
The iBiogram algorithm was evaluated by using data before the last 6 months and comparing the performance of predicted *best* treatments to the actual treatments and outcomes in the last 6 months of the data. Physicians' decisions and iBiogram prediction decisions were evaluated as successful if the identified organism was susceptible to any of the prescribed or recommended antibiotics. For physicians' empiric therapy choices, we considered antibiotics prescribed between 24 hours before and 8 hours after the culture was ordered. Considering antibiotic stewardship and building on the conducted mortality analysis, we used predicted-susceptibility targets developed by Cressman et al [29] to rank potential treatments for a given syndrome based on the risk of mortality or prolonged LOS. Prescribed and suggested therapeutic regimens were further scored on the use of protected antibiotics and essential medicines according to World Health Organization's Action for Welfare and Awakening in Rural Environment Classification Database [30]. This classification groups therapies into *Access group Antibiotics*, those that are broadly active but minimal risk for resistance, *Watch group antibiotics* that are high priority therapies at substantial risk for developing resistance without stewardship, and *Reserve group antibiotics* that are saved only for use in life-threatening multidrug-resistant infections.

Results

Data Summary

Figure 1 depicts an overview of all susceptibility tests for gram-positive and gram-negative organisms over the full 5-year data set at the UCSDHS. A complete table is available in the Multimedia Appendix 2. Here, we re-envision a general static antibiogram, summarizing prevalence (dot area) and resistance patterns (red is increasing prevalence). Although printed antibiograms display only the current quarter, including more data can result in a higher predictive value for a specified patient, as a larger number of cases reduces the effect of outliers. An analysis of larger time windows found no significant differences between quarterly antibiograms and data, including up to 7 quarters (Multimedia Appendix 3).

Figure 1. Overview of antibiotic resistance: Summary of the analyzed data for the most commonly tested antibiotics and causal agents. Each dot represents all isolates with a given causal agent (horizontal) and tested antibiotic (vertical). The number of isolates is indicated by dot-size and the probability of resistance is encoded as color ranging from blue (0% resistance) over red (>20% resistance) to black (100% resistance). CN: Coagulase Negative Staphylococci; CRE: Carbapenem-resistant enterobacteriaceae; CRPA: Carbapenem-resistant Pseudomonas aeruginosa; ESBL: Extended Spectrum Beta Lactamase producing Enterobacteriaceae; GNR: Gram negative rod; MRSA: Methicillin-resistant Staphylococcus aureus; MSSA: Methicillin-susceptible Staphylococcus aureus; VRE: Vancomycin-resistant Enterococcus.



Factors Influencing Microbial Ecology, Resistance, Mortality, and LOS

The risk factors influencing organism prevalence and resistance at UCSDHS range from well-known contributing factors such as prior antibiotic use to more specific insights, such as the influence of a specific transplant history. Figure 2 depicts the principal factors that drive AMR, Multimedia Appendices 3-6 supply additional data. They were assessed and reported as adjusted ORs for changes in organism prevalence (left) and resistance (right). Expected contributing factors included sex, age, and context, such as whether a patient presented in an outpatient setting, to an emergency department, or developed illness while hospitalized. Certain historic patient factors (eg, diabetes, cystic fibrosis, hemodialysis, or history of transplantation) were linked to significantly higher rates of multidrug-resistant organisms. For instance, patients on hemodialysis had higher rates of carbapenem-resistant Enterobacteriaceae (CRE; OR 2.4, 95% CI 1.7-3.3). Patients with health care–associated pneumonia were at increased risk for *Acinetobacter* (OR 3.4, 95% CI 2.7-4.4), CRE (OR 3.3, 95% CI 2.7-4.1), and carbapenem-resistant *Pseudomonas aeruginosa* (CRPA; OR 3.3, 95% CI 2.7-4.1). Cystic fibrosis presented the strongest effects in both ecology and resistance, showing drastic shifts to *Pseudomonas* (OR 12.4, 95% CI 11.4-13.5), CRPA (OR 22.7, 95% CI 18.8-27.3), *Stenotrophomonas* (OR 5.5, 95% CI 4.5-6.7), and methicillin-resistant *Staphylococcus aureus* (OR 1.7, 95% CI 1.5-1.9), with significant decreases in other pathogenic organisms.

The syndrome-associated 7-day all-cause mortality, as well as median LOS, differed significantly based on sensitivity to empiric treatments. The specific syndrome factors are reported in Figure 3. Failure to prescribe active antibiotics for patients presenting with a UTI or community-acquired pneumonia did not significantly influence mortality or resulted in small changes

in the LOS, whereas cases of health care–associated pneumonia and sepsis showed significant increases in mortality and LOS. For instance, nosocomial sepsis with hematologic malignancy was significantly associated with increased 7-day all-cause mortality (OR 3.2) and LOS (+19 days) when empiric antibiotics were inactive against the causative pathogen.

Figure 2. Factors influencing microbial prevalence (left) and resistance (right): Odds ratios for statistically significant factors (P<.05) influencing the probability of encountering a specific bacterium or an isolate resistant to a particular treatment were adjusted by sex and age. Sex and age were adjusted against each other. Factors include demographic information, zip code, medications, syndromes, and comorbidities as coded in International Classification of Diseases-10. In the left graph, purple indicates a higher prevalence of particular pathogens. In the right graph, red indicates a higher and blue a lower prevalence of resistant isolates. CAP: community-acquired pneumonia; CN: coagulase-negative Staphylococci; COPD: chronic obstructive pulmonary disease; CRE: carbapenem-resistant Enterobacteriaceae; CRPA: carbapenem-resistant Pseudomonas aeruginosa; ESBL: extended-spectrum β-lactamases; GNR: Gram negative rod; HAP: health care–associated pneumonia; ICU: intensive care unit; MRSA: methicillin-resistant Staphylococcus aureus; MSSA: methicillin-susceptible Staphylococcus aureus; SSTI: skin and soft tissue infection; UTI: urinary tract infection; VRE: vancomycin-resistant Enterococcus.

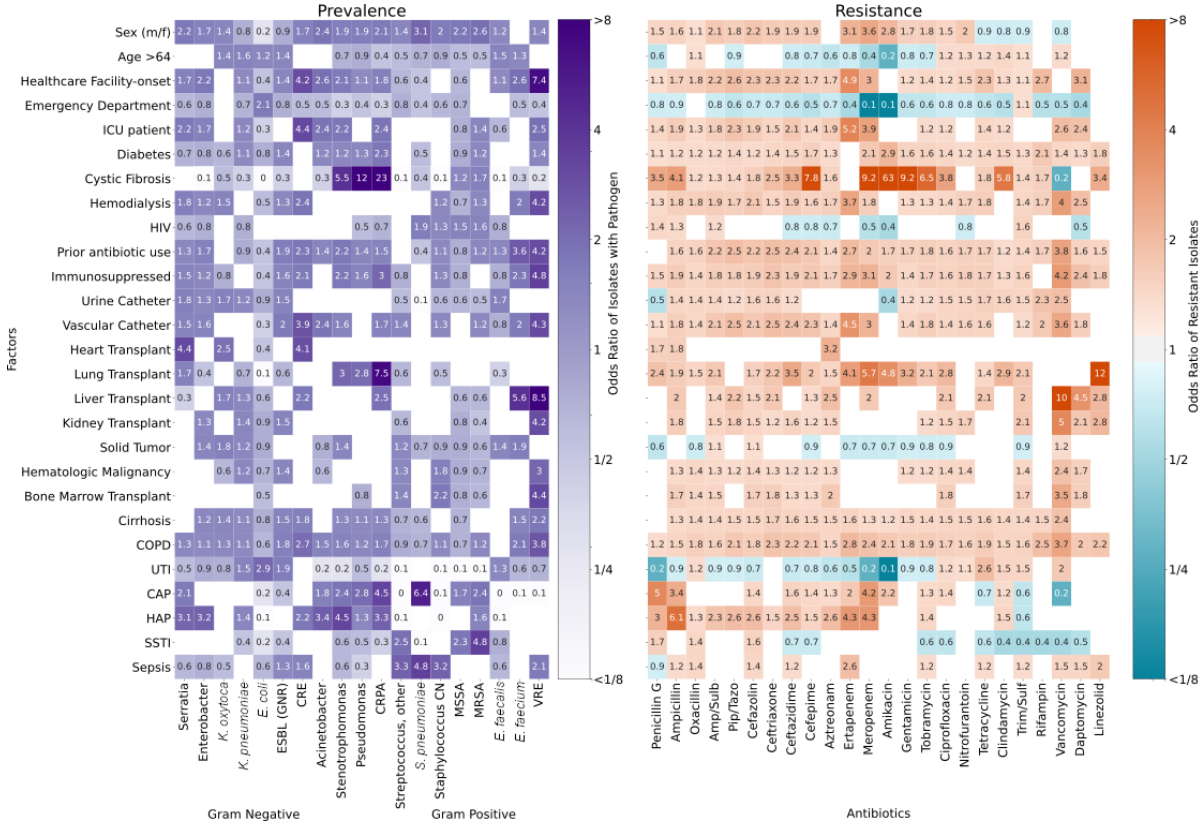


Figure 3. Influence of treatment failure on 7-day all-cause mortality (top) and median length of stay (bottom) in syndromes/risk factor combinations: A summary of the influence of resistant pathogens for syndromes modified by risk factor or comorbidity. Only significant results (P<.05) are shown. The top graph shows the age and sex adjusted 7-day all-cause mortality odds ratio for failed treatments, for example, hospital-facility sepsis patient with ineffective treatment are 4.3 times more likely to die within 7 days. The bottom graph depicts how ineffective treatment affects the median length of stay for the same combinations including only surviving patients and testing significance using the Mann-Whitney U test. For each syndrome, the mean mortality and the median length of stay is listed on the y-axis behind the syndrome name in brackets. CAP: community-acquired pneumonia; CKD: chronic kidney disease; COPD: chronic obstructive pulmonary disease; HAP: health care–associated pneumonia; SSTI: skin and soft tissue infection; LOS: length of stay; UTI: urinary tract infection.

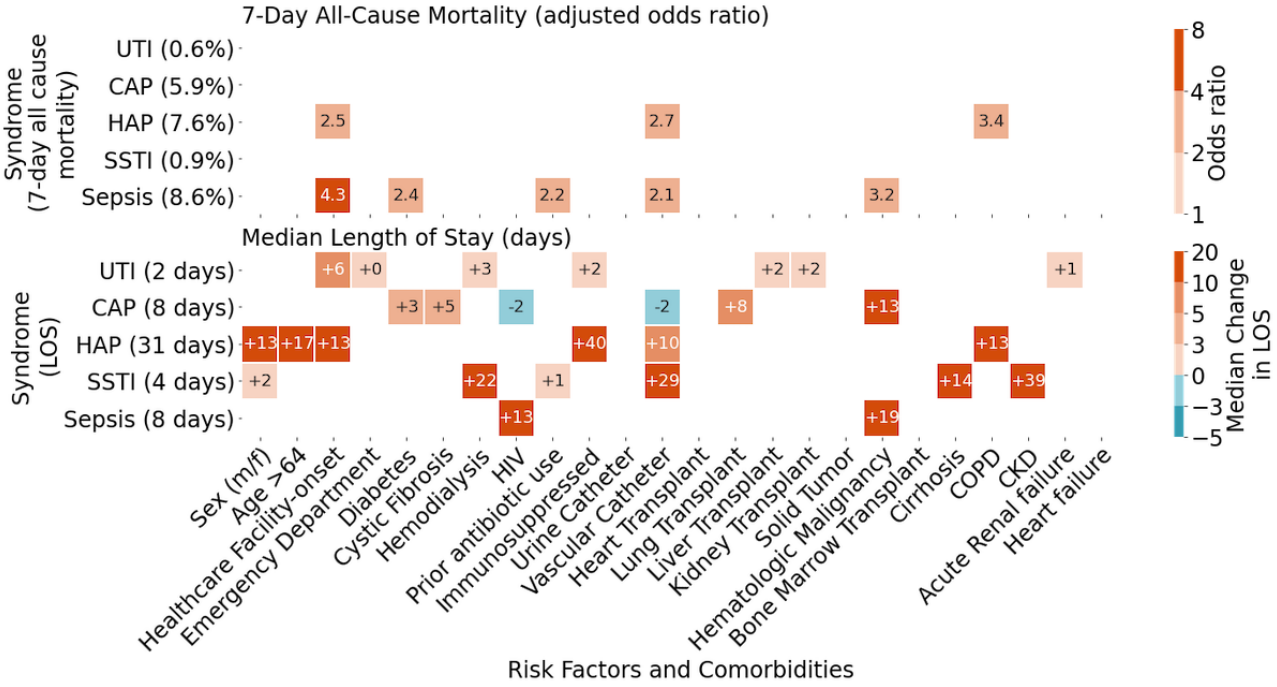
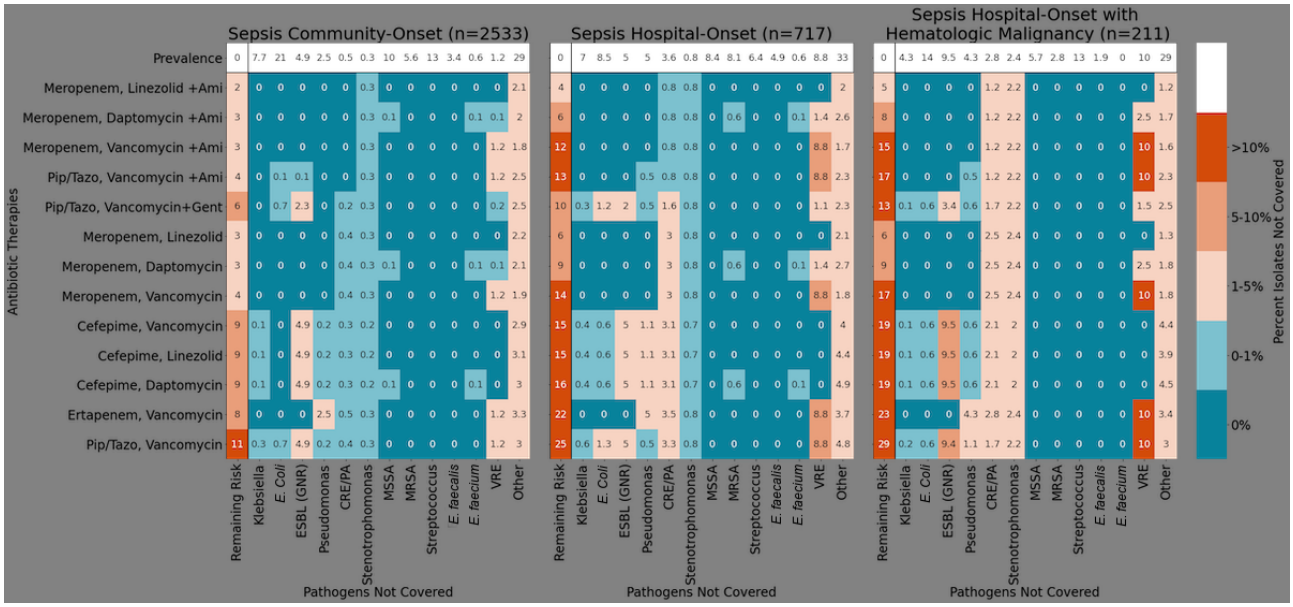


Visualizing Risk of Resistance for Empiric Therapy

The difficult tradeoff between overly broad empiric regimens and the risk of treatment failure requires a shared representation that accounts for known risk factors. Consider the scenario shown in Figure 4 where on the left, we show a filtered remaining risk antibiogram displaying the performance (chance of failure) of common empiric antibiotic regimens for patients presenting with community-onset sepsis in the emergency department. In the middle, we consider changes in risk associated with hospital-onset sepsis and on the right for the subset of these patients with a hematologic malignancy.

An antibiogram for community-onset sepsis would predict the frequently prescribed empiric therapy of vancomycin and piperacillin/tazobactam to fail in 11% of pathogens in this data set. However, after adding hospital-onset and hematologic malignancy factors, the failure risk increases to 25% and over 28%, respectively, each below the recommended target of complete or at a minimum 90% coverage (<10% remaining risk) in cases of severe sepsis [29]. At first glance, daptomycin and meropenem, less traditional first-line agents for hospital-onset sepsis, might be considered a better empiric regimen in these populations, with only 9% remaining risk of failure.

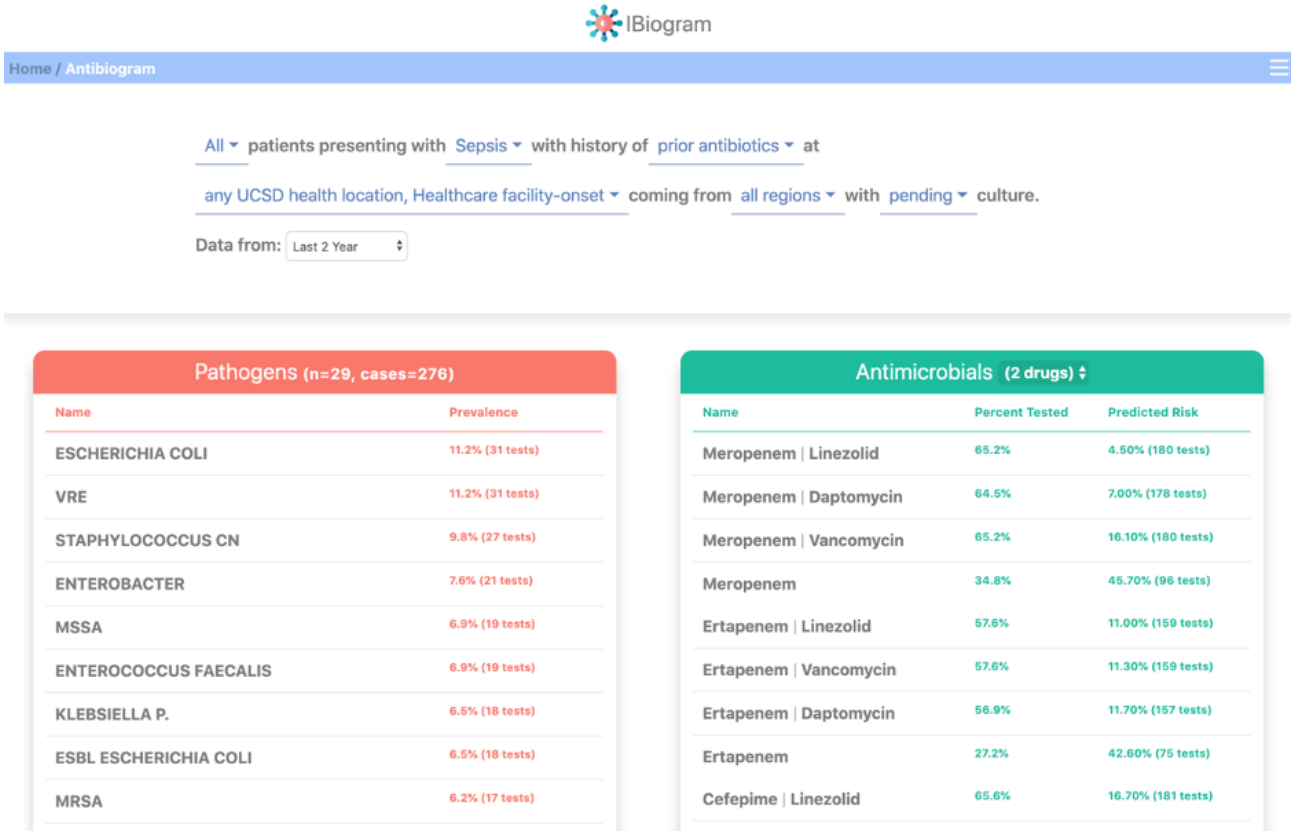
Figure 4. Remaining risk of treatment failure in sepsis: A summary of the percent risk of failure for common multidrug regimens in sepsis cases. Shown are blood culture summations from community-onset sepsis, hospital-onset sepsis, and hospital-onset sepsis in patients with a hematologic malignancy. Numeric values represent remaining risk (prevalence x predicted resistance) to a given antibiotic or antibiotics. The prevalence (top row) lists the probability of encountering the delineated causal agents. If a treatment does not cover a pathogen the risk equals the prevalence of that pathogen, for example, meropenem never covers methicillin-resistant Staphylococcus aureus. The percentage in the remaining risk column (leftmost) sums the probability of encountering a pathogen not covered by the delineated therapy. Blue color coding represents <1%, increasing in red intensity until, red ≥10%, a minimum threshold suggested for severe infection [29]. CRE: carbapenem-resistant Enterobacterales; ESBL: extended-spectrum β-lactamases; GNR: Gram negative rod; MRSA: methicillin-resistant Staphylococcus aureus; MSSA: methicillin-susceptible Staphylococcus aureus; PA: Pseudomonas aeruginosa; VRE: vancomycin-resistant Enterococcus.



Envisioning a Human-Centered Antibiogram

In Figure 5, we provide a prototype digital antibiogram capable of accounting for the factors that predict the particular ecology associated with patients sharing these factors, along with the associated resistance patterns and suggested antibiotics with their expected coverage. Here, we selected all patients over the last eight quarters who developed nosocomial sepsis while receiving antibiotic therapy. In the left panel, we can see the most prevalent pathogens in this population. The user can scroll down to see the long tail of the organisms. On the right, a list of potential treatments (1-3 drugs may be displayed) is shown with predicted coverage, and the ability to toggle and show the remaining risk. Overall, using a combination of patient factors, historic culture data, and antibiotic prescribing rules, the user can readily select key factors to generate a patient-level antibiogram that is tailored to the case at hand. The system then provides a list of therapeutic options (ranked either by predicted coverage or by remaining risk) and suggests treatments that a provider may select based on further details such as patient history of medication allergies, need for bactericidal versus bacteriostatic drugs, preferred route of administration, drug-drug interactions, and cost of treatment.

Figure 5. The iBiogram digital antibiogram: iBiogram is a web-based app that allows the user to select patient demographics, presenting syndrome, prior use of antibiotics or immune suppression, comorbid conditions, as well as the location and context of infection, the region a patient has come from and if the pending cultures have been identified as gram-positive or -negative. In the example above, all patients with diabetes on prior antibiotics and presenting with nosocomial sepsis over 2 years are shown. If the user suspects a specific organism based on history that organism can be selected, and the table will reorient to show the sensitivities for just that organism. Likewise, a user can select a treatment regimen and examine the organisms that are sensitive or resistant to the treatment. ESBL: extended-spectrum β-lactamases MRSA: methicillin-resistant Staphylococcus aureus; MSSA: methicillin-sensitive susceptible Staphylococcus aureus; VRE: vancomycin-resistant Enterococcus.



Comparing Empiric Therapy at the Time of Order Versus iBiogram Suggestions

Given that patients who received effective empiric therapy were more likely to survive and had shorter LOS, we analyzed the failure rate of prescribed empiric therapies based on final sensitivity results and compared them to the suggested iBiogram regimens (Table 1). For patients presenting to the emergency department with a UTI, the most commonly prescribed antibiotics were ciprofloxacin and ceftriaxone, and the overall failure rate was 17.7% (85/479), whereas the suggested iBiogram treatments would have been between 23% and 15.1%. For the subset of patients with UTIs in the emergency department with prior antibiotics, the empiric therapy treats only 74% (48/65; 26.2% failure), whereas suggested regimens would have achieved a reduction of 3.6%-14.2%. For community-onset sepsis, the most frequently prescribed drugs were piperacillin/tazobactam and vancomycin, and the overall failure rate considering all cases was 8.1% (31/383), compared with 5.5% for the iBiogram-suggested treatment. For cases of hospital-onset sepsis, however, where there is significant associated mortality, prescribed empiric failure rose to 16% (12/75) in comparison to 7.8% using the proposed antibiotics. Finally, in cases of hospital-onset sepsis in patients with hematologic malignancy, where we found the strongest correlation of mortality and LOS with sensitivity to prescribed antibiotics, we see failure of empiric therapy climb to 17.4% (4/27) failure, whereas suggested combinations would have failed in only approximately 13% of cases.

Table 1. Comparison of the performance of iBiogram recommendations to actual antibiotics prescribed by doctors at the time of order.[a]

Syndrome	Risk factor		Received empiric antibiotics		Retrospective comparison of prescribed empiric therapies to iBiogram suggestions				
	Total	Deceased, n (%)	Total	Deceased, n (%)	Empiric therapy (%)				iBiogram suggestion

Discussion

Research in Context

On the basis of gaps in the science noted by Curtis [17], Rawson [18], and Laka [19], this study adopted a systematic human-centered approach to analyze, visualize, and operationalize factors associated with AMR, mortality, and LOS of bacterial infections across a United States academic health care system, spanning from ambulatory and emergency to inpatient and intensive care settings. Our efforts differed from machine learning approaches that remain limited to large homogenous data sets, as well as from the robust TREAT program [25], which incorporates more assumed knowledge but may miss factor associations. This study mirrors significant efforts such as Detecting and Eliminating Bacteria Using Information Technologies (DeBUGIT) [31], Wise Antimicrobial Stewardship Support System (WASPSS) [32], and EPiC IMPOC (Enhanced, Personalized and Integrated Care for Infection Management at the Point-Of-Care) [33,34] that have each sought to optimize bug-drug combinations by fusing data-driven approaches with expert consensus or guidelines. However, we propose that our integration of morbidity and mortality with clinical and microbiological data to present the risk of failure in a mortality cost-benefit context may be more intuitive to clinicians balancing patient safety and antimicrobial stewardship across the continuum of care.

We conducted a comprehensive examination of the factors influencing microbial ecology and resistance within a large urban and suburban health care system to set the stage for the development of an antibiotic recommendation system that can support clinicians prescribing antibiotics in the absence of culture data. We identified predictive factors that may be used to create tailored empiric antibiotic choices; however, these factors may be difficult to convey using static and nondigital approaches. Alone, these factors are also insufficient to make optimal therapeutic decisions, as recommendations to prescribers

require fusion of purely probabilistic approaches with clinical heuristics, expert guidelines, and other risk benefit considerations [24].

We cleaned and created a new graphical representation of the bacterial prevalence and antibiotic resistance data. At a glance, this approach can be seen to be more readily informative of both the likelihood of encountering given pathogens and their expected pattern of resistance than current paper-based antibiograms. This approach also demonstrates the limitations of a hospital-wide and static view of AMR when attempting to map data to a specific patient and immediately suggests that more granular patient-specific data could inform better decision-making. Such a graphical overview could be generated for subsets of the data to generate and track a *fingerprint* of resistance patterns.

The complex sepsis cases in Figure 4 highlight the tension between the need for more precise, patient-specific, and readily accessible antibiograms but also indicate that actionable support for clinicians requires a complex understanding of patient factors and best practices that may be specific to an institution. For instance, closer examination and expert clinical experience revealed that daptomycin may offer little advantage over vancomycin against methicillin-resistant *Staphylococcus aureus*, merely adding coverage against vancomycin-resistant enterococci, which is generally encountered in specific situations and may be associated with higher mortality if missed empirically in these cases [35]. Likewise, the benefits of using a third agent such as amikacin, a potentially ototoxic and nephrotoxic drug, over the safer meropenem and daptomycin combination, would only be worthwhile in specific risk groups with higher rates of CRE and CRPA, such as patients with cystic fibrosis or a history of lung transplantation. The robust performance of amikacin in our data set also highlights the potential influence of a hospital's formulary, as amikacin is rarely used and is not routinely stocked in the study hospital, where other aminoglycosides are favored. The ability to track antibiotic use with antibiotic resistance data on broad scales and among various institutions with different prescribing practices will ultimately shed important light on antimicrobial stewardship priorities.

To this end, we developed a digital tool combining up-to-date hospital data with clinical rules (here syndrome-specific antibiotics from expert guidelines) as an interactive precision tool for the selection of antibiotic combinations. This tool covers many typical scenarios encountered by clinicians across the continuum of care, ranging from empiric treatment of a UTI in ambulatory patients to solid-organ transplant recipients with sepsis presenting to the emergency room and the care of complex hospitalized patients such as those with stem cell transplants or cystic fibrosis. Notably, this ecology is highly regional and often hospital specific, highlighting the need to incorporate local organism prevalence, local formulary, and patient-specific risk factors. In the future, the tool could be readily integrated into EHRs to alert clinicians when prescribed regimens are too broad in coverage or have higher than accepted chances of failure. Alternatively, more appropriate regimens can be suggested. Eventually, such tools could be used for individual patients with complicated infectious disease histories or as personalized antibiograms in ambulatory settings. This might benefit those with frequent infections such as UTI, dialysis patients with repeated sepsis, or cystic fibrosis patients with highly specific ecologies.

Our data underscore the potential benefits of more specific antibiograms as well as the continued need for careful, case-based consideration of therapeutic options by expert clinicians. Although the data presented here support the utility of multidimensional antibiograms, they also highlight the challenges in designing a balanced tool that offers generalizability to multiple syndromes and presents therapeutic options that account for the immediate need for broad coverage and the counterpoised threat of antibiotic resistance in the clinical environment. Combining associated mortality data that is specific to certain patient populations may help navigate this risk so that narrow-spectrum antibiotic regimens may be used in low-risk scenarios and broader spectrum treatments could be saved for short periods in high-stakes scenarios. Table 1 illustrates this point. Here, we see that iBiogram not only distinguished between syndromes with no mortality (UTI) and those with high (sepsis), similar to providers, but tailored treatments further based on other risk factors. Notably, providers prescribed 74% (48/65) to 75.9% (364/479) of watch antibiotics in UTI, whereas iBiogram recommended watch group therapies only in UTI cases with prior antibiotic use. In sepsis, 91% (21/23) to 95% (71/75) of provider prescriptions were the watch group and 2.1% (8/383) to 4% (3/75) reserve antibiotics, whereas the iBiogram system suggested reserve antibiotics only in high mortality cases, providing better empiric coverage.

Limitations and Future Directions

The retrospective nature of the study and the quality of the EHR data are the two primary limitations. Retrospectively distinguishing pathogenic organisms from contaminants can be challenging. Therefore, we excluded many positive cultures that did not have a corresponding ICD-10 code. Moreover, many infections are treated without culture or negative cultures are ignored. This leads to a selection bias in the analyzed EHR data, whereby only positive cultures are recorded, likely resulting in a bias toward higher acuity diseases. The presented factors rely mainly on ICD-10 codes that (1) limit granularity, (2) are prone to coding errors, and (3) may not reflect important uncharted factors, including severity and timing of disease. For instance, it was not possible to distinguish sepsis from severe sepsis based on coding alone and medical data such as blood pressure, or use of pressers, were beyond the scope of this work. Furthermore, not all antibiotics were tested against all the isolates. For example, levofloxacin is rarely tested at our institution because its resistance patterns closely match those of ciprofloxacin. Finally, new antibiotics are continuously brought to the market to treat resistant organisms, and retrospective data will, by definition, not include the newest available antimicrobials.

Similar to traditional antibiograms, the prototype described in this work currently focuses only on antibiotic coverage and does not consider other factors such as side effects, or restricted institutional antibiotics, nor does it distinguish the mode of delivery (intravenous vs oral) and the cost or risk of interactions

with other medications. It also did not present patient-specific data with regard to recent specific antibiotic exposure or past personal culture data. Finally, the current version of the iBiogram did not include data on newer broad-spectrum antimicrobials such as ceftolozane-tazobactam and ceftazidime-avibactam, which may offer more reasonable and less toxic options in the setting of a CRE or CRPA.

Finally, we propose that these methods may be applied to inter–health care system data to create regional antibiograms [36-38] or with international databases such as WHONET data, where the platform could also extend to resource-limited and rural settings [39]. Therefore, data sets grow in breadth, depth, and history, machine learning tools and recursive approaches may increasingly be applied to predict the drivers of ecology and patterns of resistance.

Conclusions

Overall, we aimed to create an interactive shared representation of the complex factors that clinicians must navigate for effective empiric prescriptions. To this end, we developed a CDSS that strives to promote effective collaboration with users, bridging the gap in presentation and reasoning between clinical guidelines, clinicians' expertise, and data science by representing local outcomes and local ecology in a user-centered tool. Overall, we propose that such tools could improve clinical and safety outcomes, reduce adverse events because of inappropriate antibiotics, provide real-time suggestions to prescribers, and lower AMR and costs of care.

Abstract

Background: Interpretation of capsule endoscopy images or movies is operator-dependent and time-consuming. As a result, computer-aided diagnosis (CAD) has been applied to enhance the efficacy and accuracy of the review process. Two previous meta-analyses reported the diagnostic performance of CAD models for gastrointestinal ulcers or hemorrhage in capsule endoscopy. However, insufficient systematic reviews have been conducted, which cannot determine the real diagnostic validity of CAD models.

Objective: To evaluate the diagnostic test accuracy of CAD models for gastrointestinal ulcers or hemorrhage using wireless capsule endoscopic images.

Methods: We conducted core databases searching for studies based on CAD models for the diagnosis of ulcers or hemorrhage using capsule endoscopy and presenting data on diagnostic performance. Systematic review and diagnostic test accuracy meta-analysis were performed.

Results: Overall, 39 studies were included. The pooled area under the curve, sensitivity, specificity, and diagnostic odds ratio of CAD models for the diagnosis of ulcers (or erosions) were .97 (95% confidence interval, .95–.98), .93 (.89–.95), .92 (.89–.94), and 138 (79–243), respectively. The pooled area under the curve, sensitivity, specificity, and diagnostic odds ratio of CAD models for the diagnosis of hemorrhage (or angioectasia) were .99 (.98–.99), .96 (.94–0.97), .97 (.95–.99), and 888 (343–2303), respectively. Subgroup analyses showed robust results. Meta-regression showed that published year, number of training images, and target disease (ulcers vs erosions, hemorrhage vs angioectasia) was found to be the source of heterogeneity. No publication bias was detected.

Conclusions: CAD models showed high performance for the optical diagnosis of gastrointestinal ulcer and hemorrhage in wireless capsule endoscopy.

Introduction

Wireless capsule endoscopy (WCE) allows the investigation of gastrointestinal mucosal lesions in a noninvasive manner. This provides approximately 50,000 to 60,000 video frames and allows visualization of the entire gastrointestinal mucosa in a single examination without causing discomfort to patients or risk of procedure-related adverse events [1,2]. Given that the small intestine has been a blind spot for gastroenterologists, WCE has become the standard investigation modality for obscure gastrointestinal hemorrhage and a widely accepted method for the assessment of small intestinal ulcers or tumors [1]. Despite easy accessibility, safety, and patients' comfort for the examination, WCE has a limitation regarding the interpretation. A tedious reading time of approximately 30 to 120 minutes is required, and a small number of abnormal video frames can be easily mistaken for a normal mucosa by endoscopists [1-3].

Artificial intelligence technology has been adopted in gastrointestinal endoscopy, and the automatic detection or diagnosis of abnormal lesions on endoscopic images or movies has been widely investigated [4,5]. The main benefit of the application of artificial intelligence would be the reduction of the laborious reading time and miss rate of important findings in WCE. Another advantage would be the highly accurate diagnostic performance, which is comparable to that of an endoscopist [6]. These artificial intelligence models are expected to aid in the automatic detection of important lesions in WCE images, thus making it possible to perform automatic reading and interpretation of the entire examination.

Previous studies have reported the performance of computer-aided diagnosis (CAD) models using artificial intelligence in WCE [7,8]. Machine learning– or deep learning–based artificial intelligence models with potential benefits have been reported in these studies. Based on these findings, 2 meta-analyses have been conducted for the pooled diagnostic performance of deep-learning models or convolutional neural network models for the diagnosis of gastrointestinal hemorrhage or ulcers using WCE [7,8]. However, the first meta-analysis searched only 1 database, and a substantial number of important articles were omitted. Moreover, an inaccurate crude number of true positives (TP), false positives (FP), false negatives (FN), or true negatives (TN) of CAD models in each study was reported [7]. This inaccurate pooled diagnostic performance can mislead the readers. The second meta-analysis searched multiple databases; however, it also did not include several important papers, and only a single medical librarian searched all the databases [8]. The main pitfall was the simple pooling of the sensitivity or specificity in each study without considering the distribution of abnormal lesions among the total included lesions in each study. Moreover, the diagnostic performance for the gastrointestinal ulcers and hemorrhage was not separated but combined into a single outcome, and quality assessments in each included study were also omitted. The method of exploring the reason for the heterogeneity and the assessment of publication bias also adhered to the interventional meta-analysis methodology in both meta-analyses but did not satisfy the diagnostic test accuracy (DTA) meta-analysis methodology. Given that the method of conducting interventional and DTA meta-analyses is different and that a widely accepted standard methodology exists in conducting the DTA meta-analysis, this can also mislead the readers (Table 1). Therefore, systematic reviews conducted thus far have been inadequate, and the real diagnostic validity of CAD models in WCE has not yet been determined. This study aimed to evaluate the DTA of CAD models for gastrointestinal ulcers or hemorrhage using WCE images through the standard methodology.

Table 1. Comparison of previous meta-analyses with the current study.

Parameters	This study	Soffer et al [7]	Mohan et al [8]
Number of included studies	20 studies on gastrointestinal ulcers and 19 studies on gastrointestinal hemorrhage	5 studies on gastrointestinal ulcers and 5 studies on gastrointestinal hemorrhage	9 studies for the diagnosis of gastrointestinal ulcers or hemorrhage (did not perform separate analysis between ulcers and hemorrhage)
Main outcome	Separate diagnostic performance of CAD[a] models for the gastrointestinal ulcers or hemorrhage using WCE[b]	Separate diagnostic performance of CAD models for the gastrointestinal ulcers or hemorrhage using WCE	Pooled diagnostic performance of CAD models for gastrointestinal ulcers and hemorrhage using WCE (not a meta-analysis with DTA[c]; lack of consideration for the prevalence of ulcers or hemorrhage in each study and thus no calculation of TP[d], FP[e], FN[f], or TN[g] in each study)
Search strategy	Search of MEDLINE through PubMed, Web of Science, and the Cochrane Library (2 independent authors searched the databases)	Search of MEDLINE through PubMed (2 independent authors searched the database)	Search of ClinicalTrials.gov, Ovid EBM[h] Reviews, Ovid, Embase, Ovid MEDLINE, Scopus, and Web of Science (a single medical librarian searched all the databases)
Inaccurate calculation (coding) of TP/FP/FN/TN	N/A[i]	Inaccurate calculation detected in the study's figures	Not a meta-analysis with DTA; lack of consideration for the prevalence of ulcers or hemorrhage in each study and thus no calculation of TP, FP, FN, or TN in each study
Determination of the heterogeneity between studies	Correlation coefficient between the logarithm of the sensitivity and specificity, beta of HSROC[j] model, visual examination of the SROC curve	I^2 statistics (DTA meta-analysis did not determine heterogeneity with I^2 statistic)	I^2 statistic (DTA meta-analysis did not determine heterogeneity with I^2 statistics)
Quality assessment	QUADAS-2[k]	QUADAS-2	Not assessed
Publication bias	Deeks funnel plot asymmetry test	Not assessed	Not assessed

[a]CAD: computer-aided diagnosis.

Methods

Adherence to the Checklist for Systematic Reviews and Meta-analyses

This study was conducted in accordance with the statement of the PRISMA (Preferred Reporting Items for a Systematic Review and Meta-analysis) of DTA Studies [9]. The study protocol was registered at the International Prospective Register of Systematic Reviews (PROSPERO) database before initiation of the systematic review (#CRD42021253454). Approval from the institutional review board of the Chuncheon Sacred Heart Hospital was waived.

Search Strategy for Relevant Literature

The authors established searching formulae using keywords related to the performance of CAD models in the detection of ulcer or hemorrhage using WCE images. Medical Subject Headings (MeSH) terminology keywords were used for the establishment of searching formulae (Textbox 1).

CAD, computer-aided diagnosis; WCE: wireless capsule endoscopy; tiab: searching code for title and abstract; Mesh: Medical Subject Headings; ab, ti, kw: search code for abstract, title, and keywords; Lang: search code for language; lim: searching code by limiting certain conditions.

Two authors, CSB and JJL, independently performed a core database search of MEDLINE through PubMed, Web of Science, and Cochrane Library using pre-established search formulae from inception to May 2021. Duplicate articles were excluded. The titles and abstracts of all identified articles were reviewed, and irrelevant articles were excluded. Full-text reviews were subsequently performed to determine whether the pre-established inclusion criteria were satisfied in the identified literature. The references of relevant articles were also reviewed to identify any additional studies. Any disagreements of results in the searching process between CSB and JJL were resolved by discussion or consultation with the other author (GHB).

Inclusion Criteria of the Literature

The literature included in this systematic review met the following inclusion criteria: designed to evaluate the diagnostic performance of CAD models for gastrointestinal ulcers or hemorrhage based on WCE images; presentation of the diagnostic performance of CAD models, including sensitivity, specificity, likelihood ratios, predictive values, or accuracy, which enabled the estimation of TP, FP, FN, and TN values of CAD models; and written in English. The exclusion criteria were as follows: narrative review articles, studies with incomplete data, systematic review or meta-analyses, comments, proceedings with only an abstract, or study protocols. A full publication with PDF files of available proceedings was considered to be a full article. Articles meeting at least 1 of the exclusion criteria were excluded from this study.

Assessment of Methodological Quality in the Selected Literature

The methodological quality of the included articles was assessed by CSB and JJL using the second version of Quality Assessment of Diagnostic Accuracy Studies (QUADAS-2). This tool comprises 4 domains, including “patient selection,” “index test,” “reference standard,” and “flow and timing,” with the first 3 domains possessing an “applicability” assessment. CSB and JJL assessed each part as having either a high, low, or unclear risk of bias [10].

Data Extraction in the Selected Literature, Primary Outcomes of This Study, and Additional Analyses

CSB and JJL independently extracted the data from each included article and cross-checked the extracted data. If data were unclear, the corresponding author of the study was contacted by email to obtain insight into the original data set. A descriptive synthesis was made by a systematic review process, and DTA meta-analysis was conducted if the included studies were sufficiently homogenous.

The primary outcomes were the TP, FP, FN, and TN values in each study. For the CAD of gastrointestinal ulcers or hemorrhage using WCE images, the primary outcomes were defined as follows: TP, the number of patients with a positive finding by a CAD model and who had ulcers or hemorrhage as evidenced by WCE images; FP, the number of patients with a positive finding by a CAD model and who did not have ulcers or hemorrhage based on WCE images; FN, the number of patients with a negative finding by a CAD model and who had ulcers or hemorrhage as evidenced by WCE images; and TN, number of patients with a negative finding by a CAD model and who did not have ulcers or hemorrhage based on the WCE images. With these definitions, TP, FP, FN, and TN values were calculated for each included study.

For additional analysis, such as subgroup analysis or meta-regression, the authors extracted the following variables from each included study: published year, geographic origin of the data (ie, Western vs Asian vs public data or unknown), type of CAD models, type of endoscopic images, number of total images included, type of test data sets (internal test vs external test), and the target disease (ulcer vs erosions, hemorrhage, or angioectasias).

Statistics

The hierarchical summary receiver operating characteristic (HSROC) method was used for the DTA meta-analysis [11]. A forest plot of the sensitivity and specificity and a SROC curve were generated. The level of heterogeneity across the included articles was determined by the correlation coefficient between logit-transformed sensitivity and specificity by the bivariate method [12]; for this, the asymmetry parameter was β, where β=0 corresponds to a symmetric ROC curve in which the diagnostic odds ratio (DOR) does not vary along the curve according to the HSROC method [11]. A positive correlation coefficient and a β value with a significant probability (P<.05) indicate heterogeneity between the studies [11,13]. Visual examination of the SROC curve was also performed to identify heterogeneity. Subgroup analysis by univariate meta-regression using the modifiers identified during the systematic review was also performed to identify the reasons for heterogeneity. STATA software version 15.1 (StataCorp), including the packages “metandi” and “midas,” was used for the DTA meta-analysis. Publication bias was evaluated using the Deeks funnel plot asymmetry test. For the subgroup analyses including less than 4 studies, the Moses-Shapiro-Littenberg method [14] was

adopted using Meta-DiSc 1.4 (XI Cochrane Colloquium) because the "metandi" and "midas" packages require the inclusion of a minimum of 4 studies for DTA meta-analysis.

Results

Study Selection

A total of 254 studies (80 studies for the CAD of gastrointestinal ulcers or erosions and 174 studies for the CAD of gastrointestinal hemorrhage using WCE) were identified following a literature search of 3 databases. Fifteen studies were additionally identified by manual screening of bibliographies. After excluding duplicate studies, additional articles were excluded after a review of titles and abstracts. Full-text versions of the remaining 54 and 118 articles were obtained and thoroughly reviewed based on the aforementioned inclusion and exclusion criteria in each topic. Among these, 133 articles were excluded from the final enrollment. Finally, 20 studies [15-34] for the CAD of gastrointestinal ulcers or erosions and 19 [17,19,24,34-49] studies for the diagnosis of gastrointestinal hemorrhage were included in the systematic review. A flowchart of the selection process is shown in Figure 1 and 2.

Figure 1. Flowchart of the search process for the diagnostic performance of computer-aided diagnosis for gastrointestinal ulcers or erosions in wireless capsule endoscopy.

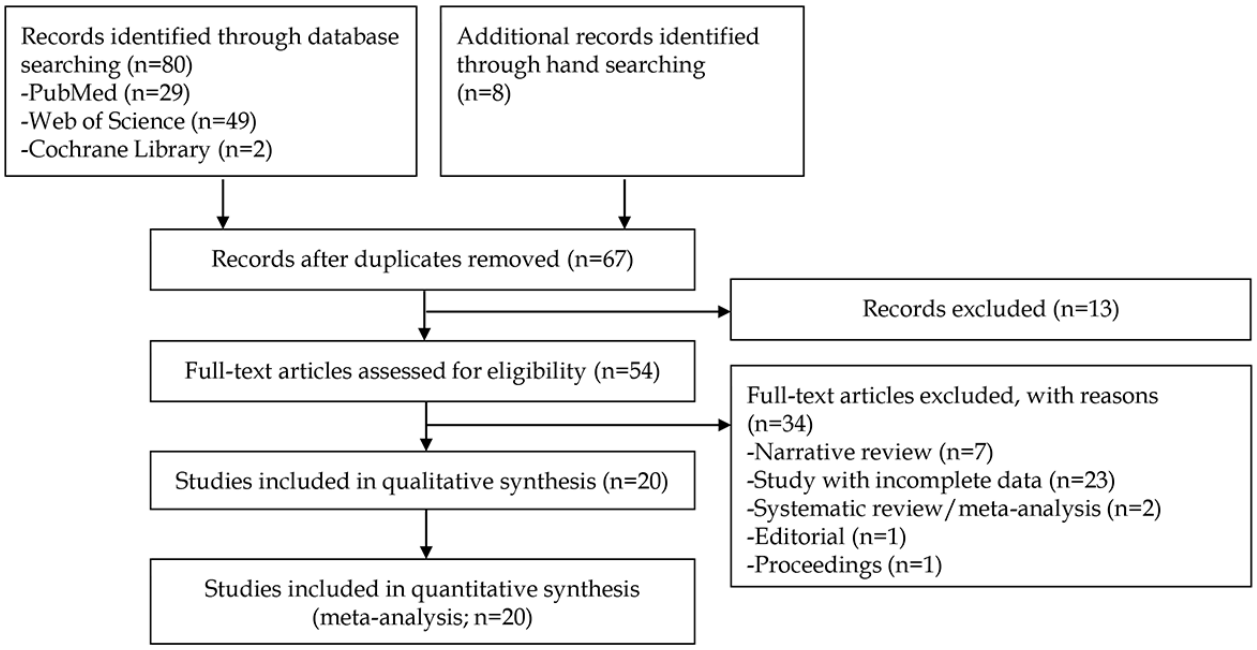

Figure 2. Flowchart of the search process for the diagnostic performance of computer-aided diagnosis for the gastrointestinal hemorrhage in wireless capsule endoscopy.

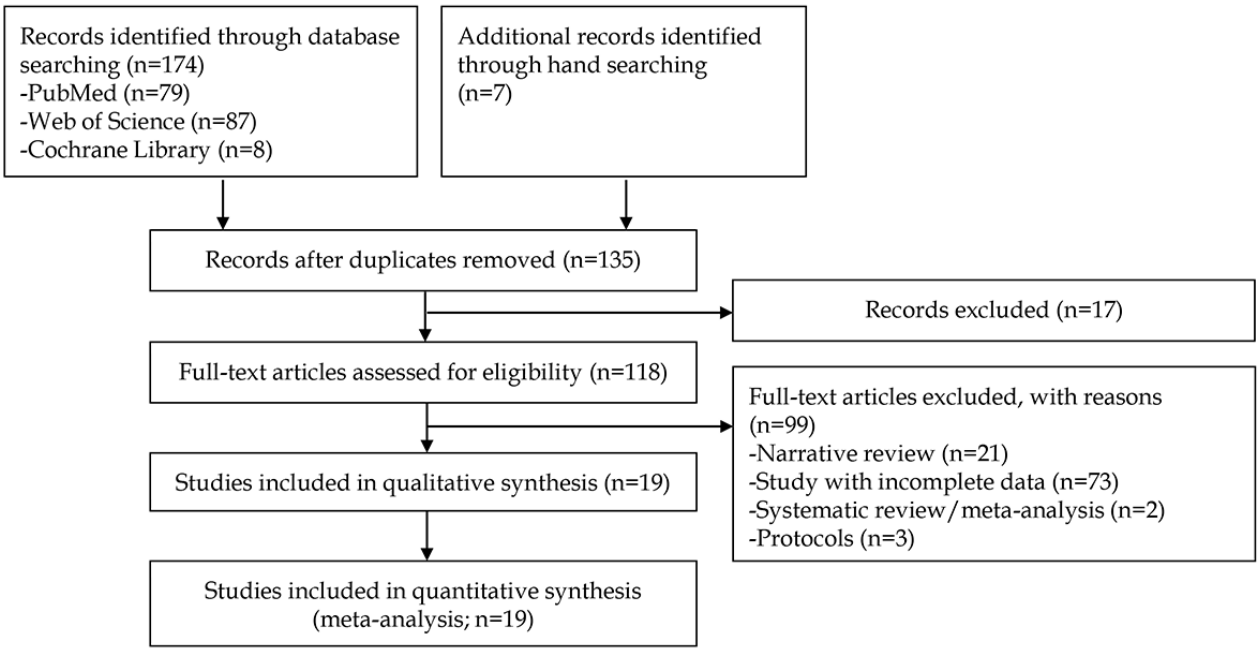

Clinical Features in the Included Studies

Among the 20 studies [15-34] for the CAD of gastrointestinal ulcers or erosions using WCE, a total of 40,809 images were identified (14,866 cases vs 25,943 controls) for the assessment of the diagnostic performance. Given that the duplicate data were identified (Karargyris et al in 2009 [15] and Karargyris et al in 2011 [20]), all the analyses used the data of 19 studies [15-19,21-34] (a study by Karargyris et al in 2011 [20] was omitted in the meta-analysis).

Ten studies [16-18,21,25-27,29,31,32] used endoscopic images from Asian populations, and 3 studies [22,23,33] used endoscopic images from Western populations. However, 6 studies [15,19,24,28,30,34] used public database images or an unknown source of images. Regarding the type of CAD model, a deep neural network or convolutional neural network was used in 9 studies [16-18,27-29,31-33], and machine learning–based models were used in 10 studies [15,19,21-26,30,34]. Most of the included studies [15-28,30-34] presented the diagnostic performance for the intestinal ulcers. However, the study by Aoki et al [29] presented an indistinguishable performance for the intestinal ulcers or erosions, and the study by Fan et al [27] presented a separate performance for the intestinal ulcers and erosions. Therefore, subgroup analyses were performed for the target lesions. Detailed clinical features of the included studies are presented in Multimedia Appendix 1.

Among the 19 studies [17,19,24,34-49] for the diagnosis of gastrointestinal hemorrhage using WCE, a total of 41,323 images were identified (6952 cases vs 34,371 controls) for the assessment of the diagnostic performance.

Five studies [17], [35], [44], [48], [49] used endoscopic images from Asian populations, and 1 study [47] used endoscopic images from Western populations. However, the remaining 13 studies [19,24,34,36-43,45,46] used public database images or an unknown source of images. Regarding the type of CAD model, the deep neural network or convolutional neural network was used in 8 studies [17,35,39,43,46-49], and machine learning–based models were used in 11 studies [19,24,34,36-38,40-42,44,45]. Most of the included studies [17,19,24,34-46,48] presented the diagnostic performance for intestinal hemorrhage. However, studies by Leenhardt et al [47] and Tsuboi et al [49] presented the performance for angiodysplasias. Therefore, subgroup analyses were performed for the target lesions. Detailed clinical features of the included studies are presented in Multimedia Appendix 2.

Quality Assessment of Study Methodology

The quality and quantity of baseline training data are important because the CAD models are established using learning features of the baseline training data. A sufficient number of training images are required for the establishment of practical CAD models, and endoscopic specialists should participate in the labeling work for the accurate preparation of training data. We also could not guarantee the quality of images in public databases searched on the internet. We determined that proper learning requires at least 30 training images (quantity standard) from real clinical hospital data (quality standard) labeled by an endoscopic specialist (quality standard). If both quality and quantity standards were satisfied, there was considered to be a low risk of bias in the patient selection domain. If only 1 of these quality or quantity standards was satisfied, there was considered to be an unclear risk of bias. If both were not satisfied, there was considered to be a high risk of bias.

In terms of the CAD of gastrointestinal ulcers or erosions in WCE, only 7 studies [25-27,29,31-34] were rated as low risk of bias, 9 studies [16-18,21-24,30,34] were rated as unclear risk of bias, and 3 studies [15,19,28] were rated as high risk of bias in the “patient selection” domain. The remaining domains were rated as having a low risk of bias in all the included studies (Figure 3). Therefore, classification of methodological quality in the “patient selection” domain was adopted as a modifier in the subgroup or meta-regression analysis.

In terms of the CAD of gastrointestinal hemorrhage in WCE, only 3 studies [44,47,49] were rated as having a low risk of bias, 10 studies [17,24,34,35,37,38,40,45,46,48] were rated as having an unclear risk of bias, and 6 studies [19,36,39,41-43] were rated as having a high risk of bias in the “patient selection” domain. The remaining domains were rated as having a low risk of bias in all the included studies (Figure 4). Therefore, the classification of methodological quality in the “patient selection” domain was adopted as a modifier in the subgroup or meta-regression analysis.

DTA Meta-analysis for the Performance of CAD Models

Among the 20 studies [15-34] for the meta-analysis of the CAD of gastrointestinal ulcers or erosions using WCE, the area under the curve (AUC), sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, and DOR were 0.97 (95% CI 0.95-0.98), 0.93 (95% CI 0.89-0.95), 0.92 (95% CI 0.89-0.94), 11.2 (95% CI 8.6-14.7), 0.08 (95% CI 0.05-0.12), and 138 (95% CI 79-243), respectively (Multimedia Appendix 3 and Figure 5). The SROC curve is illustrated in Figure 6. To investigate the clinical utility of the CAD models, Fagan's nomogram [50] was generated. Positive findings indicated that gastrointestinal ulcers or erosions were detected by the CAD models, while negative findings indicated that gastrointestinal ulcers or erosions were not detected by the CAD models. Assuming a 23% prevalence of gastrointestinal ulcers or erosions, Fagan's nomogram showed that the posterior probability of ulcers or

erosions was 76% if the finding of the CAD model was positive and that the posterior probability of ulcers or erosions was only 3% if the finding of the CAD model was negative (Figure 7).

Among the 19 studies [17,19,24,34-49] for the meta-analysis of the CAD of gastrointestinal hemorrhage in WCE, the AUC, sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, and DOR were 0.99 (95% CI 0.98-0.99), 0.96 (95% CI 0.94-0.97), 0.97 (95% CI 0.95-0.99), 38.3 (95% CI 19.6-74.8), 0.04 (95% CI 0.03-0.07), and 888 (95% CI 343-2303), respectively (Multimedia Appendix 4 and Figure 8). The SROC curve is illustrated in Figure 9. Positive findings of Fagan's nomogram indicated that gastrointestinal hemorrhage was detected by the CAD models. Negative findings indicated that gastrointestinal hemorrhage was not detected by the CAD models. Assuming a 10% prevalence of small intestinal hemorrhage in all gastrointestinal bleeding [51], Fagan's nomogram showed that the posterior probability of small intestinal hemorrhage was 81% if the finding of the CAD model was positive and that the posterior probability of small intestinal hemorrhage was only 0.5% if the finding of the CAD model was negative (Figure 10).

Assessment of Heterogeneity With Meta-regression and Subgroup Analysis

For the CAD of gastrointestinal ulcers or erosions in WCE, we first observed a positive correlation coefficient between the logit-transformed sensitivity and specificity (r=0.28) in the bivariate model analysis. However, an asymmetric β parameter in the HSROC model showed an nonsignificant P value (P=.15), implying that heterogeneity was not present among the studies. Second, a coupled forest plot of sensitivity and specificity was observed (Figure 5). Compared with the enrolled studies, the study by Karargyris et al (2009) [15] showed lower sensitivity and specificity. This study was found to have a high risk of bias in the methodology quality assessment (Figure 3). Therefore, subgroup analysis was carried out according to the methodological quality, and the performance was robust although slightly higher values were observed in the studies of high methodological quality (Multimedia Appendix 3). Third, the shape of the SROC curve for the gastrointestinal ulcers or erosions in WCE was symmetric, and the 95% prediction region was not wide (Figure 6). Fourth, meta-regression using modifiers identified in the systematic review was conducted, and published year, number of training images, and target disease (ulcer vs erosion) were found to be the source of heterogeneity (published year: P=.04; number of training images: P=.02; target disease ulcer vs erosion: P=.38; type of endoscopic image: P=.01). Finally, a subgroup analysis based on the potential modifiers was performed, and the overall performance of the studies published within 10 years (vs studies published more than 10 years ago) and studies with more than 100 training images (vs studies with fewer than 100 training images) showed higher values (Multimedia Appendix 3).

For the CAD of gastrointestinal hemorrhage in WCE, we first observed a positive correlation coefficient between the

logit-transformed sensitivity and specificity (r=0.48) in the bivariate model analysis. However, an asymmetric β parameter in the HSROC model showed an nonsignificant P value (P=.06), implying that heterogeneity was not present among the studies. Second, a coupled forest plot of sensitivity and specificity was observed (Figure 8), and there was no significant outlier. Third, the shape of the SROC curve for the gastrointestinal ulcers and erosions in WCE was symmetric, and the 95% prediction region was not wide (Figure 9). Fourth, a meta-regression using the modifiers identified in the systematic review was conducted, and published year, number of training images, and target disease (hemorrhage vs angioectasia) were found to be the source of heterogeneity (published year: P<.01; number of training images: P=.04; target disease hemorrhage vs angioectasia: P<.01). Finally, a subgroup analysis based on the potential modifiers was performed, and the overall performance of the studies published within 10 years (vs studies published more than 10 years ago) and studies with more than 100 training images (vs studies with fewer than 100 training images) showed higher values (Multimedia Appendix 4).

Evaluation of Publication bias

The Deeks funnel plot of studies for the gastrointestinal ulcers or erosions in WCE exhibited a symmetrical shape with respect to the regression line (Figure 11), and the asymmetry test showed no evidence of publication bias (P=.77). The Deeks funnel plot of studies for the gastrointestinal hemorrhage in WCE exhibited a symmetrical shape with respect to the regression line (Figure 12), and the asymmetry test showed no evidence of publication bias (P=.93).

Discussion

Principal Findings

In this study, CAD models showed high performance values for the diagnosis of gastrointestinal ulcers or erosions and hemorrhage in WCE images. Practical values in Fagan's nomogram indicated the potential to use CAD models in clinical practice. Although the main analyses found some heterogeneity among the included studies, the meta-regression showed the common reasons for heterogeneity (published year, number of training images, and target disease—ulcers vs erosions and hemorrhage vs angioectasia), and subgroup analyses demonstrated that recently published studies (vs studies published more than 10 years ago) with a greater amount of training data (vs studies with fewer than 100 training images) showed better performance of CAD models. Thorough subgroup analyses indicated the robust quality of the evidence.

Interpretation of WCE images is an important task for gastroenterologists. Due to the fact that WCE presents the images of the whole gastrointestinal tract, lesions that are difficult to detect with conventional endoscopy can be identified. Diminutive but important culprit lesions also can be found in the WCE examination. The noninvasive nature of this examination and patients' comfort have also promoted the use of this technique in the diagnosis of obscure gastrointestinal hemorrhage or small intestinal disorders. However, the interpretation process is tedious. At least 30 to 120 minutes of reading time is required for the endoscopists [1-3]. It is necessary to maintain concentration throughout the reading time so as not to miss important lesions. CAD models have the potential to automate the reading process of WCE with their high diagnostic performance, especially for sensitivity and specificity. The overall performance is slightly higher for gastrointestinal hemorrhage than for ulcers or erosions. It is presumed that this is because red-colored blood is easier to distinguish than are white- or yellow-colored ulcers or erosions, which are similar to the color of the background mucosa for the pixel-based or red-green-blue spectrum–based feature learning of CAD.

In the context of the learning way of CADs, neural network–based CAD models showed a slightly higher performance than that of traditional machine learning–based CAD models (Multimedia Appendices 3 and 4). CNN is not always better than machine learning for accurate classification. However, image recognition with local feature extraction can be highly optimized with its complex layers and deep nodes calculations and dimensional reductions for neural network CAD models. Considering that the machine learning–based models in the included studies used color or textures features in the images of WCE, neural network–based models might focus on the other local features or combined features, such as the shape of the lesions or feature differences between the lesions and background mucosa. Explainable artificial intelligence analyses are on the rise, and the application of this technique would provide a method of determination in the CAD models [52].

Although meta-analyses of same topic have already been published, this study was conducted to evaluate the DTA of CAD models for gastrointestinal ulcers or hemorrhage using WCE images with a standard methodology (Table 1) [7,8].

Although previous studies also reported the high performance of CAD models, many important articles were omitted, the heterogeneity between studies was determined by I^2 statistic (which is used in interventional meta-analysis), methodological quality assessments were omitted, and the publication bias was also not assessed.

Limitations

Despite the robust evidence in this meta-analysis, several inevitable limitations were identified. First, all the performance data were only measured in an internal-test setting in each included study. Modeling is an assumption that observations follow certain statistical rules, and external validation is a method to check whether this assumption is correct or generalizable. Therefore, the confirmation of performance in the established CAD models with unused data in the training or internal testing process is essential [53]. However, no single study conducted performance verification in an external validation setting. Second, the definition of intestinal ulcers or erosions was vague. Erosion usually refers to damage that is limited to the mucosa (loss of the epithelium but with the basement membrane or lamina propria being intact). However, the definition of ulcers usually involves more extensive loss of the mucosa beyond the lamina propria. Although the discrimination between these 2 conditions is not perfect under visual inspection, there was no clear definition in the included studies. This can lead to the underestimation or overestimation of the performance of CAD models. Third, many studies used baseline training data from a public database, and we could not guarantee the quality of images in the public databases available from the internet. The diagnostic performance of the CAD models can only be valid for the population under evaluation and depends on the prevalence of target conditions for the selected population (so-called spectrum bias or class imbalance) [2,54]. This class imbalance was not considered in the included studies. Most of the studies except for 1 [34] applied a 1:1 to 1:4 ratio (target condition:normal mucosa) of the training data set. However, Kundu et al [34] used 31 ulcer images and 1617 normal mucosal images (about a 1:52 ratio) and 65 bleeding images and 1617 normal mucosal images (about a 1:25 ratio) in the training data set. Considering that the method of establishing artificial intelligence models is changing from a model-centric (ie, change or optimize the model to improve performance) to a data-centric approach (ie, systematically change the distribution of the quality of data to improve performance), model establishment that takes into account spectrum bias is required. Overall, qualified training data with clear definitions and a focus on external validation-oriented performance CAD model establishment are required and expected for future perspectives in this topic.

In conclusion, CAD models showed high performance for the optical diagnosis of gastrointestinal ulcers and hemorrhage in WCE.

Abstract

Background: With the rapid development of artificial intelligence (AI) and related technologies, AI algorithms are being embedded into various health information technologies that assist clinicians in clinical decision making.

Objective: This study aimed to explore how clinicians perceive AI assistance in diagnostic decision making and suggest the paths forward for AI-human teaming for clinical decision making in health care.

Methods: This study used a mixed methods approach, utilizing hierarchical linear modeling and sentiment analysis through natural language understanding techniques.

Results: A total of 114 clinicians participated in online simulation surveys in 2020 and 2021. These clinicians studied family medicine and used AI algorithms to aid in patient diagnosis. Their overall sentiment toward AI-assisted diagnosis was positive and comparable with diagnoses made without the assistance of AI. However, AI-guided decision making was not congruent with the way clinicians typically made decisions in diagnosing illnesses. In a quantitative survey, clinicians reported perceiving current AI assistance as not likely to enhance diagnostic capability and negatively influenced their overall performance (β=–0.421, P=.02). Instead, clinicians' diagnostic capabilities tended to be associated with well-known parameters, such as education, age, and daily habit of technology use on social media platforms.

Conclusions: This study elucidated clinicians' current perceptions and sentiments toward AI-enabled diagnosis. Although the sentiment was positive, the current form of AI assistance may not be linked with efficient decision making, as AI algorithms are not well aligned with subjective human reasoning in clinical diagnosis. Developers and policy makers in health could gather behavioral data from clinicians in various disciplines to help align AI algorithms with the unique subjective patterns of reasoning that humans employ in clinical diagnosis.

artificial intelligence algorithms; AI; diagnostic capability; virtual care; multilevel modeling; human-AI teaming; natural language understanding

Introduction

Overview

Artificial intelligence (AI) and related technologies are rapidly evolving as part of workplace technology to support clinicians' decision making [1,2]. AI refers to the use of a collection of intelligent technologies in "the science and engineering of intelligent machines and computational part of the ability to achieve goals in the world" [3] or to "model intelligent behavior with minimal human intervention" [4-6]. Its influence has permeated retail, marketing, and human resource management [6]. Specifically in health care, considering the risks of incorrect predictions, the Consumer Technology Association (CTA) has reconceptualized health care AI as "assistive intelligence," described as "a category of AI-enabled software that 'informs' or 'drives' diagnosis or clinical management of a patient," in which "the health care provider makes the ultimate decisions before clinical action is taken" [7]. In both clinical and administrative areas of health care organizations, AI algorithms are increasingly embedded in health information technologies (HITs) to assist with clinical functions such as data monitoring, clinical research, diagnostics, and support compliance for billing and administrative tasks [8,9]. AI technology in health care is therefore expected to streamline clinicians' clinical and administrative decision making by providing prompt data analyses and the necessary recommendations to make health care more efficient and cost-effective.

Particularly within the clinical side of health care organizations, clinical decision making is based on subjective and objective patient information and other influencing variables. Clinical decision making generally refers to the process of making a choice among options aimed at diagnosis, intervention, interaction, and evaluation within a context, in which numerous interactions exist among stakeholders, background knowledge, and social and technological factors [10]. In other words, clinicians' decision making regarding patient health outcomes or health care diagnoses is largely influenced by numerous factors such as the idiosyncratic characteristics of patients and clinicians, consultation environments, and technology used [11]. In this information-rich context, the ability to access and manage appropriate and accurate information is critical for clinicians to make decisions on the patient's behalf. As reflected in the CTA definition, AI algorithms under these circumstances need to complement human cognitive processing of electronic medical records, multimedia images, or laboratory results. Once successfully incorporated, AI assistance has been shown to help clinicians reduce adverse events outside of the intensive care unit by 44% [12].

Thus far, views have been mixed on how AI may "assist" or "team up with" clinicians through the medical assessment and diagnosis processes. On the one hand, AI allows clinicians to freely follow their own paths of inquiry through patient investigations and select from a database of questions on patient history, physical examinations, and laboratory tests to make patient-specific diagnostic decisions [13]. On the other hand, training AI with a collection of data from the clinicians' own subjective diagnoses of various patient cases may not be ideal for fully utilizing AI techniques [14]. Indeed, inconsistent performance has also been reported [15]. Given that 83% of health care organizations have a strategy for AI investment and deployment in the coming years [16], particularly for electronic health record management and diagnosis [17], health care practice and training will follow such trends. However, as core users of AI, incumbent health care stakeholders in the current health care system have differential levels of technological readiness; therefore, clinicians' existing ability to incorporate analytic results from AI may hamper the leveraging of the full potential of AI. In other words, care providers' attitudes toward and positive experiences with the assistance offered by AI-enabled technologies in the process of clinical diagnosis can help health care organizations reap the benefits of AI investments by enhancing consistency, quality of care, and reducing costs [18].

However, research on whether and how clinicians assess AI assistance in decision-making processes remains limited. Thus far, in health care AI literature, clinicians' clinical task performance is known to be influenced by clinical task types and evidence-based standards that support AI's data structure and clinical integration capacity within health care institutions [19]. One stream of AI literature, which has focused on the types of tasks and medical diagnosis, claims that AI algorithms enhance human clinicians' capabilities while improving efficiency in incident reporting and reducing adverse events [20,21]. However, the quality of health care diagnostic tasks between clinicians and AI continues to be characterized by broad discrepancies [22-24]. According to literature on AI's data structure, health information management professionals' ability to improve coded data quality and data patterns is necessary to ensure the optimal adaptation of teaming with AI [25]. Moreover, per the literature on the clinical integration of AI, clinicians' perceptions should be recognized to enhance the clinical diagnosis by AI [21,26-29].

In summary, our literature review revealed that, although advanced AI algorithms have the potential to enhance the quality and efficiency of health care, the critical users of AI algorithms are clinicians whose roles are to understand and communicate with AI. Nonetheless, there has been limited focus in AI health care research on clinicians' attitudes toward AI assistance in actual diagnostic decision making, which may be due to the infancy of such AI-assisted tools, lack of trust in AI from health care stakeholders, and potential health-related risks. Therefore, there is reasonable urgency to examine clinicians' attitudes and sentiments toward AI assistance in clinical decision making, to address the gaps in the existing body of knowledge.

Background and Theory

Medical Diagnostic Knowledge Theory

Clinicians' decision making includes diagnoses or high-complexity decisions across medical specialties. A diagnosis is viewed as an iterative process of "task categorization" by decomposing patients' health symptoms into different task classes and matching the given conditions with the predefined disease categories based on their respective hypotheses [30]. Clinicians are expected to predict and determine the course of action based on their knowledge and

experience and by utilizing information on the features of the focal clinical situations. The theory of clinical diagnosis revolves around 2 important concepts: clinical knowledge and clinical reasoning. The former refers to the fundamental base of knowledge, and it can be subdivided into 3 categories: conceptual, strategic, and conditional knowledge [31]. The latter refers to a holistic process of hypothesis generation, pattern recognition, context formulation, diagnostic test interpretation, differential diagnosis, and diagnostic verification, all of which provide both the language and methods of clinical problem solving [31]. Once clinicians have obtained clinical knowledge, they then organize it using mental representations, medical scripts, or clinical examples, followed by cognitive processes to translate medical information into testable hypotheses in each context and evaluate their own clinical reasoning for clinical diagnosis [32]. Specifically, the conceptual framework of a clinical diagnosis includes the "hypothetico-deductive model" (ie, generation of multiple competing hypotheses from preliminary information provided by patients), decision analysis, pattern recognition, and intuition [33]. During this process, challenges exist as to how clinicians match patients' cases with known patterns and focus on complex patient information among many treatment options [33]. In summary, a typical clinical decision-making process consists of the speedy processing of the situational features, assessment of the relevant hypotheses, and investigations and treatments in a sequence [30].

Such clinical reasoning by individual clinicians cannot be fully supported by AI algorithms' generalized task categorization, pattern recognition, and matching [34]. The current level of AI performs well for clinical knowledge creation by simple interpretations of medical images, slides, and graphs, as well as detection of complex relational time-series patterns within data sets [35,36]. AI algorithms for clinical reasoning (ie, IBM Watson, chatbots to smartphone apps) are believed to function as decision support tools for making diagnoses, providing patient consultation, and detecting certain medical symptoms [26].

In his book *Deep Medicine*, Eric Topol [37] highlighted the role of AI in clinical diagnosis as augmented intelligence: Some clinical knowledge formation via feature selection, task categorization, and pattern recognition can be aided by AI for clinicians to perform clinical reasoning by making a clinical diagnosis. A clinical diagnosis is a high-complexity decision that needs to be based on information inquiry using idiosyncratic patient data and threshold-based decision rules. Without clearcut threshold rules for decisions, AI may not fully process and analyze idiosyncratic patient cases and inaccurate descriptions from patients; it may likewise fail to incorporate the complexity of the diagnosis and predict patients' adverse conditions [35]. Therefore, the role of AI in clinical reasoning or clinical diagnosis is expected to be more assistive, and clinicians should communicate well with AI to prevent any adverse effects of clinical reasoning on patients' health outcomes.

Artificial Intelligence Technology Use in Practice and in Simulation

In practice and in simulation, clinicians are users or collaborators of such "assistive" AI, contingent upon the extent and scope of such technologies that are defined within the context. In other words, AI can refer to algorithms that are embedded in existing HITs or holistic technological artifacts to be newly implemented as standalone software. As such, the use of AI is no longer limited to specific HITs in practice. Clinicians may have unintentionally encountered various AI technologies through system interfaces and embedded AI decision-making logic within systems used in medicine. Owing to such mixed definitions of AI in health care [38], the effects of AI-assisted diagnostic performance have been mixed in prior studies. Positive performance is expected when clinicians trust and expect the performance of AI [21], whereas information overload driven by AI algorithms can cause a loss of situational awareness, thereby negatively affecting clinicians' decision-making abilities [35]. In addition, clinicians are perceived as more trusted by patients [26] and that AI algorithms may not be effective in diagnosing unique cases. Thus, clinicians need to diagnose and communicate with patients using AI, at least for a while. The manner through which clinicians make clinical diagnoses with the support of AI technology and perceive such a diagnostic decision merits further investigation.

Unlike these practical constraints, observations and evaluations of clinicians' health care diagnostic behaviors have been methods of inducing behavioral changes in safer simulation contexts. As what is learned throughout clinical health care training has been associated with what is likely to be carried out in clinical practice [35] and similar technologies span across practice and simulation contexts [39], clinicians' AI attitudes and performance have been studied and predicted from their use of simulated AI [40]. Thus, one can examine the way clinicians have used and familiarized themselves with AI in simulation and extrapolate their behaviors in practice.

Given that clinicians' behaviors and readiness to use this technology can be predicted from simulation experiences [39], we turned to a context of clinical diagnosis simulations—whereby clinicians have familiarized themselves with AI—and evaluated their decisions in a safe and controlled context. Subsequently, we examined whether and how clinicians perceive AI assistance and how their perceptions may differ from other non-AI-based diagnostic situations.

Taken together, in simulation contexts, this study explored users' detailed experiences with AI-enabled patient diagnosis and examined the effect of AI assistance on diagnostic performance. Thus, the following research questions were formulated to shed light on clinicians' attitudes and behavioral characteristics regarding AI assistance in patient diagnosis:

- Research question 1. During patient diagnosis, what are clinicians' sentiments toward AI assistance, and how do their sentiments differ from other non-AI-based diagnostic situations?
- Research question 2. How does current AI assistance affect clinicians' perceptions of enhancing diagnosis and future care task performance?

Methods

Survey Procedure

To this end, our target population was clinicians who have experience with patient diagnosis encounters using AI-based diagnostic technology to understand clinicians' perceptions of AI-assisted diagnosis in a controlled and safe context where patient care was not compromised by potentially incorrect AI algorithms. We recruited clinicians who met the abovementioned requirement and used AI-based diagnostic technology using live patient simulations in a nursing simulation lab. We accessed 3 cohorts of family nurse practitioner (FNP) students who experienced 3 patient diagnosis simulations in the lab: encounters with live standard patients, encounters with AI assistance in diagnosing patients using multimedia patient information, and encounters with patient simulators (ie, lifelike mannequin patients). Each qualified participant was then incentivized by US $5 Amazon gift cards for their completion and the quality of their responses. Consequently, 144 clinicians were selected and invited to participate in the online simulation surveys.

In the simulation lab at the College of Nursing, AI-enabled diagnosis technology has been used in on-ground lessons, in which faculty and students collaborate to complete virtual patient cases and in home-based diagnostic decision making [13,41,42]. In our university, after an AI system developer implemented the focal AI technology and trained the graduate nursing faculty on the technology and after the successful go-live events, this technology was subsequently integrated as part of the clinical simulations for the students. The software is based on data from hundreds of actual patients compiled by experts and AI and based on physiology algorithms [13]. The use of this system is particularly emphasized in the final year of the program to promote skills building and practice in clinical diagnosis.

This interactive AI incorporates intelligence from both humans and AI physiology algorithms such that evaluators on the other end of the system can recognize any patterns demonstrated by those specific users in the process of clinical diagnosis. Clinicians are known to experience some technical features of AI, such as search ability, knowledge expression function, reasoning ability, abstraction ability, speech recognition ability, and ability to process fuzzy clinical information [13]. In our context, reasoning ability was embedded by FNP faculty in the AI-enabled diagnosis technology so that the participants could make diagnostic decisions with AI assistance and obtain feedback after completing each patient case.

Survey Instruments

Our online simulation surveys consisted of 2 parts: survey instruments and open-ended simulation questions. First, for the survey instruments, each clinician reported their perception of AI assistance and perceived performance of patient diagnosis and overall clinical tasks using a 7-point Likert scale ranging from "strongly disagree" (1) to "strongly agree" (7). Table 1 presents the key survey items sourced from existing information systems (IS) literature.

As shown in Table 1, our study had 2 dependent variables. One was diagnostic performance, which we defined as the ability to provide health care consultations and diagnose health-related issues properly both in person and via online or telehealth platforms [3]. We contextualized and operationalized clinicians' diagnostic capabilities in a virtual context (mean 5.39, SD 0.13) [30]. The other dependent variable was clinical task performance, the survey items for which were adapted from the IS literature (mean 5.48, SD 0.12) [43].

We included control variables that accounted for personal technological traits and demographics. On the one hand, personal technological traits were measured via individual levels of technological advancement, such as personal innovativeness [44], technological habits [45], and computer literacy [46]. In the IS literature, personal innovativeness and computer literacy have been salient in explaining the technology adoption behaviors of individual users. Here, we defined personal innovativeness as "the willingness of an individual to try out any new information technology" [1], whereas computer literacy is "a judgement of clinicians' capability to use a computer" [6]. We also included technology habits to control for the participants' potential automatic reactions to the use of AI-enabled diagnosis technology that includes multimedia information and similar AI algorithms on social media platforms [47]. Lastly, participants' demographic characteristics, such as self-identified gender, age, income, education, and occupation, were included in the survey to control for potential confounding effects.

Next, in the part listing open-ended simulation questions, each clinician was asked to describe their experience with patient diagnosis under 3 different diagnostic modalities: diagnosing a live patient, diagnosing a human-like mannequin, and AI-based diagnostic simulations using AI assistance. In the 3 simulation prompts, participants were asked to recall their completed patient cases during the semester and write comments using either keywords or key phrases. For example, particularly for the AI case, the scenario prompt reads as given in Textbox 1. After reading this prompt, participants described "favorite" as well as "least favorite" diagnosis experiences using keywords or key phrases in 2 open-ended questions. Each clinician's 6 diagnostic encounters were recorded as textual narratives, along with the 3 different simulation contexts of the patient diagnoses.

Table 1. Key survey items.

Variables	Survey items[a]	References
Dependent variables		
Diagnostic performance	• OO[b] system allows me to carefully evaluate the health condition of the patient. • OO system allows me to thoroughly assess the health condition of the patient. • OO system allows me to accurately evaluate the patient's health condition. • OO system allows me to think critically during the simulation experience.	[30]
Clinical task performance	• I believe that the use of OO system can increase my overall performance. • I believe that the use of OO system can increase my effectiveness with the care tasks when working with live patients in the future. • With the use of OO system, I believe I can work more efficiently for managing care tasks when working with live patients in the future. • I believe that the use of OO system can increase the quality of care. • I believe that the use of OO system can decrease error rates in communication and information sharing with other care members in the future. • I believe that the use of OO system will help me understand what I have learned.	[43]
Independent variable		
AI[c] assistance	• Clinicians' experience of AI-assisted diagnostic simulation (binary: 1, with AI assistance; 0, live patient encounter with no AI assistance)	
Key control variables		
Personal technology trait: technology habit	• The use of social media has become a habit for me at work. • I am addicted to using social media at work. • I must use social media at work. • Using social media has become natural to me at work	[44]
Personal technology trait: personal innovativeness	• If I heard about a new information technology, I would look for ways to experiment with it. • In general, I am hesitant to try out new information technologies. • Among my peers, I am usually the first to try out new information technologies. • I like to experiment with new information technologies.	[45]
Personal technology trait: computer literacy	• I could complete the health care task using health information technology if there was no one around to tell me what to do as I go • I could complete the health care task using health information technology if I had just the built-in help menu for assistance. • I could complete the health care task using health information technology if someone showed me how to do it first. • I could complete the health care task using health information if I had used similar apps before this one to do the same job.	[46]

[a]Each item uses a seven-point Likert scale ranging from "strongly disagree" (1) to "strongly agree" (7).

[b]OO system refers to artificial intelligence–enabled diagnosis technology in our research setting.

[c]AI: artificial intelligence.

Textbox 1. Example scenario of artificial intelligence (AI)–based patient diagnosis.

> You read a case description about a 50-year-old patient on an AI-based diagnosis system. His complaints are about back pain. "My back has been hurting for around five days. I bent over to pick something up in my print shop and I had this severe pain in my back. It hurts so much so it is hard to stand up. The pain is on and off throughout the day—maybe four times, for half an hour each, especially when I am walking around. It is mostly a dull aching pain."

Study Design

Using clinicians' quantitative and qualitative responses from our online simulation surveys, we utilized a mixed method to analyze our mixed data. According to Creswell [48] and Creswell and Clark [49], mixed methods research "incorporates qualitative and quantitative data to solve complex research questions and hypotheses, and it is suitable for explaining what (ie, estimating overall trends in participant behaviors within the population) and obtaining an in-depth understanding of why (ie, specific individual behaviors in the subsamples)." This method is particularly useful for exploring context-specific variables and understanding beyond the importance of research variables by delving into the underlying mechanisms using causal models.

Mixed methods research includes sequential and concurrent designs such that qualitative and quantitative data can be collected sequentially in the former, whereas both types of data are obtained at the same time in the latter [50]. Each category has a specific design typology based on the emphasis on the importance of qualitative or quantitative data, the analysis process, and theoretical emphasis (see Castro et al [50] for an in-depth discussion on designs of mixed methods research). We applied a concurrent triangulation design, because both quantitative and qualitative data were collected concurrently, and such data were used to accurately describe and examine clinicians' experiences and sentiments toward AI assistance in clinical decision making [50].

Statistical Analysis

We utilized qualitative and quantitative data using natural language understanding (NLU) and hierarchical linear modeling (HLM). Regarding the first research question—capturing clinicians' respective sentiments in 3 cases of patient diagnosis simulations—we analyzed textual narratives to understand what clinicians perceived about the diagnosis process in teaming with AI and compared it with non-AI-involved diagnostic situations using NLU. Textual comments consisted of a single sentence or a small number of keywords. To incorporate such data characteristics, we deemed NLU, as a subfield of computer science, an adequate method based on its explicit focus on the use of computational techniques to learn, understand, and produce human language content, and many information technology firms, such as Microsoft, Google, and IBM, have developed NLU platforms and algorithms [51,52]. We utilized IBM Watson Natural Language Understanding-77 for its well-known performance and cross-evaluation results. Understanding each participant's language content was more suitable than traditional text mining analytics [52-54].

Next, for quantitative data analysis, we implemented HLM estimation techniques to answer the second research question—measuring the effect of the current form of AI assistance on clinicians' diagnostic decision making and care task performance. In our data, each clinician's clinical diagnosis experience was nested within the program. In other words, under the same graduate program, each participant was exposed to the same sets of patient diagnosis simulations with 3 modalities and reported their responses with 3 diagnosis simulations repeatedly. This context could engender statistical dependency among the responses [55]. Moreover, in the research model, the outcome variable (ie, the clinical diagnosis) was at the individual level, and the AI assistance variable was at the group level (or graduate nursing program), leading to a multilevel research program in the same research model [21]. To mitigate such dependency and estimate this multilevel model, we used the STATA 16.1 (StataCorp, College Station, TX) xtmixed procedure to carry out generalized linear modeling using the restricted maximum likelihood or residual maximum likelihood estimation. The xtmixed procedure fits linear mixed models that include fixed (or standard regression coefficients) and random effects that are not estimated directly but by variance component. The default covariance structure is independent covariance. We also specified other covariance structures (eg, exchangeable and unstructured) to validate our mixed model results (see [56] for an in-depth discussion of mixed models and covariance structures).

Results

We explored clinicians' perceptions and performance prospects toward AI assistance in patient diagnosis research. These relations and sentiments are evidenced by the results of generalized linear models as well as qualitative text analysis with direct quotations from the health care worker sample.

User Statistics

A total of 114 clinicians completed our online surveys during the 2020-2021 study period (response rate: 114/144, 79.2%). In summary, 66.7% (76/114) of the participants were between 26 years old and 40 years old, 49.1% (56/114) were white, and 84.2% (96/114) identified as female. Additionally, 89.5% (102/114) worked either full time or part time in hospitals or clinics. In terms of education, 24.6% (28/114) had a graduate degree, whereas all the participants had obtained a bachelor's degree in nursing with prior clinical experience before joining the graduate program, as shown in Table 2.

Table 2. Respondent demographics (N=114).

Characteristics	Results, n (%)
Self-identified gender	
Male	16 (14.0)
Female	96 (84.2)
Not disclosed	2 (1.8)
Age (years)	
18-25	10 (8.8)
26-40	76 (66.7)
41-55	26 (22.8)
56-65	2 (1.8)
Income (US $)	
25,000-49,999	20 (17.5)
50,000-74,999	32 (28.1)
75,000-99,999	30 (26.3)

Rural	10 (8.8)
Other	6 (5.3)

Research Question 1: Sentiment Analysis Results

To identify clinicians' sentiments toward AI assistance, we compared the clinicians' perceptions regarding AI-assisted diagnosis and non-AI diagnosis contexts. Table 3 presents some narrative examples in our data set whereby the clinicians described what they liked and disliked about the patient diagnosis process with the help of AI-aided technology, with a live human patient, and with a human-like mannequin/patient simulator.

The results of the NLU analyses are reported in Tables 4, 5, and 6. We found that clinicians perceived their patient diagnosis experience differently across the 3 simulation cases. The positive

sentiment scores for the diagnosis process were 0.99 for the live patient, 0.92 for teaming up with AI assistance, and 0.41 for the patient simulator. In contrast, the negative sentiment score was the highest with the patient simulator (sentiment score = –1), followed by the live patient (sentiment score = –0.97) and AI assistance (sentiment score = –0.87). Specifically, our respondents perceived diagnostic simulations with AI technology less negatively and more positively compared with diagnosing a live human patient. Table 4 reports each positive and negative sentiment score for all 3 cases, with scores ranging from –1 to 1.

Tables 5 and 6 present the most relevant keywords from the textual narratives for the 3 simulation cases. The respondents perceived AI-based diagnostic simulations positively for the following reasons: “convenient access,” “thorough assessment skills,” “student interaction convenience,” “interactive learning rationale,” “good learning opportunities” and “[a] vast range of questions.” At the same time, they also perceived the AI-based diagnosis simulation to contain a “long system,” “strict sensitive clicking,” “differential diagnosis,” “large learning curve,” and “technical difficulties,” and they found it to be a “hard system.” These keywords indicated that the current form of AI assistance may lead to differential diagnosis logic relative to clinicians’ own logic and hypotheses, and technical difficulties could cause users to be averse to the technology.

Table 3. Some narrative examples in our data set, based on 65 recorded instances.

Narrative valence	AI[a] assistance context	Non-AI assistance context	
	Diagnosis experience with AI assistance	Diagnosis experience with live patients	Diagnosis experience with HPS[b]
Positive comments	“I don’t feel like I am under pressure and can do it at my own pace”	“interaction, being able to gauge the patient, reading facial expressions, immediate feedback”	“Very realistic, lifelike scenarios”
Negative comments	“not having an orientation on how to work the system (first time user)”	“I'm not an actor, and it felt like acting; immediate feedback”	“being watched through a one-way mirror”

[a]AI: artificial intelligence.

[b]HPS: human patient simulator. It is worth nothing that the clinicians recorded their retrospective experience with the HPS, as it was not used in the graduate program.

Table 4. Clinicians’ emotions with patient diagnosis under 3 different scenarios, based on 65 recorded instances.

Sentiment	AI[a] assistance context	Non-AI assistance context	
	Diagnosis experience with AI assistance	Diagnosis experience with live patients	Diagnosis experience with HPS[b]
Positive sentiment[c]	0.92	0.99	0.41
Negative sentiment[c]	–0.87	–0.97	–1

[a]AI: artificial intelligence.

[b]HPS: human patient simulator. It is worth nothing that the clinicians recorded their retrospective experience with the HPS, as it was not used in the graduate program.

[c]The sentiment score ranged from –1 (negative) to 1 (positive).

Quantitative Methods: Results of Mixed Models

Table 7 presents our findings for the second research question—the effect of AI assistance on clinicians' clinical diagnosis and care performance from multilevel mixed effects models. Models 1 and 2 report the results for the 2 dependent variables of diagnostic performance and clinical task performance, respectively, where the independent variable is the experience with AI assistance (binary). In terms of individual-level covariates, social media use, personal innovativeness, and computer literacy were included as personal technological traits, in addition to demographic covariates. The HLM results were compared with the baseline ordinary least squares model with clustered standard errors. The effect of AI assistance was not statistically significant in explaining the variation in enhanced clinical diagnosis. Instead, education and age, which were related to clinicians' overall practical experience, were positively associated with clinical diagnosis. The mixed model results were qualitatively identical, along with the different covariance structures.

Table 7. Results from hierarchical linear modeling (N=114 observations).

Variables	Model 1[a]				Model 2[b]			
	OLS[c] (clustered SE[d,e])	*P* values	Mixed model[f,g]	*P* values	OLS (clustered SE[d,h])	*P* values	Mixed model[f,g]	*P* values

Discussion

Principal Findings

This mixed methods study aimed to explore the status of AI-assisted decision-making patterns among clinicians and gain a detailed understanding of how this novel method of AI-human collaboration and decision making could progress in the future. The results from the qualitative methods showed that clinicians described the diagnostic process with the support of AI as more positive compared with encountering a live patient on their own. Nonetheless, the respondents' keywords revealed that AI assistance impeded clinicians from formulating their own subjective diagnoses based on their clinical reasoning and that

the main complaints among clinicians related to some of the steps in the AI algorithms. Moreover, our quantitative results showed that clinicians' perceptions of their clinical diagnostic capability neither indicated the current level of AI assistance nor enhanced their care task performance. The participants believed that their *ex ante* quality and capability, such as education, age, and daily technology habits, were more relevant in enhancing their care task performance.

Comparison With Prior Work

We expected our research to make 2 important contributions to the existing IS and health care literature. First, our findings from clinicians' keywords in their textual comments demonstrated that clinicians perceived AI assistance positively. However, the current AI interface may not align with their clinical reasoning process, and therefore, such AI interface issues can negatively affect clinicians' perception of whether AI can collaborate with them as a team member. Clinician keywords such as "long system," "strict sensitive clicking," "differential diagnosis," "large learning curve," "technical difficulties," and "hard system" demonstrated human-computer interaction (HCI) issues. In other words, this phenomenon can be linked to the topic of the user interface and explainable or understandable case scenarios in AI research. Studies on HCI have typically focused on the effect of technology on users by considering principles, guidelines, and strategies for designing and interacting with user interfaces [57]. The importance of the design aspect of AI (or AI from an HCI perspective) is more pronounced in health care because active involvement of stakeholders in the design stage can promote appropriation and sensemaking of the focal technology and increase the benefits of AI implementation [58,59]. Studies on machine learning–human interaction have emphasized "human-centeredness" in the use of AI such that humans and machines can integrate or work together as a team [60]. To do so, AI must be explainable, comprehensible, useful, and usable for clinicians in the use scenarios, both in practice and in simulation.

However, some challenges exist. First, the incorporation of fast-moving machine learning techniques into common user experience designs falls under restrictions in environment, law, and regulations in real-world scenarios [57]. Second, there are unintended consequences of AI-generated automated inferences and functions under uncertainty [61] so that, in cases where scenarios yield false positives or false negatives, AI-based decision making negatively affects clinicians' care task performance and patient health outcomes [57]. From the perspective of clinicians, case scenarios or process logic may be the primary interface faced by clinicians under the current development of AI algorithms. However, we also showed that the complexity of AI algorithms may disrupt clinicians' patient diagnostic decisions because clinicians may not understand how to access the complete functions and capabilities of the AI [36]. Thus, based on the previous literature and current evidence in this paper, our results call for more attention to HCI issues by actively involving the end users in the system development procedures and providing them with adequate education to co-create effective decision-making scenarios with AI assistance.

For another, we empirically quantified the effect of AI assistance on clinicians' decision making in a nomological network and explored whether it can serve as a factor to enhance clinical diagnostic capability and overall health task performance. Our results demonstrated that, although clinicians interacted with AI algorithms in safer simulations, the effect of AI assistance was either negative or nonexistent in the clinicians' diagnostic decisions. Instead, the clinicians' *ex ante* personal traits, that is education and age, are positively associated with enhanced outcomes. This finding corresponds with the existing understanding that years of training, professional background, and educational background affect diagnostic performance [62]. Moreover, we found that AI assistance was negatively associated with the clinicians' perceptions of task performance. This might be due to frontline health care providers' trust in AI [14] or implementation issues [63] in health care. It will be worthwhile to revisit our research model to identify AI-specific factors and test downstream effects on clinicians' AI use performance in future research.

Furthermore, we found that the clinicians' *ex ante* technological traits were statistically associated with clinical decision making. First, we found that technological habits were positively linked to clinical diagnostic and health care task performance. In this study, we viewed a technological habit as a social media habit. Clinicians have used social media technologies that may embed AI algorithms and techniques in nonhealth care contexts [64]. It is likely that processing and accessing multimedia-based information daily may help clinicians manage multimedia-based patient information on AI platforms. Second, we showed that computer literacy was negatively associated with overall health care task performance with AI assistance. In health care, clinicians' levels of literacy vary across contexts such as information [65], health [66], YouTube [67], informatics tools [68], and computers [69]. In particular, the concept of computer literacy is broad and encompasses hardware and software [69], informatics tools (eg, decision support systems), handheld devices [68], computerized statistical analysis, databases, presentation graphics, spreadsheet applications, and bibliographic database searches for evidence-based practice [70]. Such measures of literacy are related to knowledge about focal tools or interpreting health information in health care contexts. Meanwhile, a renewed concept of computer literacy has emerged, known as "digital literacy," or the combined knowledge, skills, and competencies necessary for thriving in a technology-saturated culture [71]; it encompasses various forms of literacy via visual, electronic, and digital forms of expression and communication [72]. The use of 3-dimensional virtual images in operations or virtual reality goggles in pathology laboratories [73] or the matching of doctors with professional actors in medical improvisation sessions over Zoom [74] are adequate examples of computer literacy with which clinicians should be equipped. Therefore, it is necessary to redefine and contextualize the definition of computer literacy in the domain of AI use and actively educate clinicians on this topic in practice and in training altogether.

The findings of this study have various practical implications. With an explicit focus on the clinicians' AI-assisted decision making, we found that their sensemaking of the diagnostic logic

provided by AI and the system features may pose a challenge to the health care workforce. Our findings correspond with a recent report by the National Academy of Medicine [75] that highlighted "augmented intelligence," with an emphasis on the supporting role of AI in data synthesis, interpretation, and decision making for health care multi-stakeholders, such as clinicians, patients, and other related professionals. In preparing clinicians for such a change, the report suggested that their training should incorporate education programs on how to assess and use AI products and services appropriately for new and incumbent professionals alike [75].

Moreover, to prevent AI algorithms from generating a simplified decision plan, health care providers should be involved in the case scenarios of patient diagnosis to enhance the effectiveness of the AI algorithms [36]. What is largely neglected in the discussion is the need to close gaps between practice and clinical training for increasing AI understanding. The developers of AI need to consider the clinicians' current levels of exposure to technology in practice and in simulation and then design clinician-centered algorithms and interfaces. To achieve the goal of human-AI collaboration in health care [76], beyond involving clinicians in the development of clinical AI algorithms, these algorithms and their interfaces should be more human-centered. There must be assessments of diagnoses made by AI in both practice and training to reduce the gap between theory and practice in the use of AI by the health care workforce. This can be done by gathering behavioral big data from clinicians in various disciplines to help align AI algorithms with the unique, subjective patterns of reasoning that humans employ in clinical diagnosis.

Limitations

As with all research, this study is not without limitations, and its results should be interpreted with caution. First, we employed purposive sampling techniques for the target population. Since our target audience was individuals with experience in clinical diagnosis in various scenarios, we targeted and recruited FNP students as our sample. As such, the response rate was relatively low, and missing values were prevalent in the data. Future research could benefit from increasing the sample size to compare group differences in greater depth. Although our sample represents the target population of this study, sampling at the national level would be beneficial for generalizing the results of this study. Second, our AI variable was operationalized as binary (1: AI assistance; 0: otherwise). Future research may consider a survey construct with items that capture the rich characteristics of multimedia technology variables in the research models. Lastly, as our results were derived from the use of AI-enabled diagnostic technology, our results may not be generalizable to other types of AI or other clinical decision-making categories.

Conclusions

In keeping with the recent interest in and expectations for AI-assisted decision making in health care, as a first step, our research explored clinicians' sentiments toward AI assistance and their perceptions using sentiment analysis and a mixed methods design. Our results indicated that, while there are negative or nonexistent effects of AI assistance in enhancing clinical decision making, clinicians have positive sentiments toward AI assistance in the decision-making process, comparable with their encounters with actual patients. With this potential, we suggest that health care leaders, policy makers, and AI developers need to collect clinicians' behavior data and revisit the design and user interface of AI to make it more clinician-centered and collaborative.

Authors' Contributions

HH created and distributed the survey, analyzed the results, and drafted the entire manuscript. DG created and distributed the survey and co-authored the manuscript. Both the authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Emergency department (ED) crowding has resulted in delayed patient treatment and has become a universal health care problem. Although a triage system, such as the 5-level emergency severity index, somewhat improves the process of ED treatment, it still heavily relies on the nurse's subjective judgment and triages too many patients to emergency severity index level 3 in current practice. Hence, a system that can help clinicians accurately triage a patient's condition is imperative.

Objective: This study aims to develop a deep learning–based triage system using patients' ED electronic medical records to predict clinical outcomes after ED treatments.

Methods: We conducted a retrospective study using data from an open data set from the National Hospital Ambulatory Medical Care Survey from 2012 to 2016 and data from a local data set from the National Taiwan University Hospital from 2009 to 2015. In this study, we transformed structured data into text form and used convolutional neural networks combined with recurrent neural networks and attention mechanisms to accomplish the classification task. We evaluated our performance using area under the receiver operating characteristic curve (AUROC).

Results: A total of 118,602 patients from the National Hospital Ambulatory Medical Care Survey were included in this study for predicting hospitalization, and the accuracy and AUROC were 0.83 and 0.87, respectively. On the other hand, an external experiment was to use our own data set from the National Taiwan University Hospital that included 745,441 patients, where the accuracy and AUROC were similar, that is, 0.83 and 0.88, respectively. Moreover, to effectively evaluate the prediction quality of our proposed system, we also applied the model to other clinical outcomes, including mortality and admission to the intensive care unit, and the results showed that our proposed method was approximately 3% to 5% higher in accuracy than other conventional methods.

Conclusions: Our proposed method achieved better performance than the traditional method, and its implementation is relatively easy, it includes commonly used variables, and it is better suited for real-world clinical settings. It is our future work to validate our novel deep learning–based triage algorithm with prospective clinical trials, and we hope to use it to guide resource allocation in a busy ED once the validation succeeds.

Introduction

Background

Overcrowding in the emergency department (ED) is already a global public health issue and is clearly an important patient safety issue [1]. Many countries, such as Ireland, the United States, Canada, Germany, and Australia, have shown a continuous and significant increase in the number of ED visits [2-7]. In the United States, ED visits were estimated to increase from 136.9 million in 2015 to 145.6 million in 2016, an increase of 6.4%. The 10-year volume change was 24.7% and has increased by a total of 61.2% over the past 20 years (ED visits in 1996 were estimated at 90.3 million) [8,9]. In Taiwan, ED visits were estimated to increase from 7.18 million in 2017 to 7.64 million in 2019, an increase of 6.4%. In retrospect, the number of ED visits has increased by a total of 23.6% over the past 19 years [10].

The increasing number of ED visits has also caused a periodic imbalance in the supply and demand of ED and hospital resources, which leads to longer waiting times and delays in critical medical treatments. ED crowding is related to several adverse clinical outcomes, including higher mortality and morbidity [11,12]. Therefore, it is most important to design a method to properly identify urgent patients' priorities in the ED [13].

Related Work

Several research studies have focused on developing a system for predicting hospital admissions based on the patient's ED electronic medical record (EMR) [14]. Among these studies, the National Hospital Ambulatory Medical Care Survey (NHAMCS) data set [9] is the most common data set to be analyzed. Despite using the NHAMCS data set, those studies might end up with different outcomes being achieved. Here, we briefly introduce some existing methods and implementation results, followed by a description of the concepts and methods that our system uses.

Gligorijevic et al [15] developed a system for predicting the number of resources that the patients would need. They built a bidirectional Long Short-Term Memory (biLSTM) model to extract continuous data features and medical text data features, which resulted in a binary model with prediction accuracy and area under the receiver operating characteristic curve (AUROC) of 0.792 and 0.879, respectively. Moreover, they showed that using nurses' notes can provide a significant improvement in the prediction accuracy in comparison with using only standard continuous and categorical data.

Zhang et al [16] constructed a method for analyzing the patients' reasons for a visit to predict hospital admission using principal component analysis and traditional natural language processing (NLP) combined with multilayer neural network models and logistic regression (LR) model. In their study, they tested the model using a 10-fold cross-validation method, and the AUROC was 0.84. Sun et al [17] used the chi-square test to select the association between hospital admission and various possible risk factors and inputted the extracted association features into LR model for training to develop a prediction model, which was used to predict whether a need for hospital admission exists for ED patients. The involved variables included demographics (age, sex, and ethnic group), ED visit or hospital admission in the preceding 3 months, arrival mode, patient acuity category of the ED visit, and coexisting chronic diseases (diabetes, hypertension, and dyslipidemia). The AUROC for their study was 0.85.

Graham et al [18] used 3 machine learning algorithms to create the following models: LR, gradient boosted machines, and decision trees; these models were validated using a 10-fold cross-validation method repeated 5 times, whereby the accuracy of the best result in the gradient boosted machines model was 0.8. It turns out that their study can help clinicians plan the allocation of resources in advance and avoid the bottleneck of patient congestion.

Wang et al [19] developed a data-driven and evidence-based triage method to quickly identify acute and severe patients and prevent the waste of limited resources because of overdiagnosis. They proposed an attention-based biLSTM called *DeepTriager*, which processes both structured data and textual data from a clinical record to predict an ED patient's acuity level. The method can not only predict the acuity and severity of the outpatient but can also provide visualizable and interpretable evidence on the clinical context to support decision-making. The AUROC for binary classification (acuity 1 and 2) can achieve 0.93, which is 0.03 higher than that of traditional machine learning methods.

Study Aim

The aim of this study is to establish an effective and efficient system for predicting whether patients will eventually require hospital admission to provide a reference to physicians to rank the priority of treatment of patients in advance. In this proposed system, our goal is to use both conventional structured data and unstructured data to design a binary classification model to help identify the hospitalization needs of the ED patient visits.

Methods

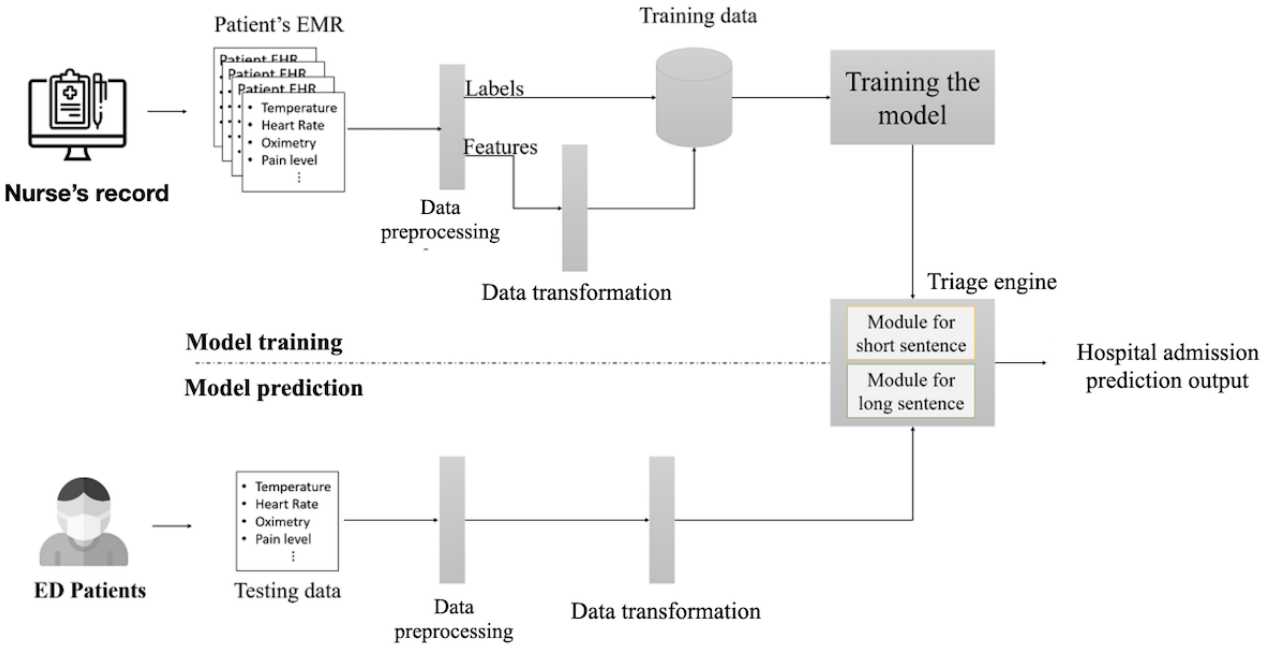
System Overview

This study focuses on establishing an effective and rapid system to predict whether patients will eventually need to be hospitalized to provide a reference to physicians to determine the priority of treatment of patients in advance. Moreover, to evaluate the effectiveness of our model for other clinical predictions, we also applied the model to other clinical outcomes and compared the obtained results with those from other algorithms.

The system overview in Figure 1 shows that our system is separated into two parts: the training part and the prediction part. The EMR values of each ED visit patient were used as input, and the patient's hospital admission decision from the physician was used as the ground truth. There were 3 steps in model training. The first step was to preprocess the input data, such as feature selection and filtering of the unusable or missing data, and the detailed method will be explained in the *Data Preparation* section. Next, the processed data were transformed into the corresponding text type. Finally, the transformed

transcript and ground truth were used to train the binary classification model. Once the training of the model was completed, it was tested against the unseen data. The unseen data were transformed to the text type, which was then fed into the model, and the output of the model was the probability of hospital admission for the ED patient visits.

Figure 1. System overview. EMR: electronic medical record; ED: emergency department.

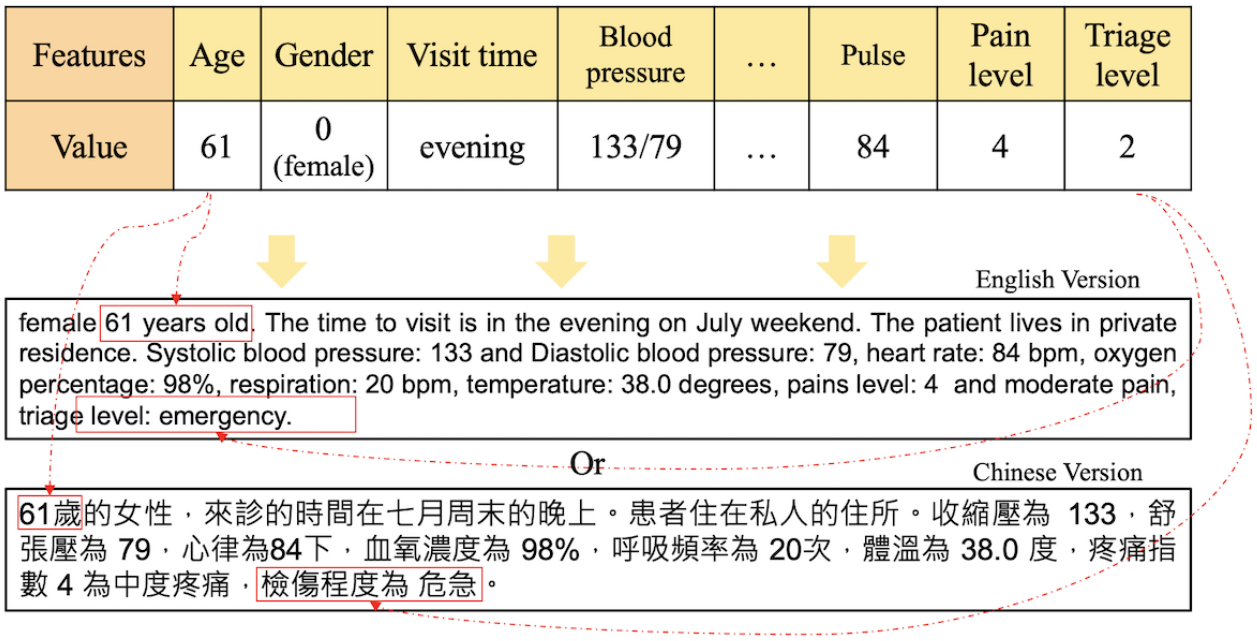


Data Transformation

To allow the mentioned data set to be more effectively handled by the proposed methods in our work, we first transformed the data into another text type. The method of transforming the original data into the text type is shown in Figure 2.

The table in Figure 2 shows the characteristics sampled from the original data set, including vital signs and other information, such as age, gender, blood pressure, oxygen, and pain index. The lower part of Figure 2 illustrates the format after data transformation in English or Chinese. Note that the original format of the data sample shown in Figure 2 reveals the features and their corresponding values. However, after transformation into text, all the feature names remained as words, but their corresponding values also appeared as words, so that the new format of the data sample now became a complete sentence. Then, we inputted the complete sentence into the model for training and analyzed the correlation between the features.

Figure 2. The method of data transformation.

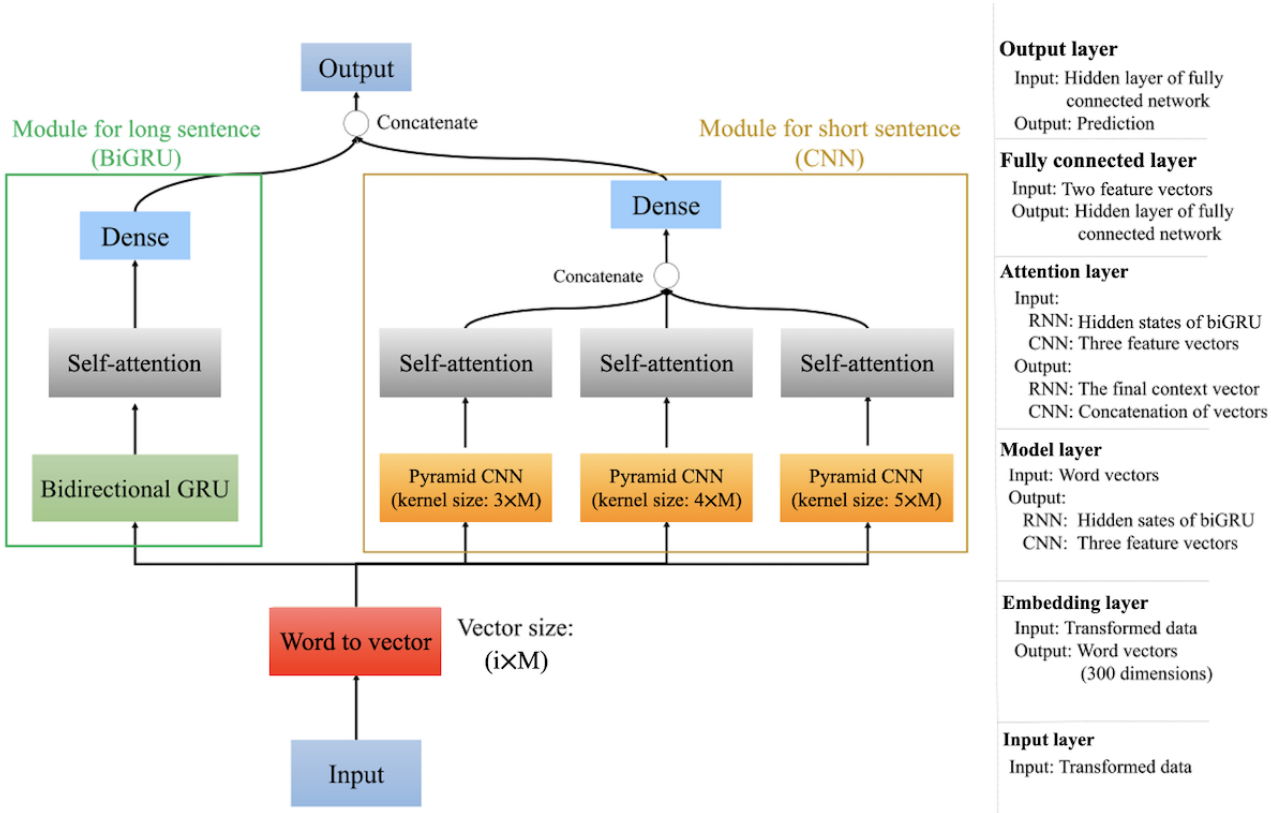


Triage Engine

Overview

In this work, our triage engine comprised 2 different parts, where the first part was used for analyzing short sentences (only convolutional neural network [CNN] type) and the second part was used for analyzing long sentences (only recurrent neural network [RNN] type). Experiments were conducted to verify the effectiveness of the triage engine after we first examined the performances of its 2 parts. Our classification engine was composed of 2 different text processing modules (ie, 2 parts). In the following section, we have introduced the characteristics of the 2 modules step by step and elaborated on the logic behind their design. The network architecture of our proposed triage engine, comprising the RNN-type module and the CNN-type module, is shown in Figure 3.

Figure 3. Network architecture of the triage engine. BiGRU: bidirectional gated recurrent unit; CNN: convolutional neural network; GRU: gated recurrent unit; RNN: recurrent neural network.



In our system, we used the data that had been converted into text format as input. As the text data contained many features, there was a certain relationship between the different features, such as the relationship between systolic blood pressure and diastolic blood pressure, pain index and pain location, and triage level and pain index. However, this relationship might have been lost after the features were converted into static word embeddings in high-dimensional space. Therefore, to be able to analyze the entire sentence for text information, we adopted the RNN structure, which has been shown to form a very useful algorithm. In fact, the RNN architecture is focused on the relationship among all the words from a sentence, and it is more appropriate to analyze the meaning of long sentences.

In addition, as the features and the corresponding values were converted into text sequentially in terms of a sentence, the name and value of a feature were in a neighboring relationship. To be able to accurately and effectively analyze the relationship among each feature and the corresponding value, the semantics of short sentences (among 3 words, 4 words, or 5 words) was very important, for example, *body temperature: 36.5 degrees*, *pain index: 5*, and *respiratory rate: 15 times*. In this short sentence analysis, CNN served as a very useful algorithm. This architecture focuses on the relationship between each word and its neighboring subjects. We will introduce it in detail later.

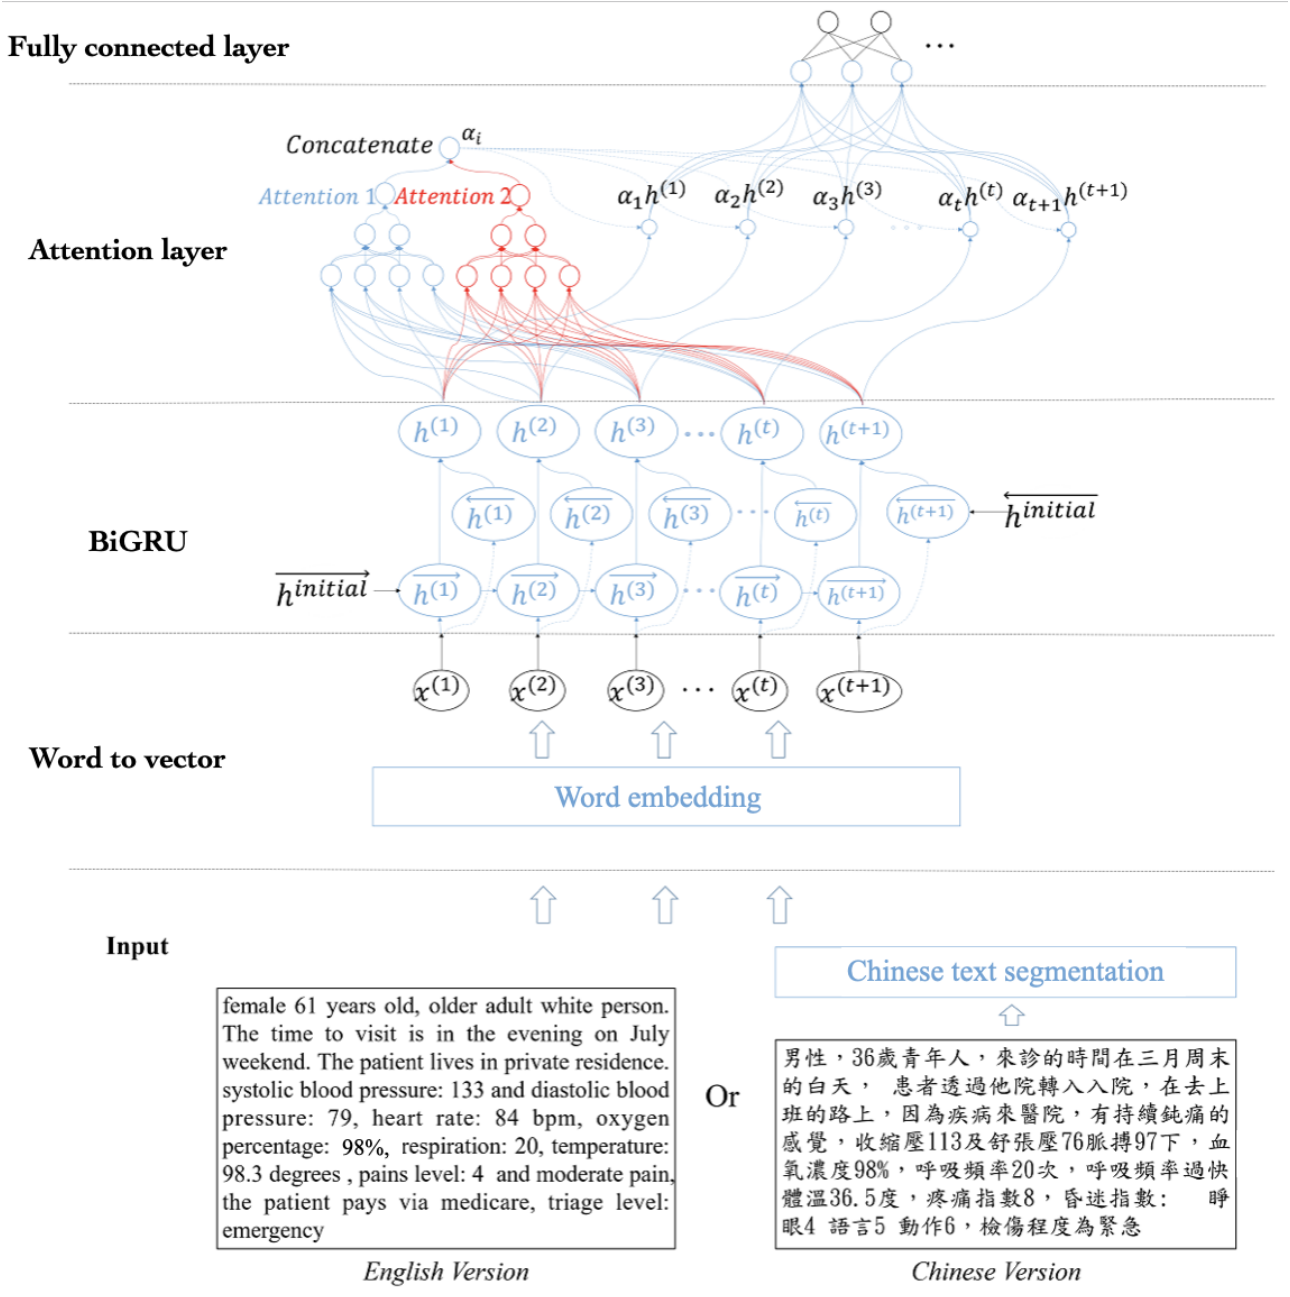
To effectively use the characteristics of the 2 learning algorithms of the 2 parts of the triage engine, we paid attention to the way in which the outputs of the 2 neural network models were effectively fused, which was also the focus of this system. In other words, we formed an overall model by merging the 2 parts to accomplish the single task, that is, prediction of the need for hospital admission. Our strategy was as follows: first, the 2 models were individually trained based on different data sets, and second, their parameters were optimized according to their respective losses and the corresponding parameter settings. After training the 2 models, we deleted the output layers of both the models and concatenated the last 2 fully connected layers, which were located before the output layers of the 2 models and the new output layer. Then, we fine-tuned the overall triage model on the 2 data sets, and the dropout was executed before the output layer. Finally, the output of the triage model predicted the probability of hospital admission for each ED visit.

Module for a Long Sentence (RNN Type)

The focus of this part of the study was on how to analyze the integrity of the text data, where the strength of feature extraction was extensive as the correlation among the patterns of the different samples was searched. Such a correlation not only involves time but also involves space. By learning from the sequence of sentences, the resulting model was able to effectively process each of the complete textual data and thus possessed a memory attribute.

The input of this model was the textual data transformed from the structural and unstructured data (EMR) of the ED visits, and the output was the vector that included the probability of hospital admission for the ED visits. Figure 4 shows the network architecture of the RNN part of the triage engine.

Figure 4. Recurrent neural network-type part of the triage engine. BiGRU: Bidirectional gated recurrent unit.



As depicted in Figure 4, first, all the words transformed from the EMR were input into the word vector layer, which was used to convert each word into the corresponding word vector. In our work, the pretrained word vector library was FastText [20,21], which is the most popular and useful library for learning word embeddings and text classification. First, as our work processed 2 data sets, one in English from NHAMCS and another in Chinese from the National Taiwan University Hospital (NTUH), we decided to develop our prediction model in both English and Chinese versions. Second, the word vectors were sequentially passed to the bidirectional gated recurrent unit (biGRU), in which the hidden sequences in 2 directions were concatenated at each time stamp to form a new hidden sequence. In general, the biGRU can obtain the features of a text more effectively. Thus, the hidden states from the biGRU were fed to the attention layer to evaluate the weights of each

hidden state, and the dot product between the evaluated weight value and each hidden state was calculated. The attention layer was composed of 2 fully connected feed-forward neural networks, using exponential linear units [22] as the activation function. For the output of the attention layer, Softmax, developed by Goodfellow et al [23], was chosen as the activation function.

The attention layer in this work was used to find the key information content units in different sentences from each ED visit's record and assess whether the patients will eventually need hospitalization. Moreover, the 2-layer attention network was used in this work as it is more effective than one with only a single layer in all sentences. Thus, the proposed system with multiple attention layers was more effective for the subsequent evaluation of the prediction performance throughout the experiment. Finally, the output from the attention layer was fed into the fully connected layers with 64 neurons.

Module for a Short Sentence (CNN Type)

This part of the study focused on extracting the local features of the text. By extracting the keywords of the document or sentence as features and training the classifier based on these features, it was possible to effectively analyze the more important and critical contexts of the sentences.

Similarly, Figure 5 shows the network architecture of the CNN part module of the triage engine. An image-like vector, whose format is $I \in$ $^{\times}$, was obtained by stacking the word vectors that are converted from the original text. More specifically, *h* and *w* denoted the height (number of words) and width (dimension of the word vector) of the image, respectively. In particular, Chinese words were processed by text segmentation first and then passed to the embedding layer. Then, the word vectors were used to perform convolution operations with 3 kernels of different sizes, which were 3, 4, and 5. Different kernels were used to find the relationships among short words, that is, various correlations between words.

For the convolutional operation, we adopted the concept from the deep pyramid CNNs [24], which is a low-complexity CNN architecture for text categorization that can efficiently represent long-range associations in a text. Instead of using the original CNN for text processing [25], we applied a simple network architecture to obtain better accuracy by increasing the network depth without significantly increasing the computational cost. Figure 6 shows the network architecture of the aforementioned pyramid CNN for text. Owing to the problem of degradation, the shortcut connections were expected to facilitate every few stacked layers to more easily fit a desired underlying mapping, and such thoughts of shortcut connections were the key concept for the pyramid CNN architecture. Therefore, according to the idea, the deep pyramid CNN under different kernel sizes was used in our work.

Figure 5. Convolutional neural network–type part of the triage engine. CNN: convolutional neural network.

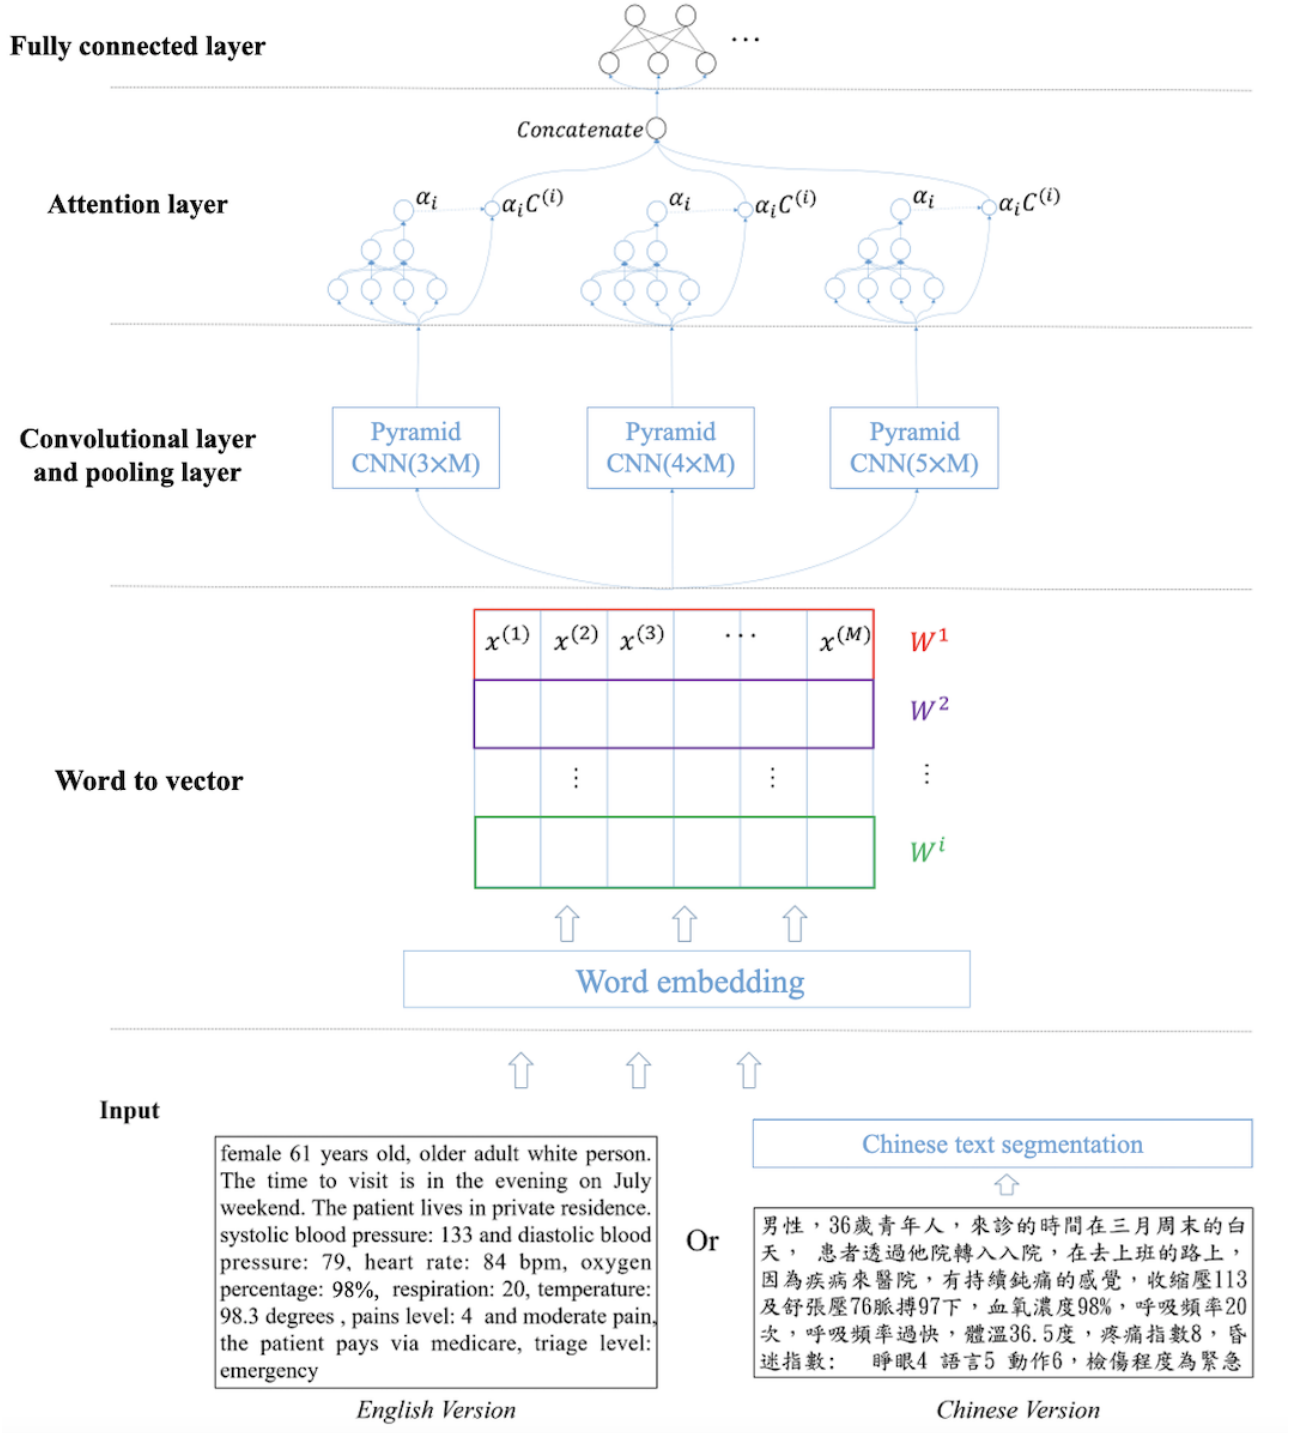


Figure 6. Architecture of pyramid convolutional neural network for text.

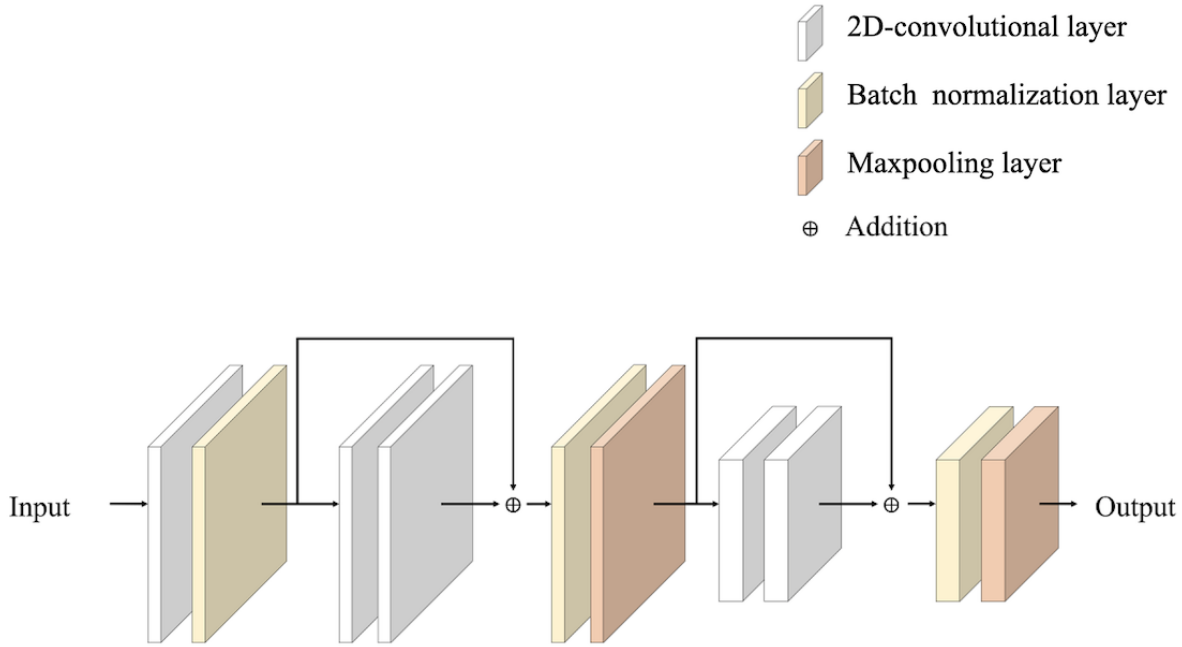

Model Synthesis by Integration of the 2 Modules

As shown in Figure 3, our final triage engine model was to integrate the 2 *pseudoengines* shown in Figures 4 and 5. Technically speaking, after the convolution operation, a feature map with the corresponding size was obtained, and each convolutional layer was followed by a max pooling layer of the corresponding size. The CNN-type part of the integrated engine was implemented to further distinguish the keywords from the transformed sentence. Then, the output of the max pooling layers was input to the self-attention layer, which was used to evaluate the weights of keyword vectors and calculate the dot product between the evaluated weight value and each keyword vector. Finally, the outputs from the 3 attention layers were concatenated and fed into fully connected layers with 64 neurons. The vector of the probability of hospital admission was calculated by applying the Softmax activation function in the fully connected layer, and we formulated the probability as follows:

$$Probability = CNN\ (k^3(X') + k^4(X') + k^5(X'))\ \textbf{(1)}$$

Model Training

The RNN-type module was trained with a learning rate of 0.00001 using an optimizer called Adam, developed by Kingma et al [26], which is a gradient descent method widely used in deep learning applications for computer vision and NLP. The batch size was set as 64, the number of iterations was set as 60, and the hidden states of the biGRU were set as 128. For the CNN-type module, the learning hyperparameters were the same as that of the RNN type. The size of the kernel was set to 3, 4, and 5, and the strides were set as 1. The loss function used for the integrated model was the cross-entropy sum between the predicted output and ground truth as follows:

$$l_{total} = l_{cnn} + l_{rnn}\ \textbf{(2)}$$

where y_i is the ground truth of class I, and $\hat{y}_i$ is the prediction of the model.

Results

Overview

A series of experiments were conducted to validate our design. To evaluate the effectiveness of our model, all the experiments were carefully conducted using stratified random sampling. The following procedure was performed separately on the NHAMCS and NTUH data sets. For internal comparison, 72% of the data were used as the training set, 8% of the data were used as the validation set, and 20% of the data were used as the hold-out testing set. The training and validation process was repeated 20 times, with 20 models generated, and the best-performing model in the hold-out testing set was selected as the final model. For external comparison, the same training and validation procedure was performed; however, only the best-performing model in the training and validation procedure was tested on the hold-out testing set to ensure a fair comparison.

Experiment Platform

We adopted Keras (Tensorflow-Graphics Processing Unit) to execute all the algorithms on computers with Nvidia GeForce GTX 1080Ti Graphics Processing Unit (with 11 GB RAM) and Intel Core i5 Central Processing Unit (with 64 GB RAM). In the processing of the loss function, we used the Adam optimizer with a learning rate of 0.00001, batch size of 64, and epochs of 60.

Data Preparation

In this study, 2 different data sets were used to evaluate the performance of the proposed system: the NHAMCS data set and the NTUH data set.

NHAMCS Data Set

In our study, the data from 118,602 ED patient visits collected between 2012 and 2016 were used. We selected 37 features, including *month*, *week*, *arrival time*, *age*, *residence*, *sex*, *race*, *did he or she come by ambulance*, *pay by insurance*, *pay by Medicare*, *pay by Medicaid*, *pay by work compensation*, *pay by self*, *no charge to pay*, *temperature*, *heart rate*, *respiratory rate*, *systolic blood pressure*, *diastolic blood pressure*, *pulse oximetry*, *pain scale*, *triage level*, *been ED during last 72 hours*, *dementia*, *cancer*, *cerebrovascular*, *COPD*, *heart failure*, *HIV*, *ECG*, *X-ray*, *CT-scan*, *MRI*, *Ultrasound*, *CPR*, *admitted to ICU*, and *hospital admission*.

NTUH Data Set

In our study, the data from 745,441 ED patient visits collected between 2013 and 2017 were used. We selected 31 features, including *age*, *sex*, *day zone*, *weekend*, *month*, *is he or she getting fever?*, *clinics by*, *clinics for*, *is job-related?*, *on the job way*, *pain character*, *pain period*, *CPR*, *ICU*, *acute change*, *account sequence number*, *systolic blood pressure*, *diastolic blood pressure*, *pulse*, *oxygen*, *respiration rate*, *body temperature*, *pain index*, *gcse*, *gcsv*, *gcsm*, *triage level*, *pain body part*, *pain period description*, *judgement description*, and *hospital admission*. All the features were recommended by Nottingham Trent University physicians.

Performance on the NHAMCS Data Set and Baseline

We verified our proposed fusion model using the NHAMCS data set and compared the results with the 2 parts of the model (RNNs and CNNs). As a result, the AUROC can achieve 0.872 using the proposed model. The other metrics of the performance of the proposed network are shown in Table 1. For our fusion model, the highest accuracy and specificity can reach 0.828 and 0.843, respectively.

So far, most existing studies have used different data sets. Here, to effectively evaluate the prediction quality of our model, we chose the traditional machine learning algorithms commonly used in other studies as our baselines for comparison, including LR, extreme gradient boosting (XGBoost), and random forest. Furthermore, we compared our model with the Bidirectional Encoder Representations From Transformers (BERT) [27] model, which is considered to be a milestone of NLP. Then, we compared the different results obtained from different methods under various metrics.

Table 2 shows 6 metrics of each algorithm. It can be seen that our proposed model scored the highest in 4 out of 6 metrics, including specificity, precision, accuracy, and AUROC, while comparing with other models. These results suggest that our proposed deep learning algorithm seems to be more promising than the traditional machine learning algorithms.

[d]Italicization indicates that the best performance was shown by our model in the metric among the different models.

Performance on the NTUH Data Set and Baseline

We also verified our proposed fusion model using the NTUH data set and compared the results with the 2 parts of the model (RNNs and CNNs), which included 10 experiments. In the RNNs part, we experimented with 6 different combinations using biLSTM and biGRU with different layers of attention mechanisms to observe the changes in the 4 metrics (sensitivity, specificity, accuracy, and AUROC) under different combinations. In the CNN part, we experimented with 3 different combinations using a traditional CNN and pyramid CNN with an attention mechanism to observe the changes in the 4 metrics under different combinations. As a result, the AUROC can achieve 0.876 using the proposed model in our fusion model (Table 3).

Similarly, to effectively evaluate the prediction quality of our model, we chose 3 kinds of traditional machine learning algorithms commonly used as our baselines—LR, XGBoost, and random forest. Furthermore, we also compared our model with 2 common methods, deep neural network for structural data with biGRU for textual data and the BERT [27] model. Then, we compared the differences in the results between the different methods.

Table 4 shows 6 metrics of each algorithm. It can be seen that our proposed model outperforms all the other algorithms. The result of our proposed model suggested a great improvement in predicting hospitalization when compared with other traditional methods.

Discussion

Comparison With Other Related Studies

According to existing research on the prediction of hospitalization, most studies used specific feature selection methods combined with traditional machine learning algorithms. As shown in Table 5, their results show a variable performance on different metrics. In this section, to compare with other studies in a fair manner, only the best-performing model in the training and validation procedure was tested on the hold-out test set.

According to Table 5, our model achieved the highest performance in AUROC while being compared in the same open data set, that is, the NHAMCS data set. In addition, our work also achieved an excellent score in accuracy in comparison with private data sets.

Table 5. Performance of different research studies.

Study	Methods	Data set	Performance			
			Sensitivity	Specificity	Accuracy	AUROC[a]

Applying on Other Clinical Outcomes

To effectively evaluate the prediction quality of our model for other clinical results, we selected other common outcomes to test and set the results of traditional machine learning algorithms as our baselines and then compared the differences in the results between different methods in various metrics.

For Mortality Rate Prediction

As mortality rate has a high correlation with the emergency severity index (ESI) 5-level triage, we applied our model to predict the mortality rate on the NTUH data set, and the results are shown in Table 6. Owing to the small number of deceased patients, we chose not to test this data set because of convergence issues.

Compared with other algorithms, including the 3 traditional machine learning algorithms, our proposed model outperforms all other methods except in *sensitivity*.

Table 6. Performance of mortality rate prediction on the National Taiwan University Hospital data set.

Model	Sensitivity	Specificity	Precision	F1 score	Accuracy	AUROC[a]
Logistic regression	0.903	0.887	0.895	0.895	0.896	0.954

[b]XGBoost: extreme gradient boosting.

[c]Italicization indicates that the best performance was shown by our model in the metric among the different models.

For Prediction of Intensive Care Unit Admission

In the probability of intensive care unit admission, we tested our model on 2 data sets, and the results are shown in Tables 7 and 8. Table 7 shows the comparison of the 4 algorithms on the NHAMCS data set, and Table 8 shows the results of the 4 algorithms on the NTUH data set.

Similarly, compared with other algorithms, including the 3 traditional machine learning algorithms, our proposed model outperformed all other methods except in *sensitivity*.

Limitations

There are several limitations to this study. First, the NTUH database used in our experiment belongs to the NTUH and is not publicly available. Hence, it is hard to fairly compare it with the models developed in other studies. However, the NHAMCS data set is publicly available and may be used to evaluate the performance of the models across studies. Second, all the evaluations are based on retrospective data, and future prospective evaluation is needed.

Conclusions

ED crowding has become one of the biggest issues in health care services. Many countries have shown a steady but significant increase in the number of ED patient visits. Although the ESI system somewhat improves the process of treatment, it still relies on the nurse's judgment and is prone to the problem where most patients are triaged to ESI level 3. Moreover, the main purpose of the ESI is to classify patients and reserve the more limited resources for those belonging to the high-acuity classes who may need them more urgently. Therefore, a system that can help physicians accurately triage a patient's condition is imperative. In this work, we proposed a system based on the patients' ED EMR to predict the need for hospitalizations after the assigned procedures in the ED are completed. This system uses CNNs combined with RNNs, together with an attention mechanism for classification.

We validated the proposed triage engine based on the developed fusion model on 2 data sets, one of which is from an open data set (NHAMCS) that contains 118,602 ED patient visits in the United States, in which the accuracy and AUROC were 0.83 and 0.87, respectively. On the other hand, we also externally validated our work on the local NTUH data set that includes 745,441 ED patient visits in Taiwan, in which the accuracy and AUROC were 0.83 and 0.88, respectively. Moreover, to effectively evaluate the prediction ability of our proposed system, we also applied the model to other clinical outcomes, including mortality and admission to the intensive care unit. The results showed that our method is approximately 3% to 5% higher in accuracy than other common methods, including 3 traditional machine learning algorithms. Furthermore, the implementation of the proposed system is relatively easy, includes commonly used variables, and is better fitting for real-world clinical settings. It is our future work to validate our novel deep learning–based triage algorithm with prospective clinical trials, and we hope to use it to guide resource allocation in a busy ED once the validation succeeds.

The unstructured data used in this work were recorded manually by a nurse. However, the text information should be directly described by the ED visits during the ED clinical examination. Therefore, future work may focus on using automatic speech recognition to directly convert and use the speech data of the ED visits. Moreover, although our work includes an analysis of short and long sentences, it does not deal with the relevance of global words. Thus, our future works may focus on combining different types of deep learning algorithms in this system to provide a more comprehensive system, such as a graph convolutional network or transformer.

Abstract

Background: Researchers face challenges in patient recruitment, especially for rare, fatal diseases such as amyotrophic lateral sclerosis (ALS). These challenges include obtaining sufficient statistical power as well as meeting eligibility requirements such as age, sex, and study proximity. Similarly, persons with ALS (PALS) face difficulty finding and enrolling in research studies for which they are eligible.

Objective: The aim of this study was to describe how the federal Agency for Toxic Substances and Disease Registry's (ATSDR) National ALS Registry is linking PALS to scientists who are conducting research, clinical trials, and epidemiological studies.

Methods: Through the Registry's online research notification mechanism (RNM), PALS can elect to be notified about new research opportunities. This mechanism allows researchers to upload a standardized application outlining their study design and objectives, and proof of Institutional Review Board approval. If the application is approved, ATSDR queries the Registry for PALS meeting the study's specific eligibility criteria, and then distributes the researcher's study material and contact information to PALS via email. PALS then need to contact the researcher directly to take part in any research. Such an approach allows ATSDR to protect the confidentiality of Registry enrollees.

Results: From 2013 to 2019, a total of 46 institutions around the United States and abroad have leveraged this tool and over 600,000 emails have been sent, resulting in over 2000 patients conservatively recruited for clinical trials and epidemiological studies. Patients between the ages of 60 and 69 had the highest level of participation, whereas those between the ages of 18 and 39 and aged over 80 had the lowest. More males participated (4170/7030, 59.32%) than females (2860/7030, 40.68%).

Conclusions: The National ALS Registry's RNM benefits PALS by connecting them to appropriate ALS research. Simultaneously, the system benefits researchers by expediting recruitment, increasing sample size, and efficiently identifying PALS meeting specific eligibility requirements. As more researchers learn about and use this mechanism, both PALS and researchers can hasten research and expand trial options for PALS.

KEYWORDS

amyotrophic lateral sclerosis; Lou Gehrig disease; motor neuron disease; clinical trials; patient recruitment; National ALS Registry; research notification mechanism

Introduction

Amyotrophic lateral sclerosis (ALS), commonly known as Lou Gehrig disease, is a progressive multifactorial neurodegenerative disease primarily affecting motor neurons. Conservative estimates suggest that approximately 17,000 Americans currently live with ALS, while 1500 new cases are diagnosed annually [1,2]. Most patients with ALS survive 2-5 years after receiving a diagnosis [3,4]. Although numerous treatments and therapeutic strategies are employed in the care of persons with ALS (PALS), there are only 2 approved medications that slow ALS progression: riluzole and edaravone. These drugs do not cure ALS, but rather modestly prolong survival or slow disease progression [5,6].

In 2008, the US Congress passed the ALS Registry Act which directed the federal Agency for Toxic Substances and Disease Registry (ATSDR) to create the National ALS Registry (Registry) [7]. The mission of the Registry is multifold and includes determining national epidemiological trends such as incidence, prevalence, and mortality; identifying and examining risk factors and potential etiologies; and facilitating and supporting ALS research [8].

Researchers face challenges in patient recruitment and enrollment, especially for rare, fatal diseases such as ALS [9]. These challenges include having sufficient sample size, satisfying narrow inclusion criteria (eg, disease duration <2 years, specific genetic mutations, forced vital capacity >70%), as well as meeting eligibility requirements such as age, sex, and study proximity [10-14]. Similarly PALS, like patients with other rare disorders, face difficulty finding and enrolling in research studies for which they are eligible [15]. In 2012, the Registry sought approval from the Centers for Disease Control and Prevention (CDC) Institutional Review Board (IRB) to use its database of patients as a recruitment tool for researchers [16]. The system is now called the research notification mechanism (RNM). The purpose of this system is to provide a tool for researchers to recruit for epidemiological, biomarker, and observational studies, as well as clinical trials. Our objective is to describe how ATSDR's National ALS Registry is connecting PALS with opportunities to participate in ALS research and trials.

Methods

Since its establishment in 2012, PALS enrolling in the ALS Registry have been provided the opportunity to consent to receive research notifications. Interested participants provide an email address for receipt of research notifications through the RNM. To use the RNM, ALS researchers seeking PALS for research or trial participation submit a completed application online at the National ALS Registry website [17]. In the application process, researchers can select specific eligibility criteria to screen patients. Such criteria could include age range, period since diagnosis, gender, family history of ALS, region (national, state, or city); however, some researchers may specify no screening criteria if their study could include all Registry participants (Table 1).

Table 1. Patient criteria under the National ALS Registry research notification application.

Prescreening	Criteria
Age range at diagnosis (years)	0-10, 11-20, 21-30, 31-40, 41-50, 51-60, 61-75, >75
Diagnosis years	From (yyyy) to (yyyy)
Gender	Male or female
City (State) of US residence	eg, Atlanta, Georgia
Family history of ALS[a]	Mother, father, brother, sister, children
No prescreening needed	Materials sent to all participants taking part in the process

[a]ALS: amyotrophic lateral sclerosis.

Proof of the researcher's IRB approval is required; however, CDC IRB approval is not required as this system was previously approved. All applications are reviewed for completeness and researchers are contacted if items are outstanding (eg, missing curriculum vitae or application form). Applications are submitted to the Registry's review committee comprising of internal and external subject matter experts to determine scientific merit based on a set of established criteria (Table 2).

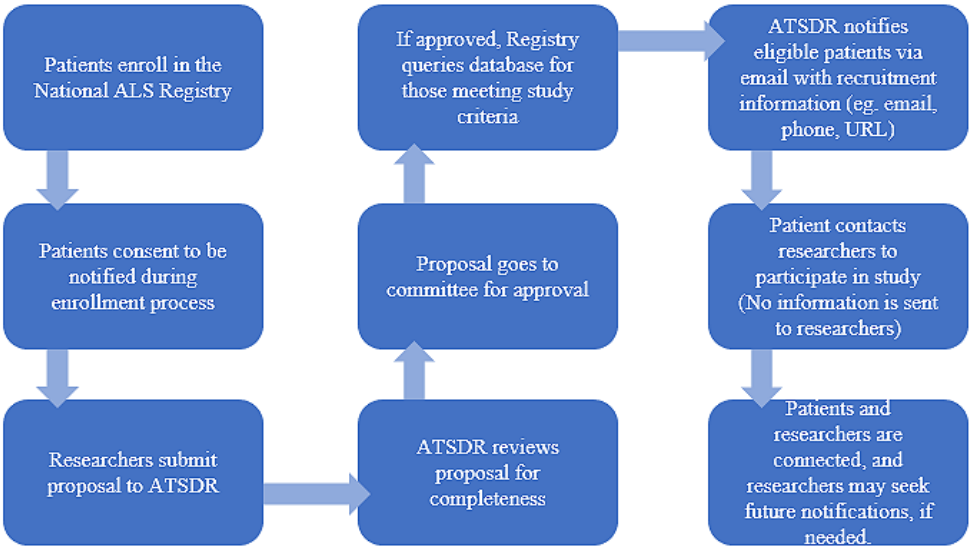
Table 2. Evaluation and approval of the application by the National ALS Registry review committee.

Evaluation	Criteria
1. Scientific merit (A-D is considered acceptable)	A. Outstanding/B. Excellent/C. Good/D. Acceptable/E. Unacceptable
2. Will the proposal provide useful information for ALS[a] patients? (A-C is considered acceptable)	A. High potential/B. Strong potential/C. Good potential/D. Limited potential/E. No apparent potential
3. Are the patient contact procedures and materials clear?	Yes/No/Requires more information
4. Are the patient contact procedures and materials appropriate, necessary, and sufficient?	Yes/No/Requires more information
5. In your judgment, would most ALS patients find the demands of the protocol reasonable?	Yes/No/Requires more information
6. Is there an acceptable risk/benefit ratio?	Yes/No/Requires more information
7. Are there adequate protections for patient confidentiality and privacy?	Yes/No/Requires more information
8. Does the proposal reach a satisfactory threshold for all 7 criteria listed above?	Yes/No
9. Do you support approval of the proposal as it has been submitted?	Yes/No
Comments for the investigators (limit of 500 words)	

[a]ALS: amyotrophic lateral sclerosis.

External committee members complete a conflict of interest form to ensure neutrality. Depending on the complexity of the application, approval time is within 3 weeks. If the committee cannot make a decision, final approval or disapproval resides with the ATSDR. Once the application is approved, Registry staff work with the researcher to coordinate a date and time for the notification, as shown in the process chart (Figure 1).

Figure 1. Flowchart of application approval process. ALS: amyotrophic lateral sclerosis; ATSDR: Agency for Toxic Substances and Disease Registry.



This communication helps the researcher to prepare for an influx of enrollment inquiries. The notification to PALS consists of a preapproved template with an attached document informing them of eligibility criteria (when applicable) and contact information for the researcher. A disclaimer is added to all notifications stipulating that CDC/ATSDR does not necessarily endorse the study and is not involved in its design or execution. PALS in receipt of the registration email can contact the research team directly to inquire about participation—no identifying information is shared with ALS researchers. RNM notifications can be sent to all registrants up to 3 times, if needed, and as requested by the researcher. In 2018, a fourth notification was implemented. The fourth communication follows the third round of notification to only newly registered patients after the 2018 implementation. All studies are posted on the Registry's website and are classified as either "Active" or "Closed." Contact information is also posted on the website for "Active" studies [18].

Results

Since the launch of the Registry in 2010, over 90% of enrollees have elected to be notified about new ALS clinical trials and epidemiological studies. From 2013 to 2019, 46 institutions,

both domestic and abroad, have leveraged this tool and 638,760 total emails were sent to consented patients. Annually, the greatest number of emails were sent in 2018 (n=293,422). In 2017, researchers at 10 institutions used the notification system—its broadest annual utilization. The median number of emails sent annually has been 41,433. The median number of emails per study was 8109 (Table 3).

Table 3. Number of emails sent to consented patients by Registry's RNM[a], 2013-2019.

Year	Studies (n=46), n (%)[b]	Emails (n=638,760), n (%)[c,d]	Yearly median
2013	4 (8.70)	5690 (0.89)	909
2014	8 (17.39)	27,035 (4.23)	5570
2015	9 (19.57)	41,433 (6.49)	5508
2016	3 (6.52)	20,007 (3.13)	2076
2017	10 (21.74)	82,114 (12.86)	9077
2018	6 (13.04)	293,422 (45.94)	30,091
2019	6 (13.04)	169,059 (26.47)	21,978

[a]RNM: research notification mechanism.

[b]Median number of studies for 2013-2019: 6.

[c]Median number of emails for 2013-2019: 41,433.

[d]Median number of emails per study: 8109.

Of the 7030 registrants who participated in the clinical notification, patients between the ages of 60 and 69 years had the highest level of participation (n=2417, 34.38%), whereas those between the ages of 18 and 39 and aged over 80 had the lowest (n=286, 4.07%, and n=218, 3.10%, respectively; Table 4). Age distribution in those who participated in clinical notification was found to be statistically different from the total registrants.

Table 4. Demographic characteristics of registrants who elected to receive notifications, January 1, 2013 to December 31, 2019.

Characteristic	Clinical notification participants (n=7030), n (%)	All registered participants (n=10,625), n (%)	*P* value[a]
Age at diagnosis, n (%)			<.001
18-39	286 (4.07)	341 (3.21)	
40-49	840 (11.95)	1041 (9.80)	
50-59	2067 (29.40)	2782 (26.18)	
60-69	2417 (34.38)	3817 (35.92)	
70-79	1202 (17.10)	2198 (20.69)	
80+	218 (3.10)	446 (4.20)	
Gender, n (%)			.71
Male	4170 (59.32)	6289 (59.19)	
Female	2860 (40.68)	4336 (40.81)	
Census region, n (%)			.18
Midwest	2076 (29.53)	3315 (31.20)	
South	2420 (34.42)	3480 (32.75)	
West	1464 (20.83)	2216 (20.86)	
East	1019 (14.50)	1556 (14.64)	
Other/Missing	51 (0.73)	58 (0.55)	

[a]*P* value, Cochran–Mantel–Haenszel test.

More males participated (4170/7030, 59.32%) than females (2860/7030, 40.68%). Furthermore, participation of 7030 patients elected to be notified for clinical and epidemiological studies varied by region of country: South at 34.42% (n=2420), Midwest at 29.53% (n=2076), West at 20.83% (n=1464), and the East at 14.50% (n=1019; Table 4). This representation is in parallel with what has been observed in all registered participants. Based on anecdotal feedback from researchers, it is conservatively estimated that over 2000 patients were recruited for clinical trials between 2013 and 2019. This was calculated using an estimated average of 50 patients recruited per study for 46 studies or 2300 patients recruited since 2013.

Some studies recruited more than 50 patients, whereas some less. Epidemiological studies conducted by Columbia University and University of Miami also demonstrated a higher percentage of patients recruited from the RNM than other sources (Tables 5 and 6).

A list of notable clinical trials and epidemiological studies is provided in Multimedia Appendix 1.

Since inception of the system, epidemiological studies have outnumbered clinical trials. These studies have focused on the evaluation of risk factors, genetics, and patient and caregiver burden, while clinical trials have focused on novel treatments to reverse or slow disease progression. A complete list of clinical trials and studies is available in the National ALS Registry website [18].

Discussion

Clinical trial recruitment for rare diseases such as ALS has evolved. Researchers are continuously looking for novel methods for outreach and recruitment. The launch of the Registry's RNM has helped to recruit patients for both clinical trials and epidemiological studies. The recruitment of participants for epidemiological studies and clinical trials is challenging [19,20]. This is especially the case for ALS where it is estimated that almost 60% of patients are not eligible for clinical trials [21]. The use of telemedicine to facilitate ALS clinical trials offers assistance with recruitment, consenting, and screening [22]. This is particularly evident with the COVID-19 pandemic and its impact on clinical research [23]. The cost of conducting clinical trials as well as the recruitment of patients are mitigating factors [24]. It is estimated that only 10% of the patient population with ALS participates in clinical trials [13].

Many factors contribute to the challenges of recruiting participants for ALS trials and a multifaceted approach is likely needed to improve research participation. Some models posit that behavior (trial enrollment) is determined by 3 main factors: motivation, access, and information [25]. Because ALS is a terminal disease, PALS are often highly motivated to enroll in trials. Unfortunately, access is still restricted for some ALS research. Almost 60% of PALS are deemed ineligible for most trials and access can be limited by mobility or geography [10,20]. The use of technology and the recent launch of the Healey ALS Platform Trial, which allows the testing of multiple treatments at once, should help reduce the cost of research, decrease trial time, and increase patient participation [26,27]. The Registry is poised to support this platform trial. This is evident by the growing list of clinical trials and epidemiological studies since 2013. The Registry's novel system provides a user-friendly mechanism for researchers to access an existing

pool of patients with ALS. Moreover, there is no charge to researchers to use the Registry to recruit patients with ALS.

Thousands of PALS have enrolled in research based on RNM notifications, and while the number of those who actually participate is challenging to determine with specificity, our estimate of 2300 PALS is based on conservative assumptions. In addition, the exact estimate of participants recruited by the Registry's system is limited because many studies have more than 1 route of recruitment and researchers do not typically ask where a patient is recruited from such as ClinicalTrials.gov or the National ALS Registry. There were more males among the notification participants than females, in line with the demographics of ALS, which affects more males than females [2,8,28]. With over 8000 notification emails sent per study, the RNM allows researchers to access a large pool of potential participants quickly and efficiently. Furthermore, sending multiple notifications (n=4) allows patients who may have missed the notification message in their email inbox to be reminded of opportunity to participate in clinical trials and epidemiological studies. Because emails have inherent limitations and to increase durability of the recruitment message, the Registry has also posted all active studies with respective contact information on the website. This gives researchers the maximum exposure for their study.

The Registry has recruited for several notable clinical trials. These include 2 Phase 2/3 clinical trials, 1 utilizing mesenchymal stem cell–neurotrophic factor cells and the other a coformulation of sodium phenylbutyrate–taurursodiol, that have shown promise as recently reported [29,30]. In addition, the Registry has provided support for several epidemiological studies. Studies from Columbia University and the University of Miami demonstrated that the notification system led enrollment efforts when compared with other methods such as print and social media.

There are limitations to the RNM; for example, the system does not recruit for all ALS clinical trials because investigators must submit an application for consideration. Besides, the RNM only recruits patients who have self-enrolled in the Registry and not those who have been identified via Centers for Medicare & Medicaid Services (CMS) or Veterans Affairs (VA) databases. The Registry is working with partner organizations such as the ALS Association, Muscular Dystrophy Association, and the Les Turner ALS Foundation to increase enrollment, especially for minority patients.

Patient registries have been found to be successful in the recruitment of clinical trials for cancers and other conditions globally [31]. The National ALS Registry's RNM is an effective tool for connecting PALS to researchers conducting clinical trials and epidemiological studies. The implementation and utilization of the RNM continues to benefit the researchers by helping to speed-up the recruitment process, increasing the study sample size, and easily and efficiently identifying patients meeting specific eligibility requirements. As more researchers learn about and use this mechanism, PALS and researchers can work together to accelerate therapy development for ALS.

Acknowledgments

The authors thank Dr Michael Benatar of the University of Miami for giving us the permission to include data on the CReATe Connect enrollment. Abstract

Background: Obtaining explicit consent from patients to use their remnant biological samples and deidentified clinical data for research is essential for advancing precision medicine.

Objective: We aimed to describe the operational implementation and scalability of an electronic universal consent process that was used to power an institutional precision health biobank across a large academic health system.

Methods: The University of California, Los Angeles, implemented the use of innovative electronic consent videos as the primary recruitment tool for precision health research. The consent videos targeted patients aged ≥18 years across ambulatory clinical laboratories, perioperative settings, and hospital settings. Each of these major areas had slightly different workflows and patient populations. Sociodemographic information, comorbidity data, health utilization data (ambulatory visits, emergency room visits, and hospital admissions), and consent decision data were collected.

Results: The consenting approach proved scalable across 22 clinical sites (hospital and ambulatory settings). Over 40,000 participants completed the consent process at a rate of 800 to 1000 patients per week over a 2-year time period. Participants were representative of the adult University of California, Los Angeles, Health population. The opt-in rates in the perioperative (16,500/22,519, 73.3%) and ambulatory clinics (2308/3390, 68.1%) were higher than those in clinical laboratories (7506/14,235, 52.7%; *P*<.001). Patients with higher medical acuity were more likely to opt in. The multivariate analyses showed that African American (odds ratio [OR] 0.53, 95% CI 0.49-0.58; *P*<.001), Asian (OR 0.72, 95% CI 0.68-0.77; *P*<.001), and multiple-race populations (OR 0.73, 95% CI 0.69-0.77; *P*<.001) were less likely to participate than White individuals.

Conclusions: This is one of the few large-scale, electronic video–based consent implementation programs that reports a 65.5% (26,314/40,144) average overall opt-in rate across a large academic health system. This rate is higher than those previously reported for email (3.6%) and electronic biobank (50%) informed consent rates. This study demonstrates a scalable recruitment approach for population health research.

Introduction

Informed consent for the research use of data and biological specimens is an essential and critical component of a robust program in precision medicine [1-3]. Although the common rule [4] considers the research use of deidentified tissue as "not human subjects" research, the National Institutes of Health (NIH) Genomic Data Sharing Policy expects consent to be obtained for future research use and broad data sharing, even if biospecimens are deidentified [5,6].

The 2017 revision to the common rule includes a new category of regulatory broad consent that provides more flexibility for researchers to consent participants for the storage, biobanking, and secondary research use of identifiable information or biospecimens [4]. Further, many advocates and ethicists have articulated an obligation to communicate that remnant tissue may be used for research and that researchers should proactively obtain informed consent [7,8]. Patients have also expressed a desire to have their preferences dictate the use of clinical specimens for research [8,9]. From this perspective, large-scale precision medicine programs that hope to engender greater trust and foster external collaborations, including collaborations with commercial entities and federal agencies, should consider proactively structuring their consent processes to include these key aspects of a broader and more informative consent process.

The emergence of digital health has also played a significant role in defining precision health approaches to obtaining electronic consent [10-12]. Obtaining in-person paper consent is often resource intensive, is not easily scalable, and precludes digital responses from being incorporated in the electronic health record (EHR) and laboratory information management systems [10-14]. Given that precision medicine research requires large-scale patient engagement, innovations in consent processes and public education [1,15] are required. Animated video consent approaches have been effective in providing comprehensive information and improving participants' understanding of content [16,17] and have thus provided an opportunity to more effectively increase the participation of traditionally underrepresented communities, as content can be tailored to participant groups.

The Engaging University of California Stakeholders for Biorepository Research (EngageUC) Consent Trial [18] was conducted to harmonize biobanking policies and procedures across 5 University of California medical campuses with the help of NIH Clinical and Translational Science Institutes (CTSI). The investigators developed an evidence-based approach that allowed for iterative stakeholder engagement to develop efficient biobank operations and equitable governance processes. The key themes that emerged were that the public should be educated about biobanking; the source of consent content should be considered knowledgeable and trustworthy; the process should be low stress and provide an opportunity to obtain answers to questions; the format and language should be easy to understand; and stakeholders, including the community, should play a role in informing and advising the institution. This framework provides a pathway for addressing the technical and ethical challenges that must be resolved to ensure that biorepositories continue to support translational research in ways that are inclusive of the populations they serve.

In 2016, the University of California, Los Angeles (UCLA), Institute for Precision Health (IPH) launched their ATLAS Community Health Initiative to engage a diverse sample of patients across UCLA Health in precision health research. The goal was to create a powerful and robust clinical and genomic data resource for cutting-edge translational research. This required innovative and scalable solutions for sustaining the program's rapid growth. The IPH partnered with this study's team to further develop and pilot their electronic universal video consent (UCON) process for biological samples, which was used to power the ATLAS precision health biobank.

In the development phase of this program, we leveraged the learnings from the EngageUC Consent Trial [18] and engaged community members across the greater Los Angeles region and internal stakeholders across the UCLA Health system, David Geffen School of Medicine at UCLA, the IPH, and CTSI as part of the initial development and pilot of the UCON process in targeted clinics at UCLA Health [19]. This "one-time" consent process gives all adult patients the autonomy to choose whether they want their deidentified biospecimens and clinical data to be made available for research.

In this paper, we describe phase 2 of the ATLAS Community Health Initiative, which focuses on the operational implementation and scalability of the UCON process. This includes its interoperability with the EHR and laboratory information management systems that power the UCLA ATLAS precision health biobank. We expanded the animated UCON process to 18 UCLA Health clinics across the Los Angeles region to test its scalability as an enterprise solution.

Methods

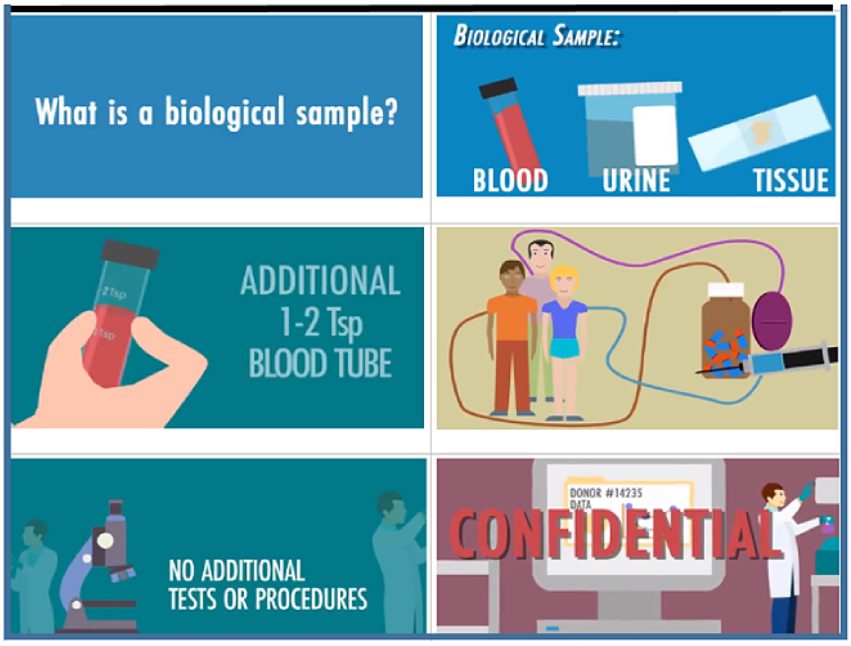
Study Setting

UCLA Health is one of the most diverse, comprehensive, and leading academic medical centers in Southern California. Ranked first in California and third in the nation, the UCLA Health system is comprised of a number of hospitals, including Ronald Reagan UCLA Medical Center and UCLA Santa Monica Medical Center, and an extensive primary care network of >180 medical offices in the greater Los Angeles area. This study was approved by the UCLA Institutional Review Board (institutional review board number: 15-001395IRB) with a waiver of written informed consent.

Electronic Video Consent

The electronic consent videos were designed to be self-administered, be fast (around 7 minutes), and meet the NIH consent threshold [19]. These fully animated (cartoon-like) videos were developed to better communicate content to lay audiences (Figure 1). The videos [20] were available in English and Spanish and included voice-overs. All of the essential components of regulatory broad informed consent were included in the videos. Our study team assembled a community advisory board (CAB) consisting of 11 respected leaders who were highly involved with organizations in the Los Angeles region that understood our diverse communities and represented their perspectives. The members were racially diverse (African American: n=2; Latinx: n=2; Asian American: n=1; Native American: n=1; Persian American: n=1; White and Non-Hispanic: n=4) and equitable with respect to gender (male: n=5; female: n=6). The CAB reviewed the results of a convenience sample of 117 patients who underwent cognitive testing. Operational feasibility was also tested with 625 additional patients. The CAB made the recommendation to move forward with the expansion to the broader UCLA Health population [19].

Figure 1. Representative screenshots of universal consent animated videos. Tsp: teaspoon.



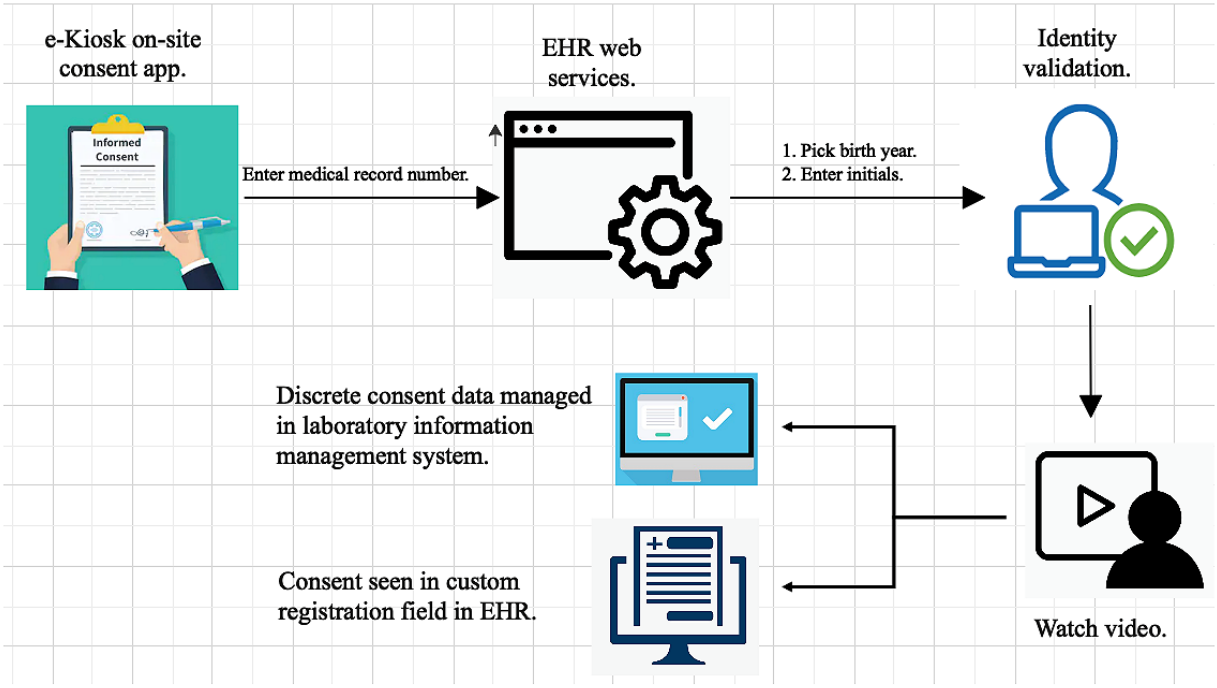
Consent Choices

With regard to patients' opt-in and opt-out statuses, patients could choose to (1) opt in to share their remnant samples plus a dedicated blood sample, (2) opt in to share remnant tissues only, or (3) opt out altogether. We also tracked the number of patients who opted in and indicated a willingness to be recontacted for future research.

Workflows

The UCON process was deployed in perioperative suites, clinical labs, and ambulatory clinics (Figure 2). In perioperative suites, patients were handed an iPad (Apple Inc), were instructed to watch the UCON video, and provided their consent decision. The iPad was then collected by nurses in the perioperative area. If a patient consented to providing an extra blood tube, the nurses placed the order in the EHR per the protocol. Patients typically waited for 30 to 60 minutes prior to their procedure, which provided ample time for completing the consent process. All extra tubes were automatically routed to the precision health biobank for DNA extraction and storage. In clinical labs, patients were handed an iPad by the front desk staff. Patients typically waited for 10 to 15 minutes prior to a lab draw and were able to watch the 5-minute UCON video and complete the consent process. Lastly, patients who were consented in ambulatory clinics completed the consent process at a self-service kiosk or by using an iPad before, during, or after a clinic visit. Patients waited for 10 to 15 minutes before moving to an exam room and another 10 to 15 minutes prior to meeting with a care provider, which provided ample time for completing the consent process. Once remnant (leftover) tissue samples became available for patients who opted in, these samples were accessioned into the ATLAS precision health biobank. DNA was extracted from whole blood and genotyped. Afterward, the remaining DNA was stored in the biobank.

Figure 2. Universal consent workflow. EHR: electronic health record.



Documentation and Tracking Within the EHR

After consent completion, consent decisions were transmitted to the precision health biobank's laboratory information management system (Biomaterial Tracking Management System; Daedalus Inc). PDF files containing patients' UCON completion statuses were sent to the EHR (Epic Systems Corporation) [21], which generated a receipt in real time in a custom registration field. The receipt ensured that patients would not be asked to complete the consent process a second time. Clinical staff used this field to determine which patients were eligible to complete the process.

Data Collection

The following data were collected from all patients who underwent the UCON process: sociodemographic information; comorbidity statuses based on the Charlson Comorbidity Index [22]; health utilization data, including ambulatory visits, emergency room visits, and hospital admissions; and consent decisions. With the exception of consent decisions, the data were all collected from the EHR by an honest broker who merged and deidentified the data via an institutional review board–approved process.

Statistical Analysis

Descriptive statistics were computed for all study variables. Quantitative variables were summarized by using means, SDs, and quartiles, while categorical variables were summarized by using frequencies and percentages. Sample characteristics were reported for the cohort that completed the consent process and for the larger UCLA Health patient population to determine whether there was sampling bias within and across clinics. US census data were used to obtain comparable summaries (where available) for residents of Los Angeles County.

Comparisons were made among the three workflows. Quantitative variables were compared by using 1-way analysis of variance *F* tests, and categorical variables were compared by using chi-square tests or Fisher exact tests, as appropriate. Consent status, which was categorized as *consented* or *declined*, was modeled via logistic regression.

A stepwise variable selection procedure was used to select a subset of predictor variables for inclusion in the model. This involved using entry and exit criteria for variables with a *P* value of <.001. The results of separate models that included 1 predictor at a time, as well as those of a multivariate model that combined all selected predictors, were reported. Odds ratios (ORs), 95% CIs, and *P* values were used to summarize model results. Model fit was evaluated by using the area under the curve. Statistical significance was defined as a *P* value of <.05. Cohort summaries and comparisons among cohorts were performed by using R version 3.5.0 (R Foundation for Statistical Computing). Logistic regression modeling was performed by using SAS version 9.4 (SAS Institute).

Results

Demographic Comparisons

The IPH consented 40,144 participants from March 2017 through June 2019 (Table 1). Of these participants, 26,314 (65.5%) opted into the ATLAS precision health biobank program. The demographics were representative of the UCLA Health population. ATLAS patients were only slightly older than the general UCLA Health population and much older than the Los Angeles County population; 30.2% (12,123/40,144) of ATLAS participants were aged ≥65 years, whereas 27.5% (160,479/583,282) and 16.6% of the UCLA Health and Los Angeles County populations, respectively, were aged ≥65 years.

The percentages of African Americans (2558/40,144, 6.4%) and Hispanic individuals (6055/40,144, 15.1%) in the ATLAS cohort were higher than those in the UCLA Health population (African Americans: 27,338/583,282, 4.7%; Hispanic individuals: 64,234/583,282, 11%) but lower than those in the Los Angeles County population (9.1% and 48.5%, respectively). The Los Angeles County data reflect census data from 2019, which only provides rates [23].

Table 1. Demographic and clinical characteristics of the cohort and reference populations.

Characteristics	Patients who completed the consent process (N=40,144)	UCLA[a] Health population (N=583,282)	Los Angeles County population[b]
Age (years), mean (SD)	53.1 (17.5)	51.6 (19.1)	—[c]
Aged ≥65 years, n (%)	12,123 (30.2)	160,479 (27.5)	16.6
Female, n (%)	22,302 (55.6)	333,998 (57.3)	50.7

[a]UCLA: University of California, Los Angeles.

[b]The Los Angeles County data reflect census data from 2019, which only provides rates [23].

[c]Not available.

Finally, the IPH patients were more likely to be male, married, and well educated compared to the UCLA Health population (Table 1).

Although the UCON video was available in Spanish, most individuals of self-reported Hispanic descent elected to complete the consent process in English (39,294/40,144, 97.9%; Table 2).

Table 2. Consent outcomes by workflow.

Consent outcomes	Perioperative and admission workflows (n=22,519), n (%)	Lab workflow (n=14,235), n (%)	Other or unknown (n=3390), n (%)	*P* value
Consented in English	21,959 (97.5)	14,004 (98.4)	3331 (98.3)	<.001
Self-administered consent	21,672 (96.2)	13,989 (98.3)	3325 (98.1)	<.001
Consent status				<.001

Unknown	983 (4.4)	1353 (9.5)	799 (23.6)	

Differences in Consent Across Clinical Settings

We observed a marked difference in the willingness to opt in between patients presenting to different clinics (perioperative suites: 16,500/22,519, 73.3%; ambulatory setting: 2308/3390, 68.1%; Table 2) and patients in the laboratory medicine workflow (7506/14,235, 52.7%; *P*<.001). Patients in perioperative settings were more likely to share an extra tube (10,640/22,519, 47.2%) than patients in other clinic settings (*P*<.001). The number of patients who decided to opt in and provide a dedicated extra tube was highest in perioperative suites (10,640/22,519, 47.2%), second highest in ambulatory settings (1361/3390, 40.1%), and lowest in clinical labs (4047/14,235, 28.4%; *P*<.001). Further, the number of patients who were willing to be recontacted was highest in perioperative suites (9545/22,519, 42.4%), second highest in ambulatory settings (1152/3390, 34%), and lowest in clinical labs (4716/14,235, 33.1%).

Multivariate Analysis of Consent Variables

The most substantial differences in consent rates were observed in the perioperative setting. Those who were consented by using the laboratory workflow were significantly less likely to opt in than those who were consented by using the perioperative workflow (OR 0.43, 95% CI 0.42-0.46; *P*<.001; Table 3). There were also significant but less dramatic differences in opt-in rates based on self-reported ancestry; African American (OR 0.53, 95% CI 0.49-0.58; *P*<.001), Asian (OR 0.72, 95% CI 0.68-0.77; *P*<.001), and multiple-ethnicity populations (OR 0.73, 95% CI 0.69-0.77; *P*<.001) were less likely to opt in compared to those who self-identified as White (Table 3). More frequent health care utilization was also a significant predictor—those with greater than 1 inpatient admission had an OR of 1.28 (95% CI 1.22-1.35) for providing consent (*P*<.001). However, this was not the case for those who were frequent visitors of the emergency department, since those with greater than 1 emergency department visit had a lower consent rate than the average (OR 0.86, 95% CI 0.82-0.91; *P*<.001).

Table 3. Stepwise logistic regression model of any consent versus declines.

Variables	Unadjusted models		Multivariable model	
	Odds ratio (95% CI)	*P* value	Odds ratio (95% CI)	*P* value
Race (reference: White)		<.001		<.001
Asian	0.66 (0.61-0.70)	<.001	0.72 (0.68-0.77)	<.001
Black or African American	0.52 (0.48-0.57)	<.001	0.53 (0.49-0.58)	<.001
Native Hawaiian or other Pacific Islander	1.06 (0.71-1.57)	.78	1.07 (0.71-1.60)	.76
American Indian or Alaska Native	0.77 (0.52-1.12)	.17	0.72 (0.49-1.07)	.10
Multiple races, other, unknown, or refused	0.67 (0.64-0.71)	<.001	0.73 (0.69-0.77)	<.001
Marital status (reference: married, significant other, or partner)		<.001		<.001
Single	0.81 (0.78-0.85)	<.001	0.89 (0.85-0.93)	<.001
Divorced, separated, dissolved, or widowed	1.00 (0.94-1.07)	>.99	0.95 (0.88-1.02)	.12
Other or unknown	0.60 (0.50-0.72)	<.001	1.00 (0.83-1.22)	.98
≥1 inpatient admission	1.41 (1.34-1.47)	<.001	1.28 (1.22-1.35)	<.001
≥1 emergency department–only visit	0.90 (0.86-0.94)	<.001	0.86 (0.82-0.91)	<.001
Workflow (reference: perioperative and admission workflows)		<.001		<.001
Lab workflow	0.41 (0.39-0.43)	<.001	0.43 (0.42-0.46)	<.001
Other or unknown	0.78 (0.72-0.84)	<.001	0.83 (0.76-0.89)	<.001
Consented in English	0.72 (0.62-0.84)	<.001	0.74 (0.63-0.87)	<.001

We also tracked the number of patients who reached out to the biobank with questions about their participation (n=13). The low number of patients may suggest that the UCON process was self-explanatory and did not require additional support to complete; however, this was not measured directly.

Discussion

In this study, we demonstrate that an integrated, institutional population–based electronic video consent process for the use of remnant biomaterials and deidentified phenotype data in research is feasible and scalable in large populations. The use of an animated, electronic video consent process is novel and innovative; ours is one of the few large-scale implementation studies that was conducted across a large health system and provided an enterprise solution for precision health research. Other reported efforts have been small, local, and nonrepresentative [24]. Compared to in-person paper consent, electronic video consent requires fewer human resources and less physical space and can be translated to reach diverse populations. A recent review of electronic consenting suggested that this modality is well received by participants, especially if it is accessible, user-friendly, and engaging and is tailored to specific patient populations [25,26]. The literature also suggests that this modality improves patient-centered outcomes, such as satisfaction and understanding [27]. At UCLA Health, we have implemented the translation of the UCON video into 8 languages that are represented widely across Los Angeles County. Other large precision health initiatives, such as the NIH All of Us Research Program, use more traditional consenting approaches and are limited to English and Spanish. In this regard, the expansion of the UCON process to several clinics across UCLA Health demonstrates the scalability of the UCON process as a recruitment engine that can power a large precision health program.

One of the goals of our precision health efforts is to ensure the inclusion of diverse populations and improve the accuracy of genetic prediction for all patients, regardless of ancestry. The inclusion of approximately 38.1% (15,304/40,144) of non-European patients in our biobank was likely achieved because we are located within one of the most diverse counties in the country. We note however that approximating the total diversity of Los Angeles County is a more daunting task that will require further, more significant outreach efforts. Although underrepresented populations are thought to have a lower willingness to participate in biobank research [28,29], community-based participatory research strategies have been shown to be effective [30-32]. Studies have shown that variations in the willingness to consent are mediated by different levels of trust in the health care and medical research system [33-35]. Patients are unsure about their rights over their biobank data [8] and have concerns about secondary research use [8,9]. Educating patients on the importance of genetic diversity for precision health approaches and creating toolkits to explain why their participation in large-scale programs is necessary will be important to the field.

This study also has its limitations. First, the UCON video was deemed to be at the ninth-grade reading level instead of the targeted seventh-grade reading level due to the use of many scientific terms and monosyllabic words. However, its success may reflect the demographics of the West Los Angeles population, which tends to be more educated and affluent. Despite this, we were successful in recruiting a diverse population for our expansion across UCLA Health. Future work

will include working with community partners at our affiliated community hospitals to adapt the UCON process to communities with lower health and linguistic literacy. Our data are also slightly skewed toward older patients, as they make up a large proportion of patients in our procedure units (ie, those in ambulatory, laboratory medicine, and perioperative settings). Although we identified some sociodemographic and health characteristics that predicted the willingness to opt into the ATLAS program, our multivariate models, while predictive, did not explain all of the variance. As such, it is likely that there are considerable unmeasured factors that influence an individual patient's decision process. The differences in consent rates across different clinical settings may suggest that patients are more willing to participate in biobank research in clinics, where there are higher rates of touch interactions between health care providers and patients.

Another potential limitation is that there was no measure for religiosity (how deeply religious an individual may be), which, in large national samples, has been shown to drive the willingness to participate in biobank research [36,37]. Additionally, our data only generalize to adults and do not generalize to pediatric patients. These populations often require specifically tailored consent and assent processes. Previously reported data show that patients' willingness to consent differs from their willingness to allow their child to participate in research [37]. However, adolescents have a high capacity for consent—similar to normal adults—and consider themselves capable of making voluntary choices [38]. Future work has been planned with pediatric patients within UCLA Health to shed light on this issue. Lastly, the consenting process has not been tested across multiple institutions but rather represents a single institutional study conducted at UCLA, which resides in the large metropolitan area of Los Angeles where approximately 79% of adults aged >25 years have a high school diploma [23]. Discussions are underway to expand the consenting process to other University of California sites where using a standard consent process is important for collaboration and data sharing (eg, when federal and state requirements change or when conducting international studies in which a high level of consent is required) [29,39-41].

In conclusion, the use of the UCON process is a scalable and highly efficient approach for population-based consenting and the recruitment of patients for precision health research. This study shows that the UCON process can be deployed to any number of devices and implemented at multiple medical locations, making it suitable for large-scale efforts with modest incremental costs. Implementation strategies using this approach need to balance obtaining a large sample of consenting participants with ensuring a representative sample. Moreover, since this consenting approach is largely self-administered, combining our consent process with community outreach and education may be essential to reaching underserved populations and those that may have strong health beliefs about participation in research activities. We believe that our consent video and process offer an approach that allows for the more robust inclusion of institutions that do not have the financial resources for using employees to obtain in-person consent. Given the current reality that many such institutions serve patients who are chronically ill, are of lower socioeconomic status, and are from underrepresented populations, our consent video and process offer the possibility for these groups to become better represented in precision medicine research.

Acknowledgments

The Clinical Translational Science Institute and Institute for Precision Health at the University of California, Los Angeles (UCLA), wish to thank all the patients who participated in this study. The authors would also like to acknowledge all of the members in the community advisory board. This study was supported by Federal Fund, National Institutes of Health, National Center for Advancing Translational Science (award number: UL1TR001881-01S2; grant title: *UCLA Clinical Translational Science Institute*).

Abstract

Background: Chronic obstructive pulmonary disease (COPD) has become one of the most critical public health problems worldwide. Because many COPD patients are using video-based social media to search for health information, there is an urgent need to assess the information quality of COPD videos on social media. Recently, the short-video app TikTok has demonstrated huge potential in disseminating health information and there are currently many COPD videos available on TikTok; however, the information quality of these videos remains unknown.

Objective: The aim of this study was to investigate the information quality of COPD videos on TikTok.

Methods: In December 2020, we retrieved and screened 300 videos from TikTok and collected a sample of 199 COPD-related videos in Chinese for data extraction. We extracted the basic video information, coded the content, and identified the video sources. Two independent raters assessed the information quality of each video using the DISCERN instrument.

Results: COPD videos on TikTok came mainly from two types of sources: individual users (n=168) and organizational users (n=31). The individual users included health professionals, individual science communicators, and general TikTok users, whereas the organizational users consisted of for-profit organizations, nonprofit organizations, and news agencies. For the 199 videos, the mean scores of the DISCERN items ranged from 3.42 to 4.46, with a total mean score of 3.75. Publication reliability (P=.04) and overall quality (P=.02) showed significant differences across the six types of sources, whereas the quality of treatment choices showed only a marginally significant difference (P=.053) across the different sources.

Conclusions: The overall information quality of COPD videos on TikTok is satisfactory, although the quality varies across different sources and according to specific quality dimensions. Patients should be selective and cautious when watching COPD videos on TikTok.

KEYWORDS

COPD; information quality; social media; short-video apps; TikTok

Introduction

Chronic obstructive pulmonary disease (COPD) has become one of the most critical public health problems, which has resulted in huge health care expenditures [1]. In 2015, COPD caused approximately 3.17 million deaths worldwide, which accounted for 5% of global deaths for that year [2]. COPD is notably more severe in low- and middle-income countries than in high-income countries. From 2014 to 2015, approximately 5.9% of adults in the United States were reported to be living with COPD [3], whereas the estimated prevalence was 13.6% in China during the same period [4].

COPD is a preventable and treatable disease, and there are many opportunities to reduce the risk of COPD before and after diagnosis [5,6]. For example, general health consumers could reduce the risk of contracting COPD by quitting smoking and avoiding secondhand smoke [7]. Even after a COPD diagnosis, maintaining a healthy lifestyle can help patients prevent exacerbations and improve well-being [8]. However, limited access to information about COPD has become a significant problem for patients and their caregivers [9]. People living with COPD often report limited knowledge on several points such as the causes of COPD and its consequences [10]. Patients have also often received inadequate guidance about how to recognize the disease, and avoid and manage exacerbations [10,11]. Therefore, effective health communications that inform patients on recommended actions are important for better disease prevention and management, and information communication technologies can play a substantial role in such communication and intervention [12].

Emerging technologies provide great health communication opportunities that can inform and empower COPD patients in regard to disease management [13]. For example, mobile technologies have been extensively used to help COPD patients achieve an early diagnosis [14], make medical appointments [15], promote physical activity [16], consistently self-monitor [17], enhance self-management [18], and reduce COPD exacerbation [12]. Recently, visually rich social media (eg, YouTube, Pinterest) have become popular among COPD patients [19,20]. In general, rich social media have several advantages in health communication. The information can be illustrated, which makes it easier to process and remember than information in the form of plain text [21]. Imagistic health information can elicit affective reactions and motivate consumers' health actions [22]. Some prior studies suggest that COPD patients exposed to visually rich social media are more willing to engage with COPD-related messages [19,23].

Despite the promising potential of any emerging technology, patients' actual use of a technology can be fraught with problems. Some evidence suggests that information quality is one of the most significant concerns when COPD patients seek health information online [24]. Evaluating the quality of online health information sources is not an easy task for most laypeople [25,26], especially for many COPD patients who have low health literacy [27]. According to a survey of COPD patients, approximately half of the respondents reported difficulty distinguishing between high- and low-quality health resources on the internet [27]. Therefore, health care providers should assess the information quality of online COPD information and advise their patients about it.

To the best of our knowledge, the quality of online COPD information in video-based social media has yet to be sufficiently investigated. Stellefson et al [20] reviewed 223 videos employing the instruments of HONcode (Health on the Net) principles; they found that the majority of YouTube COPD videos (69.1%) were of high quality and were mainly created by authoritative sources (eg, health agencies, organizations, news agents, and professionals). Recently, the short-video app TikTok has attracted significant research attention in regard to its health communication. For example, during the COVID-19 pandemic, TikTok's coronavirus-related videos were viewed 93.1 billion times as of July 2020 [28]. The originality, interactivity, and sociable nature of TikTok have given the younger generation a better user experience and sense of engagement while seeking health information [29]. TikTok affords rich information modalities (eg, text, image, audio, and video), and contains ample technology features such as commenting, chatting, following, liking, and live-streaming [30]. These features make the app easier for the general public to use as a source of health information, and penetration and usage of TikTok are also on the rise among some older age groups [31].

We observed that there are many COPD-related videos on TikTok. However, the quality of the information they offer remains unclear. Therefore, to fill this gap, the aim of this study was to evaluate the information quality of COPD videos on TikTok.

Methods

Search Strategy and Data Extraction

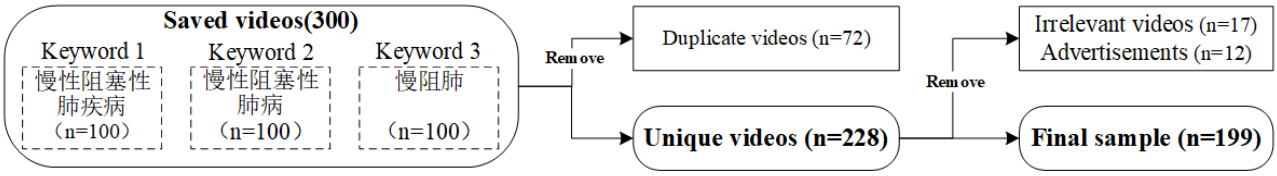
We employed three Chinese words, "慢性阻塞性肺疾病" (chronic obstructive pulmonary disease), "慢性阻塞性肺病" (chronic lung disease related to obstructed airflow), and "慢阻肺" (COPD), to retrieve the relevant COPD videos on TikTok. In its search function, TikTok provides three ways to sort items: "overall ranking," "most recent," and "most likes." Overall ranking is the default mode of sorting recommended by TikTok, which also comprises the other two modes. Given that most users employ the default, we used the overall ranking mode to retrieve the top 100 videos posted from December 6 to December 10, 2020, under each of the three keywords, which resulted in a total of 300 videos. We chose the threshold number of 100 for two reasons. First, TikTok's search function encompasses the consideration of topic relevance; the pertinent COPD videos mostly appear at the top of the result list, and it is hard to observe any relevant videos when the results go beyond 100. Second, most general health consumers apply the "least effort" principle in their online information-seeking activities; thus, they usually view the top search results instead of going very far [32].

To choose the most relevant videos, we removed videos that were (1) duplicates (n=72), (2) not directly related to COPD

topics (n=17), and (3) advertisements (n=12). Finally, a total of 199 videos remained for data analysis (see Figure 1).

We used Microsoft Excel to extract and code the basic information from each video. This included a description of the video; the URL; the upload date; the duration (in seconds); the user ID of the uploader; and the numbers of views, likes, and comments.

Figure 1. Search strategy and video screening procedure.



Instruments

We employed DISCERN as the instrument for assessing the quality of the information in each video. DISCERN is a brief questionnaire designed to help health consumers and researchers assess the quality of health information. The questionnaire contains three parts, devoted to the reliability of a publication (8 items), the quality of information on treatment choices (7 items), and an overall rating of the publication (1 item) [33]. Each of the 16 questions is rated on a scale of 1 (lowest score) to 5 (highest score). We chose DISCERN for several reasons: (1) it is one of the most widely used instruments for studying the quality of health information [34], (2) it has proven to be effective in Chinese contexts [35], and (3) it has proven to be useful for assessing information quality on other video-based platforms (eg, YouTube) [36]. The full instrument is presented in Multimedia Appendix 1.

Moreover, we adopted six questions from Goobie et al [37] to evaluate the video content. These six questions ask to what degree a video addresses the definition of a disease, its signs and symptoms, risk factors, evaluation, management, and outcomes. Each aspect was scored on a three-item scale: not addressed (0 points), partially addressed (1 point), and sufficiently addressed (2 points).

Coding Procedure

Two raters (MZ and YZ) independently evaluated the information quality of each video, employing the DISCERN instrument. Both raters are certified physicians who worked in a local hospital in the division of respiratory disease. The coding procedure contained three stages.

In the first stage, we recorded the basic information of the video publishers (eg, account name, self-description, identity verification status) and the basic information of the videos (eg, publication date, video length, number of likes, number of comments, number of shares). Regarding the video publishers, we categorized the video sources into two main types (ie, individual users and organizational users) by their account names and identity verification status. Further, we identified several subcategories within each source type by their account names, self-description, and video publication records. For example, if a video publisher described themselves as a "scientific writer," we would code the source as an "individual science communicator."

In the second stage, we assessed the video content using the six categories from Goobie et al [37]: the definition of a disease, its signs and symptoms, risk factors, evaluation, management, and outcomes. When we had independently scored the first 30 videos, we found that we were able to reach a consensus on whether a video contains a certain category of content. One rater (MZ) then finished rating the rest of the videos and the other rater (YZ) validated the codes, followed by discussion and resolution of any inconsistencies between the two raters.

In the third stage, we evaluated the information quality by applying the DISCERN instrument. Before starting to score the videos, the two raters first reviewed the official DISCERN scoring instructions, discussing how the tool could be operationalized for evaluating video-based content and making necessary adjustments. Using the DISCERN questions, the two raters scored all videos independently. The overall rating agreement (Cohen κ) was 0.793 (P<.001), which indicated that the rating process had satisfactory interrater reliability. Any between-group analyses regarding DISCERN scores were performed using the Kruskal-Wallis H test in SPSS 22.

Results

Video Characteristics

The COPD videos on TikTok came mainly from two types of sources: individual users and organizational users. Most of the COPD TikTok videos in our sample were contributed by individual users (168/199, 84.4%), whereas a relatively small share was contributed by organizational users (31/199, 15.6%). For each type, we identified three subcategories (see Table 1). Among individual users, health professionals created the most videos, followed by individual science communicators and general TikTok users. Among organizational users, for-profit organizations published the highest number of videos, followed by nonprofit organizations and news agencies.

In the sample, the durations of the videos varied from 10 to 4116 seconds. The videos published by nonprofit organizations were significantly longer than videos from other sources, whereas the videos published by news agencies had the shortest average duration. Videos published by individual science communicators had the second-longest average duration. The average duration for the other sources was under 1 minute (Table 2).

The most recent video was published 22 days prior to data collection, whereas the oldest had been on TikTok for more than 1 year. The 199 videos received a total of 1,696,725 likes and 175,703 comments prior to data collection. The number of

likes varied from 0 to 662,000 for each video, and the number of comments ranged from 0 to 18,000. The videos published by health professionals received the most likes and comments, whereas the videos uploaded by individual science communicators received the least likes and comments. Since their publication, the videos in the overall sample had been shared a total of 167,473 times. The videos uploaded by health professionals were shared the most frequently, whereas the videos created by individual science communicators were shared the least frequently, as shown in Table 2.

Table 1. Characteristics of the sources of chronic obstructive pulmonary disease–related TikTok videos (N=199).

Source	Description	Videos, n (%)
Individual users		
General users	Common TikTok users	30 (15.1)
Individual science communicators	Individuals who participate in general scientific communications, which may include but are not limited to health care domains	39 (19.6)
Health professionals	Individuals who describe themselves as health professionals	99 (49.7)
Organizational users		
For-profit organizations	Private sector organizations	18 (9.0)
Nonprofit organization	Organizations or hospitals operating in the public sector	8 (4.0)
News agencies	Organizations providing news services	5 (2.5)

Table 2. Characteristics of chronic obstructive pulmonary disease–related TikTok videos, by source

Source of videos	Days on TikTok, median (IQR)	Video duration (seconds), median (IQR)	Number of likes, median (IQR)	Number of comments, median (IQR)	Number of shares, median (IQR)
Organizational users					
For-profit organizations	180 (39-297)	59 (37-129)	364 (115-4915)	17 (7-32)	19 (7-133)
Nonprofit organizations	148 (44-225)	158 (74-206)	24 (14-40)	1 (0-2)	1 (0-8)
News agencies	145 (22-147)	34 (18-51)	12 (1-18)	0 (0-0)	3 (1-3)
Individual users					
Health professionals	407 (144-490)	57 (49-59)	1031 (170-3203)	54 (8-161)	58 (12-334)
Individual science communicators	303 (147-491)	85 (45-116)	3 (1-11)	0 (0-1)	0 (0-5)
General users	237 (133-394)	40 (15-59)	19 (9-49)	2 (1-5)	1 (0-7)
Overall	276 (119-478)	57 (43-88)	125 (12-1597)	7 (1-91)	12 (1-118)

Information Quality

The videos covered the six predefined content areas to different degrees, as shown in Figure 2. The results suggested that more than half of the videos (122/199, 61.3%) sufficiently addressed COPD outcomes, whereas only 16 (8.0%) made no mention of outcomes. The second most frequently introduced area concerned the signs or symptoms of COPD, with almost half of the videos (100/199, 50.3%) sufficiently addressing them and 76 (38.2%) only giving partial mentions. Moreover, approximately half of the videos only partially mentioned the topics of COPD evaluation, management, and risk factors. The least frequently mentioned topic was the definition of COPD; only 25 videos (12.6%) sufficiently addressed this and 47 videos (23.6%) did not mention it at all.

We calculated the mean scores for each DISCERN item for the total sample. The scores ranged from 3.42 to 4.46 (mean 3.75). The scores of the eight items measuring publication reliability (items 1-8) varied from 3.42 to 4.46 (mean 3.90). For the seven items assessing the quality of information on treatment choices (items 9-15), the scores ranged from 3.45 to 3.69 (mean 3.56). The remaining item (item 16) measuring overall information quality achieved a mean of 3.85 out of 5 points. We categorized the DISCERN items into three sections according to the original instrument indicated: reliability of the publication, quality of information on treatment choices, and overall rating of the publication (see Table 3).

Videos published by nonprofit organizations had the highest reliability, whereas the videos contributed by general users had the lowest reliability. The differences in publication reliability across the six types of video sources were statistically significant. Regarding the quality of information on treatment choices, the nonprofit organizations provided the highest-quality videos, whereas the general users provided the lowest-quality videos; however, the differences among the various information sources were only marginally significant. With regard to the last item concerning overall rating, the highest-quality videos were created by news agencies and the lowest-quality videos

were generated by for-profit organizations. The overall rating of information quality showed significant differences according to different sources. Overall, the total scores of the entire DISCERN questionnaire across the different sources exhibited significant differences (Table 3).

Figure 2. Percentage of videos addressing each chronic obstructive pulmonary disease topic.

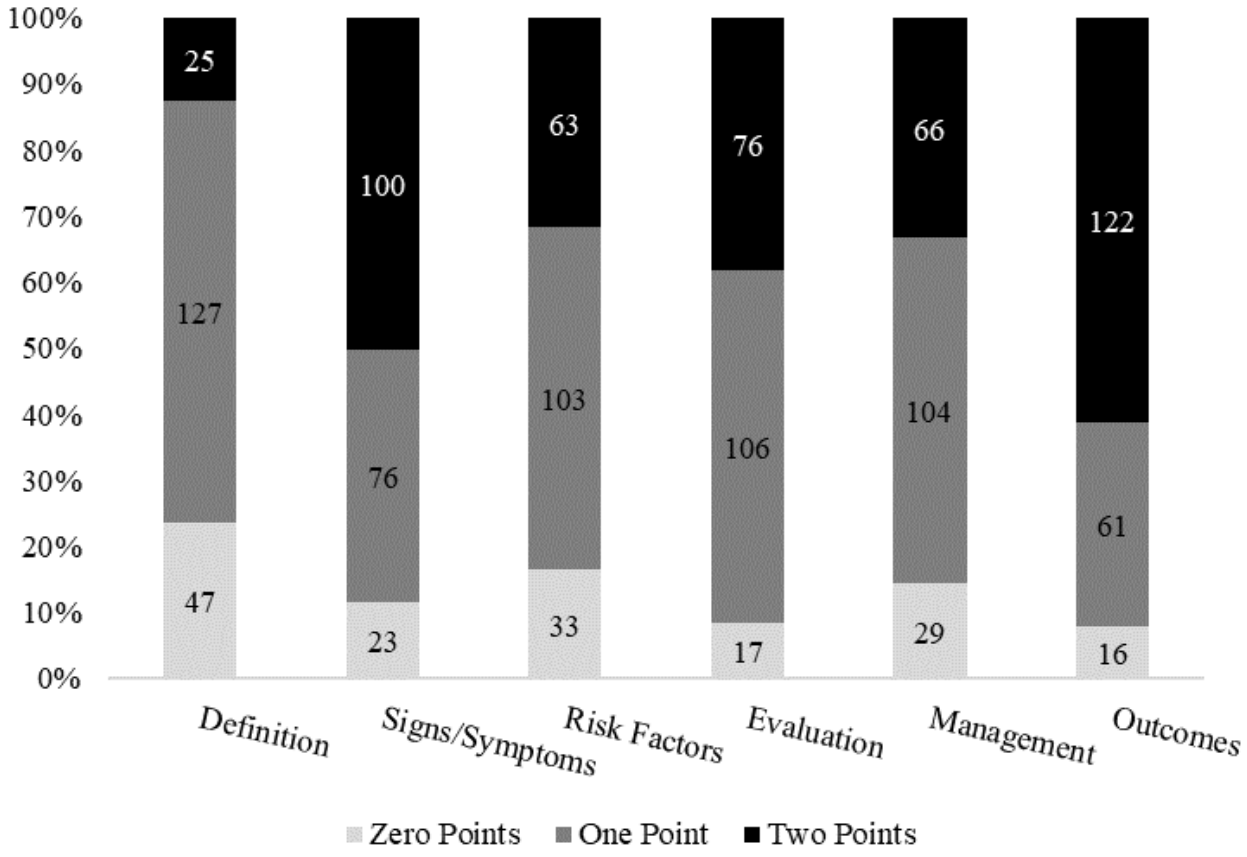


Table 3. DISCERN scores of chronic obstructive pulmonary disease–related TikTok videos by source (N=199).

Discussion

TikTok as a Health Information Source

Recently, video-based social media platforms and apps have been gaining popularity among patients with chronic conditions [38]. For example, YouTube has become a prominent platform for generating and spreading health-related videos, covering topics related to chronic disease management, including disease prevention, diagnosis, and treatment [39]. Although some recent evidence indicates that TikTok has had vast communication potential during the COVID-19 pandemic [40], the role of TikTok in disseminating chronic disease information remains unclear.

Our results suggest that TikTok could be a promising channel for disseminating COPD information. The 199 videos surveyed in our study have received approximately 1.7 million likes and 176,000 comments since they were published. Given that most of the videos were published within 1 year, the numbers of likes and comments are relatively high. Therefore, we suggest that health care professionals and institutions leverage short-video apps (eg, TikTok) to improve patient education and health communication.

Information Quality

To the best of our knowledge, the quality of online information about COPD is understudied. Specifically in regard to short-video apps, the information quality of COPD videos remains unclear. As one of the earliest studies to tackle this problem, this study yielded results suggesting that the general information quality of COPD videos on TikTok is relatively satisfactory. Although there is a concern that TikTok may differentiate itself from other social media by targeting quirky videos rather than serious professional content [30], our results indicate that the quality of health information found on TikTok, particularly that related to COPD, is acceptable. These results are consistent with a recent survey of coronavirus-related videos on TikTok, which found that the information provided in these videos was generally credible, containing merely 4.3% misinformation [41].

Our findings show that the COPD videos on TikTok more or less touched on all of the preidentified COPD-related content. More than half of the videos sufficiently described the outcomes and the signs and symptoms, and partially addressed the topics of evaluation, risk factors, and management. However, few videos offered definitions of COPD. A possible explanation for this is that TikTok videos are created for a target audience of laypeople. Therefore, introducing aspects of disease management is more important than discussing academic definitions of COPD.

Sources of COPD-Related Videos on TikTok

This study reveals that both individual users and organizational users are engaged in creating COPD videos on TikTok. We identified three specific subcategories for each of these two general categories of sources (ie, individual users and organizational users). Individual users included health professionals, general TikTok users, and individual science communicators. We found that many health professionals were active in communicating COPD knowledge; they contributed almost half of the videos in our sample. Organizational communicators of health information included nonprofit organizations, for-profit organizations, and news agencies. Recently, some researchers have suggested that video-based social media such as TikTok are playing increasingly important roles in providing general health information sought or encountered by consumers [40,41]; therefore, health experts and traditional institutions should harness and leverage social media platforms and apps to better disseminate health information and medical knowledge to the public [41,42]. In general, the findings of this study indicate that health professionals and reputable organizations are actively engaged in communicating health information on TikTok.

In addition, the results suggest that the information quality of COPD videos on TikTok varies according to the source. The videos published by nonprofit organizations had the highest average score for the reliability of publications, while the videos created by general TikTok users had the lowest average score; the differences were statistically significant. The nonprofit organizations and general TikTok users earned the highest and lowest average scores for the quality of information on treatment choices, respectively, although the differences were only marginally significant. For the overall rating of information quality, the news agencies contributed content of significantly higher quality than that of other sources. All of these results are consistent with prior studies in YouTube settings, where organizational users were found to create videos of significantly higher quality than those of individual users [20,37].

Communication performance varied among the sources. In our sample, the videos published by health professionals received the most likes and comments, and were most frequently shared by users. The videos created by individual science communicators received the least likes and comments and were least likely to be shared by users. Interestingly, despite the significant differences in communication performance, we found that the two sources had comparable levels of objective information quality, as assessed by the DISCERN instrument. Prior information credibility studies suggest that credibility depends on the perception of the information recipient, which may not necessarily reflect the objective quality of the information [25,43], and users' credibility perception predicts whether or not they will adopt and share health information on social media [44]. The discrepancy between information quality and communication performance may partially confirm such findings. We suspect that health professionals convey a higher level of expertise and thus generate greater credibility, whereas general science communicators convey low expertise in medicine when they upload videos with wide topic coverage extending beyond the medical domain. We call for future research to investigate the discrepancies between the actual quality of health information and users' credibility perception.

Limitations and Future Research

This study has some limitations. First, we employed only the DISCERN instrument, which was chosen because it has worked well in prior studies that assessed the quality of information in health-related videos. However, there are other instruments

available, such as the JAMA (Journal of the American Medical Association) benchmarks and the HONcode, and future research could expand these investigations by using different instruments. Second, this study only assessed the information quality of Chinese COPD videos. Although the locality did not impact the overall results, the conclusions may not necessarily be generalizable to COPD videos in other languages; therefore, we call for more cross-language comparative studies in the future.

Conclusion

This study investigated the information quality of COPD videos on the world's largest short-video app, TikTok, employing the DISCERN instrument. The results show that both organizational and individual users generate COPD-related content. The overall information quality of the COPD-related videos in the sample was satisfactory, although the quality varied across the different video sources and specific quality dimensions. The results suggest that patients should remain cautious and selective when watching COPD videos on TikTok. Videos from identifiable sources (eg, nonprofit organizations) are much more strongly recommended than those from other nonverified sources. Based on the limitations of this study, we have proposed several directions for future research.

Acknowledgments

We thank Dr Ya Zhang for her contribution to the data analysis and the anonymous reviewers and editors for their helpful comments on the manuscript. The study is supported by the National Science Foundation of China (grant numbers 72174083, 72074112, and 71774083) and the Postgraduate Research & Practice Innovation Program of Jiangsu Province (grant number KYCX19_0022).

Abstract

Background: Health care organizations are tasked with providing web-based health resources and information. Usability refers to the ease of user experience on a website. In this study, we conducted a usability analysis of academic medical centers in the United States, which, to the best of our knowledge, has not been previously carried out.

Objective: The primary aims of the study were to the following: (1) adapt a preexisting usability scoring methodology to academic medical centers; (2) apply and test this methodology on a sample set of academic medical center websites; and (3) make recommendations from these results on potential areas of improvements for our sample of academic medical center websites.

Methods: All website usability testing took place from June 1, 2020, to December 15, 2020. We replicated a methodology developed in previous literature and applied it to academic medical centers. Our sample included 73 US academic medical centers. Usability was split into four broad categories: accessibility (the ability of those with low levels of computer literacy to access and navigate the hospital's website); marketing (the ability of websites to be found through search engines and the relevance of descriptions to the links provided); content quality (grammar, frequency of information updates, material relevancy, and readability); and technology (download speed, quality of the programming code, and website infrastructure). Using these tools, we scored each website in each category. The composite of key factors in each category contributed to an overall "general usability" score for each website. An overall score was then calculated by applying a weighted percentage across all factors and was used for the final "overall usability" ranking.

Results: The category with the highest average score was technology, with a 0.82 (SD 0.068, SE 0.008). The lowest-performing category was content quality, with an average of 0.22 (SD 0.069, SE 0.008). As these numbers reflect weighted percentages as an integer, the higher the score, the greater the overall usability in that category.

Conclusions: Our data suggest that technology, on average, was the highest-scored variable among academic medical center websites. Because website functionality is essential to a user's experience, it is justified that academic medical centers invest in optimal website performance. The overall lowest-scored variable was content quality. A potential reason for this may be that academic medical center websites are usually larger in size, making it difficult to monitor the increased quantity of content. An easy way to improve this variable is to conduct more frequent website audits to assess readability, grammar, and relevance. Marketing is another area in which these organizations have potential for improvement. Our recommendation is that organizations utilize search engine optimization techniques to improve their online visibility and discoverability.

(J Med Internet Res 2021;23(12):e27750) doi:10.2196/27750

KEYWORDS

website usability; digital health; health care website; academic medical center; usability testing; web crawler

Introduction

Background

A medical center's website is often the first point of contact with the public; its initial impact is responsible for returning users and attracting new visitors [1,2]. It has the potential to be the first step in improving patient satisfaction as well as attracting new patients [3]. In a time when information is expected to be readily available, medical centers use their websites as a key tool for both patient communication and education [4-6]. The users expect to find current and reliable information on websites that are easily accessible in order to make health-related decisions [7]. With many sources available (eg, WebMD), medical centers are looking to improve their internet presence to better engage with potential consumers [3].

Website Usability

Improving website usability is a noteworthy way in which medical centers can improve their internet presence to attract and retain more users and thus reach a larger audience with accurate and reliable information. Usability goes beyond surface-level design [8] but refers broadly to a product's "user experience," such as ease of navigation or encountered problems within a website [9]. It addresses the question of how easy or pleasing a website is to use (which can influence how many users engage with it), the level of engagement, and a website's ability to achieve other objectives. When users are not able to easily access and use a website, they are unlikely to continue using that given source. Alternatively, improved usability can enhance the reach of a website. For this reason, websites are facing the increasing need to conform to user expectations, desires, and requirements [10,11]. Various industries have established standardized guidelines for accessibility, content, marketing, and technology in order to improve usability [12-14].

Usability for Academic Medical Centers

Studies have sought to apply usability analyses to e-commerce, e-government, mobile news apps, and library websites [15-18]. In health care, other studies have looked at usability for hospitals, children's hospitals, digital health centers, residencies, and cancer center websites [3,19-21]. However, to our knowledge, no studies of usability have been conducted exclusively on academic medical centers in the United States, which included all websites falling under the academic medical centers' domain. Academic medical centers are the intersection of health professional schools, patient care, and academic research. Since an academic medical center comprises numerous institutions that function on their own part to be a part of a greater whole, they play a key role in the advancement of medical care [22]. Web presence is the way in which an academic medical center can demonstrate its advancements in their health professional schools, patient care, and academic research. It is important for these organizations to utilize usability metrics to not only improve user experience, but to represent themselves well as leaders in innovation.

Objectives

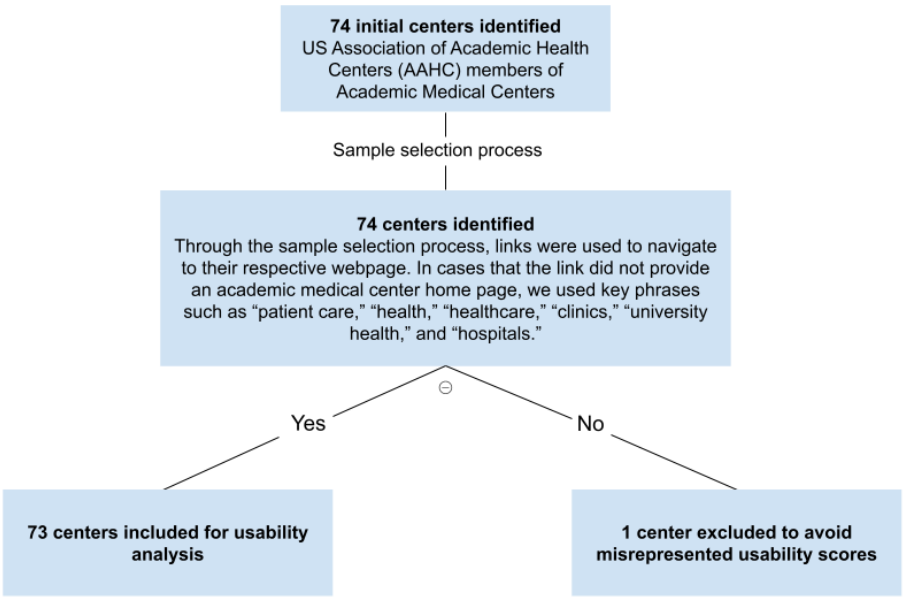
The primary aims of the study were to adapt a usability scoring methodology to academic medical centers; to apply and test this methodology on a sample set of digital health center websites; and to make recommendations from these results on potential areas of improvements for our sample of academic medical center websites.

Methods

Sample Selection

Our focus was on academic health centers in the United States. Indexing every academic medical center in the United States was not in the scope of our review; rather, this study focused on 74 academic medical centers listed on the members page of the Association of Academic Health Centers (AAHC) [23]. A link was provided for each of the academic medical centers listed, and the links were used to navigate to the appropriate academic medical center's page. Some of the links navigated to the affiliated university's website; therefore, terms such as "patient care," "health," "healthcare," "clinics," "university health," and "hospitals," were used to find the appropriate academic medical center's main webpage. One link was removed from analysis, the University of California System, as this link provided a list of academic medical centers in California that were already included in the current analysis. This provided a total of 73 academic medical centers that were used for usability testing (Figure 1).

Figure 1. Sample selection criteria for academic medical center websites.



Overview

All website usability testing took place from June 1, 2020, to December 15, 2020. We began by adapting a methodology developed in previous health care website ranking literature [3,19,24]. We kept the weighted percentages from the previous studies and applied specific formulas to those calculated percentages to create a relative scale for comparing usability scoring (Multimedia Appendix 1). Of note, the previous methodology used a consistent scoring system that used the relative maximum as the reference point of 1 so that every usability test fell between 0 and 1 [24]. However, we found that one of these tests did not follow this format, so our methodology improved the previous testing and applied the same reference range to the values.

Usability was sorted into the following four broad categories in order to ensure quantifiable, objective, and actionable recommendations for the websites: (1) accessibility: the ability of those with low levels of computer literacy to access and navigate the hospital's website; (2) marketing: the ability of websites to be found through search engines and the relevance of descriptions to the links provided; (3) content quality: grammar, frequency of information updates, material relevancy, and readability; and (4) technology: download speed, quality of the programming code, and website infrastructure [3,19].

Each of these categories represents areas of usability in which academic medical centers can communicate more effectively with their audiences. The factors that contribute to each category were originally discussed by Huerta et al [3]. To add to the comprehensive nature of this study, we further defined these categories by utilizing support tools that bolster the credibility and reproducibility of the results of this analysis. These tools were chosen based on their ability to address each of the individual factors in the category criteria and their availability for public ease of use and implementation.

Analysis

All of the websites were analyzed using a set of established usability tools. These tools were chosen based on their ability to specifically assess the individual factors selected. The tools were also chosen based on their ability to meet industry standards for evaluating the selected factor and for their relative ease of use. The process for utilizing each tool was based on the tool's specific instruction manual. The authors collaboratively ensured the proper use of each tool and the proper value to be recorded. There were 2 researchers who collected data, and each underwent specific training on utilizing the suite of analytic tools and data entry. Questions and discrepancies were addressed by the project supervisor as they arose. Factors such as speed, which can vary from second to second, were averaged across 2 separate tools to provide the most accurate values possible. Overall, all the tools were run on a total of 2 computers to minimize as many outlying technology errors as possible. The selected tools can be viewed in Multimedia Appendix 1.

We began building a database of the top-level URLs associated with each website in our data set. The web crawler processes the URL and creates a topographical map of the website, including all its subpages. For instance, a top-level domain, corresponding to a website's home page, may be associated with the URL "www.healthcare.org." A subpage of this center might be a page on the team members and associated with the URL "www.healthcare.org/team." There may be other subpages for specific topics such as the emergency medicine department, the pediatric department, and so forth. Once the web crawler has created a topographical map of a website, that website can then be analyzed for page errors, amount of page content, metadata (ie, titles, keywords, and descriptions), or other preprogrammed factors [25].

Using these usability tools, we scored each website on the four previously mentioned categories. The composite of key factors

in each of those categories contributed to an overall "general usability" score for each website. Lastly, an overall score was calculated by applying a weighted percentage across all factors and used for the final ranking system.

Below, we will describe each of the categories we evaluated and their contributed significance.

Accessibility

Accessibility is a category that refers to how well a website engages a broad audience with varied levels of technical ability, literacy, and disability. This category includes the following components: meta description, functionality, readability, and the overall layout of the website. A meta description refers to the "snippet" page summary presented in a search engine result. Functionality refers to a website's ability to provide content that appeals to a broad range of literacy levels. Functionality also includes features that allow users to access different parts of a website. It is estimated that 43% of American adults have basic or below-basic literacy levels [26]. The usability of assistive technologies such as screen readers and magnifiers for websites is also assessed by the accessibility category [27]. In this study, we utilized tools that apply algorithmic scales to rank website reading difficulty and to determine the grade level required to comprehend a website's content.

Content Quality

The content quality category refers to our assessment of the attributes of the content on a website. This can include the relevancy of the written information to that particular point in time on a specific topic, generated metadata, and the use of the website's multimedia for imagery. For instance, a website dedicated to supplying information on current closed-loop insulin pumps for patients with diabetes may be evaluated on its ability to provide relevant, fact-driven answers to questions that people are seeking answers for (ie, relative costs, ease of use, etc). The multimedia on a website may also be evaluated for issues such as quality (eg resolution) and the available metadata function to add support to the composed content. Content quality also includes written text and may evaluate grammar and spelling.

Marketing

The marketing category refers to our assessment of the discoverability of a website, with a particular emphasis on its search engine results pages (SERP), which refers to the websites presented to users when they search for something online using a search engine such as Google. Higher placement in search results can lead to greater visibility, and SERPs are considered by some to be one of the most important elements of digital marketing. The field of search engine optimization (SEO) deals with optimizing a website to place better in SERPs, and effectively implementing SEO may allow health care websites to uphold a corporate image as industry leaders [28]. However, technical SEO auditing, specifically, was beyond the scope of this study.

Technology

The technology category refers to our assessment of the technical functionality of a website, as opposed to its content. It evaluates the quality of a website's technology and technological design and performance, including its front-end design and user experience as well as back-end coding infrastructure and server management. The front end is what the users of the site view when browsing a website. It also involves the analysis of HTML elements to ensure that the user has an easily navigated layout and that the site can be scalable across devices (ie, computers, mobile phones, and tablets). The back end involves the programming code upon which the website runs. This code and other website components, such as its databases, are stored on servers, which functionally allow people to view websites from their own devices. The servers also affect the speed of the site (eg, how quickly it loads for users), which can play a crucial role in gaining and maintaining users and followers. For instance, a previous study conducted by Google [29] showed that a website that takes longer than 3 seconds to load on a mobile device will lose approximately 53% of its users; problematically, that same study revealed that the average mobile website speed is upwards of 18 seconds.

General Usability

This was a composite of all the metrics from the prior four categories. This category aims to answer the question, "How good is my website?" This metric may serve as a starting point for health care organizations to perform an initial audit of their website to look for areas of improvement.

Overall Usability

An overall usability rank order calculation was included to create a comprehensive evaluation of all major and minor factors across all of the five aforementioned categories. From there, we assigned a percentage weight to create an all-inclusive usability ranking system.

Results

Scores were assigned to all (N=73) academic medical centers found on the AAHC members list [23].

The category with the highest average score was technology, with 0.82 (SD 0.068, SE 0.008). Accessibility was the second highest scoring subcategory, with an average score of 0.77 (SD 0.059, SE 0.007). The third highest scoring subcategory was marketing with an average score of 0.43 (SD 0.066, SE 0.008). The lowest performing category was content quality, with an average of 0.22 (SD 0.070, SE 0.008). The summary statistics across all five categories are presented in Table 1, and a description of the usability tools used in each of the categories can be found in Multimedia Appendix 1.

The overall rankings for the 73 assessed domains for all categories are reported in Multimedia Appendix 2.

Table 1. Academic medical center websites: summary statistics from usability analysis.

Category	Mean (SE)	SD	Minimum	Maximum
Accessibility	0.77 (0.007)	0.059	0.58	0.86
Content quality	0.22 (0.008)	0.069	0.09	0.50
Marketing	0.43 (0.008)	0.066	0.26	0.63
Technology	0.82 (0.008)	0.068	0.66	0.97
General usability	0.62 (0.005)	0.047	0.48	0.71

The top leaders across all usability ranking categories are as follows: (1) accessibility—Duke University; (2) content quality—University of Pittsburgh; (3) marketing—University of Southern California; (4) technology—Rosalind Franklin University of Medicine and Science; and (5) general usability—University of Southern California. The top-performing website in terms of overall usability was that of the University of Southern California.

Discussion

Comparison With Prior Work

This study assessed academic medical center websites utilizing the methodology outlined by Calvano et al [24] in a publication that ranked usability of digital health care center websites. Previous studies enabled Calvano et al to assess website usability trends including that of hospitals, digital health centers, and children's hospitals [3,19,24]. In previous studies, content quality was the highest scoring category. This was postulated to reflect the health care industry's emphasis on providing adequate information for website users. However, investment in content quality is accompanied by a lower investment in other usability categories.

Another major trend in previous studies was that the technology category was the lowest scoring category [3,20,21,24]. Interestingly, when these study methods were applied to academic medical center websites, we found the opposite. Technology was the highest scoring category, and content quality was the lowest. One possible explanation for this is that the significant amount of time elapsed between the studies enabled website technology to be updated. In addition, compared with community hospitals and digital health centers, academic medical centers are larger institutions with more financial capital to invest in website functionality. Academic medical centers also have more expansive websites, which may cause difficulty in monitoring the quality of the large amount of content produced.

With reference to academic medical centers, we assert that an increased level of importance should be placed on monitoring content quality, thereby ensuring a higher standard of information presented to the general public. As medical advancements continue to become more complex and patients become more comfortable with technology use, a larger number of individuals will turn to the internet for assistance in understanding key medical concepts. Therefore, it is of utmost importance that academic medical centers realize their vital role in providing targeted and relevant content for their website users. This includes providing germane, concise answers to common medical questions people may be searching for to obtain new users and maintain the existing ones.

Another difference between previous studies and our findings involved the accessibility category. In the assessment of children's hospital websites, previous studies found accessibility to be the lowest scoring category [19]. However, we found accessibility to be the second highest scoring category. One possible explanation for this might be that academic medical centers better understand the importance of creating content that is built at the proper literacy levels and technical complexity to ensure ease of access for a broad audience. Academic medical centers tend to serve as leaders in the medical community and are often sought for guidance by the general public in areas of medical concern, such as the current COVID-19 pandemic. With this in mind, academic medical centers may understand the importance of creating content that is easily comprehended by a range of website users.

Marketing scores were noted to be lower than originally anticipated [19]. Pertaining to health care, marketing is important to ensure users can easily locate an organization's website within search engine results. It is imperative that academic medical centers employ search engine optimization techniques to enable improved public visibility of their information compared to less authoritative sources.

A specific goal of this research is to promote standardization of website analysis across the health care industry, as it has been neglected previously despite being an important facet of other sectors [12-14]. Recent technological advancements have driven down costs in medicine and increased quality of care [22]. Usability analysis is an important element in this process and enables health care organizations to improve their website presence. With the heightened awareness of technology's importance in health care due to the COVID-19 pandemic, the web presence of academic medical centers is even more essential to ensuring the proper dissemination of health information.

Limitations

This study has several limitations. Not all of the social media accounts were directly accessible from the website, making them more difficult to find through Twitter and Facebook's respective search engines. In most cases, an affiliated Facebook or Twitter page was found. A total of 5 academic medical centers were not associated with a Twitter page, and a total of 2 academic medical centers were not associated with either a Facebook or Twitter page. For the academic medical centers that did not have affiliated Facebook or Twitter pages, this either was because one had not been created for the institution or

because a link was not provided on their webpage and was not able to be found using the social media's search function.

Assessments of a website's speed can vary depending on the time of the day or the day of data collection. This could be due to changes to the website's servers, internet connectivity, or computer hardware. To minimize sampling bias, the same computer on the same network was used when measuring parameters such as website speed.

All of this information was collected over the course of several months; therefore, some measures may have changed since initial evaluation.

The AAHC provides their own definition of an academic medical center, which includes three main components: "...an allopathic or osteopathic medical school; one or more other health profession schools or programs…, and one or more owned or affiliated teaching hospitals or health systems" [30]. In accordance with the definition of an academic medical center provided by the AAHC, a clinic webpage would not be considered an academic medical center. However, for consistency of using the full sample of academic medical centers provided on the AACH website, we decided to use clinic webpages for usability analysis if no other institution could be found that better met the definition of an academic medical center. In total, 4 clinic pages were used in the analysis. For example, in the case of Des Moines University's Osteopathic Medical Center, only the university's clinic page was able to be found via their webpage; therefore, this was the link that was used in the usability analysis.

Our data set was much larger than that of previous studies [21,24] because we analyzed entire institution websites; many of which had between 500,000 and over 1 million URLs. The websites were cut off at 750,000 URLs during web crawling as this was felt to be a sufficient sample size without running into RAM limitations.

Conclusion

As an increasing number of individuals look to the internet for medical information, responsibility will be placed on academic medical centers to maintain high quality websites, given their status as respected sources of current medical information and research. This study offers an analysis of the overall need for improvement in website usability by academic medical centers. The average general usability score was 0.62, showing the necessity for improving usability measures. Academic medical centers may benefit from taking steps to improve various components of their websites in order to reach their audiences. A suggested step is for these organizations to perform periodic usability audits of their websites to identify areas for improvement. Several of these institutions have significant room for improvement of their overall usability, specifically with content quality and marketing, the lowest scoring categories in this analysis. Using content audit tools, institutions can gather data regarding their webpage content and improve upon several factors, including ensuring every webpage has a title of appropriate length, that every webpage has an H1 heading, and that the meta descriptions on the page are concise. Content audits of webpages should be focused on improving the quality of information presented by enhancing aspects such as navigability. Navigability of information can be improved upon by fixing broken web links that are cited on the website, adding alternative text to images, and correctly utilizing keywords on the pages. In terms of marketing, we also recommend confirming that Facebook pages and other social media links are highly visible on home screens. In addition, we recommend ensuring that there is enough content on those social media pages. These and other webpage improvements will lead to the enhanced usability of the webpages for patients and academicians alike, thereby furthering the quality of health care information available online.

Acknowledgments

We would like to thank Dr. Regan Stiegmann and Dr. Cole Zanetti, co-directors of the Digital Health Track at Rocky Vista University, for their support of this project.

Abstract

Background: Although the COVID-19 pandemic has significantly boosted the implementation of digital services worldwide, it has become increasingly important to understand how these solutions are integrated into professionals' routine work. Professionals who are using the services are key influencers in the success of implementations. To ensure successful implementations, it is important to understand the multiprofessional perspective, especially because implementations are likely to increase even more.

Objective: The aim of this study is to examine health and social care professionals' experiences of digital service implementations and to identify factors that support successful implementations and should be considered in the future to ensure that the services are integrated into professionals' routine work.

Methods: A qualitative approach was used, in which 8 focus group interviews were conducted with 30 health and social care professionals from 4 different health centers in Finland. Data were analyzed using qualitative content analysis. The resulting categories were organized under the components of normalization process theory.

Results: Our results suggested 14 practices that should be considered when implementing new digital services into routine work. To get professionals to understand and make sense of the new service, (1) the communication related to the implementation should be comprehensive and continuous and (2) the implementation process should be consistent. (3) A justification for the service being implemented should also be given. The best way to engage the professionals with the service is (4) to give them opportunities to influence and (5) to make sure that they have a positive attitude toward the service. To enact the new service into professionals' routine work, it is important that (6) the organization take a supportive approach by providing support from several easy and efficient sources. The professionals should also have (7) enough time to become familiar with the service, and they should have (8) enough know-how about the service. The training should be (9) targeted individually according to skills and work tasks, and (10) it should be diverse. The impact of the implementation on the professionals' work should be evaluated. The service (11) should be easy to use, and (12) usage monitoring should happen. An opportunity (13) to give feedback on the service should also be offered. Moreover, (14) the service should support professionals' work tasks.

Conclusions: We introduce 14 practices for organizations and service providers on how to ensure sustainable implementation of new digital services and the smooth integration into routine work. It is important to pay more attention to comprehensive and continuing communication. Organizations should conduct a competence assessment before training in order to ensure proper alignment. Follow-ups to the implementation process should be performed to guarantee sustainability of the service. Our findings

from a forerunner country of digitalization can be useful for countries that are beginning their service digitalization or further developing their digital services.

Introduction

Background

The number of new digital services has been rapidly growing in the health care setting in recent years. Moreover, the COVID-19 pandemic has significantly boosted the implementation of digital services with unprecedented speed and influence [1,2]. The pandemic has also taken the usefulness and potentials of digital services to a whole new level. In doing so, it has also provided an opportunity to add these services to health care systems in the long term [3]. However, despite the pandemic having recently favored the transition to digital solutions [4], digitalization in health care has been slow and complicated, even though major investments have been made [5].

Implementations of digital services tend to fail more often in the health care setting than in other settings because the environment is complex, and therefore the integration into practice is difficult and slow [6-8]. Failure to implement may even lead to a reduction in quality, safety, and efficiency in care [9]. According to the World Health Organization (WHO), guidance for digital health, research, and assessment of the impact of digital service implementations on health care are essential [4]. It is important to identify barriers and success factors when implementing new digital services [10].

A recent systematic review provided a list of barriers and success factors for the implementation of digital services from the organizational point of view [11]. The most mentioned barrier was limited knowledge of the service, and the most mentioned success factor was the services' ease of use. Resistance from professionals is a major problem for organizations, and therefore it is important to understand their point of view [12]. Health and social care professionals are key influencers in the implementation [13-15] because their attitudes and behaviors influence patients' capacity to use services and their trust in the services [15,16].

Previous findings show that implementation should include users' participation at different implementation phases, using champions or other key staff, providing sufficient training and support, and monitoring the use of the system at the early stages of implementation [13,15,17-19]. However, these studies have mainly focused on examining implementation in certain groups of professionals [11,20] or a single digital service in a particular environment [21-25]. There are relatively few recent studies about health and social care professionals' experiences of the implementation of the digital services from a multiprofessional perspective, especially now when the number of implementations has grown and different professional groups have more practical experience about the implementations.

Moreover, now when the COVID-19 pandemic has further accelerated the adoption of the implementations, it is increasingly important to understand how these solutions are integrated into routine work [4]. Digital services are used for varying tasks and purposes, and creating a current overview of the experiences of professionals over a wide range of digital service implementations rather than focusing on 1 specific implementation would be of benefit. In addition, because Finland is the leading country for the third year in a row in digitalization according to the International Digital Economy and Society Index (I-DESI) [26], perceptions from Finnish professionals about the implementations can provide valuable information for many organizations that are further developing their digital services and systems.

Objectives

The aim of this study is to examine health and social care professionals' experiences of digital service implementations and to identify factors that support successful implementations and should be considered in the future to secure that the services are integrated into professionals' routine work. Normalization process theory (NPT) was used as an analytic framework [27]. This enables an understanding of how digital services can be normalized into professionals' routine work and workflow.

Methods

Design and Settings

A qualitative descriptive design with group interviews was used. The design was chosen because it allows information to be collected directly from those who are experiencing the phenomenon under investigation, as in this study from health and social care professionals [28]. We sought to examine health and social care professionals' experiences with successful implementations by asking them to share hindering and facilitating factors and what should be considered to achieve a successful implementation in routine work. This study followed the Consolidated Criteria for Reporting Qualitative Research (COREQ) guidelines [29].

The interviews were conducted at 4 different health centers located in different parts of Finland. These health centers were selected because they were forerunners in digitalization as they had adopted new ways of working and operating digitally before and during the COVID-19 pandemic. Each of these health centers were either pilots or pioneers in the implementation of various digital services (eg, digital symptom questionnaires, self-management instructions, and remote health care

appointments). More examples of the level of each health center's digitalization and the services it provides can be found in Multimedia Appendix 1.

In Finland, health care services are divided into primary health care and specialized medical care. Municipalities (local governments) operate health centers, which represent citizens' first points of contact in public health care. Health centers provide a wide scope of primary health care services, such as general practice outpatient care, maternity and child health clinics, health promotion, oral health care, medical rehabilitation, home nursing, and laboratory and basic imaging services, as well as community hospital care. In some health centers, services may also include some specialized care, such as mental health and substance abuse services [30].

Participants

The participants were health and social care professionals (N=30) working in 4 health centers (Table 1). They were purposely selected by asking clinic managers to recruit volunteers. The inclusion criteria were that the participants had to be health and social care professionals who did client work at health centers that have implemented digital services into their work, and therefore they had recent experience with digital service implementations. Those professionals who had indicated their willingness to participate were contacted via email with information about the study and were asked their willingness to participate in the interviews. All participants provided written informed consent.

Table 1. Demographic characteristics of interviewed professionals (N=30).

Category and variables	Value, n (%)
User group	
Registered nurses	8 (27)
Public health nurses	5 (17)
Practical nurses	7 (23)
Physicians	5 (17)
Social workers	3 (10)
Social counselor	1 (3)
Digital counselor	1 (3)
Gender	
Male	3 (10)
Female	27 (90)
Age (years)	
<30	5 (17)
30-40	11 (36)
41-50	10 (33)
51-60	4 (14)
Career in this organization (years)[a]	
<1	1 (3)
1-5	15 (50)
5-10	3 (10)

≥20	3 (10)
Career in total (years)[a]	
<1	1 (3)
1-5	7 (23)
5-10	6 (20)
10-20	6 (20)
≥20	5 (17)

[a]Not all of the participants answered this question.

Data Collection

The data were collected with 8 semistructured focus group interviews. The focus group interview method is often used as a qualitative approach when the aim is to obtain data from a purposely selected group of individuals [31], for example, multiprofessional groups such as those in our study. We conducted 2 interviews in each organization. In each focus group, there were 4-6 participants from different professional groups, including physicians, registered nurses, public health nurses, practical nurses, social workers, social counselors, and digital counselors (Table 1). Five of the interviews were conducted face to face, but because the COVID-19 pandemic got worse in Finland, the rest of the interviews were conducted remotely using the Microsoft Teams application. The interviews were performed by 3 interviewers (authors JN, A-MK, and EL) from a research team with previous experience in conducting qualitative interview studies and experiences with digital service implementations.

The questions in the interview guide were based on the literature [11,15,17,18] and defined in collaboration with the research team (Multimedia Appendix 2). The interview guide included questions about the professionals' experiences with digital service implementations, such as which factors facilitated or hindered the implementations and what kind of suggestions the professionals had for future implementations to ensure that services integrate into routine work. Demographic questions related to age, gender, education, and working years in the current organization and total years of working.

The questions in the interview guide were tested in a pilot interview with 1 health care professional by using the Microsoft Teams application. In addition, participants in the first focus group were asked to rate the understandability and relevance of the questions. No changes were required to the interview guide, so the pilot interview was included in the study with the consent of the interviewees. With the permission of the participants, the interviews were recorded and then transcribed by a transcription company. The transcribed text was generated on 168 pages with a line spacing of 1.15, 11-point font, and the font style Verdana. The duration of the interviews ranged from 41 to 79 min, and the total duration of all the interviews was 501 min.

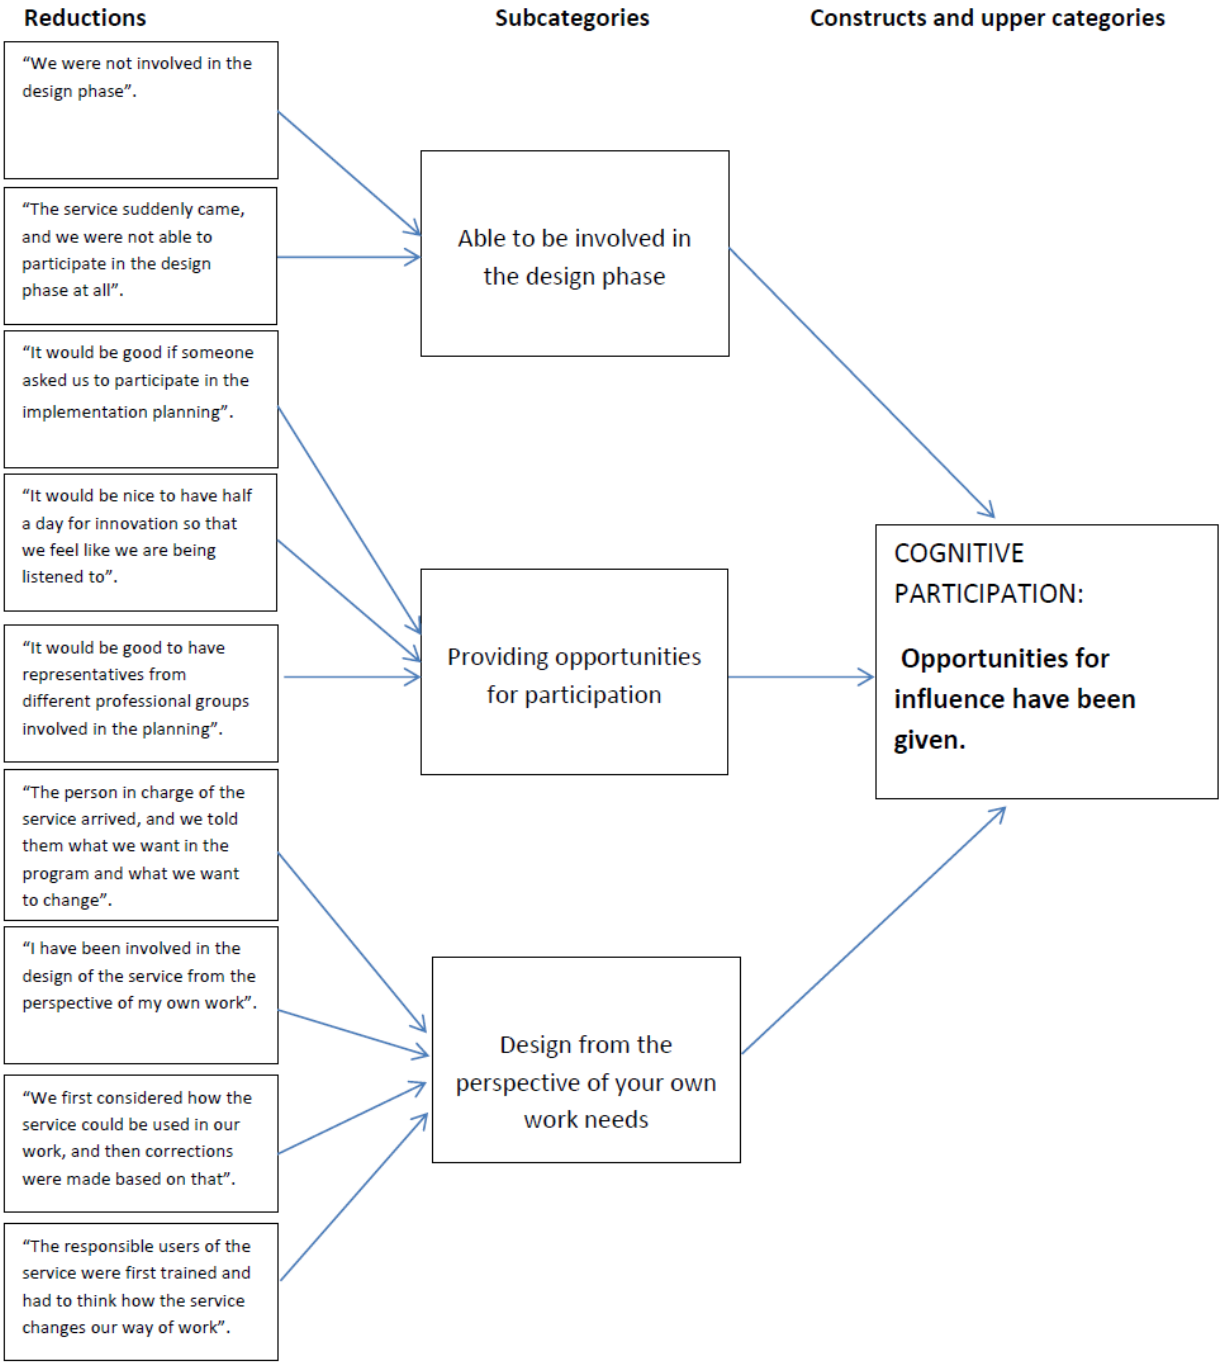
Data Analysis

We discussed the data saturation after the sixth focus group [32], recognizing that responses began to replicate one another and professionals had similar types of experiences with the implementation. The data were analyzed by using content analysis with an inductive-deductive approach [33]. First, 1 researcher (JN) read all the transcribed interviews a couple of times to form a preliminary image of the data. Then, all the expressions that responded to the aim of the study were extracted from the text and formed into codes (n=224) using ATLAS.ti software (ATLAS.ti Scientific Software Development GmbH). The codes were reductions of professionals' thoughts. Subcategories were then formed by grouping codes with similar content, which were then formed into upper categories. At this point, 2 other researchers (authors A-MK and SK) looked at the coding and the formed subcategories and upper categories, and discussions were held to reach an agreement on the content and names. The deductive method was then followed, in which the upper categories were divided into 4 different components according to the NPT framework (Figure 1).

We chose the NPT framework because it is a commonly used framework in implementation studies describing how new technologies and other complex interventions are normalized into routine work in health care settings [34]. It is an action theory, which means that it is concerned with explaining what people do rather than their attitudes or beliefs. Thus, it allowed us to understand the key actions that either promote or inhibit the implementation and integration of the services into professionals' routine work [35]. Moreover, we chose this theory for our study because it can be used to describe and judge the potential of the implementation, but it also has the ability to design and improve complex interventions [27]. We used all 4 of the NPT's components to obtain an overview of the implementations, contrary to previous studies, which mainly focused on just some of the components [36].

The first component (coherence) seeks to explain how the new service changes work and what are the aims and benefits of the service [27]. The second component (cognitive participation) focuses upon the work undertaken to engage people using the service and get them to buy into it [36]. The third component (collective action) refers to work that enables the implementation to happen [36]. It requires the organization to be supportive and people to have the necessary skills and training to perform the tasks associated with the digital services [27]. The fourth component (reflexive monitoring) includes questions such as whether people try to change the practice to fit their work, how they value the new digital services, and what effects the service has on peoples' work [27].

Figure 1. An example of the development of the content analysis process.



Ethics Statements

The Research Ethics Committee approval (THL/2304/6.02.01/2020) was applied for ethical support from the Finnish Institute for Health and Welfare. The data collected in the study were treated confidentially, and the results are reported in a way that does not identify an individual respondent.

Results

Major Findings

We identified 14 practices that, based on the experiences of the professionals, support successful implementation. A detailed description of how the different practices are distributed under the components of the NPT is given in Table 2. The quotation abbreviation meanings are as follows: I=interview and P=participant.

Table 2. Good practices when implementing digital services based on NPT[a] components (n=224).

NPT component and good practices[b]	Mentions[c], n (%)
Coherence (sense-making work): how professionals understand and make sense of the new service (n=38, 17%)	
Communication is comprehensive and continuous: • The information is multichannel • The service presentation reaches everyone. • The service has been informed	28 (13)
The implementation process is consistent: • The implementation process needs to be clear • There is enough time to get ready for the implementation	7 (3)
The use of the service is justified: • The reasons for using the service are given	3 (1)
Cognitive participation (relational work): how professionals engage and participate in the service (n=20, 9%)	
Opportunities for influence have been given: • Professionals are able to be involved in the design phase • Professionals are provided opportunities for participation • The design is from the perspective of the professionals' own work needs	15 (7)
The attitude toward the service is positive: • Previous positive experiences toward eHealth implementations occur • Professionals show interest in the service • Professionals accept the need for the implementation	5 (2)
Collective action (enacting work): the work that individuals (professionals) and organizations have to do to enact the new service (n=136, 60%)	
Support is provided from several fast and efficient sources: • Support is given • The support model is clear • Support is close and easily accessible • Support is given by champions • Support is received from the work community itself • Faster/more efficient sources of support are needed	39 (17)
Sufficient time is provided for familiarization with the service: • Time is provided for familiarization with the service • Independent information retrieval and usage learning are required • The service must be learned alongside the work • A demo version is needed to practice before deployment	36 (16)
Enough knowledge of the service is provided: • Coworkers teach each other with sufficient skills • There are no shortcomings in basic technical skills • There is a need for nonstop training • Sufficient and clear information about the use of the service to support its use is provided • Training is systematically planned	31 (14)
The training is targeted according to work tasks and competence: • There is a need for a competence survey • Training is targeted according to professionals' work tasks • Training is targeted according to professionals' skill level/needs	18 (8)
Various teaching methods are provided: • Versatile teaching methods are available • Good and clear written instructions are provided • Video training is needed to support learning	12 (5)
Reflexive monitoring (appraisal work): how professionals reflect on or appraise the effects of the services (n=30, 13%)	

NPT component and good practices[b]	Mentions[c], n (%)
The service is easy to use: • The assumed heavy usability of the program prevents successful deployment • Experiences with poor usability affect introducing new programs • The service is easy to use • The service has no functional weaknesses	12 (5)
Usage monitoring takes place: • There is continuity of deployment monitoring and evaluation	9 (4)
Giving feedback on the service is possible: • The feedback channel is known • Sending the feedback forward is smooth	5 (2)
The service supports work tasks: • The service is perceived as useful	4 (2)

[a]NPT: normalization process theory.

[b]The categories inside the NPT's components are sorted in the order in which the participants mentioned the most.

[c]How many times the participants mentioned this category.

Coherence: How Do Professionals Understand and Make Sense of the New Service?

The participants considered that the implementation should be prepared by *comprehensive and continuous communication*. They experienced that the communication had failed while announcing that information about the upcoming implementation happened unexpectedly and therefore the presentations had not reached everyone. For future implementations, participants suggested that the communication be done through different communication channels so that it reaches as many employees as possible and avoids uncertainties in the implementation of the service.

> *Implementation is considered successful when the communication is multichannel, which includes a video, a brochure, and a physical person to talk about the service.* [I7, P3]

According to the participants, for digital service implementation to be successful, *the implementation process must be consistent*. The implementation process needs to be clear, and the professionals should have enough time to get ready for the upcoming implementation. The participants had previous experiences with how implementations had taken place on a tight schedule, and thereby a lot of ambiguity had been associated with the process. Some of them had previous experiences where they were first told that the service was going to be implemented but later it was canceled and they attended unnecessary trainings. They started to lose their trust in future implementations and changes.

> *You will lose trust for any change when you experience unclear implementation experiences.* [I2, P1]

In addition, the participants also felt that it is important *to provide a good justification for using the service*. They felt that telling them why the service was implemented and why it needs to be used gave them the motivation to use it in their routine work. In addition, accepting the digitalization and understanding it as a mandatory way of working were contributing factors. Some of the participants even felt that the time is apt for digitalization and that they must simply go with the flow. They also considered it important that the benefits of using the digital service (from the perspective of their own work) were emphasized.

> *Implementation is enabled by the fact that the employee [themselves] perceive the service as useful and good in [their] own work.* [I3, P1]

Cognitive Participation: How Do Professionals Engage With and Participate in the Service?

The participants noted that in good implementation, champions who have an interest and additional training in the service should be involved in implementation from the beginning. They also highlighted that it is important to give everyone, not only the champions, *an opportunity to influence and participate* by giving insight for the service of one's own work needs. The participants suggested that implementation be facilitated by involving professionals from different professional groups in the design phase so that everyone would have a voice. In addition, the participants mentioned that it is important that they have been given the option to use working hours when participating in the design phase of digital services.

> *Usually, we have no time to innovate. It would be nice if there was, for example, half a day for development, which would give the staff a voice.* [I2, P3]

Ensuring that the professionals have a *positive attitude toward the service* enables successful implementation according to the participants. If the professionals had prejudices or negative attitudes toward the digital services, they were reluctant to use them. The participants expressed that usually these negative emotions were consequences of a lack of involvement in the design phase. Prejudices were also often related to the usability of the service. It was feared to be too difficult to use or the

professionals simply had bad experiences with previous implementations.

> *Prejudices can negatively affect successful implementation because you may have some perception or fear that the service [that] is being implemented is too difficult to use.* [I7, P3]

Collective Action: The Work That Professionals and Organizations Must Do to Enact the New Service

The participants pointed out that *support should be available from a variety of sources*. Lack of support or the support model being unclear was found to hinder successful implementation. They noted that everyone should know how the support is provided, whom to contact in the case of a problem, and where to find all the related contact information. The participants had 2 views on the source of support. Some believed that support required a person physically present who could be approached quickly in problem situations. Especially after the first weeks of implementation, this was considered important. For some, remote support was thought to be adequate, as this would allow support to remotely connect the user's computer, if necessary, thus quickly supporting the user in the event of a problem. Nevertheless, what was considered to be the most important thing was that the support should be close and readily available.

> *The person providing the support does not have to be physically present, but it would be good to have support remotely that is easily and quickly available so that [they] can remotely show how to do these things with the service.* [I8, P3]

In addition to the support provided by the organization, support was often received from one's own workplace, most often from one's own colleagues. Some of the participants had experiences of champions supporting the use of the service. In addition to receiving support from their own colleagues, some of the participants also received support from their own supervisors. However, only a few considered it to be important that the supervisors support employees in the implementation process. For them, the attitude of supervisors toward digital services was the more substantial contributing practice to successful implementation.

Most of the participants mentioned that there should be *enough time to get familiar with the service.* They experienced that they had not been provided enough time to get to know the service but had to learn to use it alongside their work while the patient was at the reception. They suggested that by having a demo version, they would get an opportunity to practice the service independently or with colleagues before using it with patients. It would also give them the chance to practice it in peace and when it suits them best. However, some of the participants saw that the use of the service would be learned over time while working or through mistakes at the latest.

> *When you fail enough times, you will get it right eventually. You will learn from your mistakes.* [I6, P3]

According to the participants, well-planned and scheduled training regarding the use of the service, as well as equal opportunities and time to participate in these training sessions, are important. The training should also be nonstop so that it would train as many employees as possible and even the shift workers could attend. The participants also pointed out that having *enough knowledge on how to use the service* is important for the success of the implementation. They believed that having enough knowledge would help them achieve confidence in using the service. The participants described problematic situations where the coworkers had taught other coworkers with insufficient knowledge. Furthermore, with such experiences, they mentioned that effective and clear information about the use of the service ensures that it is used correctly.

In addition, 1 of the key practices that the participants pointed out was that the service provider or the organization should *provide different training methods* for employees. One-sided training methods prevented successful implementation. For example, watching training videos alone did not guarantee sufficient skills to successfully use services. However, some of the participants experienced that video training enabled recounting whenever they needed it. In addition to various training methods, participants mentioned that it is important to have, especially after its implementation, written instructions on how to use the service.

The participants hoped that their skills could be assessed to map their training needs. Targeting training according to the level of competence would be useful, as some people may need to learn more basic technical skills, while others already master them well and may be able to cope with shorter training sessions. It was also mentioned that the individuals who embrace the program more easily, such as recent graduates, may find the video training enough and no other forms of training will be needed. The importance of targeting training according to the competence requirements set by the job tasks was also emphasized.

> *I would have wished for targeted training for my own professional group because now they have been general. It would be more efficient if the [training sessions] were more targeted, so you could focus on the things you need in your own work.* [I8, P2]

Reflexive Monitoring: How Do Professionals Reflect on or Appraise the Services' Effects?

The participants noted that after the implementation, it is important that the service be perceived to work well, because experiences of poor usability were believed to jeopardize successful implementation. Thus, the *service should be easy to use* and should not have usability vulnerabilities.

> *Usability and especially the ease of using the service plays a huge role if you want the implementation to be successful.* [I2, P1]

In addition, after the implementation of the service, *monitoring its use* was also considered important. This meant, for example, regular monitoring of the correct use of the system and the use of all included features. The participants were concerned about the misuse of the system due to a lack of sufficient training and monitoring of everyday use.

> *The problem is that no one comes back and asks if you have learned to use the service; a follow-up visit is needed.* [I7, P3]

The participants also pointed out the importance of getting an *opportunity to provide feedback* on the new service after the implementation and that the feedback be used to develop the service. It was essential for the functioning of the feedback channel that it be known by everyone and that the feedback process be perceived as smooth. If it was not perceived as being smooth, there was no desire to give feedback.

> *If you come up with a good idea, taking it forward was not made easy; if it takes a lot of time, it is often left undone.* [I2, P2]

According to the participants, the use of the digital services that are being implemented should be *useful for one's own work.* The service was not used nor recommended, for example, to patients if the participant considered the service unbeneficial for one's own work.

Discussion

Principal Results

This qualitative study identified factors that support successful digital service implementations and should be considered in the future to make sure that the services are integrated into health and social care professionals' routine work. According to professionals' implementation experiences and by using the NPT framework, we suggest 14 practices that should be considered when implementing new services into professionals' clinical work.

To get professionals to understand and make sense of the new service, (1) the communication related to the implementation should be comprehensive and continuous and (2) the implementation process should be consistent. (3) A justification for why the service is going to be implemented should also be given. The best way to engage professionals with the service is (4) to give them opportunities to influence and (5) to make sure that they have a positive attitude toward the upcoming service. To enact the new service into professionals' routine work, it is important that (6) the organization take a supportive approach by providing support from several easy and efficient sources. The professionals should also have (7) enough time to become familiar with the service and have (8) enough know-how about the service. The training should be (9) targeted individually according to skills and work tasks, and (10) it should be diverse. The impact of the implementation on the professionals' work should be evaluated. The service (11) should be easy to use, and (12) usage monitoring should happen. An opportunity (13) to give feedback on the service should also be offered. Moreover, (14) the service should support professionals' work tasks.

Comparison With Prior Work

According to our study, to ensure that the service makes sense (the NPT's component coherence) for the users, the communication related to the implementation should be comprehensive and continuous. In earlier studies, the importance of good information has been highlighted when implementing digital services [14,17,18,37]. However, previous studies do not mention specifically what kind of good communication would best support professionals in their work. In our study, the professionals suggested that the communication should happen from a variety of different channels so that it reaches everyone, including shift workers. Our results highlight that when the implementation process happens under a tight schedule, such as during the COVID-19 pandemic, the importance of comprehensive and continuous communication increases.

In our study, the professionals also highlighted that it is important to justify why the service is going to be implemented in order to ensure that it makes sense for the users. The benefits of using the service seemed to be especially important from the perspective of the professionals' own work. Sanders et al [38] presented in their study that usually the difficulty in implementations is a failure to clarify coherence to the users. If the professionals fail to understand the way of working as helpful and relevant, they may be unwilling to use it. In addition, May et al [37] highlight the importance of coherence; if there is a desire for the service to be normalized into the professionals' work, it is important that the service make sense for the users [27,36]. In the review by Mair et al [19], the sense making was not highlighted as being that important when implementing eHealth systems. However, it is good to note that this review was conducted 10 years ago.

Some earlier studies have pointed out that involvement is 1 of the key contributing factors when implementing new digital services [17-19]. In addition, the NPT [27,36] highlights the importance of engagement and participation (cognitive participation component) with the service to get it normalized into routine work. In our results, the professionals underlined the importance of everyone getting an opportunity to influence and participate in designing the service. Our results therefore support previous results; however, the main problem according to our results is that time for involvement is not given to professionals. The heavy workload and the lack of staffing of health and social care settings have increased in recent years, which may influence the time given for innovation and design [39].

According to our results, to make sure the enactment of the work happens (collective action component), the support should be provided from a variety of fast sources. However, it was interesting that the professionals did not highlight the importance of supervisors' support, whereas previous studies have recognized the lack of support from supervisors as 1 of the major barriers to implementation [17,18,40]. However, we found that the positive attitude toward the service is more important. In addition, enactment of the work happens if people have the necessary skills and training to perform the tasks associated with the services. In our study, it was important for the professionals to have enough knowledge about the service and time for its familiarization. In previous studies, the lack of time [11,18] and the lack of information [18,19] were also experienced as inhibiting factors.

In our study, it was important to use various teaching methods and training, which was targeted according to work tasks.

Professionals also suggested to target the training according to the competence assessment. Previously, the training and competence of professionals have been found to be key factors when implementing new digital services [11,18,19], but competence assessments have received less attention. Mair et al [19] mentioned the importance of training, but they did not specify what kind of training would be required. Therefore, more information is needed in the future about what, how, and how much training should be provided.

In our study, it seems that the evaluation of a new digital service depends on how well the service supports professionals' work tasks and whether users perceive the service use usable (reflexive monitoring). Our results suggest that follow-ups are important, because after the implementation, the users expected someone to monitor whether they were using the services in an appropriate manner. Gagnon et al [17] also found that monitoring the use of the system should happen at the early stages of implementation to ensure immediate response to users' feedback [17]. It is important that the organizations and service providers keep on engaging with the service users after the implementation has taken place. This also provides an opportunity to ensure that the service is used correctly. In addition, in our study, being able to give feedback about the service was considered important because it gave the users the feeling that they can influence. This also gives the organizations and service providers an opportunity to further develop the service based on the users' needs.

The NPT framework seemed to be a suitable choice for our research because our findings were well interpreted with the components of this framework. The NPT offered us a useful tool for organizing the important practices involved in the data, which enabled the development of recommendations for future implementations. We had difficulties sometimes in understanding and applying coding to some of the NPT components, especially coherence and cognitive participation, which are more related to time before implementation. However, even when we used all 4 components, collective action frequently got many mentions, maybe because it describes the enactment of the work most comprehensively. May et al [37] suggested that for future studies, it is important to connect collective action much more closely to the context in implementation studies.

Strengths and Limitations

The strengths of this study include multilevel information about experiences from different professional groups when implementing a different kind of new digital service in the era of the COVID-19 pandemic. The fact that a fairly large number of interviewees (n=30) took part can also be considered a strength. Our results are from the forerunner country in digitalization and from 4 different health centers that are pioneers in digitalization and located in different parts of Finland. Thus, we were able to obtain important information from pioneer organizations for many organizations that are further developing their digital services and systems. A qualitative research method was able to give us a more in-depth overall picture of the situation during the era of COVID-19.

Credibility was established in this qualitative study by following the criteria of reliability presented by Lincoln and Cuba [41]. To establish confidence that the results were true, we collected data generated by 3 interviewers, 1 of whom was a more experienced interviewer. In the Results section, we used quotations to make sure the results were authentic. Credibility and interrater reliability were increased by having several sessions of peer debriefing with the research team about the interviews, the analyses process, and the name of the codes. Dependability was guaranteed by describing the study methods, data collection process, and analysis process as thoroughly as possible. Confirmability was guaranteed by collecting data from different groups of professionals, who were performing different kinds of tasks in a health and social care setting. Transferability was guaranteed by purposely sampling different kinds of professionals to participate in the focus group interviews.

This study had some limitations. One limitation was that because the COVID-19 epidemic got worse during data gathering, we had to conduct some of the interviews using the Microsoft Teams application instead of face-to-face interviews. The focus group interviews' aim is to get people to talk in a group, and with Microsoft Teams, it was more difficult and required more effort from the interviewers. However, fortunately, our interviewers were experienced and were able to plan a strategy for promoting discussion. Interrater reliability was also 1 limitation, because if we had performed the coding by double-coding it, we could have compared the unity of the coders more closely instead of only discussing it [42]. One more of the limitations was that the interviews were conducted in Finnish health centers; compared to other countries, Finland is ahead in digitalization and it can therefore influence implementation attitudes and experiences. So, transferability to other countries must be done with caution, especially related to countries with a low level of digitalization. The interviews were conducted in health centers, where there can be certain types of digital services in use, and therefore the results may not be transferable to other health care contexts. However, a previous review (eg, Mair et al [19]) showed corresponding results even when the environment varied. In addition, given that these 4 health centers were purposely selected because they were advanced in digitalization, it may have also influenced the results. Finally, 1 of the limitations was that most of the professionals who attended the interviews were from the health care sector, and therefore future studies about social care professionals' experiences with digital service implementations should be conducted.

Conclusion

In this study, we examined health and social care professionals' experiences with digital service implementations and identified factors that support successful implementations and should be considered in the future to ensure that the services are integrated into professionals' routine work. Based on the results, we suggested 14 practices for organizations to consider when implementing new digital services. Due to practical reasons, such as limited time and resources and a high number of implementations in organizations, it may not be realistic to expect all the practices to be fully executed. However, these practices can guide organizations to find appropriate ways to

support professionals and help organizations to pursue successful implementations. Our findings can be useful for countries that are beginning their service digitalization or further developing their digital services. For future studies, it is essential to examine implementations in a different phase of the process. The digital services add workload on already busy schedules [17], and thus, it would be beneficial to study how the implementations influence professionals' well-being at work.

Acknowledgments

This study was supported by the Strategic Research Council at the Academy of Finland (project nos. 327145 and 327147) and Finnish Institute for Health and Welfare (THL)-coordinated funding for COVID-19 research included in the Finnish government's supplementary budget. None of these entities had any role in the design of the study or in its data collection, analysis, interpretation of data, or writing of this study. The authors wish to thank all of the interviewees.

Authors' Contributions

JN contributed to conceptualization, methodology, formal analysis, writing (original draft, review and editing), and visualization; A-MK was responsible for conceptualization, methodology, formal analysis, writing (review and editing), and visualization; SK contributed to conceptualization, methodology, formal analysis, and writing (review and editing); EL aided in formal analysis and writing (review and editing); PH, JK, and IK contributed to writing (review and editing); TH aided in conceptualization, writing (review and editing), and supervision.

Abstract

Background: Patients undergoing coronary artery bypass graft surgery (CABGS) may fail to adhere to their treatment regimen for many reasons. Among these, one of the most important reasons for nonadherence is the inadequate training of such patients or training using inappropriate methods.

Objective: This study aimed to compare the effect of gamification and teach-back training methods on adherence to a therapeutic regimen in patients after CABGS.

Methods: This randomized clinical trial was conducted on 123 patients undergoing CABGS in Tehran, Iran, in 2019. Training was provided to the teach-back group individually. In the gamification group, an app developed for the purpose was installed on each patient's smartphone, with training given via this device. The control group received usual care, or routine training. Adherence to the therapeutic regimen was assessed using a questionnaire on adherence to a therapeutic regimen (physical activity and dietary regimen) and an adherence scale as a pretest and a 1-month posttest.

Results: One-way analysis of variance (ANOVA) for comparing the mean scores of teach-back and gamification training methods showed that the mean normalized scores for the dietary regimen (P<.001, F=71.80), movement regimen (P<.001, F=124.53), and medication regimen (P<.001, F=9.66) before and after intervention were significantly different between the teach-back, gamification, and control groups. In addition, the results of the Dunnett test showed that the teach-back and gamification

groups were significantly different from the control group in all three treatment regimen methods. There was no statistically significant difference in adherence to the therapeutic regimen between the teach-back and control groups.

Conclusions: Based on the results of this study, the use of teach-back and gamification training approaches may be suggested for patients after CABGS to facilitate adherence to the therapeutic regimen.

KEYWORDS

teach back; gamification; treatment regimen; coronary artery bypass graft; patient training

Introduction

Background

The most important objective of coronary artery bypass graft surgery (CABGS) is to improve the patient's quality of life by reducing angina symptoms and maintaining coronary circulation [1,2]. However, this approach also has complications, despite its many benefits. For example, patients may be exposed to side effects, such as respiratory problems, atelectasis, pneumonia, surgical site infection, gastrointestinal problems, and mood disorders, usually for reasons such as inappropriate adherence to a therapeutic regimen (generally including medication, dietary, and movement regimens) [2,3]. A lack of, or improper, training of patients may be accompanied by serious complications and re-admissions [3,4], although some of these side effects are preventable. Self-care and understanding of one's illness, lifestyle changes, and improvement of the patient's quality of life require the transfer of knowledge and education from the health professional to the patient. Despite recognizing the importance of patient education, several studies have shown that training of these patients may not be effective. Accordingly, effective educational methods should be used for people of different ages and with different levels of literacy to improve the patient's understanding of the disease condition and the treatment process [5,6].

There are several patient-training methods, such as direct (lectures, individual discussion, group discussion, and teach back) and indirect (booklet, pamphlet, CD, animation-based training, and gamification) methods. The choice of the right educational approach is different depending on the level of literacy and educability of the patient, the mastery of the nurse of the relevant method, and the availability of educational facilities, time, and educational space [7-12]. A number of studies have been conducted on the use of direct methods, such as the teach-back method of patient education [13,14]. This is a comprehensive and evidence-based approach that takes into account health literacy and leads to a better understanding of patients and their caregivers from the training provided by giving them information and asking for them to reflect the key points [15,16]. Despite the demonstrated benefits of this method, studies have shown that nurses are either not using this training method or have not found it to be effective [13,17]. Some of the disadvantages of this method are the time-consuming nature of the training, the large amount of content provided, the lack of repetition of the content at different times, and the lack of skill of the trainer [13,18,19]. In addition, some believe that the increasing speed of science and technology has diminished the role of direct teaching methods in the educational process, emphasizing the use of indirect methods, such as animation-, web-, and smartphone-based training.

In recent years, a new method called gamification has been used as a form of indirect patient training. "Gamification" is the term used to define the concept of applying game design and mechanics to nongaming applications. It gives patients the ability to set goals, track progress for achieving them, and get rewarded in return. Gamification also helps to increase users' self-control and is designed to promote positive behavior change. Gamification has been used to train patients with heart failure, myocardial infarction, rheumatoid arthritis, diabetes, breast cancer, and Alzheimer's disease and has also been used for smoking cessation and blood pressure control, yielding positive results [20-22]. However, the method has its critics. Some commentators believe that this training method may lead to addictive behavior, that it is costly, that there is a lack of skilled practitioners, and that there is a lack of appropriate infrastructure for its use [22-24].

Research Aim

Due to the importance of patient education in the development of self-care and the increasing use of modern educational approaches, the aim of this study was to compare the effect of gamification and teach-back training methods on adherence to the therapeutic regimen in patients after CABGS. The primary outcome was a score on adherence to the therapeutic regimen.

Methods

Study Design

This randomized clinical trial was performed with a sample size of 123 people in 2019. The study population consisted of all CABGS patients admitted to the intensive care units of hospitals affiliated to the Tehran University of Medical Sciences, Tehran, Iran. The patients who met the study inclusion criteria were randomly divided into three groups of 41 each using randomized block design and software. To decrease the predictability of allocated groups and ensure randomizing participants in an equal number, we used block randomization with size 4. Allocation in each group was random but equal in size.

Inclusion and Exclusion Criteria

Inclusion criteria were an age range of 18-60 years, an Android phone for the patient, nonuse of psychotropic drugs, the ability to understand and speak Persian, willingness to participate in the study, lack of hearing and speech disorders, and the ability

to receive phone calls after discharge. Exclusion criteria were the patient's unwillingness to continue an education process and acute illness requiring emergency intervention

Intervention

For patients in the gamification group, informed consent was obtained and a pretest questionnaire completed. The training program was installed on each patient's smartphone during discharge, and the researcher explained to the participants how to use the game. The app developed for the program included three main sections (dietary regimen, medication regimen, and movement regimen) and one assessment section at the end of each main section. The training was in the form of animation, images, and sound (Figure 1). In the assessment section, which was in the form of a question, the correct answer received 6 stars (reward, motivation); the screen of the phone was full of stars (excitement), and it moved to the next step. If a false answer was given, 3 stars were deducted from the total score (punishment), and the same step was continued until a correct answer was obtained. For a false answer, a sound (eg, a ding) was made (Textbox 1). Each patient was able to see the sum of their scores and those of other patients on the home screen. The patient was also able to see their score chart relative to those of the other participants, and consistent with social comparison theory, thereby motivating them to learn more in comparison to others. The questionnaire was recompleted 30 days later by an in-person visit to the patients' home.

Figure 1. Sample screenshot from the physical activity section.

Textbox 1. Delban (the app, which means "heart protector") application specifications.

Section 1

Includes the dietary regimen. The scientific content in this section is divided into 7 groups (general recommendations, bread and cereals, meat and beans, dairy, fruits, vegetables, and fat), and finally an assessment is included.

Section 2

Includes the medication regimen. General recommendations are given in three subsections for better patient access. The most commonly prescribed heart medications for these patients include β-blockers (eg, Metoral), antihypertensive drugs (eg, Losartan and Valsartan), antiplatelets (eg, Plavix and aspirin), lipid-lowering drugs (eg, Atorvastatin), diuretics (eg, Lasix, Aldactone, triamterene-H, and hydrochlorothiazide), anticoagulants (eg, warfarin and enoxaparin), and vasodilator drugs (eg, SUSTAC). Finally, an assessment is included.

Section 3

Includes physical activity. General recommendations are given in three parts. Other areas include walking, using a spirometer, breathing activity, sexual activity, returning to work, driving, and foot edema. In addition, the recommended exercises during the second phase of cardiac rehabilitation after surgery are provided to the patient for 4 weeks. The last part includes an assessment.

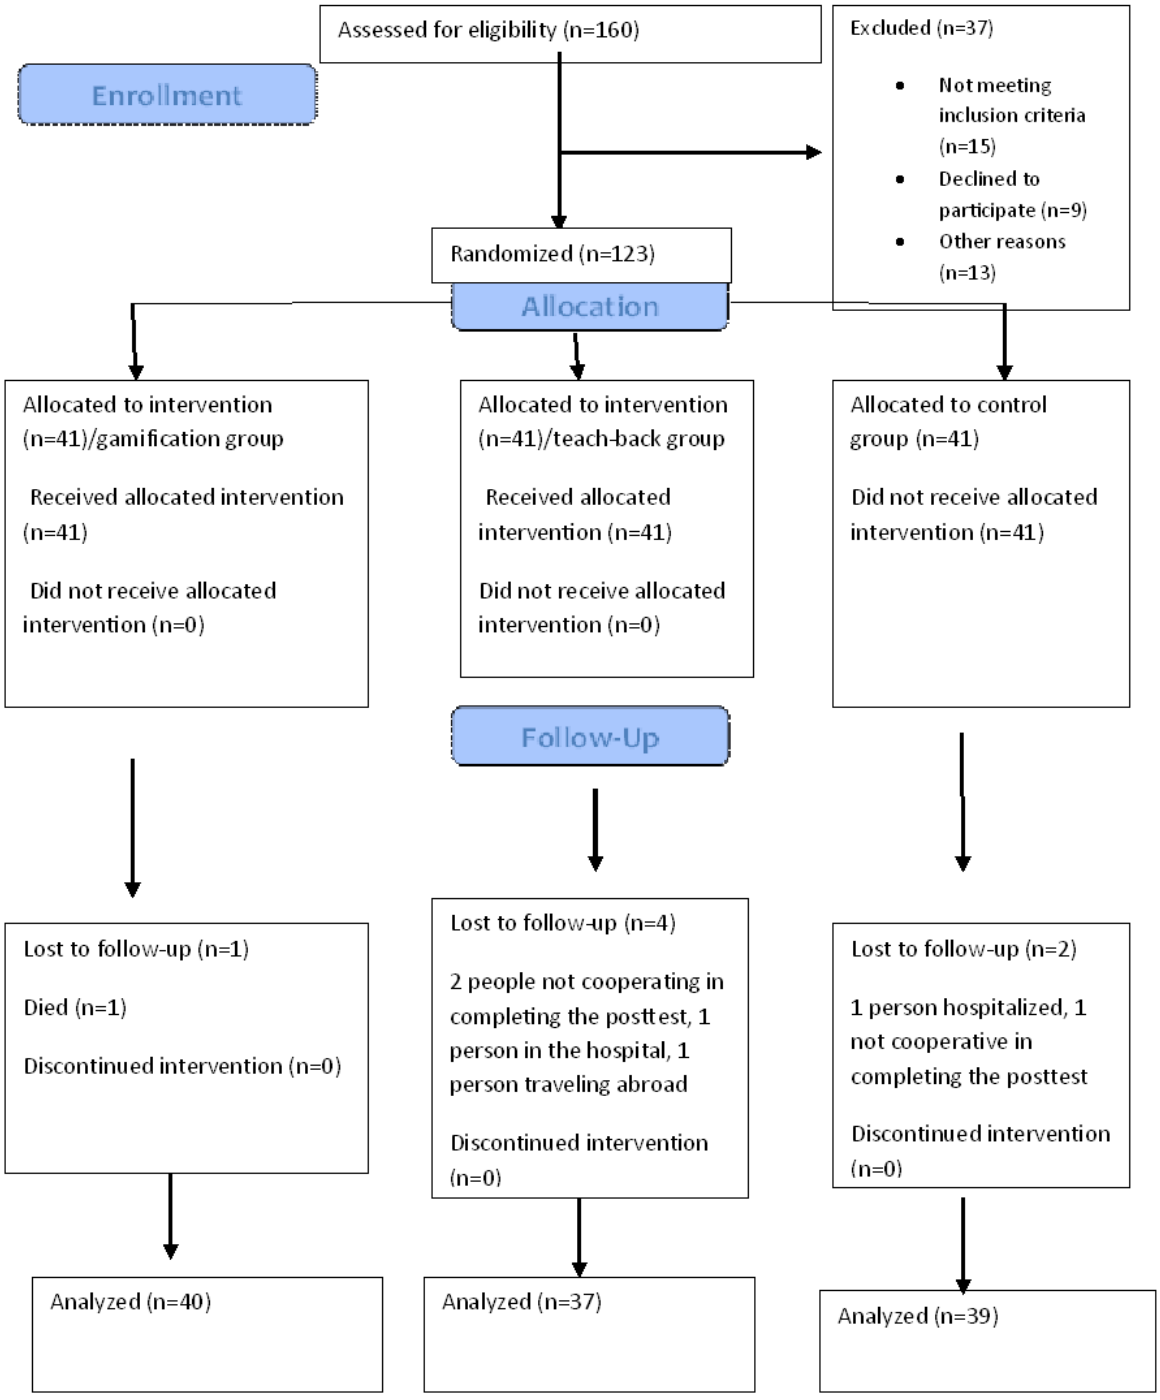
Section 4

Includes scoring and assessment. The patient's assessment section answers the questions considered. The correct answer receives 6 stars (reward, motivation), and the screen of the phone is full of stars (excitement), with progression to the next step. In the case of a false answer, 3 stars are deducted from the total score (punishment), and the same step is continued until the answer is correct. For a false answer, a sound (eg, a ding) is made. The patient sees the sum of their scores and those of other patients on the home screen. The patient also sees their score chart relative to the those of others, which motivates them to learn more in comparison to others.

For patients in the teach-back group, after obtaining informed consent and completing the pretest questionnaire, training was presented in the following steps by the researcher: (1) training information in a simple and understandable language without medical terminology, (2) expressing information in the language of the patient without embarrassment, (3) correcting the patient's misunderstanding, (4) re-asking the patient to make sure the patient was aware of any error, and (5) checking the patient's correct understanding. The duration of training varied from 45 min to a maximum of 60 min, depending on the patient's physical and mental condition. In addition, training was provided individually and outside of the inpatient ward, in a separate room, to prevent data transfer to other patients. In addition, a training booklet was given to patients in the teach-back group in order to access information within a 30-day period. Finally, 30 days later, the questionnaire was recompleted by visiting the patient at home, in person. It should be noted that the educational content of both groups was identical.

In the control group, no training was provided by the researcher, and the group received only the usual training given by the ward nurse. The questionnaire was completed by the patients before discharge and then 30 days later during a home visit (Figure 2).

Figure 2. Consolidated Standards of Reporting Trials (CONSORT) flow diagram of this study.



Data Collection Tools

Prior to training, each patient completed an informed consent form, a demographic questionnaire, a questionnaire on adherence to a therapeutic regimen (physical activity and dietary regimen) designed by Sanaie et al [25], and an adherence scale.

The demographic questionnaire included information about age, sex, education, and source of information about the study. In addition, the patient's health record was referred to obtain details on medical history, past surgery, and type of medication. The questionnaire on adherence to a therapeutic regimen designed by Sanaie et al [25] consists of two sections. The first part contains 30 questions about the patient's dietary regimen (consumption of salt, fat, meat, dairy, etc). Options (4-point Likert scale) are divided into the number of uses per week, with a total score of 100 points per question. Finally, the total adherence rate of the dietary regimen, where 100% represents a total score of 3000, is decided as follows: <50% of the total

score (<1500), undesired adherence; 50%-75% of the total score (1500-2250), relatively desired adherence; and >75% of the total score (>2250), desired adherence.

The second part includes 19 questions about the patient's movement regimen (eg, walking, breathing exercises, and spirometer). The options are scored from never to always (0 to 110) using a 5-point Likert scale. The total adherence rate of the physical activity regimen, where 100% represents a total score of 1900, is considered as follows: <50% of the total score (<950), undesired adherence; 50%-75% of the total score (950-1425), relatively desired adherence; and >75% of the total score (>1425), desired adherence. The reliability of the questionnaire was measured by the Cronbach alpha value (α=.81).

To confirm content validity, the questionnaire was presented to 10 faculty members of the School of Nursing and Midwifery, Tehran University of Medical Sciences, in addition to a nutritionist, a physiotherapist, a sports medicine specialist, a cardiologist, and an interventional cardiologist. After collecting their comments, corrective and suggested comments were applied.

The MMAS has 7 yes/no options (yes=0 and no=1) and 1 5-point Likert scale (never=0, rarely =1, sometimes=2, often =3, almost always=4). A score of 6 and higher is considered to represent the desired level of adherence to the therapeutic regimen. The MMAS has been translated into Persian by the corresponding author and coauthors, and its validity and reliability (Cronbach α=.82) confirmed [26].

Statistical Analysis

Data were analyzed with SPSS Statistics version 20 (IBM) and STATA version 12 (StataCorp) using the Fisher exact test, chi-square test, independent t-test, analysis of variance (ANOVA), and Dunnett test.

Ethical Considerations

This study was approved by the ethics committee of the Tehran University of Medical Sciences, with the code of ethics IR.TUMS.FNM.REC.1398.029, and registered on the database of the Iranian Registry of Clinical Trials (IRCT), with the code IRCT20111203008286N8. Prior to the intervention, the patients signed written informed consent. At the end of the study, the educational content was provided to the control group.

Results

The results of this study showed that 64.68% of the samples in the gamification group, 51.35% in the teach-back group, and 62.66% in the control group were male. Other demographic characteristics of the patients are listed in Table 1.

In addition, the results of this study showed that the mean (SD) scores of dietary and movement regimen adherence were higher in the gamification group than in the other two groups (Table 2).

[c]COPD: chronic obstructive pulmonary disease.

Table 2. Comparison of mean (SD) scores of dietary and movement regimen adherence in the study groups.

Study group	Mean (SD)	95% CI[a]
Diet regimen		
Control	–0.7639 (0.5200)	(–0.9885, –0.5393)
Gamification	1.033 (0.655)	(0.815, 1.251)
Teaching	–0.347(0.700)	(–0.575, –0.119)
Movement regimen (physical activity)		
Control	–0.9095 (0.3253)	(–1.0961, –0.7229)
Gamification	1.104 (0.653)	(0.923, 1.285)
Teaching	–0.2745 (0.5270)	(–0.4641, –0.0848)
Medication regimen		
Control	–0.398 (0.679)	(–0.726, –0.071)
Gamification	0.555 (0.924)	(0.238, 0.873)
Teaching	–0.200 (1.107)	(–0.533, 0.133)

[a]CI: confidence interval.

Initially, for each outcome, the analysis was performed without dropout management and then with dropout data considered. The results of the analysis showed that no significant difference was found. The implication of these results is that dropout did not play a role in the significance level of the study results. Moreover, the one-way ANOVA test for comparing the mean scores of teach-back and gamification training methods showed that the mean normalized scores for the dietary regimen (P<.001, F=71.80), movement regimen (P<.001, F=124.53), and medication regimen (P<.001, F=9.66) before and after the intervention were significantly different between teach-back, gamification, and control groups. After the heterogeneity of these scores was determined, the Dunnett test was used to compare teach-back and gamification groups with the control group. In addition, in the dietary and movement regimen adherence, there was no overlap in the gamification method with the teach-back method due to the confidence intervals (CIs) of the mean difference with the control group, which indicates that the gamification approach performs significantly better than the teach-back method (Table 3). In the adherence to the therapeutic regimen, the CIs of the mean difference with the control group overlapped in the gamification approach (0.438, 1.469) and the teach-back approach (-0.330, 0.727), which shows that the gamification approach is not significantly different from the teach-back approach (Figure 3).

Table 3. Dunnett simultaneous tests for level mean–control mean.

Difference of levels	Mean difference[a]	SE[b] of difference	95% CI[c]	*P* value
Diet regimen				
Gamification-control	1.797	0.157	(1.443, 2.151)	<.001
Teaching-control	0.417	0.161	(0.055, 0.779)	.021
Movement regimen (physical activity)				
Gamification-control	2.013	0.131	(1.719, 2.307)	<.001
Teaching-control	0.635	0.134	(0.334, 0.936)	<.001
Medication regimen				
Gamification-control	0.954	0.230	(0.438, 1.469)	<.001
Teaching-control	0.199	0.235	(-0.330, 0.727)	.61

[a]Individual confidence level=97.29%.

Discussion

Principal Findings

This clinical trial was conducted in 2019 with the aim of determining and comparing the effects of gamification and teach-back training methods on adherence to a therapeutic regimen by patients after CABGS. The study found that the gamification training method performs better than the teach-back training method in dietary and movement regimen adherence, but there was no statistically significant difference in adherence to a medication regimen between the two groups. In addition, sensitivity analysis results showed that the dropout did not play a significant role in the significance level of the study results.

A study by Ghanbari et al [27] on the effect of an educational program based on the teach-back method on adherence to a treatment regimen in patients with end-stage renal disease on dialysis showed that the mean score of treatment adherence in 3 areas of hemodialysis, namely drug therapy, fluid restriction, and dietary regimen, in the intervention group in both the posttest (7 days after intervention) and follow-up (30 days after intervention) was significantly higher than in the control group (P<0.01) [27]. In this study, the use of a teach-back training method in relation to movement and dietary regimens showed adherence to the therapeutic regimen, a finding that is in line with Ghanbari et al [27]. However, the use of the teach-back training method in relation to adherence to the medication regimen is inconsistent with their findings. The inconsistency between the results of Ghanbari et al [27] and this study may be due to a longer period of treatment and the periodic nature of hemodialysis compared with open heart surgery and the repetition of teaching during hemodialysis treatment, thus producing a more positive result. In addition, since the medication regimen is such an important pillar of treatment adherence in patients on hemodialysis, more attention may be paid to this area of treatment in patient education using additional information resources, including other patients and treatment staff. Dalir et al's [28] study of the effect of a teach-back intervention aimed at improving self-care in 62 patients with heart failure found that the teach-back training method is effective in improving self-care (P<0.001) [28]. Our study was able to show improvements in relation to movement and diet; however, it did not have the same positive result on the medication regimen that was demonstrated by Dalir et al [28]. The lack of effectiveness in relation to medication adherence in this study may be attributed to the duration of the training. In the Dalir et al [28] study, the patients were taught over 3-4 days, while in this study, the training was presented in a single 45-60-min session. Other studies have also shown the benefits of longer periods of patient education using teach-back training methods. These include White et. al's [29] study of patients with heart failure, whose education occurred over a 13-month period when hospitalized.

Finally, in relation to previous research on gamification effects, Allam et al' [30] RCT on the effect of social support features and gamification on a web-based intervention for patients with rheumatoid arthritis found that physical activity increased in patients in the intervention group who had access to gamification and social support. The use of health care decreased for patients who received social support and for those who received social support and gamification. The study showed that the use of gamification alone or in conjunction with website intervention increases physical activity as well [30]. These significant differences in relation to physical activity using the gamification approach are consistent with our study, as are design elements such as the use of game elements to create excitement and motivation and the awarding of prizes to the "winning" patients.

Limitations

We had to rely on the patients' self-report on exercising at home and following the dietary and medication regimens. In addition, the patients did not record the number of games and browse the application. The app did not include the feature to send reminders and the ability for patients to interact with it. We suggest further studies with a larger sample size and an interactive app with the ability to record usage and to send reminders. In addition, it is recommended that studies be

performed in the presence of active family member inpatient care using these approaches.

Conclusion

Using a game-based smartphone app as a support program to educate patients can affect the patients' adherence to their therapeutic regimen. In addition, with this program, the patients can access the training on their smartphones at any time and place and can repeat the instructions, if necessary. The combination of game elements and patient education together can lead to a better, more engaging learning experience, faster feedback, and more readily available reminders of educational content. However, according to social factor theory, the social signs in multimedia messages (eg, the presentation of an educational agent along with a human voice) causes learners to consider computer-centered learning environments as discourse environments. Signs that speak in the form of a friendly factor on the monitor screen with a human voice and movements increase the ability to transmit positively. The theory of social mediation suggests that bringing verbal (eg, spoken words) and nonverbal (eg, gestures, gaze, and movement) social cues into multimedia environments can simulate human-to-human communication, facilitating engagement of learners in the learning process. According to this theory, by combining a multimedia learning environment and a moving factor as a visual and verbal social symbol, virtual communication between that factor and learners becomes a suitable alternative for human interactions. This study showed that the use of new technology-based approaches can replace previous educational methods. Therefore, by using this method, the process of educating patients can be made more up to date and more attractive by making optimal use of smartphones. Based on the positive results of this study, the teach-back training method is a strategy that can used to increase patients' understanding and is widely accepted by health care organizations as an effective way to communicate information. Easy access, low cost, and the interactive nature of this method are other notable benefits. Training ends when the patient reaches an acceptable level of understanding of the subject. The teach-back approach can be considered an effective and alternative training method instead of traditional ones, such as pamphlets and booklets.

Acknowledgments

This study has been registered with the Nursing and Midwifery Care Research Center (NMCRC), School of Nursing and Midwifery, Tehran University of Medical Sciences (98-01-99-41601) with the code of ethics IR.TUMS.FNM.REC.1398.029. FB expresses his gratitude to this center and the patients participating in this study.

Authors' Contributions

This outcome study was mainly developed by BGH, FBH, ACJ, and FSH. The first draft of the manuscript was written by FB, BGH, ZM, and MN. All the authors confirmed the final draft of the manuscript. The statistical analysis was mainly conducted by FSH and MN. All the authors contributed to the design of the clinical study or the critical revision of the manuscript.

Abstract

Background: Mobile health applications are being increasingly used for people's health management. The different uses of mobile health applications lead to different health outcomes. Although active usage of mobile health applications is shown to be linked to the effectiveness of mobile health services, the factors that influence people's active usage of mobile health applications are not well studied.

Objective: This paper aims to examine the antecedents of active usage of mobile health applications.

Methods: Grounded on the 3-factor theory, we proposed 10 attributes of mobile health applications that influence the active usage of mobile health applications through consumers' satisfaction and dissatisfaction. We classified these 10 attributes into 3 categories (ie, excitement attributes, performance attributes, and basic attributes). Using the survey method, 494 valid responses were collected and analyzed using structural equation modeling.

Results: Our analysis results revealed that both consumer satisfaction (β=0.351, *t*=6.299, *P*<.001) and dissatisfaction (β=–0.251, *t*=5.119, *P*<.001) significantly influenced active usage. With regard to the effect of attributes, excitement attributes (β=0.525, *t*=12.861, *P*<.001) and performance attributes (β=0.297, *t*=6.508, *P*<.001) positively influenced consumer satisfaction, while performance attributes (β=–0.231, *t*=3.729, *P*<.001) and basic attributes (β=–0.412, *t*=7.132, *P*<.001) negatively influenced consumer dissatisfaction. The results of the analysis confirmed our proposed hypotheses.

Conclusions: Our study provides a novel perspective to study the active usage of mobile health applications. By categorizing the attributes of mobile health applications into 3 categories, the differential effects of different attributes can be tested. Meanwhile, consumer satisfaction and dissatisfaction are confirmed to be independent from each other.

Introduction

Background

With the introduction of smartphone devices in the world, mobile health applications are being increasingly used by consumers. By 2019, more than 2.5 billion people owned smartphones worldwide [1], while more than 50% of them had installed mobile health applications in their smartphones by 2017 [2]. The total market size of mobile health applications worldwide was forecasted to reach nearly US $100 billion in 2021 [3]. In the United States, more than 60% of patients use mobile health applications and other digital devices to manage their health [4], while in China, the number of active users of the most popular mobile health applications was over 10.5 million in January 2020 [5]. The most common mobile health applications were related to the weather, fitness, and nutrition in the United States [6] and healthy living information,

measuring/recording of vital signs, and health and medical reminders in China by 2017 [7]. Therefore, mobile health applications have become an important component of individual health management.

Mobile health applications are internet-based applications in mobile devices to support medical and health activities [8]. Generally, mobile health applications provide functions to monitor consumers' health status, record consumers' health-related data, provide medical references, and assist in medical decision making [9]. Mobile health has been shown to affect consumers' health behaviors, including physical activity, diet, alcohol, sexual behavior, and medication adherence [10]. Meanwhile, mobile health has been used to help manage health conditions, including diabetes, asthma, depression, hearing loss, anemia, and migraine [11]. However, the market of mobile health applications is still developing, even with their recognized benefits [12]. In addition to the effect of mobile health applications on people's health status, the usage of mobile health applications affects the success of mobile health services [13].

According to usage status, mobile health application usage could be classified into active and passive. Active usage refers to consumers' high engagement and complete usage of mobile health applications, while passive usage is the occasional and limited use of mobile health applications [14]. Compared with passive usage, active usage of mobile health applications not only uses different functions, such as posting and updating personal information or using nontraditional functions, but also has different antecedents. Since active usage of mobile health applications is linked to the effectiveness of mobile health services, including improving psychological flexibility [15], promoting the maintenance of health-related changes [16], and improving wellness [17], it is meaningful to study the active usage of mobile health applications.

The previous literature has studied the adoption or use of mobile health applications or services based on information system acceptance theories, such as the technology acceptance model (TAM), the theory of reasoned action (TRA), the theory of planned behavior (TPB), and the unified theory of acceptance and use of technology (UTAUT). For example, Hoque and Sorwar [18] extended UTAUT by incorporating technology anxiety and resistance to change in the study of mobile health adoption among older adults and found that only facilitating conditions do not have a significant effect. Alam et al [19] extended UTAUT with perceived reliability and price value and considered gender's moderating role to study mobile health adoption and found that effort expectancy and price value do not influence adoption intention. A comprehensive literature review of mobile health adoption and usage is presented in Multimedia Appendix 1. However, few previous studies have considered the impact of mobile health application attributes and examined the factors that influence the active usage of mobile health applications. Since few prior studies on mobile health applications have examined active usage, we also consider the literature on active use or usage in other contexts. For example, Wu et al [20] studied the active usage of mobile instant messaging applications from an attachment perspective and categorized the predictors into 3 aspects: symbolism, aesthetics, and necessity. Davenport et al [21] found that narcissism is significantly related to active usage in college students but not in adults. A comprehensive literature review of active usage of information systems is presented in Multimedia Appendix 2. Although the previous literature has found several predictors of active usage, none of the predictors reflect the context of mobile health. Considering the importance of active usage of mobile health applications, this study seeks to understand and address the specific research question *What factors influence the active usage of mobile health applications?* Accordingly, we ground our research on the 3-factor theory and propose that consumer satisfaction and dissatisfaction could serve as the mechanisms of the effect of the factors on the active usage of mobile health applications. With regard to the factors, we mainly focus on the attributes of mobile health applications.

By addressing this research question, our study makes 3 important contributions: (1) We explore the factors of active usage of mobile health applications, which has largely been understudied; (2) we categorize and link the attributes to the active usage of mobile health applications based on the 3-factor theory; and (3) we extend and validate the 3-factor theory in the context of mobile health. The rest of the paper is organized as follows: In the next section, we review the literature on the 3-factor theory and consumer satisfaction/dissatisfaction, followed by our model and hypotheses. The subsequent section provides the research methodology and data analysis. Next, the results of the analysis and implications of our study for research and practice are discussed. We conclude with the limitations of this study and avenues for future research in the last section.

Theoretical Background

In this study, the 3-factor theory was used as the overarching theory to construct the research model. Meanwhile, we discuss the theoretical background of satisfaction and dissatisfaction in this section.

3-Factor Theory

The 3-factor theory is the extension of the 2-factor theory, originally proposed to explain job satisfaction in an organizational context [22]. However, the 2-factor theory was criticized for its oversimplification of influential factor categories and no context consideration [23]. Kano et al [24] refined the 2-factor theory and formulated the 3-factor theory to categorize product qualities into 3 factors that meet consumers' needs. The 3 factors are termed as basic factors, excitement factors, and performance factors, aggregating 5 attributes of quality. In Kano's model, basic factors correspond to hygiene factors in the 2-factor theory and represent consumers' basic requirements, which do not affect satisfaction. Excitement factors correspond to motivation factors, which cause excitement but do not cause dissatisfaction when not present. The third category, termed "performance factors," lies between basic and excitement factors, which cause satisfaction when present and dissatisfaction when not present.

The 3-factor theory has been widely applied in different contexts. In the previous literature, the 3-factor theory has been used to categorize online shopping website design attributes [25], test information systems qualities [26], and sort telecom service attributes [27]. Therefore, previous studies have

demonstrated the validity and power of the 3-factor theory in examining the factors influencing usage and adoption and can provide a comprehensive understanding of the antecedents of mobile health application usage.

Consumer Satisfaction and Dissatisfaction

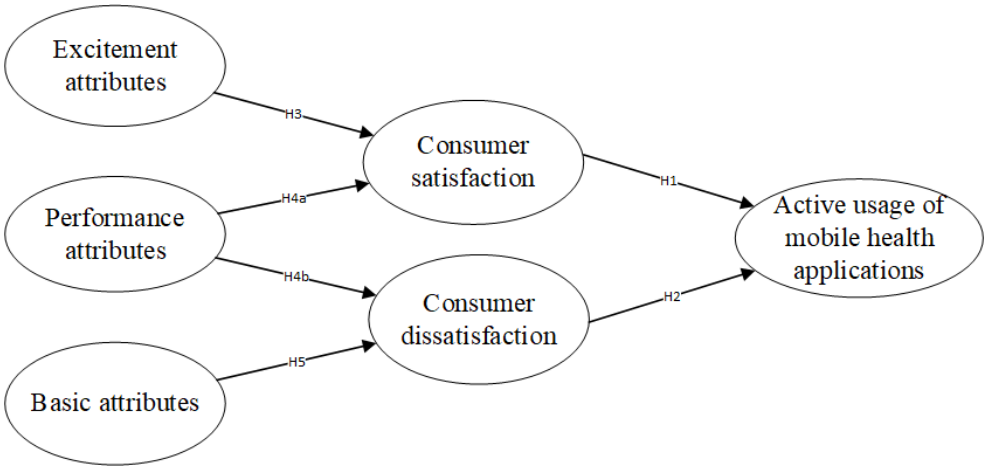
With regard to the relationship between consumer satisfaction and dissatisfaction, previous research has proposed 2 distinct views of the dimensionality of consumer satisfaction [21,28,29]. One view assumes that consumer satisfaction is unidimensional. Thus, consumer satisfaction and dissatisfaction are the 2 ends on a continuum. Another view postulates that consumer satisfaction is bidimensional. Therefore, consumer satisfaction and dissatisfaction are 2 independent constructs. In this study, we argue that consumer satisfaction and dissatisfaction are 2 separate constructs that follow a bidimensional view. The reason consumer satisfaction is not just opposite to consumer dissatisfaction in the current context is that consumer satisfaction and consumer dissatisfaction may also be caused by different factors, which are suggested by the 3-factor theory [23]. Some of the antecedent factors have a significant effect on consumer satisfaction but do not affect consumer dissatisfaction. Meanwhile, consumers' satisfaction levels may not correspond to their dissatisfaction levels. Therefore, consumer satisfaction and dissatisfaction could coexist at the same time [27].

The previous literature also provides evidence that consumer satisfaction is bidimensional. Babin and Griffin [30] demonstrated that the 2-factor model of satisfaction and dissatisfaction could have an acceptable goodness of fit, which indicates that satisfaction and dissatisfaction are distinct. Chen et al [27] found that consumer satisfaction and consumer dissatisfaction have within-construct convergence and between-construct discriminant validities. Kim et al [31] found that factors linked to satisfaction and dissatisfaction of full-service hotels are distinct. Therefore, it is feasible to apply a bidimensional view of consumer satisfaction in our study.

Research Model and Hypothesis Development

According to the 3-factor theory, we proposed that the attributes of mobile health applications will result in satisfaction or dissatisfaction with the applications. Such satisfaction and dissatisfaction may lead to active usage of mobile health applications. Meanwhile, we classified the attributes of mobile health applications into basic attributes, excitement attributes, and performance attributes. The research model is presented in Figure 1.

Figure 1. Research model.



Effect of Consumer Satisfaction and Dissatisfaction

According to the process view, consumer satisfaction refers to the assessment of whether the actual performance of a product or service conforms to one's expectations [32,33]. When the actual performance of a product or service matches or goes beyond consumers' expectations, they feel satisfied. Once they feel satisfied, they improve their attitudes toward the product or service [34,35], engage in positive word-of-mouth activities [36], and increase commitment [37].

Since active usage of mobile health applications can be a reflection of a strong commitment to the relationship between consumers and mobile health applications [38], it could be considered the behavioral representation of consumer engagement in using mobile health applications. Therefore, when consumers feel satisfied using a mobile health application, they will commit and engage in using that mobile health application. Hence, we hypothesize:

> *Hypothesis 1 (H1): Consumer satisfaction positively affects consumers' active usage of mobile health applications.*

Consumer dissatisfaction reflects a consumer's evaluation process during nonconformation of the consumer's expectations and the actual performance of products or services [39]. The previous literature reveals that consumer dissatisfaction might lead to negative behaviors, such as switching [40], complaining [41], or participating in negative word-of-mouth communication [36]. Nonconformity between consumers' expectations and the actual performance of mobile health applications result in negative emotions, such as regret and disappointment [42]. Such negative emotions may only lead to poor commitment of the consumer at best toward using mobile health applications. Hence, we hypothesize:

> *H2: Consumer dissatisfaction negatively affects consumers' active usage of mobile health applications.*

Attributes of Mobile Health Applications

To identify the attributes that influence consumers' active usage of mobile health applications, we conducted interviews as well as a thorough literature review. First, we conducted open-ended interviews with 50 mobile health application users in China by asking them questions such as *Which attributes of mobile health applications influence you to use them actively?* We recorded the responses regarding satisfaction/dissatisfaction in the form of keywords and short sentences. Two PhD students then conducted the content analysis of the recorded responses to identify the items that may reflect the attributes of mobile health applications. Disagreements between them were resolved through discussion. Second, we screened the literature on mobile health adoption to identify possible attributes and established an attribute pool by combining the attributes from the interviews and our thorough literature review. We then selected attributes based on whether they were applicable in mobile health applications. The definitions of the attributes and their sources are summarized in Table 1. Finally, we divided the attributes into 3 categories based on the 3-factor theory.

Table 1. Summary of mobile health applications' attributes.

Number	Attribute	Definition	Source
1	Design aesthetics	The degree of attractiveness or beauty of a mobile health application's interface	Lavie and Tractinsky [43]
2	Customization	The degree to which mobile health application providers tailor their products for different consumers	Srinivasan et al [44]
3	Enjoyment	The degree of fun or pleasure consumers get from using mobile health applications	Van der Heijden [45]
4	Mobility	The degree to which consumers can use mobile health applications regardless of location and time	Hong et al [46]
5	Sociability	The extent to which mobile health applications support social interaction between consumers	Preece [47]
6	Informational support	The degree to which mobile health applications provide information for solving consumers' health concerns	Liang et al [48]
7	Emotional support	The degree to which doctors and other consumers convey their care and understanding to consumers through mobile health applications	Liang et al [48]
8	Perceived security	The extent of security of consumers' private and sensitive information in using mobile health applications	Chang and Chen [49]
9	Technical functionality	Consumers' assessment of mobile health application accessibility, stability, response time, and operation	Ou and Sia [25]
10	Information quality	Consumers' assessment of the accuracy, relevance, and timeliness of information generated by mobile health applications	Delone and Mclean [50]

Combining the definitions of specific attributes with the definitions of the 3 categories, we could categorize the identified attributes into those 3 categories. According to the 3-factor theory, excitement and performance attributes would cause consumer satisfaction, while performance and basic attributes would drive consumer dissatisfaction. With the presence of different attributes, consumer satisfaction and dissatisfaction may coexist. To be specific, we categorized design aesthetics, customization, and enjoyment as excitement attributes because the 3 specific attributes are not the primary concern of consumers but bring additional value to them. Next, we categorized sociability, informational support, and emotional support as performance attributes because these specific attributes can facilitate consumer interaction and communication with health professionals, which are consumers' main purposes of using mobile health applications. Finally, we categorized mobility, perceived security, technical functionality, and information quality as basic attributes because these specific attributes are the basic requirements of any mobile application [51]. This categorization was also preliminarily confirmed by using a card-sorting method [52]. In this study, we treated excitement, performance, and basic attributes as second-order formative constructs that contain the attributes proposed by us and confirmed by the card-sorting method. The relationship between the attributes and consumer satisfaction/dissatisfaction is specified next.

With regard to excitement attributes, design aesthetics, such as the choice of color, shape, or layout of mobile health applications, decide consumers' aesthetics [43]. Meanwhile, design aesthetics can fulfill people's needs for aesthetics in using mobile health applications [53]. Therefore, design aesthetics may influence consumers' satisfaction from using mobile health applications. Customization increases consumers' perceived control toward a mobile health application and signals the quality of the mobile health application [54]. The perceived control and high quality of mobile health applications can influence consumers' satisfaction from using the mobile health applications. With regard to enjoyment, providing consumers with an enjoyable experience is critical for influencing their perception of mobile health applications [45]. Enjoyment in using a mobile health application would be an intrinsic motivation for consumers in using the mobile health application [55]. Therefore, enjoyment reflects the satisfaction of consumers' intrinsic motivation. Hence, we hypothesize:

> *H3: Excitement attributes, which are characterized by design aesthetics, customization, and enjoyment, positively affect consumers' satisfaction.*

With regard to performance attributes, mobile health applications integrate various forms and functions to support the communication and interaction among consumers [47]. Facilitating interaction between health professionals and consumers produces a flow experience in using mobile health applications and increases consumers' satisfaction from using mobile health applications [56]. If mobile health applications cannot facilitate interaction, a consumer may be dissatisfied. Therefore, sociability may lead to satisfaction if mobile health applications have this attribute and dissatisfaction if mobile health applications do not have it. Meanwhile, informational support and emotional support are both dimensions of social support. Health information from mobile health applications could satisfy consumers' needs to deal with their health problems. In contrast, emotional support from doctors and other consumers using mobile health applications might provide emotional support and meet consumers' emotional needs [57]. If mobile health applications cannot afford informational support and emotional support, consumers' health needs may not be satisfied and the evoked negative emotions may make them feel dissatisfied with using mobile health applications. Summarizing the reasonings above, we hypothesize:

H4a: Performance attributes, which are characterized by sociability, informational support, and emotional support, positively affect consumer satisfaction.

H4b: Performance attributes, which are characterized by sociability, informational support, and emotional support, negatively affect consumer dissatisfaction.

With regard to mobility, a basic attribute, which enables consumers to use mobile health applications anywhere and anytime, does not just belong to mobile health applications but also to mobile devices [58]. Given that mobility is shared by other applications on mobile devices [59], it could be considered the basic factor behind using mobile health applications. Therefore, mobility may lead to dissatisfaction if mobile health applications do not have this attribute. Perceived security is 1 of the key drivers for building trust to use any IT [49]. Although some mobile health applications do not integrate mobile shopping functions, and consumers do not suffer any monetary loss, consumers' private information may still be subject to unauthorized access, use, storage, or transmission. Consumers may require application providers to ensure the security of their private information in using mobile health applications. Therefore, perceived security is the basic attribute that may only affect consumers' dissatisfaction. With regard to technical functionality, the technical functions of mobile health applications, such as response speed, stability, and accessibility, may define consumers' usage experience [60], but these functions are not only specific to mobile health applications but also crucial for other IT artifacts. Therefore, technical functionality is a basic attribute and may only influence consumer dissatisfaction if this attribute does not perform well. Regarding information quality, the 3 main aspects that define it are relevance, timeliness, and accuracy of the transmitted information [61]. The quality of communication from using a mobile health application depends upon the quality of information that is transmitted through the mobile health application [62]. Therefore, information quality also serves as the basic condition to complete the main purposes of using mobile health applications and leads to consumer dissatisfaction if it is absent. Hence, we hypothesize:

H5: Basic attributes, which are characterized by mobility, perceived security, technical functionality, and information quality, negatively affect consumer dissatisfaction.

Methods

Measurement Instrument

The survey method was used in this study to validate our proposed research model. The measurement instrument was developed by adapting previously validated scales. The constructs and items sources are presented in Table 2. All items were measured on a 7-point Likert scale with anchors ranging from 1=strongly disagree to 7=strongly agree. In addition, our study included several control variables that measured consumers' characteristics, such as age, gender, education, length, and frequency of using mobile health applications. The length of using mobile health applications reflects how long users have been using mobile health applications, while the frequency of using mobile health applications indicates how many times users use mobile health applications per day.

Table 2. Instrument sources.

Construct	Source
Active usage	Pagani and Mirabello [63]
Satisfaction	Taylor and Baker [64]
Dissatisfaction	Babin and Griffin [30]
Design aesthetics	Lavie and Tractinsky [43]
Customization	Srinivasan et al [44]
Enjoyment	Sun and Zhang [65]
Sociability	Animesh et al [56]
Mobility	Hong et al [46]
Informational support	Liang et al [48]
Emotional support	Liang et al [48]
Information quality	Ou and Sia [25]
Technical functionality	Ou and Sia [25]
perceived security	Cheung and Lee [66]

Since this study was conducted in China and the respondents were primarily Chinese, we translated the survey into Chinese using the back-translation method. The English instrument was first translated into Chinese by 1 bilingual author. Next, another bilingual author back-translated the Chinese version into English. The 2 authors then compared the 2 English versions for inconsistencies. Next, 8 experts of health information systems and 16 users of mobile applications were interviewed to identify ambiguous or repetitive items and suggestions obtained to improve the quality of the survey instrument. Finally, we revised the questionnaire according to the comments and suggestions received. The details of the survey instrument are presented in Multimedia Appendix 3.

Data Collection

The data were collected in China, which is 1 of the largest mobile markets in the world [67]. The online survey was conducted by using a paid service from a popular web survey company in China. The institutional review board of Tongji Medical College, Huazhong University of Science and Technology, China, approved our study procedures (no. 2017S319). Through a 3 weeks' survey in May 2020, we sent the questionnaire to 782 users of Chinese mobile health application users through the online survey company randomly in their users' pool and obtained a total of 674 responses. Therefore, the response rate of our survey was 86.2%.

Given we used an online survey, possible issues, including convenience sample, superrespondents, abnormal respondents, or common method bias, might have existed. By following the guidelines of online surveys, we took several actions that are recommended to ensure data quality [68]. First, our choice of a paid service of online survey company could deal with the issue of a convenience sample since the company has users with diverse backgrounds in different areas. Second, we set screening questions to ask whether the respondents were actual mobile health application users, eliminating respondents who may have produced irrelevant responses. The screening questions included *Do you have mobile health applications in your smartphone or tablet?How many mobile health applications have you installed on your smartphone or tablet?* Actual users could be identified by checking whether they were using mobile health applications according to their answers to these screening questions. Third, to address the issue of superrespondents who were good at filling online questionnaires, we eliminated responses with an unreasonably short time (less than 5 minutes) to finish the questionnaire. Fourth, we eliminated responses where respondents did not correctly answer reverse-coded and attention-trap questions and gave too many same answers for all questions (more than 90%) in order to eliminate haphazard responses. A reverse-coded question is negative worded, and its score needs to be reversed for further data analysis, while an attention-trap question is easy to be answered with only 1 correct option. Finally, we conducted procedural remedies to deal with the common method bias, including randomizing items and using different response formats [57].

After cleaning the collected data, we were left with 494 complete and valid responses. In this sample, most of the respondents were in the age group of 18-30 years, were female (280/494, 56.7%), possessed a college degree, and were familiar with mobile health applications. The demographic distribution of the sample in our study is consistent with the China Internet Network Information Center report of the national profile of mobile internet users [69]. The specific demographic information of our final sample is summarized in Table 3.

Table 3. Demographic information (N=494).

Characteristics	n (%)
Age (years)	
18-25	151 (30.6)
25-30	222 (44.9)
>30	121 (24.5)
Gender	
Male	214 (43.3)
Female	280 (56.7)
Education	
High school	14 (2.8)
College	414 (83.8)
Master degree and above	66 (13.4)
Length of using mobile health applications (years)	
<1	11 (2.3)
1-3	222 (44.9)
>3	261 (52.8)
Frequency of using mobile health applications	
Almost 1 time/day	22 (4.5)
1-10 times/day	280 (56.7)
>10 times/day	192 (38.8)

Data Analysis

This study used partial least squares (PLS), a technique of structural equation modeling, to analyze the data. PLS is a second-generation multivariate causal analysis method and can analyze complex structural equation models [70]. PLS can also be applied in exploratory studies and aims at theory building rather than theory testing. In addition, PLS can model constructs with either formative or reflective indicators. The analysis was conducted using SmartPLS 2.0.3M (SmartPLS GmbH) [71]. Following the 2-stage approach suggested by Anderson and Gerbing [72], we analyzed the measurement model to test reliability and validity, followed by the analysis of a structural model to test our research model. To test reliability and validity, confirmatory factor analysis was conducted, while we implemented a bootstrapping procedure with PLS to analyze the structural model. The results of reliability and validity of our developed measurement instrument and structural model are presented in the Results section.

Results

Reliability and Validity

The indicators of reliability and validity are summarized in Tables 4-6. In Table 4, all Cronbach α and composite reliabilities are >.7, thus demonstrating reliability for all constructs. The value of the average variance extracted (AVE) of each construct was >0.5, thus demonstrating good convergent validity [73]. Based on the results in Tables 5 and 6, each item loading for its assigned construct was >0.7 and even higher for other constructs, while the square roots of the AVEs were all greater than the interconstruct correlations, thus demonstrating discriminant validity [74]. Hence, we concluded that the quality of the measurement model is adequate for testing hypothesized relationships.

Table 4. Construct reliability and convergent validity.

Construct	Composite reliability	AVE[a]	Cronbach α
Active usage	0.84	0.64	.71
Satisfaction	0.92	0.80	.88
Dissatisfaction	0.94	0.84	.91

[b]Not applicable.

We also examined the possibility of common method bias in our study. First, we investigated the correlation coefficients between variables in Table 4 and found that none of the pairs had a high correlation (r>.90) [75]. Second, we conducted the Harman single-factor test using principal component analysis in SPSS Statistics 18.0. In total, 10 factors were extracted, and the first factor in the unrotated solution explained 39.61% of the variation, which is <50% [76]. Third, we employed the marker variable technique to test common method bias [77]. Organizational commitment was chosen as the marker variable since it was theoretically unrelated to our research model. We found organizational commitment had no significant effect on the active usage of mobile health applications (β=.014, P>.05).

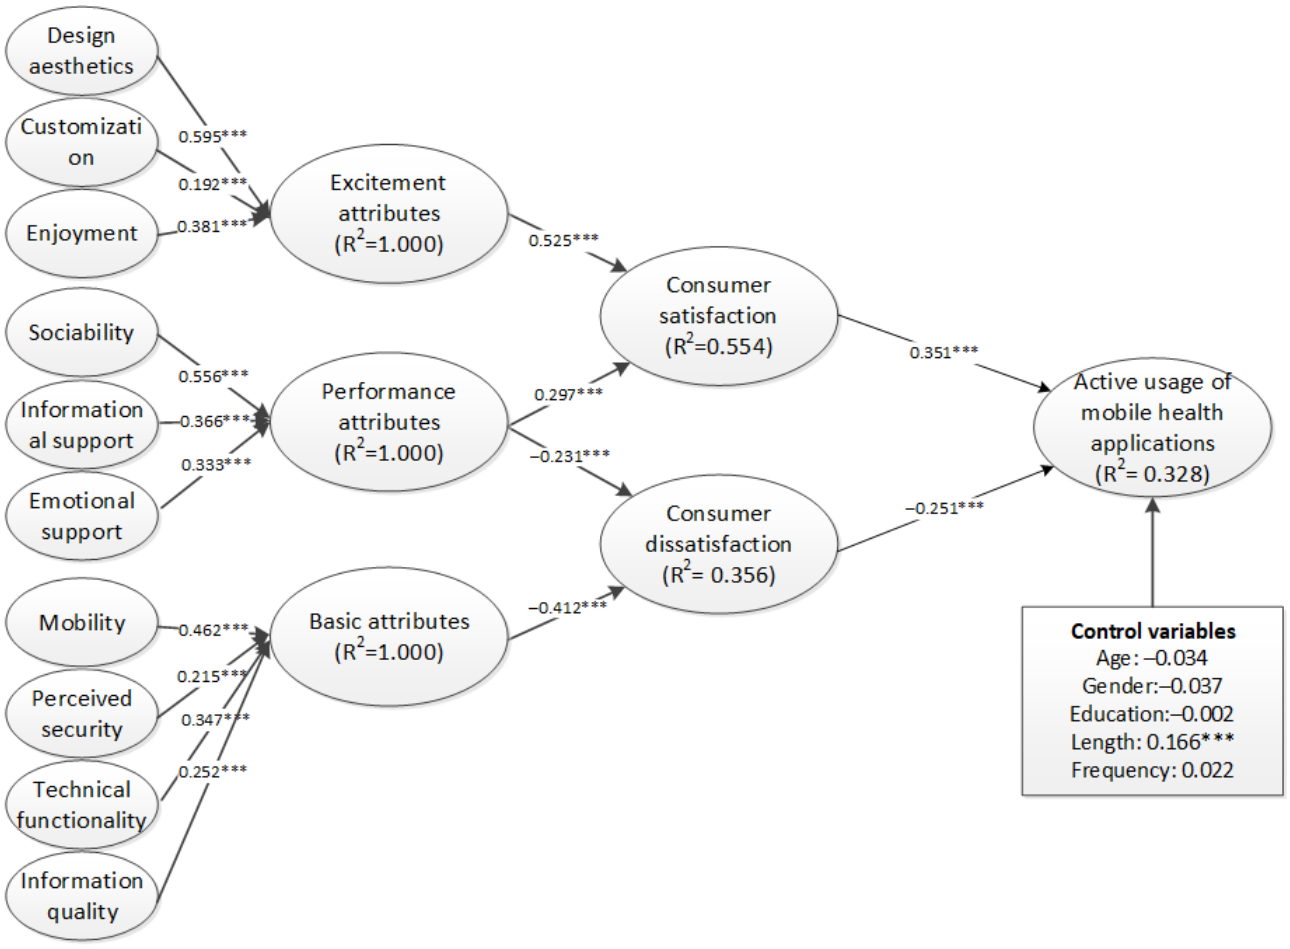
Hypotheses Testing

The descriptive statistics of variables in our research model are presented in Table 7. The results of structural model analysis are summarized in Figure 2. The results reveal that both consumer satisfaction (β=.351, t=6.299, P<.001) and dissatisfaction (β=–.251, t=5.119, P<.001) significantly influence consumers' active usage of mobile health applications, thus supporting H1 and H2. This implies that the 3-factor theory is a useful theoretical perspective for predicting consumers' active usage of mobile health applications.

Table 7. Descriptive statistics of variables.

Construct	Mean (SD)
Active usage	6.00 (0.83)
Satisfaction	5.90 (0.78)
Dissatisfaction	2.07 (0.80)
Design aesthetics	5.70 (0.86)
Customization	4.93 (1.20)
Enjoyment	5.91 (0.77)
Mobility	6.04 (0.84)
Sociability	5.95 (0.82)
Information quality	5.46 (1.06)
Informational support	6.12 (0.72)
Emotional support	6.39 (0.67)
Perceived security	5.21 (1.27)
Technical functionality	5.91 (0.81)

Figure 2. Structural model analysis results.



Note: * Significant at *P*< .05, ** Significant at *P*< .01, *** Significant at *P*< .001

As a second-order formative construct, excitement attributes (β=.525, *t*=12.861, *P*<.001) were revealed to significantly influence consumer satisfaction. Therefore, H3 is supported. Moreover, the corresponding first-order constructs, including design aesthetics, customization, and enjoyment, together comprised excitement factors. With regard to performance attributes, the results also show that they influence both consumer satisfaction (β=.297, *t*=6.508, *P*<.001) and dissatisfaction (β=–.231, *t*=3.729, *P*<.001) significantly. Therefore, H4a and H4b are supported. Meanwhile, the

corresponding first-order constructs, including sociability, informational support, and emotional support, are necessary components of performance factors. With regard to basic attributes (β=–.412, t=7.132, P<.001), which include mobility, perceived security, technical functionality, and information quality, they were found to have a significant influence over consumer dissatisfaction. Therefore, H5 is supported. These results showed that the categorization of basic factors is valid. Finally, the effect of control variables was considered. Only the length of using mobile health applications was significantly associated with active usage of mobile health applications.

Discussion

Principle Findings and Implications

In this study, we identified 10 attributes of mobile health applications that would influence people's active usage. Based on the 3-factor theory, we divided the attributes into 3 categories to correspond to 3 factors, namely excitement attributes, performance attributes, and basic attributes. Excitement and performance attributes are assumed to significantly affect consumer satisfaction, while performance and basic attributes are supposed to significantly impact consumer dissatisfaction. Both consumer satisfaction and dissatisfaction would influence active usage of mobile health applications. Excitement attributes include design aesthetics, customization, and enjoyment; performance attributes include sociability, informational support, and emotional support; and basic attributes include mobility, perceived security, technical functionality, and information quality. To validate the categorization and the effect of attributes on active usage of mobile health applications, we used the survey method and analyzed the data using the PLS technique. The empirical results confirmed our hypothesized differential effects of the 3 attributes on consumer satisfaction and dissatisfaction and then on the active usage of mobile health applications. Meanwhile, all the first-order constructs were also found to be significantly linked to their corresponding second-order constructs. Therefore, the feasibility and validity of the 3-factor theory were manifested in our study. The interestingness and uniqueness of our findings in terms of theoretical and practical implications are further discussed.

From a theoretical perspective, we made several contributions. First, we contributed to health information system usage and adoption literature by studying the active usage of mobile health applications, thus uncovering insights into the use or adoption of mobile health applications. Since most studies do not consider active usage of mobile health applications, as was done in this paper [18,19], considering the importance of active usage toward the effectiveness of mobile health applications, the results of this paper provide a better and deeper understanding of mobile health application adoption and usage.

Second, we also contributed to health information system usage and adoption literature by identifying several influential attributes of active usage of mobile health and categorizing them based on the framework of the 3-factor theory. Previous literature focuses little on the effects of attributes of mobile health applications. This study not only identifies the underlying attributes but also distinguishes the different roles of various attributes of active usage of mobile health applications based on the 3-factor theory. For example, excitement and performance attributes can drive the active usage of mobile health applications, whereas performance and basic attributes could impede the active usage of mobile health applications. Moreover, the study results also reveal a valid categorization of identified attributes.

Third, we contributed to health information system usage and adoption literature by studying the active usage of mobile health applications. Previous studies of active usage of information systems have focused on mobile instant messaging [20], social media [21], or online communities [78-80], a few of them revealing factors driving active usage of mobile health applications. Therefore, our study enriches the literature of active usage of health information systems. At the same time, our study reflects the characteristics of the active usage of mobile health applications by exploring the unique attributes that lead to active usage, such as informational support and emotional support.

Finally, we contributed to the 3-factor theory literature by extending it to the context of mobile health applications. The previous literature mainly applies the 3-factor theory in contexts such as website design or telecom service [25,27], while our study validates the feasibility of the 3-factor theory in the mobile health context. Meanwhile, based on the 3-factor theory, we propose both satisfaction and dissatisfaction as mediators between the antecedents of the usage of mobile health applications and active usage of mobile health applications. Our result provides further support for the distinctiveness between satisfaction and dissatisfaction.

From the practical perspective, this study will help policymakers and medical providers identify active users by using our measurement items of active usage of mobile health applications. For example, the time spent in using mobile health applications, the usage frequency, and some traces of consumers' usage behavior, such as the volume of consumer-generated content in mobile health applications, could be used to compose some indices to locate active users. The thresholds for spending time, usage frequency, generated content, or other tracks could be set to decide who are active users and who are passive users. After identifying the different usage status of different users, policymakers and medical providers could use corresponding strategies to promote the engagement of different users in using mobile health applications.

This study empirically identifies attributes that could be useful for predicting consumers' active usage of mobile health applications and help policymakers and application designers promote proper mobile health applications for consumers. For example, to improve consumers' usage, mobile health applications should focus on excitement attributes and performance attributes, including design aesthetics, customization, enjoyment, sociability, informational support, and emotional support on the premise that mobility, information quality, perceived security, and technical functionality of the mobile health applications are acceptable.

Finally, because consumer satisfaction and dissatisfaction both influence active usage, practitioners should not only emphasize

consumer satisfaction in using mobile health applications but also reduce consumer dissatisfaction from using mobile health applications. Once a consumer feels dissatisfied with using any aspect of a mobile health application, they may become a passive user from being an active user. If they continue to remain dissatisfied with using the mobile health application, and the barriers to switching are low, then they may switch to other mobile health applications.

Limitations and Future Research

The results of this study could be interpreted in light of its limitations. First, although we identified several antecedents of mobile health application usage, the explained variances of active usage of mobile health applications still have the potential to be improved. Our literature review of mobile health application usage and adoption revealed that social, personal, and motivational factors could influence mobile health application usage and adoption, whose effects on active usage of mobile health applications are worth to be examined. Future studies may examine other factors to better understand consumers' active usage.

Second, the generalizability may be restricted because our sample was restricted to Chinese consumers. In China, the most popular mobile health application is Ping An Good Doctor [5], but in other countries, other mobile health applications, such as Pedometer in Sweden [78] or Samsung Health in the United States [79], are leading. There are differences between mobile health applications in different countries. Future studies may conduct cross-country comparisons to better generalize the results of this study.

Finally, our study was mainly a cross-sectional one, where constructs are measured at the same point of time. However, since consumer behavior and mobile health applications are both dynamic, the results may change over time. Therefore, the cross-sectional method may not reflect the dynamics of mobile health application usage. A longitudinal study with a multimethod approach may help address this issue.

Conclusion

In this study, we explored the factors influencing consumers' active usage of mobile health applications based on the 3-factor theory. According to the 3-factor theory, we focused on the attributes of mobile health applications and divided them into 3 categories: excitement, performance, and basic. The 3 categories of attributes are assumed to influence the active usage of mobile health applications through consumer satisfaction and dissatisfaction. The proposed relationships were validated by using a survey method. The analysis results not only imply that consumer satisfaction and dissatisfaction are independent from each other, but also confirm the categorization of attributes for active usage of mobile health applications. Meanwhile, our study could inspire designers and policymakers to make patients actively use mobile health applications.

Abstract

Background: Attempts to use virtual reality (VR) as a treatment for various psychiatric disorders have been made recently, and many researchers have identified the effects of VR in psychiatric disorders. Studies have reported that VR therapy is effective in social anxiety disorder (SAD). However, there is no prior study on the neural correlates of VR therapy in patients with SAD.

Objective: The aim of this study is to find the neural correlates of VR therapy by evaluating the treatment effectiveness of VR in patients with SAD using portable functional near-infrared spectroscopy (fNIRS).

Methods: Patients with SAD (n=28) were provided with 6 sessions of VR treatment that was developed for exposure to social situations with a recording system of each participant's self-introduction in VR. After each VR treatment session, the first-person view (video 1) and third-person view (video 2) clips of the participant's self-introduction were automatically generated. The functional activities of prefrontal regions were measured by fNIRS while watching videos 1 and 2 with a cognitive task, before and after whole VR treatment sessions, and after the first session of VR treatment. We compared the data of fNIRS between patients with SAD and healthy controls (HCs; n=27).

Results: We found that reduction in activities of the right frontopolar prefrontal cortex (FPPFC) in HCs was greater than in the SAD group at baseline (t=–2.01, P=.049). Comparing the frontal cortex activation before and after VR treatment sessions in the SAD group showed significant differences in activities of the FPPFC (right: t=–2.93, P<.001; left: t=–2.25, P=.03) and the orbitofrontal cortex (OFC) (right: t=–2.10, P=.045; left: t=–2.21, P=.04) while watching video 2.

Conclusions: Activities of the FPPFC and OFC were associated with symptom reduction after VR treatment for SAD. Our study findings might provide a clue to understanding the mechanisms underlying VR treatment for SAD.

KEYWORDS

anxiety; social anxiety disorder; virtual reality; fNIRS; brain activity; prefrontal cortex; effectiveness

Introduction

Social anxiety disorder (SAD) is a common psychiatric disease, with 8.4%-15% of the population worldwide diagnosed with it [1]. According to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), SAD is characterized by fear or anxiety in situations in which people receive negative attention from others [2]. Individuals with SAD avoid social situations and have difficulties in maintaining interpersonal relationships, with serious impairment in academic, occupational, and social functions [3]. Comorbidities, such as depressive disorders, anxiety disorders, substance use disorder, obsessive compulsive disorder, and avoidant personality disorder, typically accompany SAD. Moreover, patients are likely to be single and unemployed and develop suicidal ideas, low self-esteem and a low quality of life, and chronic illnesses without treatment [4,5].

Effective pharmacological agents for SAD treatment include selective serotonin reuptake inhibitors, serotonin and norepinephrine reuptake inhibitors, benzodiazepines, and beta-adrenergic antagonists. Furthermore, nonpharmacological therapies, such as cognitive behavior therapy (CBT) or social skill training, and a combination of pharmacological and nonpharmacological therapies are considered treatment modalities [6-8]. Although these treatments are effective, patients with SAD may be reluctant to receive psychiatric medication, have difficulty in visiting the treatment room, and drop out of treatment to avoid social situations or spatial constraints. Thus, patients may not actively participate in treatments [9,10].

To overcome the limitations of conventional therapeutics, digital intervention strategies, such as virtual reality (VR), that incorporate advanced technology into conventional therapies have been developed. Since the 1990s, VR has been used in various clinical treatments in medicine. However, initially, it could not reproduce reality well due to technical limitations, but with gradual developments in digital technologies, such as graphics and sounds, the treatment effects of realistic VR have improved considerably [11-13].

Since Rothbaum et al [14] reported the effects of progressive exposure therapy using VR in acrophobia, many studies have reported the effects of VR in various psychiatric disorders, such as specific phobia, posttraumatic stress disorder, SAD, attention deficit hyperactivity disorder, autism spectrum disorder, schizophrenia, depressive disorders, anxiety disorders, eating disorders, addiction, and mild cognitive impairment [13,15-19]. VR therapy has numerous advantages because it enables self-directed treatment at home or in locations where the patient feels comfortable. Furthermore, VR motivates patients toward treatment, mitigating the limitations of conventional therapist-led therapy [15,20,21]. VR can depict various social situations that cannot be reproduced in real treatment spaces because of spatial or human constraints and allows modification of patient treatment for specific situations [22].

Although VR treatment for SAD has attracted considerable attention, it is still a novel treatment modality. Pertaub et al [23] identified that social anxiety can be induced by virtual situations, which yielded results similar to conventional exposure therapy. Robilard et al [24] reported improved detection of anxiety symptoms with VR-CBT in patients with SAD. Randomized controlled trials have reported the effects of VR exposure therapy in patients with SAD [25-27]. However, limited clinical studies have been performed for investigating the effectiveness of VR treatment, and most studies have only identified effectiveness based on psychological assessments that relied on patients' subjective expressions [28].

In this study, we designed an advanced therapeutic tool compared with existing VR treatments. During the sessions, the participants' own voices were recorded, and scenes were constructed with the participants' self-introduction in first person and third person to introduce participatory and interactive features that could be used therapeutically. The use of this VR program for measuring the psychological scale changes in patients with SAD has been reported earlier in a study [29]. In this study, we examined changes and responses in brain frontal region activities using functional near-infrared spectroscopy (fNIRS). fNIRS can be used to examine the functional activity in certain areas of the brain by measuring changes in the concentrations of oxygenated hemoglobin (HbO_2) and deoxygenated hemoglobin (HbR) in brain tissue to assess neurological activation. fNIRS is safe, portable, and easy to use compared with neuroimaging tools such as functional magnetic resonance imaging (fMRI) [30]. Previous neuroimaging studies have reported changes in the medial prefrontal cortex (MPFC), ventrolateral prefrontal cortex (VLPFC), amygdala, anterior cingulate cortex (ACC), and posterior cingulate cortex (PCC) in SAD. The changes in the prefrontal cortex (PFC) were reported before and after VR therapy and during treatment [31].

The purpose of this study is to identify the neural correlates of symptom improvement after VR treatment in SAD based on the efficacy of the VR program reported previously [29]. We used VR-derived video clips with first- or third-person interviews to observe changes in brain activity. The neural correlates of symptom improvement after VR treatment in patients with SAD were studied by analyzing and assessing changes in neuronal activities using fNIRS compared with healthy controls (HCs).

Methods

Study Participants

In total, 40 patients with SAD and 34 HCs matched for age, sex, and handedness were enrolled in the study. After data quality verification with fNIRS, we included 28 patients (19 [68%] women) diagnosed with primary SAD and 27 HCs (13 [48%] women) in the study. The SAD and HC groups were recruited from universities through online advertisements on bulletin boards. The inclusion criteria for the SAD group were as follows:

- Korean-speaking men or women aged between 19 and 31 years
- Satisfy DSM-IV criteria for SAD according to the Mini-International Neuropsychiatric Interview (MINI; a psychiatrist conducted MINI to select the SAD and HC groups in this study) [32]
- Psychotropic medication–naive patients without psychiatric comorbidities (excluding depressive and panic disorders)
- Patients not undergoing psychotherapy
- Patients without a history of neurological disorders
- Patients without a history of psychotic symptoms upon VR exposure
- Patients who experience epilepsy and are not vulnerable to visual stimuli

The exclusion criteria were as follows:

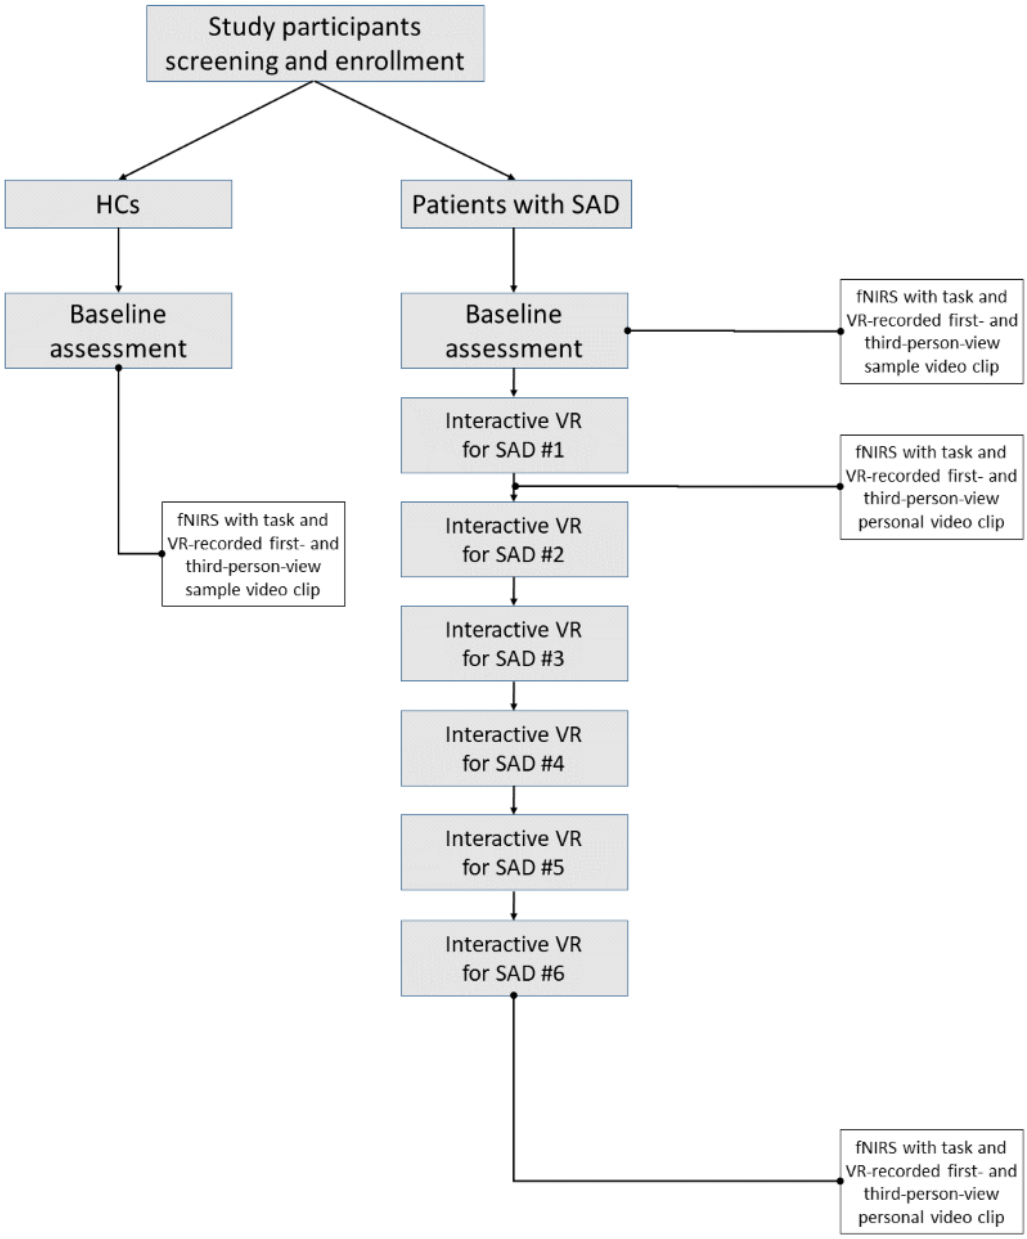
- History of intellectual disability or organic brain damage
- Individuals who experience psychotic symptoms upon VR experiences
- People vulnerable to visual stimuli
- People who are unsuitable for participation in fNIRS research (eg, people who cannot sustain the fNIRS test because of discomfort or anxiety in wearing fNIRS equipment or experiences of side effects, such as headache)

The HC group did not have preexisting neurological or psychiatric conditions. The Korean Social Avoidance and Distress (K-SAD) scale was prepared using an online questionnaire, and patients with a score of 82 or above were enrolled in the SAD group. All participants provided informed written consent after explanation of the study procedures and were required to pass an fNIRS scanning safety eligibility test. The study was approved by the Korea University Anam Hospital institutional review board (IRB no. 2018AN0377). The study was conducted in accordance with the Declaration of Helsinki ethical principles.

VR Therapy for SAD

An overview of the participatory VR treatment for SAD is available in previous reports [29,33]. Here, a similar participatory VR program was used for the treatment of patients with SAD. The VR program had an introduction, a core, and a finishing phase, with 3 levels depending on the difficulty of the core phase. In the introductory phase, participants learned how to use VR for relaxation and meditation. During the core phase, virtual situations were set up. In these virtual setups, several participants met to perform team tasks. Participants were exposed to social situations and introduced themselves to an audience. The level of difficulty was gradually increased, and participants were required to engage in discussions, and the activities were repeated. Each video clip was recorded in first- and third-person views [34]. The mirroring techniques in treatment were modified, and a hybrid treatment was used in the study. Namely, we attempted to maximize the effectiveness of treatment by consulting or discussing with participants by reconfirming VR treatment performed by themselves from the first- and third-person views. Each participant underwent 6 sessions of the treatment program. Participants were allowed to select the difficulty level of the program according to their comfort level after the first session. The researchers supervised each session to ensure the safety of the participants. The psychological scales were evaluated before the commencement of the VR program and after its completion. When the participants were watching the video clip in first and third person, we measured neuronal activities in the desired brain regions using fNIRS before VR treatment initialization and after the first and sixth sessions (Figure 1).

Figure 1. Overall schematic structure of the study. Patients with SAD and HCs were enrolled in a participatory and interactive VR treatment study. The HC group implemented fNIRS once by watching first- and third-person-view video clips at baseline. The SAD group implemented fNIRS 3 times in total at baseline, after the first and sixth sessions of VR treatment. fNIRS: functional near-infrared spectroscopy; HC: healthy control; SAD: social anxiety disorder; VR: virtual reality.



Clinical Symptom Assessments

The clinical symptoms of the participants were assessed using psychological scales. Subjects with SAD were scanned in 2 testing sessions, before and after VR therapy. We reported an analysis of psychological scale changes to evaluate the effectiveness of VR therapy for patients with SAD [29]. In this study, we studied the correlation between fNIRS results and psychological scales. Diagnostic assessment was measured using MINI [31]. Additionally, for social anxiety, we considered the Korean version of the Beck Anxiety Inventory (BAI) [35], and State-Trait Anxiety Inventory-X (STAI-X) [36]. Moreover, the Internalized Shame Scale (ISS) [37], the Post-Event Rumination Scale (PERS) [38], the Korean version of the Social Phobia Scale (K-SPS) [39], and the Korean version of the Social Interaction Anxiety Scale (K-SIAS) [39] were evaluated. Next, we also incorporated the Brief-Fear of Negative Evaluation (BFNE) scale [40], the K-SAD scale [41], and the Liebowitz Social Anxiety Scale (LSAS) [42].

For the HC group, fNIRS was evaluated once, whereas for the SAD group, it was measured 3 times (at baseline, after the first VR session, and after the sixth VR session). In each measurement, a 2-back task was conducted between the first- and third-person versions. We used a procedure similar to Wagner's task [43]. Working memory in the SAD group was studied previously using the N-back task, in which the SAD group exhibited lower accuracy and longer response times than the HC group [44]. Similarly, cognitive function was assessed using the N-back task, which measured working memory. To provide human-recorded first- and third-person views, fNIRS

was performed before and after the N-back operation to predict the expected therapeutic effect of VR-based psychotherapy. The 2-back task required the participants to determine whether the current stimulus was similar to the stimulus presented earlier in the trials. The task paradigm was composed of a block design that was repeated 3 times with alternate rest and task periods of 30 seconds.

fNIRS Data Analysis

The fNIRS system (NIRSIT, OBELAB Inc., Seoul, Republic of Korea), which monitors activation in the PFC, is a portable, wireless, wearable, and multichannel (48 channels) brain imaging system that covers the entire forehead. Wavelengths of 780 and 850 nm were used, and 48 regions of light source and detectors separated by 3 cm were considered. The weight of the device is 550 g, and the sampling rate is 8.138 Hz. To remove high-frequency noise due to environmental artifacts and low-frequency noise due to the blood circulation in the body, the fNIRS signal was filtered using a bandpass filter with a cutoff frequency of 0.005-0.1 Hz. Considering the signal-to-noise ratio, the signal quality of each channel was evaluated after filtering, and values less than 30 dB were eliminated as unreliable.

Using the wavelength-dependent hemoglobin absorption coefficient and differential path length coefficient, the modified Beer-Lambert law was applied to the filtered signal, and changes in oxyhemoglobin (ΔHbO_2) [45] and deoxyhemoglobin (ΔHbR) concentrations were extracted [46]. To account for the time-dependent change in hemodynamics, baseline correction was performed by subtracting the average from the calculated change in the oxygen concentration. Next, based on the Montreal Institute of Neurology standardization space (ICBM152), all 48 channels were grouped into 8 regions. After grouping each region of the PFC, the rejected channels identified during the channel rejection process were filled with the average ΔHbO_2 of the channels allowed within each region.

Statistical Analysis

The mean and standard deviation of demographic data, such as age and educational year, were calculated for both groups. After evaluating the variance equality through the Levene test, the difference in ΔHbO_2 between the HC and SAD groups was analyzed by conducting an independent t test. One-way repeated ANOVA and post hoc analysis were conducted to understand subject variation in the SAD group from baseline. After the first and sixth VR sessions, the Box test for equivalence check and the Mauchly test of sphericity were conducted to analyze fNIRS data. Data processing was performed using the NIRSIT package in MATLAB (version 2019b; MathWorks Inc., Natick, MA, USA). Finally, we used the Pearson correlation coefficient to identify the relationship between psychological scale scores and area-specific changes in brain activation. Additional statistical analyses were performed using IBM SPSS Statistics 21 (SPSS Inc., Chicago, IL, USA), where the criterion for statistical significance was set at $P<.05$.

Results

Demographic Data

In this study, we analyzed the data from 28 patients with SAD and 27 people in the HC group. The mean age (SD) for patients with SAD were 23.74 (3.55) years, and for the HC group, they were 23.18 (3.27) years. The mean (SD) educational years for the SAD and HC groups were 15.00 (1.88) and 14.63 (1.37), respectively. No difference was observed between the groups in terms of age and years of education.

The mean (SD) K-SAD scores were 106.68 (15.33) for the SAD group and 48.93 (17.10) for the HC group. Significant differences were observed in the severity of SAD symptoms (Table 1).

Table 1. Demographic and clinical data between SAD[a] patients and HCs[b].

Demographic and clinical data	Patients with SAD	HCs
Gender, n (%) male/n (%) female	28 (9 [32%]/19 [68%])	27 (14 [52%]/13 [48%])
Age in years, mean (SD)	23.74 (3.55)	23.18 (3.27)
Education years, mean (SD)	15.00 (1.88)	14.63 (1.37)
K-SAD[c] score[d], mean (SD)	106.68 (15.33)	48.93 (17.10)
STAI-S[e] score[d], mean (SD)	49.21 (10.17)	35.48 (7.81)
STAI-T[f] score[d], mean (SD)	53.21 (10.30)	34.19 (7.19)
ISS[g] score[d], mean (SD)	51.86 (16.70)	15.22 (9.74)
BFNE[h] score[d], mean (SD)	44.39 (8.91)	27.74 (7.35)
PERS[i] score[d], mean (SD)	46.96 (8.34)	32.81 (11.61)

Psychological Scale Scores of SAD and HC Groups

In this study, the scores of the SAD group were considerably higher than those of the HC group for all the tested scales that assessed associated anxiety symptoms (Table 1). In the SAD group, after VR treatment, the scores on the psychological scales for the SAD group decreased in all cases except 2, namely STAI-S (subscale of STAI, $P=.11$) and the Liebowitz Social Anxiety Scale-anxiety (LSASanx, subscale of LSAS, $P=.16$). (In a previous paper, we detailed the psychological scales used in the study and their purposes of assessment. Furthermore, we previously reported the changes in psychological scales according to VR treatment [29]).

Baseline PFC Activity in SAD and HC Group Measure Using fNIRS

We conducted fNIRS measurements for study participants before VR treatment to analyze brain activity in each region of the PFC, such as the dorsolateral prefrontal cortex (DLPFC), the VLPFC, the frontopolar prefrontal cortex (FPPFC), and the orbitofrontal cortex (OFC); see Figure 2. Brain activities among the SAD and HC groups were compared. A reduction in activation was measured by viewing first-person video clips (video 1), especially in the right FPPFC ($P<.05$). However, a negligible difference was observed between the two groups when the 2-back task was executed, and video clips in the third person were used for the treatment program (video 2). Next, while executing the 2-back task, activations in the left-brain areas of the HC group were lower than those of the SAD group, but the difference was not significant (Table 2).

Figure 2. Activity of the PFC in the HC and SAD groups measured by fNIRS at baseline. When fNIRS was performed while both groups watched video 1, the activity of the right FPPFC was more decreased in the SAD group than in the HC group (P<.05). However, when implementing the 2-back task and watching video 2, there was no significant difference in the activity of the PFC between both groups. fNIRS: functional near-infrared spectroscopy; FPPFC: frontopolar prefrontal cortex; HC: healthy control; PFC: prefrontal cortex; SAD: social anxiety disorder.

Changes in PFC Activity in SAD After VR Treatment Using fNIRS

We compared the brain activities measured by fNIRS (1) at baseline with those obtained after the first and sixth sessions of treatment in patients with SAD and (2) those obtained after the first session with those obtained after the sixth session. We observed significant differences in the right FPPFC ($P=.01$) and OFC ($P=.045$) and the left FPPFC ($P=.03$) and OFC ($P=.04$) when the treatment plan included video 2 for patients with SAD (Table 3 and Figure 3).

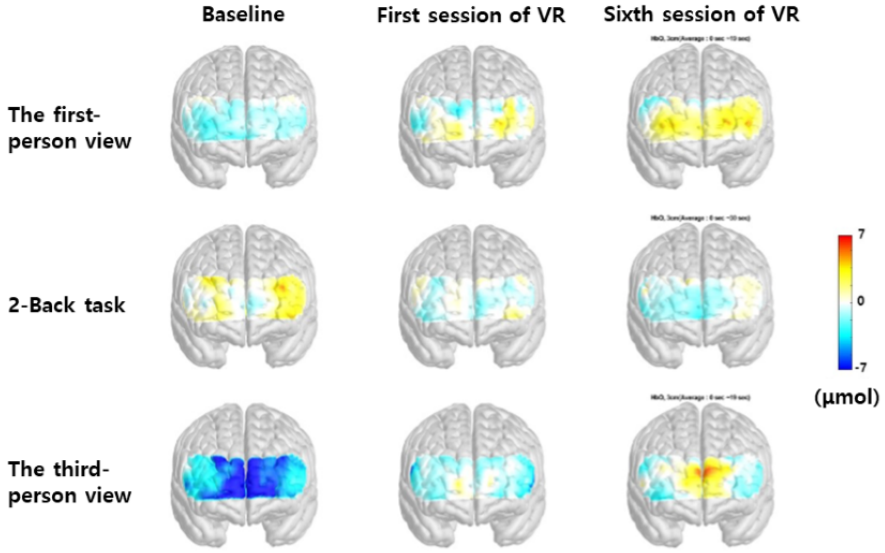
Figure 3. Activity of the PFC of patients with SAD at baseline, after the first VR session and after the sixth VR session. Comparing between baseline and after the first VR session, when watching video 2, there were significant differences in activity in the right FPPFC (P<0.01) and OFC (P<0.01) and in the left FPPFC (P<0.05) and OFC (P<0.05). Comparing between baseline and after the sixth VR session, when watching video 2, there were significant differences in activity in the right FPPFC (P<0.01) and OFC (P<0.05) and in the left FPPFC (P<0.05) and OFC (P<0.05). When patients with SAD were performing the 2-back task, there was a significant difference in activity in the right OFC (P<0.05) between baseline and after the sixth VR session. There was no significant difference in PFC activity when watching video 1. FPPFC: frontopolar prefrontal cortex; OFC: orbitofrontal cortex; PFC: prefrontal cortex; SAD: social anxiety disorder; VR: virtual reality.



Correlations Between Brain Activities and Psychological Scale Results

We analyzed the correlations between psychological scales and brain activities through fNIRS before and after VR treatment in patients with SAD. The STAI-S scores showed significant correlations with the activities of the right and left FPPFC, the right and left OFC, and the left DLPFC. Furthermore, the STAI-T scores were significantly correlated with the right and left OFC, and the ISS was significantly correlated with the right and left FPPFC and the right and left OFC in video 1. We also determined that STAI-S scores were significantly correlated with the right and left VLPFC, the right FPPFC, and the left DLPFC; the ISS was significantly correlated with the right and left DLPFC, the left VLPFC, the right and left FPPFC, and the right and left OFC; and the BFNE was significantly correlated with the right VLPFC in video 2. IN addition, PERS was significantly correlated with the right OFC, the K-SAD scale was significantly correlated with the left OFC, and LSASanx was significantly correlated with the right DLPFC, VLPFC, FPPFC and the right and left OFC while executing the 2-back task (Table 4).

Discussion

Principal Findings

To the best of our knowledge, this study is the first to determine the effects of VR therapy on SAD by using fNIRS measurements. From this study, we found that changes in activity in specific brain regions, such as the FPPFC and OFC, are closely related to VR treatment. In addition, we developed a VR program to enhance the efficacy of the treatment by creating first- and third-person views of exposure situations. In the first-person view, the patients directly present content to an audience, and in the third-person view, the patients visualize themselves speaking to an audience objectively.

The effects of VR treatment on patients with SAD were studied by measuring the changes in PFC brain activity using fNIRS. We were able to find that the activation of the right FPPFC was higher in the SAD group than in the HC group when watching video 1. This can be understood in a similar context as the blood flow of the MPFC decreases in situations in which anxiety is predicted in healthy individuals [47,48]. A positron emission tomography (PET) study reported that the blood flow in the right DLPFC, left inferior temporal cortex, and left amygdaloid-hippocampal region increases in patients with SAD [48]. However, using fNIRS analysis, we did not observe any difference in activation between the right DLPFC among the study groups. Previously, an fNIRS scan revealed that the activation change in the VLPFC in patients with SAD was less than that in the HC group during a verbal fluency task [49]. Here, the activation change in most regions of the left PFC was low and not significant.

In this study, we observed changes in the prefrontal area before and after VR treatment. Thus, activation in the right FPPFC and OFC and the left FPPFC and OFC significantly increased when patients with SAD were watching the video in the third-person view. By using PET after pharmacological treatments, Evans et al [50] reported that the regional brain metabolism of the ventromedial prefrontal cortex (VMPFC) in patients with SAD increases. Further, Hiser et al [51] reported that the activation of the anterior VMPFC increases upon pharmacological treatment or psychotherapy. We obtained similar results to these previous studies. However, the metabolism in the medial dorsal PFC decreased in patients with SAD after pharmacological treatment [52].

We obtained positive self-referential stimuli (positive words), neutral self-referential stimuli, and negative self-referential stimuli (negative words) after VR treatment to identify the activation changes in the brain region measured through fMRI in a previous study [33]. Therefore, patients with SAD exhibited increased activation in the right PCC/precuneus, lingual gyrus, left inferior temporal gyrus, precentral gyrus, and postcentral gyrus for positive self-referential stimuli. Patients with SAD also revealed increased activation in the left middle occipital gyrus, parahippocampus, left Rolandic operculum, and left caudate nucleus for negative self-referential stimuli. In this study, we observed the brain activity of participants watching the video clips, unlike the previous study, and determined the neural correlates by fNIRS, which were used to measure the activation of the prefrontal area, unlike fMRI, which can be used to measure the activation of the whole brain area.

Lastly, we identified correlations between psychological states in patients with SAD with brain areas activated upon VR therapy. The STAI-T scores and OFC activation, and ISS scores and prefrontal region activation (except the right VLPFC) were correlated. Studies have reported the correlation between the severity of SAD symptoms and the activation of certain brain areas. Klumpp et al [53] reported that improvements in the symptoms are correlated with the increase in the activation of brain areas, such as the medial orbitofrontal and dorsomedial frontal gyrus. Marin et al [54] reported that hypoactivation of the VMPFC is correlated with the severity of anxiety. Based on fNIRS analysis, Yokoyama et al [49] reported that changes in VLPFC activation are negatively correlated with social fear and activation of the left DLPFC is positively correlated with social anxiety [55].

Studies have reported that amygdala activation is high in patients with SAD [48,56]. Here, we could not study amygdala activation, because measuring subcortical brain regions with

fNIRS is difficult. The VMPFC and the VLPFC are known to be associated with the amygdala in patients with SAD. Generally, the VMPFC regulates social functions and inhibits the amygdala to regulate the fear response [51]. Thus, increased activation of the ventromedial prefrontal regions from social anxiety treatments is beneficial. In addition, the degree of functional connectivity between the VLPFC and the amygdala is negatively correlated with the severity of anxiety [57]. This result supports our results that activation of the VLPFC and the degree of anxiety treatment are correlated.

The blood flow in the right DLPFC decreased in patients with SAD during the repetition task [48]. We observed that activation of the right OFC during the 2-back task in our study increased after treatment, which contradicts the results of some previous studies. Further, regional cerebral blood flow of the rhinal cortex, amygdala, hippocampal region, and parahippocampal region decreases in patients with SAD during task performance. The regional cerebral blood flow of the middle frontal cortex and dorsal ACC changes in patients with SAD, particularly in patients who effectively perform the task [58]. We obtained similar results in our study.

Differences were observed in brain activation in high anxiety–provoking situations rather than in low anxiety–provoking situations [59]. Patients with SAD were more anxious during the first-person view than during the third-person view, which resulted in differences in activation in the HC group. In addition, the changes in brain activation appeared earlier when the video in the third-person view was used, because the patients felt less anxious. However, the effects of the treatment appeared later when the video in the first-person view was used, probably because the patients felt more anxious. Therefore, the effectiveness of the treatment modality should be verified by conducting more treatment sessions.

Limitations

This study had some limitations. First, the sample size was relatively small. However, our analysis was thorough, and we were able to investigate functional brain activity after VR therapy in patients with SAD. Second, the number of sessions for VR treatment was small, and the follow-up period was relatively short. We observed the changes in psychological scale scores and brain activities measured through fNIRS after VR treatment. However, after the sixth session of treatment, the anxiety levels observed on most psychological scales in the SAD group were higher than in the HC group. This could be because changes in brain activity due to VR treatment were not prominent as yet. Perhaps more treatment sessions are required. Thus, more VR treatment sessions should be conducted for a larger sample size to observe prominent therapeutic benefits. Third, we could not measure the brain activity in real time. Applying electroencephalography to a VR head-mounted display (HMD) has enabled measurement of brain waves [60]. However, we were not able to apply fNIRS and VR HMD because of several technical limitations. Lastly, we could not observe changes in brain areas other than the PFC (especially amygdala), owing to mechanical limitations of portable fNIRS. Although fMRI has the advantage of being able to perform comprehensive and in-depth measurement of the entire brain function, it is difficult to apply various tasks and has a high economic burden, so there are obvious limitations in actual clinical application. However, in terms of cost and usability, portal fNIRS has a high possibility of being applied to actual clinical practice in combination with VR, so it is worthy of overcoming the disadvantages of measurement compared to fMRI.

Conclusion

We conducted VR therapy on patients with SAD to prove the treatment effects after developing a VR treatment program that was exposed to social situations in the first- and third-person views. We identified the brain activity changes in the FPPFC and OFC in patients with SAD after VR treatment in this study, which can provide functional clues in specific brain area for VR treatment. In addition, we found that the STAI-T scores were correlated with the activity of the OFC and the ISS scores were correlated with most of the PFC except the right VLPFC. This can be a clue that the change after treatment in some psychological domains in SAD is related to a specific PFC region. Future studies are required to identify and confirm the neural correlates of VR treatment in patients with SAD for sufficient periods in large sample sizes.

Abstract

Background: Existing systems to document adverse drug events often use free text data entry, which produces nonstandardized and unstructured data that are prone to misinterpretation. Standardized terminology may improve data quality; however, it is unclear which data standard is most appropriate for documenting adverse drug event symptoms and diagnoses.

Objective: This study aims to compare the utility, strengths, and weaknesses of different data standards for documenting adverse drug event symptoms and diagnoses.

Methods: We performed a mixed methods substudy of a multicenter retrospective chart review. We reviewed the research records of prospectively diagnosed adverse drug events at 5 Canadian hospitals. A total of 2 pharmacy research assistants independently entered the symptoms and diagnoses for the adverse drug events using four standards: Medical Dictionary for Regulatory Activities (MedDRA), Systematized Nomenclature of Medicine (SNOMED) Clinical Terms, SNOMED Adverse Reaction (SNOMED ADR), and International Classification of Diseases (ICD) 11th Revision. Disagreements between research assistants regarding the case-specific utility of data standards were discussed until a consensus was reached. We used consensus ratings to determine the proportion of adverse drug events covered by a data standard and coded and analyzed field notes from the consensus sessions.

Results: We reviewed 573 adverse drug events and found that MedDRA and ICD-11 had excellent coverage of adverse drug event symptoms and diagnoses. MedDRA had the highest number of matches between the research assistants, whereas ICD-11 had the fewest. SNOMED ADR had the lowest proportion of adverse drug event coverage. The research assistants were most likely to encounter terminological challenges with SNOMED ADR and usability challenges with ICD-11, whereas least likely to encounter challenges with MedDRA.

Conclusions: Usability, comprehensiveness, and accuracy are important features of data standards for documenting adverse drug event symptoms and diagnoses. On the basis of our results, we recommend the use of MedDRA.

adverse drug events; health information technology; data standards

Introduction

Background

Adverse drug events are the harmful and unintended consequences of medication use and are a leading cause of emergency department visits and hospitalizations in Canada and internationally [1-4]. Adverse drug events comprise various types of medication-related problems, including adverse drug reactions (ie, noxious effects that occur within a standard dosing range of a prescription drug). Adverse drug events frequently recur without documentation and communication, which compromises patient safety [5]. The incidence, severity, and recurrence of adverse drug events suggest a need for greater documentation and communication of such events to avoid patients being re-exposed to harmful medications [5].

Adverse drug event reporting is voluntary for clinicians in Canada but has recently become mandatory for hospitals [6]. The implementation of mandatory reporting for hospitals introduces concerns about the added burden of documentation for clinicians. There is often a disconnect between adverse drug event reporting and clinical care activities because of time constraints and a poor fit between standardized nomenclatures built into inflexibly designed reporting systems [7]. The existing electronic medical records include data fields for documenting allergies but can be restrictive and inappropriate for documenting adverse drug reactions and other types of adverse drug events [7]. Furthermore, allergies and adverse drug reactions are a fraction of all the reportable clinically significant adverse drug events [5]. Even when broader input fields are available to document adverse drug events, they are often in free text format, and thus, the resulting data are unstructured, nonstandardized, and prone to misinterpretation. As a result, clinicians who diagnose and treat adverse drug events rarely report them in the existing electronic systems [1,4,8]. Enabling data entry using standardized terminology may reduce the ambiguity of adverse drug event reports, ease the data entry process, improve the utility of the systems, and thereby improve patient safety [9,10]. However, the use of standardized data systems that are incompatible with clinical work may also compromise patient safety and reduce the quality and availability of data for research purposes [11].

Objective

System designers may leverage a number of existing national and international standards to support documentation; however, few studies have examined which data standard is preferable for capturing details about adverse drug events. This study aims to understand and compare the utility of different clinical data standards in capturing adverse drug event symptoms and diagnoses. This has been undertaken in relation to a new law in Canada that mandates the reporting of serious adverse drug reactions [6]. We hope to provide insight into the strengths and weaknesses of different standards as vendors begin to develop software to support adverse drug event documentation.

Methods

Study Design

This was a mixed methods substudy of a multicenter retrospective chart review [5]. We used a convergent mixed methods design in which we collected and analyzed quantitative and qualitative data concurrently and separately and then merged and compared them during the interpretation phase [12].

Setting and Population

We reviewed the research records of all patients who were diagnosed with ≥1 adverse drug event in 1 of the 3 prospective multicenter studies [13-16]. The first study enrolled 1591 patients presenting to the emergency departments of 2 tertiary care hospitals—Vancouver General Hospital (VGH) and St Paul's Hospital—in Vancouver, British Columbia, Canada, from 2008 to 2009 and derived a clinical decision rule to identify the patients at high risk of adverse drug events [13]. The second study enrolled 10,807 patients presenting to the emergency departments of VGH, Lions Gate Hospital (an urban community hospital in North Vancouver, British Columbia), and Richmond Hospital (an urban community hospital in Richmond, British Columbia) between 2011 and 2013 and evaluated the impact of a pharmacist-led medication review on health outcomes [14,16]. The third study enrolled 1529 patients presenting to the emergency departments of VGH, Lions Gate Hospital, and the Ottawa Civic Hospital (an urban tertiary care hospital in Ottawa, Ontario, Canada) from 2014 to 2015 and validated the previously derived clinical decision rule [15].

In all 3 prior studies, the research assistants used a systematic selection algorithm to select and enroll a representative sample of emergency department patients (Multimedia Appendix 1). A clinical pharmacist and physician evaluated all the enrolled patients with adverse drug events at the point of care and documented the events in research and medical records. All the cases in which the clinical pharmacist diagnoses and physician diagnoses were concordant were considered final. An independent committee adjudicated all the cases in which the assessments were discordant or uncertain by reviewing the research and medical records.

Inclusion and Exclusion Criteria

This study included all adverse drug events that met our case definition and were diagnosed in 1 of the 3 primary studies (see *Case Definition* section). We excluded events with alternative diagnoses, those for which records could not be retrieved or were illegible, and those that were not unique with respect to the drug and presenting symptom or diagnosis [13-16].

Case Definition

Adverse drug events included adverse drug reactions, drug interactions, supratherapeutic or subtherapeutic dosing, untreated indications, drug withdrawal, ineffective drugs, nonadherence, and errors in prescribing, dispensing, or medication administration [5,13-16]. These adverse drug events had to be

classified as moderate, resulting in a change in medical management, diagnostic testing, or consulting or severe, resulting in hospital admission, permanent disability, or death [5,16].

Chart Review Data Collection Methods

A total of 2 research assistants (EC, a clinical pharmacist and VC, a pharmacy student) retrospectively reviewed the research records of the enrolled patients. They were independent and blinded to one another's data collection and applied the different data standards to document up to 4 symptoms or diagnoses that they felt were appropriate to describe each adverse drug event using an electronic data collection form (Multimedia Appendix 2). If the research assistants were unable to identify an appropriate symptom or diagnosis, they selected *No Match*. The research assistants then documented whether they thought the terms selected in the data standard accurately described the case.

We conducted a pilot period to ensure the quality of the data collected and identify any potential questions about the application of our research protocol. During the pilot period, the research assistants collected data on a sample of 20 adverse drug events and subsequently provided feedback on the data collection form. We edited the form following the provision of feedback, which the research assistants then piloted on a new sample of 20 records, resulting in a total of 40 records being piloted.

During the pilot period, the research assistants met weekly to discuss discordant cases in which there were disagreements in the identified symptoms or diagnoses for each data standard to ensure consistency in case interpretation. After the pilot period, the research assistants met monthly to discuss the discordant cases in which there was disagreement in the accuracy of the data standard in describing the case. We considered all cases in which the research assistants reached a consensus on the various data standards as final (Multimedia Appendix 3).

We randomly selected 100 adverse drug events for the research assistants to assess twice to evaluate intrarater reliability.

Qualitative Data Collection Methods

During the chart review, the research assistants electronically recorded notes on their process, general impressions, and any case-specific challenges they encountered for each data standard. A qualitative researcher (SS) attended the meetings between the research assistants to observe the discussion of the discordant cases and took notes on the discussion to capture emerging themes and points of convergence and divergence. This produced a richer understanding of the human factors that influence the perceived utility of data standards.

Data Standards

We used four data standards to document the symptoms and diagnoses of each adverse drug event: Systematized Nomenclature of Medicine (SNOMED) Health Concern and Diagnosis (SNOMED HC) reference set, SNOMED Adverse Reaction (SNOMED ADR) reference set, Medical Dictionary for Regulatory Activities (MedDRA), and International Classification of Diseases (ICD) 11th Revision. We selected these as various levels of government and other organizations in Canada recommend their use in different clinical contexts related to adverse drug event reporting and documentation.

SNOMED HC Reference Set

SNOMED Clinical Terms (SNOMED CT) is an international clinical terminology coding system that includes diagnoses, signs, symptoms, and diagnostic procedures. We used the SNOMED CT Canadian Edition, which was developed specifically for use in Canada and released in October 2018 [17]. The SNOMED HC reference set is a subset of SNOMED CT, which is designed to map terminology to the ICD-9 and ICD-10 codes and the Canadian Emergency Department Diagnosis Shortlist for use in electronic medical records and clinical information systems. We included SNOMED CT as it is maintained and recommended by Canada Health Infoway to support the capture and exchange of clinical data in Canada [18].

SNOMED ADR Reference Set

The SNOMED ADR reference set highlights the allergies and intolerances found in SNOMED CT. This is a baseline reference set under development, which will continue to expand based on feedback. The Northern Health Authority in British Columbia has integrated this data standard into their electronic medical record system. Users select the terminology through a search function, which creates a filtered dropdown selection list. We included SNOMED ADR as it is under development for use specifically in British Columbia [19].

MedDRA Preferred Terms

MedDRA version 22.0 is an international standardized medical terminology dictionary that supports classification of adverse event information associated with biopharmaceuticals and other medical products [20]. MedDRA's hierarchical structure comprises 5 terminological levels that map to one another, arranged from very specific to very general. We used the *Preferred Terms* level, which presents terms as distinct descriptors for symptoms, signs, disease diagnoses, therapeutic indications, investigations, surgical or medical procedures, and medical, social, or family history characteristics. We modified some terms from their original British spelling to their American spelling by referring to corresponding Lower Level Terms in the MedDRA hierarchy. We included MedDRA as its use is recommended by Health Canada for adverse reaction reports submitted to their pharmacovigilance database [21].

International Classification of Diseases 11th Revision

ICD-11 is an international standard for reporting diseases and health conditions for clinical and research purposes [22]. The World Health Organization released the 11th revision in 2018 for piloting, and it will come into use in 2022. This version provides a coding system designed for easy adoption into electronic environments and updated clinical content, including explicit coding to capture adverse drug events. We included ICD-11 as it is used by physicians in British Columbia for claims submissions to the provincial Medical Services Plan [23].

Quantitative Analysis

We used descriptive statistics to describe the baseline characteristics of all included adverse drug events using

proportions. To determine the coverage of a specific data standard to capture an event, we used the research assistants' ratings of whether a data standard contained a match for the characteristics of an adverse drug event. We used the consensus assessments to calculate the frequency and proportion of adverse drug events with symptoms or diagnoses found within a given data standard.

We allowed entries for up to 4 terms per data standard. To identify whether the research assistants agreed on the term selected within a given data standard, we examined whether the first selected term for each data standard matched (first term match). Then, we examined whether there were any matches across the 4 terms between the terms used by both research assistants for each data standard (all terms match).

Qualitative Analysis

We coded comment fields from the data collection forms and notes from our observations using NVivo (version 12; QSR International) qualitative data analysis software. We began by inductively coding field notes to generate a provisional coding structure that we then applied to the comment fields. We iteratively reviewed the data and coding to identify emerging themes. We completed an interim review of the coding and emerging findings to contextualize the results with quantitative data and validate them with the research assistants' experiences. Following discussion, we generated a final coding structure and used a descriptive approach to describe the classification challenges.

Results

Quantitative Results

Figure 1 displays the flow of patients in the study sample. Overall, we included 673 adverse drug events in 573 patients in our sample. The top 5 most common culprit drugs and diagnoses of the included adverse drug events are presented in Table 1. The most common culprit medication overall was warfarin (62/673, 9.2%, 95% CI 7.1%-11.7%), and the most common diagnosis was allergic reaction (38/673, 5.7%, 95% CI 4%-7.7%).

Table 2 displays the coverage of the different data standards for the adverse drug events in our sample. Of the data standards, MedDRA (671/673, 99.7%, 95% CI 98.9%-99.9%) and ICD-11 (667/673, 99.1%, 95% CI 98%-99.6%) had the highest frequency of having an appropriate symptom or diagnosis available. SNOMED ADR had the lowest frequency (576/672, 85.7%, 95% CI 82.7%-88%).

Figure 1. Flow diagram of patients through the study. ED: emergency department; ADE: adverse drug event.

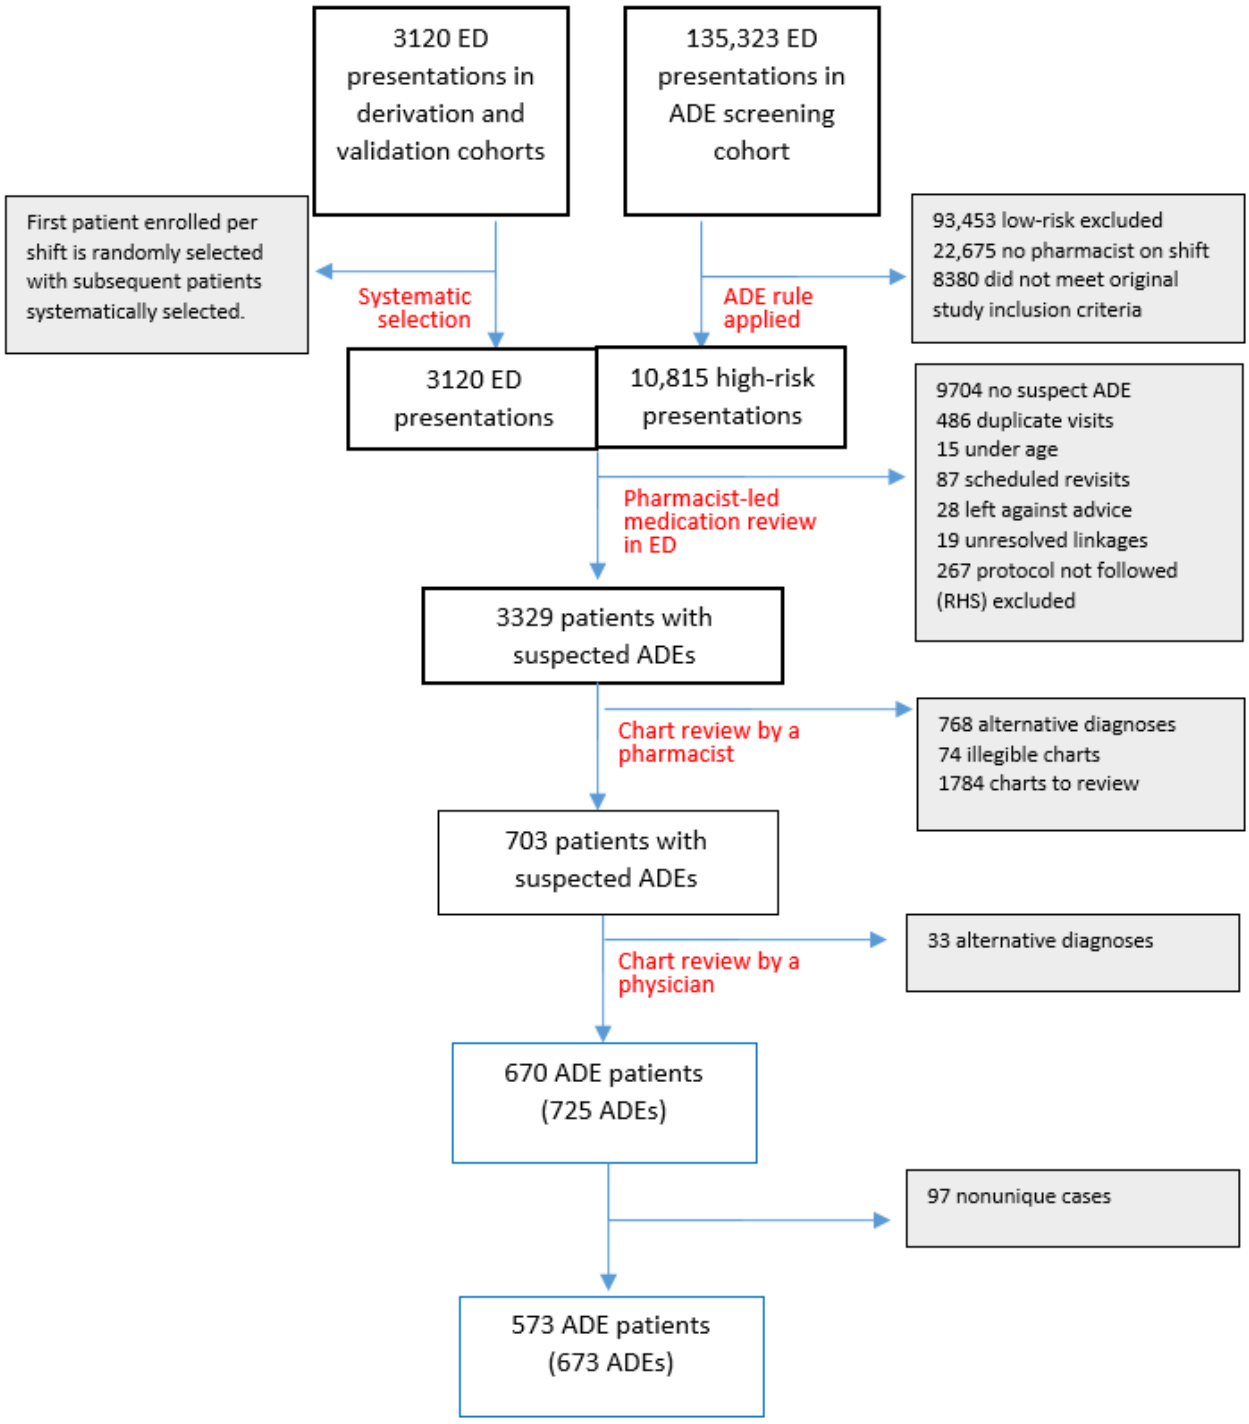

Table 1. Adverse drug event (ADE) characteristics of the study sample (N=673).

Characteristics	ADEs, n (%)
Culprit medication	
Warfarin	62 (9.2)
Furosemide	37 (5.5)
Acetylsalicylic acid	37 (5.5)
Hydrochlorothiazide	26 (3.9)
Insulin	21 (3.1)
ADE diagnosis	
Allergic reaction	38 (5.7)
Laboratory abnormality	36 (5.4)
Stroke	22 (3.3)
Hypoglycemia	20 (3)
Atrial fibrillation	19 (2.8)

Table 2. The percentage of having an appropriate symptom or diagnosis available to describe the adverse drug event cases by data standard (N=673).

Data standard	Symptom or diagnosis option available, n (%, 95% CI)
MedDRA[a]	671 (99.7, 98.9-99.9)
SNOMED ADR[b,c]	576 (85.7, 82.7-88)
SNOMED HC[d]	650 (96.6, 94.9-97.79)
ICD-11[e]	667 (99.1, 98-99.6)

[a]MedDRA: Medical Dictionary for Regulatory Activities.

[b]SNOMED ADR: Systematized Nomenclature of Medicine Adverse Reaction.

[c]N=672.

[d]SNOMED HC: Systematized Nomenclature of Medicine Health Concern and Diagnosis.

[e]ICD-11: International Classification of Diseases 11th Revision.

Table 3 presents the percentage agreement between the research assistants for the first term match and for any term match for each data standard. For the first term match, SNOMED HC (409/673, 60.8%, 95% CI 57%-64%) yielded the most matches between the research assistants and ICD-11 (286/673, 42.5%, 95% CI 38.8%-46.3%) yielded the fewest matches. In terms of having any term match, MedDRA performed the best (673/673, 100%, 95% CI 99.4%-100%) and ICD-11 yielded the lowest proportion of matches (583/673, 86.6%, 95% CI 83.9%-89%). Semantic differences between terms with identical meanings within a data standard may have artificially lowered the number of matches for a given data standard. For example, in SNOMED HC, 1 research assistant selected the term *frank hematuria*, whereas the second research assistant selected the term *blood in urine* to describe hematuria. In SNOMED ADR, 1 research assistant selected *muscle weakness*, and the second selected *asthenia* to describe weakness. In ICD-11, 1 research assistant selected *candidiasis of lips or oral mucous membranes*, and the second selected *thrush disorder* to describe thrush. The complete list of adverse drug events that did not have a match on any of the data standard terms is presented in Multimedia Appendix 4.

Table 3. The percentage agreement between the research assistants in coding the adverse drug events by data standards (N=673).

Data standard	First term match, n (%)	Any terms match, n (%)
MedDRA[a]	400 (59.4)	673 (100)
SNOMED ADR[b]	379 (56.3)	601 (89.3)
SNOMED HC[c]	409 (60.8)	629 (93.5)
ICD-11[d]	286 (42.5)	583 (86.6)

[a]MedDRA: Medical Dictionary for Regulatory Activities.

[b]SNOMED ADR: Systematized Nomenclature of Medicine Adverse Reaction.

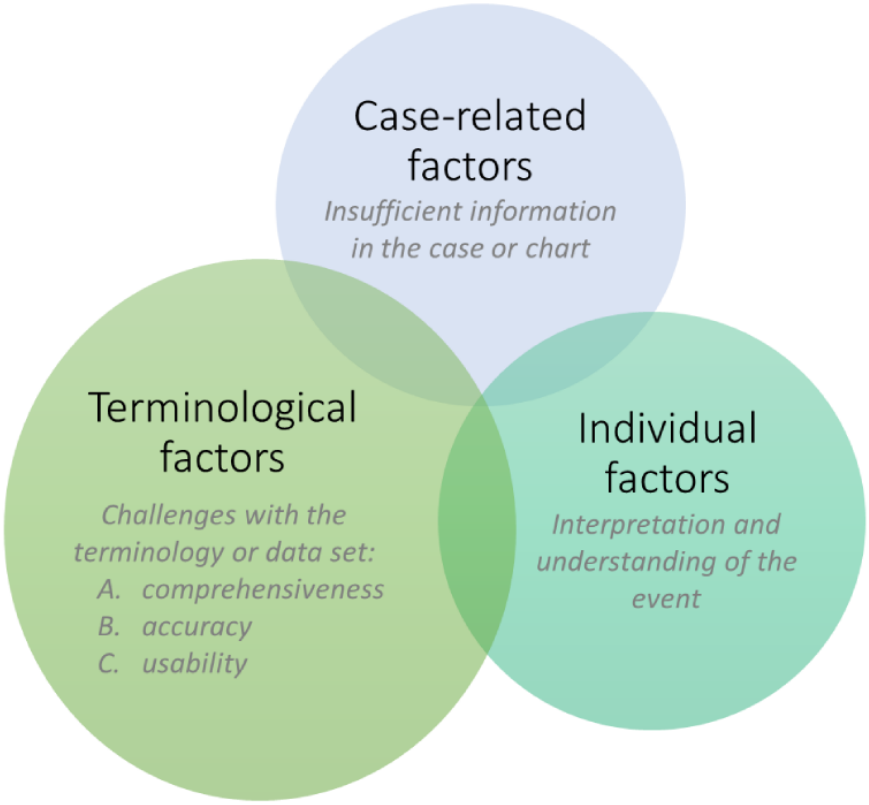
[c]SNOMED HC: Systematized Nomenclature of Medicine Health Concern and Diagnosis.

[d]ICD-11: International Classification of Diseases 11th Revision.

Qualitative Results

We found 3 primary factors that affected the classification of adverse drug event symptoms and diagnoses: (1) terminological factors specific to the terminology or data standard, (2) case-related factors in which there was not enough information in the patient's chart to classify the event appropriately, and (3) individual factors related to interpretation and recall (Figure 2).

Figure 2. Classification challenges in qualitative analysis.



Terminological Factors

Terminological challenges were the most common factors that affected the adverse drug event classification. We assessed the overall utility of each data standard according to 3 key terminological factors: comprehensiveness (conceptual coverage or breadth; eg, is the data source comprehensive enough to select appropriate terms?), accuracy (terminological correctness or exactness; eg, does the available terminology accurately describe the case?), and usability (ease of use; eg, is it easy to find an appropriate term using the data source?).

We used the ability to locate any term to describe the main symptom or diagnosis as a proxy variable for comprehensiveness. For example, both research assistants noted that the primary symptom and diagnosis of an adverse drug event were *hemiparesis* and *stroke*; however, there was no option to describe this case in SNOMED ADR. Poor comprehensiveness was found most often when using SNOMED ADR and rarely when using MedDRA, which is consistent with our quantitative findings related to coverage.

Issues with the accuracy of data sources emerged when the terms did not fully capture or represent the case, were too

specific, or were too vague. In the case of the main adverse drug event symptom or diagnosis being *fall*, the research assistant found partial terminology in SNOMED ADR, including *weakness* and *syncope and collapse*; however, during consensus, the research assistant noted that the patient did not have syncope. In this case, although some terms were available, they did not produce a complete and clinically meaningful or accurate description of the event. An instance in which the terminology was too specific arose with ICD-11, wherein the only term available to describe a hematoma case included the qualifier *of other specified site complicating a procedure*; however, there was no indication that this hematoma was in fact complicating a procedure. An example of exceedingly broad or vague terminology arose when the research assistants could not find a specific term for *Clostridium difficile* in SNOMED ADR, which led to a discussion of whether the term *diarrhea* was adequate. These challenges occurred most often with SNOMED ADR and least often with MedDRA.

Unusual terminology and phrasing or unfamiliar spelling compromised the usability of the data sources. Usability challenges emerged when the research assistants reported that they felt a term adequately described the case but that it was difficult to find, it was only identified during consensus, or they had to rely on external sources to identify the term (eg, Google). In the case of a *rash*, the research assistants identified the term *allergic disorder of the skin* in ICD-11 as the closest descriptor but felt that it was atypical phrasing. Another issue was the use of British English spellings for certain terms (eg, *haemorrhage* instead of *hemorrhage*). Usability challenges were most common with ICD-11; however, the research assistants encountered them less often than the issues with accuracy or comprehensiveness.

Case-Related Factors

In some cases, there was insufficient information in the chart to classify the event independent of the data source. For example, in a case, the research assistant noted that the selected term was broad enough, but the classification would have been improved if there were more details about the patient's documented *bizarre behavior*. The research assistants also encountered cases with insufficient information to classify the event in the context of the data standard's limitations, often because of vague case descriptions that could only be classified using high specificity terms. For example, in SNOMED ADR, the terms to describe headaches were often too specific, such as *frontal headache* or *migraine with aura*, whereas case descriptions tended to use only the term *headache*.

Individual Factors

Individual factors, such as recall and interpretation, had an effect on the classification of events. During consensus, the research assistants discussed instances where 1 research assistant did not identify the correct term that the other had identified. This occurred because they forgot the terminology (eg, the research assistant had been searching for the term *kidney* rather than *renal* to describe abnormal renal function), did not consider alternate wording (eg, the research assistant did not think of the term *spasticity* to refer to *rigidity* or *stiffness*), or were unable to locate a term that they felt was acceptable (eg, the research assistant could not find a term related to the patient's history of noncompliance). In almost all of these instances, the research assistant agreed with the other's selection during the consensus.

Discussion

Principal Findings

Previous studies have demonstrated gaps in the existing terminological standards in health care [24,25]. Our findings add a nuanced examination of these gaps and other shortcomings of multiple terminological standards rooted in clinical practice. We explored the utility of 4 data standards to document adverse drug event symptoms and diagnoses. Our quantitative analysis demonstrated that MedDRA and ICD-11 were most likely to have an appropriate symptom or diagnosis available. MedDRA most often had any match documented, whereas ICD-11 had the fewest matches. SNOMED HC performed the best in terms of the first term that the research assistants selected for matching. SNOMED ADR performed the worst in terms of having the lowest capture of a symptom or diagnosis. These results are consistent with our qualitative findings. The research assistants were least likely to encounter terminological challenges with MedDRA and most likely with SNOMED ADR. We found that ICD-11 was most likely to present usability challenges because of unusual terminology or spelling, which may provide a rationale for why ICD-11 had the fewest matches. The research assistants also found ICD-11 to be the most time consuming for searching terms because of the lengthy list of returned matches with descriptive terms, whereas SNOMED HC and SNOMED ADR were the least time consuming, with a shorter list of returned matches with more straightforward terms to select from. Overall, across all the indicators, we found that MedDRA was the strongest data standard, whereas SNOMED ADR performed poorest. We acknowledge that SNOMED ADR is a working data set at this time and thus could be strengthened through further study and use.

Implementing clinical information systems with data standards that lack comprehensiveness, accuracy, or usability in clinical practice will affect data entry and generate downstream negative effects on data quality and the information generated. In the absence of correct or accurate terminology, research assistants were more likely to make compromises or use workarounds by selecting a term that was close enough or only partially described the event. In clinical practice, challenges with data entry, along with time constraints and other external pressures, may result in a clinician opting to abandon data entry altogether, thus lowering data quantity and quality. Conversely, semantic standardization may lead to more consistent and complete reporting for pharmacovigilance activities if the appropriate data standard is used, which may produce higher data quality and facilitate data analysis [26-28]. Reliable coding for adverse drug reactions is likely to yield more meaningful data for the end user and may facilitate data integration across different electronic health systems [28,29].

Recent efforts to map terminology across different standards may be used to develop clinical information systems with specific data standards while facilitating data integration across systems and pharmacovigilance organizations. Reich et al [30]

demonstrated that it is feasible to map ICD-9 diagnosis codes for medical conditions to SNOMED CT and MedDRA, making both suitable options for standard vocabularies. However, to our knowledge, there has been no study that has compared these data sets with one another or investigated their use specifically for documenting adverse drug events [30]. The WEB-RADR 2 Project seeks to develop a bidirectional mapping of a subset of pharmacovigilance terms between SNOMED CT and MedDRA [31]. Mapping and testing were scheduled to be completed in 2020, with a production version of the map available to SNOMED and MedDRA users in 2021. In addition, the National Institutes of Health's National Library of Medicine has also developed a Unified Medical Language System that maps SNOMED CT to ICD-10 to support reimbursement and statistical analyses [32]. Further research should examine the effect of mapping data standards on data quality.

In addition to the efforts to map terminology across data standards, advances in natural language processing increasingly offer a new and promising approach to the analysis of adverse drug event reports for pharmacovigilance activities. Using natural language processing, system designers may enable free text data entry from clinicians to increase the ease of use. Such systems would then algorithmically analyze the entered data to produce standardized data for monitoring and regulatory purposes [33]. A recent systematic review found that many studies on natural language processing of incidents, adverse events, and medical error reports have focused primarily on binary classification, which does not account for the complexity of adverse drug event documentation that we sought to capture and limits the subsequent clinical utility of data to support continuity of care [33]. In addition, in instances where cases contain insufficient information for classification, which we encountered in this study, natural language processing is unlikely to improve the results. Continued research in this field should explore natural language processing, aim to produce multimodal analyses of reports, and increase integration across clinical information systems.

In the absence of an agreed-upon standard for data capture and with the advent of increased mapping across terminologies, we suggest that health system designers prioritize the implementation of a data standard that is clinically useful and relevant to ensure high usability for clinicians who are asked to document the event while being immersed in clinical activities. For this purpose, MedDRA was the strongest data standard among the data sets in our study, and we recommend it be used as the standard for Canadian pharmacovigilance activities in support of federal legislation that requires all Canadian health institutions to report serious adverse drug reactions to Health Canada [6]. MedDRA is also currently used in other pharmacovigilance systems, such as the US Food and Drug Administration Adverse Drug Event Reporting System and Vaccine Adverse Event Reporting System databases, the European Medicines Agency Eudrawatch system, and the Japanese prescription event monitoring system, which makes it a strong option to advance international collaborative efforts in pharmacovigilance.

Limitations

There are limitations to this study. Our research team is more familiar with MedDRA, which may have led to bias when selecting the most comprehensive data standard. However, one of our research assistants had previously never worked with our team and thus was unfamiliar with MedDRA at the outset of this study. We also relied on the American translation of British MedDRA terminology, which may have facilitated the identification of terms and resulted in more matches. The ICD-11 terms remained in their original British spelling, which may have initially resulted in fewer matches. We observed that this effect was offset as the research assistants became familiar with these patterns over time and with use. SNOMED ADR is designed to describe adverse drug reactions; however, we applied it to describe a broader range of adverse drug events. This may have positioned SNOMED ADR to perform poorly from the outset and falsely lowered its capture of a symptom or diagnosis compared with the other data standards. We were also unable to obtain more information than what was available in the research records, as they were from a previous multicenter chart review study, which may have limited the terms we could have selected for a given data standard.

Conclusions

Usability, comprehensiveness, and accuracy are the key features of a data standard for documenting adverse drug event symptoms and diagnoses. On the basis of these factors, we found that MedDRA is the most suitable data standard for coding adverse drug events in electronic reporting systems. Although data standardization is important, not all standards are created equally. As our analyses demonstrate, each data standard has different affordances and constraints. Hence, it is important to critically evaluate competing standards to ensure that the data standards adopted in clinical information systems support patient safety rather than compromise it. When the appropriate data standard is selected, the standardized terminology may result in more consistent adverse drug event documentation and better data quality and quantity as a by-product of routine care.

Abstract

Background: Accurate medication reconciliation reduces the risk of drug incompatibilities and adverse events that can occur during transitions in care. Community pharmacies (CPs) are a crucial part of the health care system and could be involved in collecting essential information on conventional and supplementary drugs used at home.

Objective: The aim of this paper was to establish an alliance between our cancer institute, Istituto Romagnolo per lo Studio dei Tumori (IRST), and CPs, the latter entrusted with the completion of a pharmacological recognition survey. We also aimed to integrate the national information technology (IT) platform of CPs with the electronic medical records of IRST.

Methods: Cancer patients undergoing antiblastic treatments were invited to select a CP taking part in the study and to complete the pharmacological recognition step. The information collected by the pharmacist was sent to the electronic medical records of IRST through the new IT platform, after which the oncologist performed the reconciliation process.

Results: A total of 66 CPs completed surveys for 134 patients. An average of 5.9 drugs per patient was used at home, with 12 or more used in the most advanced age groups. Moreover, 60% (80/134) of the patients used nonconventional products or critical foods. Some potential interactions between nonconventional medications and cancer treatments were reported.

Conclusions: In the PROF-1 (Progetto di Rete in Oncologia con le Farmacie di comunità della Romagna) study, an alliance was created between our cancer center and CPs to improve medication reconciliation, and a new integrated IT platform was validated.

Trial Registration: ClinicalTrials.gov NCT04796142; https://clinicaltrials.gov/ct2/show/NCT04796142

Introduction

Medication reconciliation is the process of drawing up a complete and accurate list of all medications being taken by an individual patient, including drug name, dosage, frequency, and route of administration, and comparing them with the medications listed in the patient's medical records or medication prescriptions. The aim of reconciliation is to reduce the risk of errors of omission, duplication, incorrect doses or timing, and adverse drug-drug or drug-disease interactions [1-3]. The Joint Commission on Accreditation of Health Care Organizations added the concept of reconciliation across the continuum of care as a national patient safety goal [4]. It has also been defined as one of the best strategies for maintaining the quality of care by the Agency for Healthcare Research and Quality [5] and is one of the 5 elements in the "High 5s Project" launched by the World Health Organization [6].

Reconciliation must be periodically performed at both the hospital and territorial level [7] and at every transition of care [8], especially when new medications are prescribed or rewritten as several professionals may be involved. The efficacy and quality of this process depends mainly on a preliminary pharmacological survey (recognition step), which not only takes into account the medications prescribed to the patient, but also the phytotherapeutic and homeopathic products, supplements, and foods taken, as well as any habit that might negatively affect patient safety [5]. The success of the recognition step depends on the interlocutor's ability to promote within the patient a sense of empowerment and responsibility in relation to treatment adherence [9]. The use of innovative drugs for the treatment of cancer is constantly increasing [10], and many are unknown to the vast majority of nonexperts in the field. This increases the risk of pharmacological discrepancies in the medications prescribed (or self-prescribed) in the interval between each access to the cancer center caring for the patient [11-13]. In particular, nonconventional medicinal and health preparations such as over-the-counter products, herbal medicines, and supplements are sources of potential pharmacological discrepancy and should be closely monitored [5]. Cancer patients frequently resort to such remedies in an attempt to improve their quality of life, often compromised by the side effects of the treatments, or to help them cope with the emotional aspects related to living with cancer.

Therapy errors have economic implications. The World Health Organization has estimated the cost of therapy errors to be at US $42 billion annually and has set a goal of reducing these costs (which are attributed to weaknesses in health care systems) by 50% within the next 5 years [14]. In the area of oncology, the extent of the economic risk is increased by the burden of expected outcomes and by the high costs of anticancer treatments for the UK National Health Service. In 2018, in Italy, these costs were estimated to be at €5659 million (US $6360 million), constituting the first item of public health expenditure and exceeding that of cardiovascular drugs [15].

Community pharmacies (CPs) are a crucial part of the health care system. They are neighborhood health care facilities whose activities include dispensing medications, treating minor ailments, and offering advice on well-being. CP staff also frequently build up a close relationship with their clients, and they are highly knowledgeable about food supplements as they are responsible for around 80% of the sales of these products on the market [16]. It is therefore relatively easy for CPs to gather information to obtain a complete and accurate picture of the use of conventional drugs and supplements at home.

The territory of Romagna has a population of 1,281,243, spread over 3 provinces (Forlì-Cesena, Ravenna, and Rimini), and represents 28.6% (366,436/1,281,243) of the Emilia-Romagna region in northern Italy. There are 356 CPs in Romagna. Our cancer institute (IRCCS Istituto Romagnolo per lo Studio dei Tumori [IRST], "Dino Amadori") is also based in this area. The center has a high level of computerization and standardization of all therapeutic, clinical, and experimental processes, guaranteeing maximum safety for patients and full traceability of the actions carried out by each professional, clinician, pharmacist, and nurse during their daily activities. The national association representing private CPs (Federfarma) recently developed an information technology (IT) platform (Dottorfarma) in collaboration with an e-commerce company (Promofarma) that can be used by CPs nationwide.

Given these premises, an alliance created between IRST and the CPs of Romagna seemed to provide the perfect opportunity [17] to improve the pharmacological reconciliation process and to bridge the "pharmaceutical gap" between the health care system and the patients. We carried out a prospective, interventional, nonpharmacological study of the first phase of the network project in oncology with the community pharmacies of Romagna (Progetto di Rete in Oncologia con le Farmacie di comunità della Romagna [PROF-1]) on a new model for medication reconciliation. Our overall aims were to create an organizational model and IT platform, assess their ability to promote the shared management of therapies by patients, pharmacists, and health care professionals (thus improving adherence to treatment and the home management of side effects), and evaluate the acceptability of this model by patients.

Methods

The team of investigators included the IRST oncology group (oncologists, hospital pharmacists, and nurses), IRST and Federfarma IT Services, CPs, and scientific representatives of private and public pharmacy associations. The study team also worked closely with lawyers from Federfarma and Promofarma to take care of the delicate aspects of professional responsibility and data privacy. During the feasibility analysis of the project (PROF-1 trial), the basic network model was defined by jointly identifying the individual professionals and their respective responsibilities. The investigators agreed that each of the professionals would be responsible for the accuracy of the

information provided, while the medication reconciliation process would be the exclusive responsibility of physicians. This decision meant that the data transmitted from a CP to IRST would only be valid after the clinician had downloaded, integrated, and confirmed the information. Regarding the CPs' task of collecting patient data, it was agreed that the pharmacist transmitting data directly to IRST medical records would not be able to view or modify the entered information.

A drug recognition form was created and validated in a pilot study carried out on breast cancer patients [18]. The form was divided into 5 sections (medications, critical foods, supplements, phytotherapeutic products, and homeopathic products). Information would be gathered for each compound (eg, active ingredient and trade name; pharmaceutical form and route of administration; dosage, posology, start or end of intake, reason for intake, and prescriber). Initially conceived as a paper document, the form was digitized in both the Dottorfarma IT platform and IRST medical records for the purposes of the trial.

A total of 200 patients were considered for the PROF-1 study. A formal sample size calculation for this prospective study was not performed due to the lack of preliminary data and the exploratory intent of the study. Eligible patients were required to meet the following criteria: being adults ≥18 years old, of either gender; having an Eastern Cooperative Oncology Group performance status of ≤1; undergoing anticancer treatment; having a clear understanding of the Italian language; and granting written informed consent.

When the patients came to the institute for anticancer treatment, health care professionals provided information about the trial and obtained written informed consent from those willing to take part. The patients were asked to choose one of the CPs accredited for the trial and to book an appointment for the pharmacological recognition step. The accredited pharmacist, after ensuring that the patient had provided written informed consent and completed a privacy form, interviewed the patient in a private consultation area, completing the online drug recognition form in the Dottorfarma IT platform (Figure 1), which has the same format as that of IRST electronic medical records. The pharmacist took into account the information provided by the patient or delegated caregiver and that retrieved from drug packages or other products used by the patient at home (and brought to the interview), paper referrals, or prescriptions from specialists. The recognition data were sent to IRST through the Dottorfarma IT platform and automatically saved in a specific medical history file in the electronic medical records (Figure 2). Upon confirmation of the next course of chemotherapy, the oncologist downloaded the pharmacological recognition form and performed the reconciliation process. For the purposes of the present trial, the processes of recognition and reconciliation were carried out only once for each enrolled patient. Following the completion of the drug recognition and reconciliation processes, the patients were asked to complete a satisfaction questionnaire.

Descriptive statistical analyses were performed on all case series (absolute and relative frequency for categorical variables and median and quantiles for continuous variables). All statistical analyses were carried out using SAS Software, version 9.4 (SAS Institute).

This study was reviewed and approved by the AUSL (Azienda unità sanitaria locale) Romagna/IRST Ethics Committee (approval number 1722, October 26, 2016) and was conducted in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and later versions. The participants provided written informed consent to take part in the study.

The data sets generated and analyzed during the current study are available from the corresponding author upon reasonable request.

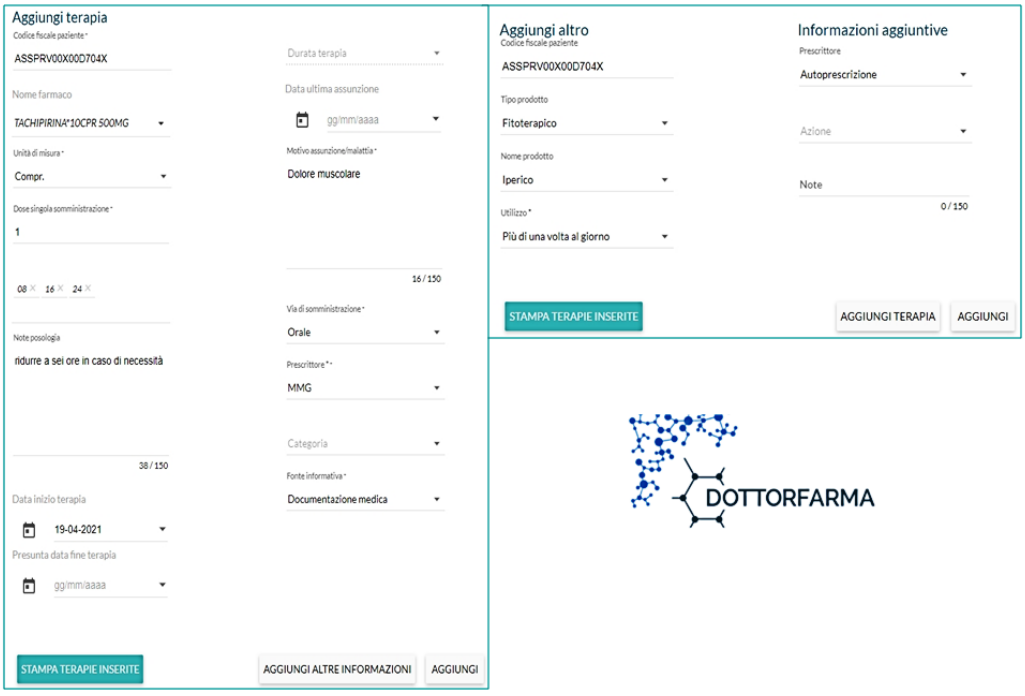

Figure 2. Drug history section of the IRST (Istituto Romagnolo per lo Studio dei Tumori) electronic medical records.

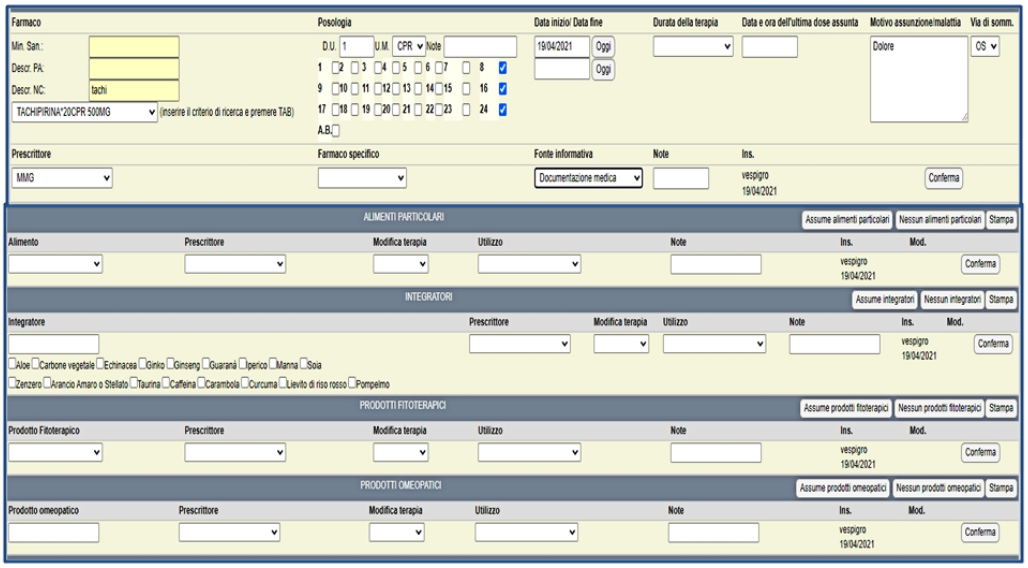

Results

A dialog between IRST and local CP associations was opened, leading to the creation of a specific agreement between the 2 parties. The first step involved the implementation of the Dottorfarma IT platform, initially with a one-way communication flow. The pharmacological recognition form was digitized on both the Dottorfarma IT platform and IRST electronic medical records, and the 2 systems were synchronized.

Pharmacy Recruitment and Training

Following an open invitation, out of 365, 120 (34%) of the public and private CPs of Romagna initially agreed to take part in the study. Pharmacy managers or a representative from each CP took part in a brief training course organized by IRST to inform the participants about the recognition and reconciliation process, to present the PROF-1 study, and to provide instructions on how to complete the pharmacological recognition form. A total of 108 CPs (84 private and 24 public CPs) finally agreed to participate in the trial (36 in the province of Forlì-Cesena, 26 in the province of Rimini, and 46 in the province of Ravenna). The enrolled patients chose 66 of these to complete the pharmacological recognition survey (Multimedia Appendix 1).

Patients

From April 2017 to April 2018, 200 patients were enrolled onto the trial. Among these, 137 (68.5%) underwent the pharmacological recognition interview as planned, while 63 (31.5%) were not evaluable, 39 (19.5%) withdrew consent, 11 (5.5%) were excluded for technical problems, and 13 (6.5%) spontaneously dropped out) (Multimedia Appendix 1). Patient characteristics are shown in Table 1.

The majority of the patients were female (83, 61%), with a median age of 63 years Most patients lived in the province of Forlì-Cesena, where our institute is based. The majority were undergoing chemotherapy (alone or in combination with targeted therapies), mainly administered intravenously. The list of anticancer drugs administered to the enrolled patients is reported in Table 2.

The analysis of the data entered by CPs revealed a total of 805 medications declared by the patients, with an average of 5.9 drugs per patient taken at home. As many as 12 or more medications were being taken by 6 patients over the age of 65 years. Drug distribution, identified in the recognition form according to the Anatomical Therapeutic Chemical classification, is reported in Table 3 (1st and 2nd levels).

Of the total 805 declared drugs, 29.4% (n=237) and 20.7% (n=167) were used to treat problems in the gastrointestinal and cardiovascular systems, respectively. The former drugs were mainly used to contrast chemotherapy side effects and cancer-related symptoms (eg, proton pump inhibitors and antacids, antiemetics, laxatives, and antidiarrheals), while the latter mainly included antihypertensive drugs and statins. Drugs for the central nervous system represented 13.2% (n=106) of all drugs and comprised mainly analgesics and antidepressants or anxiolytics. Hormones (55, 6.8%), drugs for musculoskeletal disorders (47, 5.8%), antithrombotic or antianemic drugs (43, 5.3%) and systemic antimicrobials (32, 4%) were also being taken. Although the recognition of anticancer drugs was not required (this information was already present in the medical records), some patients reported oral anticancer drugs in their list of medicines. Further interesting information was obtained from the recognition form; ie, 87.6% (n=705) of drugs were taken orally. Moreover, sources of information varied, coming from medical documents (145, 18%), drug lists (227, 28.2%), product packages (86, 10.7%), patient declarations (270, 33.5%), and caregiver declarations (73, 9.1%). The main prescribers were specialist physicians (542, 67.3%) and general practitioners (204, 25.3%), while 1.5% (n=12) of the patients were self-prescribers.

[a]ATC: Anatomical Therapeutic Chemical.

[b]NSAIDs: nonsteroidal anti-inflammatory drugs.

In addition, of a total of 137 patients, 83 (60.5%) reported an intake of 201 nonconventional medications (supplements, phytotherapeutics, or homeopathic products), and 39 (28.5%) reported having taken foods considered critical for the potential interactions with medications (Table 4). A detailed analysis of the recognition form revealed that the most widely represented critical substances were coffee (23 patients, 16.8%), green tea (11 patients, 8%), aloe (6 patients, 4.4%), turmeric (5 patients, 3.6%), fermented red rice (5 patients, 3.6%), ginger (3 patients, 2.2%) and manna (3 patients, 2.2%).

An evaluation of drug-drug interaction was not carried out as it was not one of the aims of this paper. However, we investigated the potential for interaction between nonconventional products and cancer treatments (Table 4), identifying 2 possible interactions with aloe vera, 3 with manna, 1 with echinacea, 1 with ginseng, 2 with ginger, and 3 with red yeast rice. After analyzing the components present in the supplements taken by the patients but not present in our list of critical compounds, the following possible interactions emerged: 2 interactions with milk thistle, 2 with berberine, 1 with alpha lipoic acid, 1 with vitamin C, 1 with folic acid, and 1 with *Cordyceps sinensis*.

A total of 106 patients completed and returned the satisfaction questionnaire. Of these, 77 (72%) considered the reconciliation process as very important, 74 (70%) thought that the involvement of the pharmacist was very useful, and 87 (82%) reported no difficulty in going to the chosen pharmacy to complete the pharmacological recognition survey.

Table 4. Critical foods, nonconventional products, and potential interactions with cancer treatments.

Product	Value	Potential interaction
Critical foods, n (%)		
Coffee	23 (16.8)	—[a]

[a]Not applicable.

[b]Not reported in the official list of critical compounds, but with possible critical interactions in the post hoc analysis.

Discussion

Principal Findings

The PROF-1 trial achieved its goal of creating a new model for medication recognition and reconciliation processes in oncology thanks to the close cooperation between our institute and CPs, the implementation of an integrated IT platform, and the active participation of cancer patients.

An interest in being actively involved in the setting up of a new hospital territory network was clearly demonstrated by both public and private CPs in their willingness to take part, at no cost, in the project. A total of 120 CPs participated in the training course, and 108 agreed to enrol patients, the latter process involving a commitment of around 30 minutes for each survey to integrate into routine pharmacy activities. To the best of our knowledge, this was the first trial addressing the problem of medication reconciliation to include private entities not directly involved in the care of cancer patients.

PROF-1 confirmed the high number of medications used by patients at home (an average of 5.9 drugs per patient), especially in the most advanced age groups. Even more striking was the evidence of an increasing number of patients who used nonconventional products or critical foods. These results underline the importance of pharmacological recognition and reconciliation processes, which, despite being mandatory ministerial measures [1,3], are often neglected by oncologists because of the pressures of daily clinical activity. An alliance with CPs could thus lead to a significant improvement in the situation [19-21]. Numerous attempts have been made to

improve the medication reconciliation process, including pharmacist-related interventions and IT platforms, with interesting results in terms of reduction in medication discrepancies and potential adverse events [22]. However, none of the proposed models included the presence of community pharmacists.

Our study highlighted some limitations in this new model, the first concerning patient empowerment. Although the patients were personally involved and expressed a high degree of satisfaction through the questionnaire, a certain number who signed the informed consent did not go to the chosen CP to complete the recognition step. This may have been due to a deterioration in their clinical conditions or to the side effects of chemotherapy, given that the study population was recruited among those undergoing antiblastic therapy, regardless of prognosis or type of treatment. This is an important aspect to bear in mind as it suggests that some patients may not be suitable for this type of project. A review of the communication channels between patient and CP, including the use of the telephone or email rather than direct access, could perhaps improve this issue. Another important limitation was that, given the exploratory nature of the trial, only one recognition-reconciliation process was planned for each patient, making it impossible to verify the advantage of a continuous exchange of information from a series of repeated processes to monitor changes in medications taken at home. A new trial (PROF-2) is ongoing to further implement and validate the model, this time incorporating the repetition of the recognition-reconciliation processes before each chemotherapy cycle. Another imitation concerns drug-drug interactions. As stated above, the use of a surprisingly high number of drugs, supplements, and nonconventional products were declared by patients, raising the question of possible interactions. However, we did not focus on the drug-drug interactions that emerged from the reconciliations performed by oncologists, as this was not an aim of the study. Conversely, our analysis of the potential interactions between cancer drugs and nonconventional products confirmed the importance of this issue. Finally, the difficult reproducibility of the proposed model must be emphasized as a possible limitation because of some basic requirements (ie, a high level of computerization of the centers taking part and the strict regulation of data processing and patient privacy). The strengths that made it possible to complete the project were the solidity of the computerized medical records present in our cancer institute, the presence of an IT platform that could be shared by all private and public CPs, and the approval of the project by the local ethics committee after in-depth teamwork to resolve the issues of professional responsibility, data ownership, and privacy management.

Based on the results from this pilot study, the alliance between the cancer center and the CPs of Romagna has led to the creation of a cancer network which, albeit initially established to meet a specific need, could help to systematically establish safety pathways for drugs used at home. This initiative could also contribute to increasing adherence to innovative drugs, essential not only for the success of treatment but also for the sustainability of the national health service of every nation. It could also improve the management of ancillary drugs for the prevention of toxicities, often underestimated or self-managed by patients [23]. The PROF-1 project was conceived and designed some years before the COVID-19 pandemic, which has forced the community to acknowledge the importance of the territory in the management of patients' needs. Within this context, our model proved highly functional not only in terms of the study's main aim (pharmacological reconciliation), but also in terms of the successful creation of a hospital community network whose impact may well exceed what was originally hypothesized.

Conclusions

The PROF-1 trial represents an important step forward in medication reconciliation in oncology. The alliance established between our cancer institute and local CPs to enhance medication reconciliation in transitions in care led to the creation of an innovative organizational model and the validation of a new integrated IT platform.

Acknowledgments

The authors wish to thank the late Professor Dino Amadori for his important contribution to the study design and for his support of this ambitious project from the very beginning. They also wish to thank all the patients who agreed to use the CPs (community pharmacy) involved in the study, thus contributing to the development of this experimental model; the CP pharmacists who took part in the project; Chiara Crispo and Andrea Tarozzi, Professor of Pharmacology at Bologna University, for their help with the analysis of drug interactions. Many authorities and professionals must be thanked for the support given to the project: the regional and provincial presidents of Federfarma in office at the start of the project and those currently in office (Daniele Raganato, Benedetta Camerani, Domenico Dal Re, Achille Gallina Toschi, Alberto Lattuneddu, Roberto Deluigi, and Pietro Gueltrini); Ernesto Toschi, the regional president of Assofarm, and Barbara Pesci and Bruna Baldassarri of the Municipal Pharmacy Company of Ravenna; Bruno Foresti of Federfarma and Giulia Fatano of Promofarma; Giovanni Petrosillo and Daniele D'Angelo, former directors of Promofarma, and Claudio Montalto, IT engineer formerly at Promofarma; Marco Cossolo, president of the National Federfarma, Venanzio Gizzi, president of Assofarm, and Annarosa Racca, the former president of the National Federfarma; Susanna Ciampalini of the Quality Office of the General Directorate of Health Planning, and Ester Sapigni from the Drug Policy Service of the Emilia Romagna Region.

Authors' Contributions

MVM, RV, and ON conceived the idea for and designed the study. MVM, AP, and RV collected patient data. AP, MVM, ON, PS, RV, CD, FF, SP, GT, PFG, GM, MA, and GLF were responsible for data interpretation. ON performed the statistical analyses. AP and MVM drafted the paper. All coauthors reviewed the paper, providing important feedback to improve the manuscript. All authors read and approved the present version of the manuscript for submission.

Conflicts of Interest

None declared.

Abstract

Background: Unique patient identification remains a challenge in many health care settings in low- and middle-income countries (LMICs). Without national-level unique identifiers for whole populations, countries rely on demographic-based approaches that have proven suboptimal. Affordable biometrics-based approaches, implemented with consideration of contextual ethical, legal, and social implications, have the potential to address this challenge and improve patient safety and reporting accuracy. However, limited studies exist to evaluate the actual performance of biometric approaches and perceptions of these systems in LMICs.

Objective: The aim of this study is to evaluate the performance and acceptability of fingerprint technology for unique patient matching and identification in the LMIC setting of Kenya.

Methods: In this cross-sectional study conducted at an HIV care and treatment facility in Western Kenya, an open source fingerprint application was integrated within an implementation of the Open Medical Record System, an open source electronic medical record system (EMRS) that is nationally endorsed and deployed for HIV care in Kenya and in more than 40 other countries; hence, it has potential to translate the findings across multiple countries. Participants aged >18 years were conveniently sampled and enrolled into the study. Participants' left thumbprints were captured and later used to retrieve and match records. The technology's performance was evaluated using standard measures: sensitivity, false acceptance rate, false rejection rate, and failure to enroll rate. The Wald test was used to compare the accuracy of the technology with the probabilistic patient-matching technique of the EMRS. Time to retrieval and matching of records were compared using the independent samples 2-tailed *t* test. A survey was administered to evaluate patient acceptance and satisfaction with use of the technology.

Results: In all, 300 participants were enrolled; their mean age was 36.3 (SD 12.2) years, and 58% (174/300) were women. The relevant values for the technology's performance were sensitivity 89.3%, false acceptance rate 0%, false rejection rate 11%, and failure to enroll rate 2.3%. The technology's mean record retrieval speed was 3.2 (SD 1.1) seconds versus 9.5 (SD 1.9) seconds with demographic-based record retrieval in the EMRS (P<.001). The survey results revealed that 96.3% (289/300) of the participants were comfortable with the technology and 90.3% (271/300) were willing to use it. Participants who had previously used fingerprint biometric systems for identification were estimated to have more than thrice increased odds of accepting the technology (odds ratio 3.57, 95% CI 1.0-11.92).

Conclusions: Fingerprint technology performed very well in identifying adult patients in an LMIC setting. Patients reported a high level of satisfaction and acceptance. Serious considerations need to be given to the use of fingerprint technology for patient

identification in LMICs, but this has to be done with strong consideration of ethical, legal, and social implications as well as security issues.

biometrics; patient matching; fingerprints; unique patient identification; electronic medical record systems; low- and middle-income countries (LMICs)

Introduction

Background

Unique patient matching and identification across health services is an operational challenge in many health care settings [1-4]. Commonly used identifiers such as patient names, ID numbers, national ID numbers, and dates of birth are often inadequate at guaranteeing unique patient identification, and sometimes these data may not be available [5-7]. Failure to correctly match patients largely contributes to inefficiencies in care delivery, resulting in medical errors that can affect patient safety [8]. In the United States alone, an estimated average of 400,000 deaths occur annually because of medical errors [9]. The problem is even more significant in low- and middle-income countries (LMICs), with many of these countries yet to implement accurate and comprehensive person identification procedures that ensure unambiguous identification of all citizens and residents [10].

Patient identity management has relied heavily on either deterministic or probabilistic algorithms, as well as other statistical matching procedures [11,12]. Deterministic matching algorithms use exact match or comparisons between 2 fields [13]. These algorithms compare identifiers such as national IDs for each record to determine a match. Probabilistic matching, which is by far the most widely implemented technique for record matching [14], does not necessarily depend on unique identifiers [15]. This technique assigns weights to records to calculate the probability of linkage among them; it then uses the observed frequency of agreement and disagreement patterns among the records. The total linkage weight is then compared with a threshold above which pairs are considered a match [16-18]. The challenge with deterministic algorithms is their lack of scalability and the requirement for expensive customization and business rule revisions as databases grow in size [19]. Furthermore, not all probabilistic algorithms applied to the same set of circumstances yield results with the same degree of accuracy because they are based on field-specific weights rather than value-specific weights [20]. Application of statistical matching approaches is further limited where patients may have isolated sets of their information distributed across multiple disparate systems. In addition, people may not consistently use their official names, with some preferring to use abbreviations or alternative expressions. Name misspellings and name-order transpositions are also encountered [21,22].

In our own institutional experience, the evaluation of various 4-string manipulation strategies to improve the performance of probabilistic models of patient matching based on Kenyan names revealed a suboptimal specificity and positive predictive value of <50% when matching patient names from 2 independent clinical databases [23]. This was indeed a low level of performance accuracy, especially in a health care setting. It is therefore imperative that better patient-matching approaches are determined, especially as settings start to exchange, aggregate, and centralize clinical data from multiple sources. Beyond matching performance, any approach to be considered has to be relatively affordable, feasible, and acceptable in LMIC care settings.

Use of Fingerprinting

Biometric approaches offer a potential solution to the challenge by trying to tackle some of issues identified in the traditional patient-matching algorithms [24]. The use of fingerprinting is already quite common in many LMICs, often for national-level voter registration and immigration services, among others. Fingerprinting and other biometric technologies are not without challenges. Special consideration needs to be given to the ethical, cultural, social, and legal implications of these solutions [25]. For example, some people may have concerns about the safety, encryption, and secondary use of their biometric data [26]. Studies have cited concerns by users about the hygiene of touching these devices [27-29]. Given the potential benefits of these technologies for improving patient matching and the poor performance of existing statistical patient-matching models, rigorous evaluations need to be conducted that weigh fingerprinting benefits (improving matching) against concerns by key stakeholders.

The basic principle of biometric authentication is that everyone is unique and can be identified by their intrinsic physical or behavioral traits [30]. Biometric technologies such as fingerprinting offer a potentially promising solution given that fingerprinting scanners are ubiquitous, the technology is relatively easy to acquire and use [31], the scanners require minimal database memory requirements, and there have been several demonstrated instances of their large-scale implementation and dominance in other sectors [32,33]. A fingerprint consists of a pattern of ridges and valleys in the surface of the fingertips, and its formation is related to the earlier fetal months [34]. It is the ridges and valleys that are extracted as minutiae that are converted into a template for storage in the database. The template is always retrieved and compared with a fresh scan (new template) during matching and identifications processes [35]. In this study, we set out to (1) evaluate the performance of using fingerprint biometric technology for patient matching within an LMIC setting and (2) evaluate acceptability and patient perception of using this system for patient identification and matching.

Methods

Study Setting and Participants

This study was conducted at care facilities served by the Academic Model Providing Access to Healthcare (AMPATH) in Western Kenya. The program offers HIV care and treatment services, with more than 100,000 patients who have tested positive for HIV currently under care. The program operates in partnership with Kenya's Ministry of Health and with support from the United States Agency for International Development. This study was conducted at AMPATH clinical facilities located in Eldoret, Kenya. The study population included consenting patients aged ≥18 years visiting the AMPATH clinics for care. Patients aged <18 years were excluded because of the intricacies involved in obtaining their consent and in filling surveys. AMPATH uses an adaptation of the Open Medical Record System, an open source electronic medical record system (EMRS) deployed widely in LMICs [36,37]. Patient records in the system contain demographic information that includes several patient attributes, for example, name, age or birthdate, national ID number if available, and telephone number. The Fellegi–Sunter algorithm is used within the EMRS for patient matching. The Fellegi–Sunter algorithm is a weighted probabilistic-based record linkage approach that relies on matching weights to compute a maximum likelihood estimate that determines whether a record pair is a match or nonmatch [38].

Study Design

The mUzima Fingerprint Module version 1.0 was developed to work as an integrated module within the EMRS in a client server–model architecture. The module was developed using Java Web Start (Oracle Corporation), which uses the Java Network Launching Protocol to download and run the fingerprint application locally on the client machine. This particular technology provides an easy 1-click activation of remotely hosted applications, guaranteeing application efficiency and elimination of complicated installation or upgrade procedures [39].

Fingerprint Technology–Matching Algorithm

The fingerprint-matching technology was based on the Bozorth3 fingerprint-matching algorithm (National Institute of Standards and Technology) [40]. Bozorth3, a minutiae-based algorithm, does both one-to-one and one-to-many matching operations. The recommended Bozorth3 threshold is the integer 40. However, during the technology testing phase, test runs at a threshold of 40 often produced false positives, and after numerous tests, a threshold of 70 proved to be a better measure to work with for this study. For every patient, 3 instances of the same left thumbprint were captured, converted into templates, and stored in the database. A patient was identified positively if any of the 3 instances returned a matching value of ≥70, the set threshold; otherwise, it returned a nonmatch.

Fingerprint Technology User Interface

The fingerprint module user interface provided 2 options for searching a patient either by their demographic information (name) or by fingerprint. A name search using the probabilistic patient-matching algorithm of the current EMRS returned all database instances with the same or similar name, with matches refined as more information was entered (Figure 1). However, when the same person was searched using their fingerprint as the identifier, a distinct and unique result was returned (Figure 2). The workflow for the fingerprint technology module is presented in Multimedia Appendix 1.

Figure 1. Screenshot showing the output of a patient search ("Mark") using a probabilistic-based algorithm.

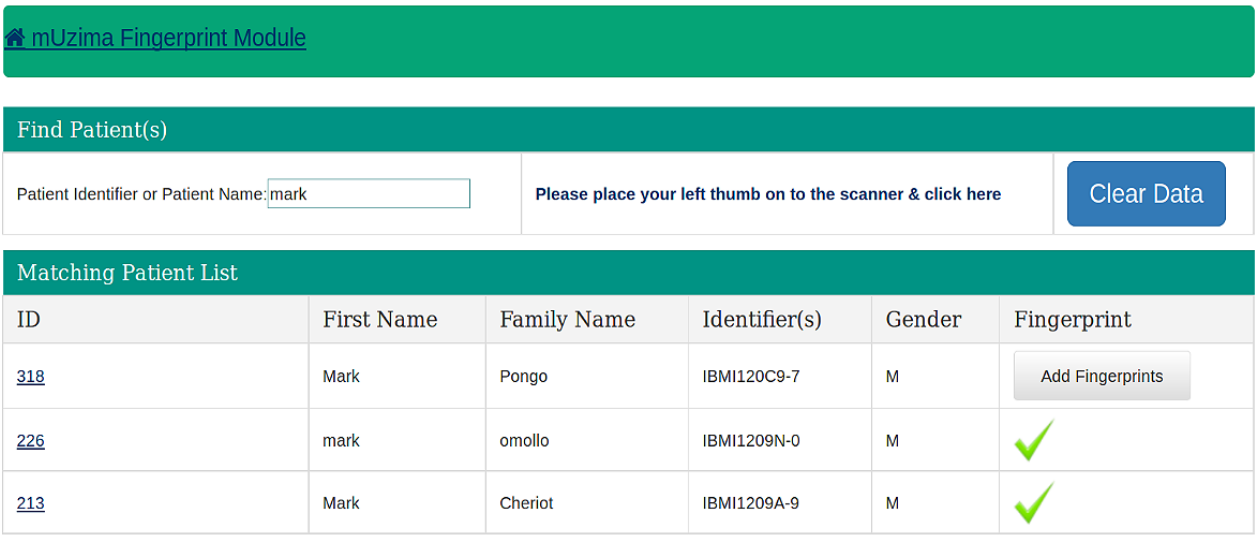

Figure 2. Screenshot showing the output of a patient search ("Mark") using fingerprint technology.

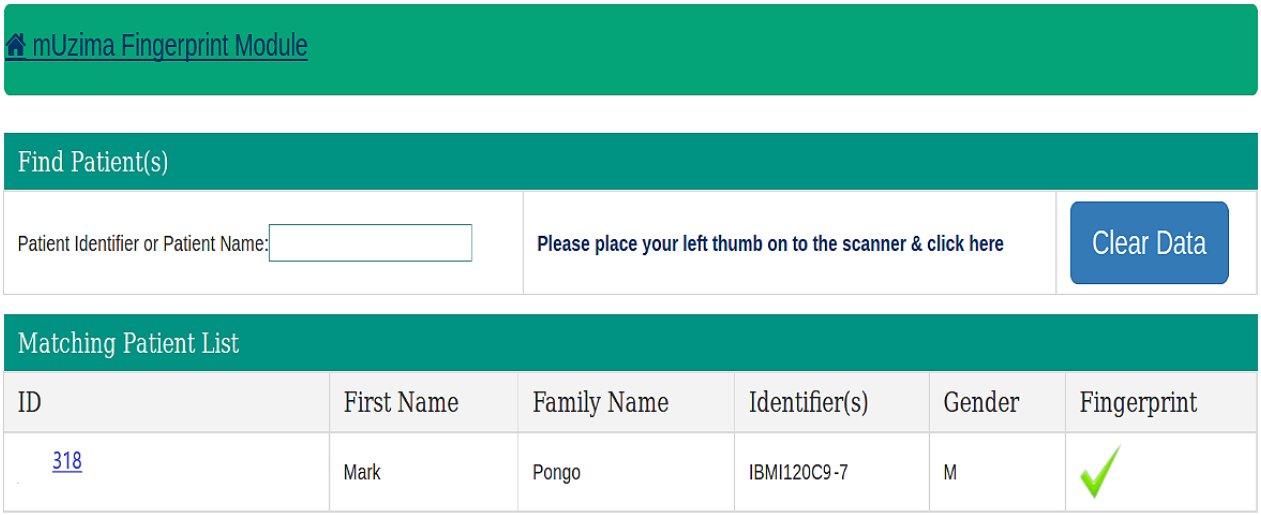

Matching Accuracy and Time to Retrieve Records (Fingerprint Technology vs Probabilistic Matching)

The current probabilistic patient-matching method used within the AMPATH EMRS was compared with the integrated fingerprint-matching and identification module. A convenience sample of 300 patients was recruited and enrolled for the study. When the patients arrived at the clinic for the visit, they received informed consent from the study researcher (NJK), and if they consented, 3 instances of their left thumbprint were captured through the EMRS interface. The fingerprint module converted the captured prints into a template and stored them in the database for later use, to either match or retrieve records. Record retrieval was performed at different points of care within the facility, as would have been required of a provider retrieving a patient record before offering care.

The performance of the fingerprint technology was evaluated using standard measures: participants correctly identified, sensitivity, false acceptance rate (FAR), false rejection rate (FRR), and failure to enroll rate (FER). The Wald test for proportions was used to compare the accuracy of the fingerprint technology with that of the Fellegi–Sunter probabilistic patient-matching technique used within the EMRS. Time to matching and retrieval of records (measured in seconds using a timer) were compared when records were retrieved through matching of data entered by clinical personnel against those retrieved through fingerprint technology–based patient matching. A survey was also administered to evaluate participants' acceptance and satisfaction of the fingerprint technology (Multimedia Appendix 2). The survey evaluated participants' understanding, comfort, perception, and willingness to accept the use of fingerprint technology for patient identification.

Fingerprint Technology Performance Measures (FAR, FRR, and FER)

Data entry and analyses were performed using STATA software (version 13.1 SE; StataCorp LLC). Age was summarized using mean and the corresponding SD. Categorical variables, for example, gender, level of education, and occupation, were summarized using frequencies and the corresponding percentages. Calculations were also performed on the standard biometric measures (Table 1).

Table 1. Calculated fingerprint technology performance measures.

Measure	Definition	Formula
Sensitivity	The ability of a system to correctly identify and match patients enrolled in the database	True positives/(true positives + false negatives) × 100
Specificity	The ability of the system to correctly reject patients not enrolled in the database	True negatives/(true negatives + false positives) × 100
False acceptance rate	The probability that a user who should be rejected is accepted by the system	False acceptance/total number of attempts × 100
False rejection rate	The probability that a user who should be accepted is rejected by the system	False rejection/total number of attempts × 100
Failure to enroll rate	The rate at which attempts to create a template from a scanned image are unsuccessful	False attempts/total number of attempts × 100

Acceptability of the Fingerprint-Matching System

Acceptability of the fingerprint biometric system was derived using 3 stand-alone variables: willingness to use the fingerprint system in the future, threats to patient privacy as a result of using the biometric system, and comfort while using the system during registration. The association between categorical variables and acceptability was assessed using the Pearson chi-square test. The logistic regression model was used to assess the predictors of acceptability of the fingerprint biometric system. Odds ratios and the corresponding 95% CIs were reported. The Wald test for proportions was used to compare the level of accuracy of the fingerprint technology with the null value (level of accuracy reported of the probabilistic patient-matching approach).

This study was approved by the institutional review and ethics committee at Moi University in Eldoret, Kenya (MU/MTRH-IREC approval number FAN: IREC 1832).

Results

Overview

A total of 307 participants who were approached consented to the study, of whom 300 (97.7%) were registered using the fingerprint technology for enrollment into the study; the other 7 (2.3%) could not be enrolled because of difficulties in acquiring their prints, thus leading to an FER of 2.3%.

Demographic details of those enrolled are outlined in Table 2. The participants' mean age was 36.3 (SD 12.2) years. Of the 300 participants, 174 (58%) were women and 215 (71.7%) had secondary or higher level of education (Table 2).

Table 2. Sociodemographic characteristics of participants (N=300).

Variable	Values
Age (years), mean (SD)	36.1 (12.3)
Gender, n (%)	
Male	126 (42)
Female	174 (58)
Education level, n (%)	
Informal	10 (3.3)
Primary	75 (25)
Secondary	78 (26)
Tertiary (college or university graduate)	137 (45.7)
Occupation, n (%)	
Student	66 (22)
Working or retired	125 (41.7)
Informal employment	109 (36.3)

Fingerprint Technology Performance

Considering the 300 appropriately scanned fingerprints, the system had a sensitivity of 89.3% (268/300) and a specificity of zero. However, the 32 unidentified fingerprints during the patient-matching exercise were included as false negatives (32/300, 10.7%; Table 3).

Table 3. False acceptance rate (FAR), false rejection rate (FRR), and failure to enroll rate (FER) for the fingerprint technology.

Metric	Calculation	Result (%)
FER	7/307 × 100	2.3
FAR	0/300 × 100	0
FRR	32/300 × 100	10.7
Sensitivity	268/(266 + 32) × 100	89.3
Specificity	0/(0 + 0) × 100	0

FAR, FRR, and FER

The fingerprint technology had an FAR of 0%, signifying that the technology was able to perfectly determine that an individual was not yet enrolled into the system, returning such instances as nonmatches. However, of the 300 enrolled individuals, 32 (10.7%) were falsely considered nonmatches (FRR), signifying that some individuals who were in the system could sometimes not be matched (Table 3). The reasons for the slightly high FRR were as follows: (1) weak finger pressure on the scanner (12/32, 37%), (2) faded prints (6/32, 19%), (3) scars on the thumb (6/32, 19%), (4) scanner response failure error (5/32, 16%), and (5)

low-quality images (3/32, 9%). Of these reasons, (4) and (5) were system-generated notifications, whereas the rest were manually observed and tallied by the research team during the exercise.

Matching Accuracy and Time to Retrieve Records (Fingerprint Technology vs Probabilistic Matching)

The accuracy of the fingerprint technology compared with that of the already established accuracy levels of the EMRS that ranged from a minimum of 50% to a maximum of 70% showed a value of $P<.001$ at both minimum and maximum levels, with a power of >99%. It took an average of 3.2 (SD 1.1, range 1.0-6.8) seconds to retrieve patient records using the fingerprint technology compared with 9.5 (SD 1.9, range 6.0-13.0) seconds ($P<.001$) using the probabilistic algorithm of the AMPATH Medical Record System.

Participants' Perception of Biometric Systems

Of the 300 participants, only 107 (35.7%) had heard of a biometric system before; 34 (11.3%) had used a fingerprint identification system before and 11 (3.7%) a facial recognition system, whereas none had used either an eye or iris identification system or a voice-based identification system. Of the 300 participants, 255 (85%) either strongly agreed (65.7%, 197/300) or agreed (19.3%, 58/300) that a biometric system could improve identification, 30 (10%) disagreed, and 15 (5%) responded "Don't know" to this question. Of the 300 participants, 289 (96.3%) were comfortable or very comfortable with using the fingerprint system, 290 (96.7%) expressed satisfaction with the system, and 271 (90.3%) were willing to use fingerprint technology for patient matching and identification in the future (Table 4). Most (241/300, 80.3%) of the participants did not think that technology threatened their privacy.

Table 4. Participants' perception of the piloted fingerprint biometric system (N=300).

Variable	Values, n (%)
Level of comfort during registration using fingerprint system	
Very comfortable	228 (76)
Comfortable	61 (20.3)
A little comfortable	5 (1.7)
Not comfortable	3 (1)
Would rather not say	3 (1)
General perception of the system	
Satisfied	290 (96.7)
Dissatisfied	10 (3.3)
Willing to use fingerprint system in future	
Yes	271 (90.3)
No	8 (2.7)
Don't know	21 (7)
Technology threatens own privacy	
Yes	45 (15)
No	241 (80.3)
Don't know	14 (4.7)

Acceptability of Fingerprint Matching

Acceptability of the fingerprint technology was derived from 3 variables: participants' comfort: 96.3% (289/300), willingness to use the fingerprint technology in the future: 90.3% (271/300), and participants' concerns regarding their privacy: 15% (45/300). The variables used to denote acceptability were further combined, that is, acceptability=yes if a participant was willing to use the fingerprint biometric system in the future, was comfortable or very comfortable using the fingerprint biometric system during registration, and did not feel that their privacy was threatened. The derived composite revealed that up to 77% (231/300) of the participants demonstrated acceptability of the fingerprint biometric system.

The Pearson chi-square test demonstrated no association between sociodemographic characteristics and acceptability of the fingerprint technology. However, the findings revealed that the respondents who agreed that the fingerprint technology offered an improved solution for patient matching were associated with the acceptability of the fingerprint technology for future use, 87.5% (202/300) versus 76.8% (53/300; $P=.03$). Similarly, the respondents who were satisfied with the fingerprint technology for identification were also associated with the acceptability of the fingerprint system for future use, 99.1% (229/300) versus 88.4% (61/300; $P=.001$; Table 5).

After adjusting for the opinion on whether the fingerprint biometric system offered an improved solution, opinion on whether the current patient identifiers (eg, IDs and patient numbers) offered an appropriate solution for identification,

previous knowledge of biometric systems, and occupation, participants who had previously used fingerprint biometric systems for identification were estimated to have more than thrice the increased odds of accepting the fingerprint biometric system (odds ratio 3.57, 95% CI 1.0-11.92; Table 6).

Table 5. Bivariate associations of participants' perception of biometrics and acceptability of the fingerprint technology system (N=300).

Variables	Acceptable in the future, n (%)		*P* value
	No (n=69)	Yes (n=231)	
Have ever heard of biometric systems before			
No	42 (60.9)	151 (65.4)	—[a]
Yes	27 (39.1)	80 (34.6)	.49
Have ever used fingerprint biometric system before			
No	65 (94.2)	203 (87.9)	—
Yes	4 (5.8)	28 (12.1)	.14
Opinion on whether the current patient identifiers (eg, IDs and patient numbers) offer an appropriate solution for identification			
Agree or strongly agree	30 (43.5)	79 (34.2)	.16

Discussion

Principal Findings

The matching speed of the fingerprint technology was significantly lower and better than that of the demographic-based retrieval matching technology, that is, 3.2 (SD 1.1) seconds versus 9.5 (SD 1.9) seconds (P<.001). The system operated in a mode where no imposter was falsely considered a match in 300 attempts. However, 10.7% (32/300) of the genuine attempts were falsely considered as nonmatches (FAR 0/300 = 0.0% at an FRR 32/300 = 10.7%). The participants' acceptability of the technology was demonstrated with most (289/300, 96.3%) of them indicating that they were comfortable with the technology and 90.3% (271/300) being willing to use the technology in the future. Although concerns about performance and acceptability of biometric technologies, especially fingerprint technology, are often discussed, few studies have comprehensively evaluated this technology in LMICs, despite fingerprint technology being widely available and affordable in these settings. Existing studies have largely described development of fingerprint technology systems without reporting on the performance using standard measures [41,42]. The few that have evaluated performance have not looked at the perceptions and acceptability of these systems [43]. To our knowledge, this is the first study to comprehensively evaluate performance, acceptability, and attitudes toward the use of fingerprint technology in an LMIC setting. The accuracy of the fingerprint technology–matching algorithm was significantly higher than that of the existing Fellegi–Sunter probabilistic algorithm. This is in line with the previous demonstration of the accuracy of fingerprint systems through systematic reviews, for example, a study of this technology in Nigeria recorded a success rate of 94% [43]. Not only did we demonstrate that fingerprint technology performed well, but we also demonstrated that it was more efficient than the traditional record-searching mechanisms at retrieving patient records from the EMRS. Data from this study add to the body of evidence of the potential of fingerprint technology to improve patient identification and matching in LMICs, which often lack unique identifiers and which experience other challenges to patient identification.

Despite performing better than traditional patient-matching approaches, the technology still failed to enroll a small number of individuals (FER 2.3%, 7/300) and to match 10.7% (32/300) of the registered individuals (FRR 10.7%, 32/300). A key reason for the failure to identify 10.7% (32/300) of the registered individuals was related to issues with the thumbprint of the individual patient (worn out thumbprint), signifying that performance of these systems could be improved by considering alternative or multiple fingers when one did not suffice. The other reasons were related to operator and technology issues, also suggesting that improving the scanner and software could improve system performance. To reduce costs, we tested the technology using only 1 scanner type (DigitalPersona U.are.U 4500; DigitalPersona, Inc) with open source software, but we recognize that there are other scanners that could perform better. There also needs to be better training of operators and improved level of machine-generated notifications to improve performance. In the COVID-19 pandemic era, it is important to not only understand how to operate these systems beyond simply recording fingerprints, but to also learn how to ensure that scanners are cleaned well and social distancing is maintained between the operator and the patient whose fingerprint is being captured. The aforementioned findings also suggest that fingerprint technology should not necessarily be seen as a replacement for traditional deterministic and probabilistic methods; rather, it should be looked upon as an additional and complementary enhancement.

This study indicated that fingerprint technology would be acceptable to patients in these settings. A surprisingly high number of participants (271/300, 90.3%) were willing to use the technology and expressed satisfaction with its use (290/300, 96.7%). This aligns with the findings from another study on adoption of fingerprint scanning during contact investigation for tuberculosis in Kampala, Uganda, where fingerprint technology was found to be feasible and acceptable [44]. A notable finding in our study was that participants' sociodemographic characteristics and their perceptions were generally not associated with acceptability of the fingerprint technology. Previous users of the fingerprint technology biometric system were associated with more than thrice the increased odds of accepting the fingerprint biometric solution, signifying that if implemented well, fingerprint technology is likely to achieve even more acceptance with patients.

Only 15% (45/300) of the participants felt that the technology threated their privacy. Previous studies have demonstrated similar lower concern regarding privacy in LMICs. As an example, in a study evaluating authentication options for mobile health apps in younger and older adults, only approximately 10% of the participants were concerned about the storage of their face scans, whereas only 4% were concerned about the privacy requirements [45]. Users' concerns regarding privacy tend to be paradoxical because they sometimes vary depending on the technology and user knowledge of the subject [46]. Despite our participant responses, privacy remains a key concern with fingerprint technology. In LMICs, there is a particular need for patient education and sensitization on the privacy and security of these technologies. Furthermore, there should be strong frameworks, guidelines, and standard operating procedures that cover ownership, control, and use of, as well as access to, patients' biometric data [47]. In fact, in settings such as those of LMICs, more protections are needed, given that patients might be vulnerable simply because they may have less understanding of the technology. As previously described, ethical guidelines to consider while implementing biometrics should include, but not be limited to, the following: (1) secondary principles and rights (right of access to information and data protection principles), (2) surveillance society issues (choice, power, empowerment, transparency and accountability, consent, and communication with the user), and (3) health and hygiene concerns regarding biometrics (physical contact between people providing the biometric data and the official enrolling the individuals) [48].

This study included several limitations that deserve a mention. The technology was tested on only 1 scanner type (DigitalPersona U.are.U 4500), and only the thumbprint was used. Although the system performed very well, there is room

for improvement to incorporate the capture of more fingers and to leverage the features of other scanners. In addition, infants were not catered for in this study, given the known challenges with fingerprint capture in this population [49,50]. Beyond attitudes and perceptions of patients, it would also be important to capture the perceptions of other stakeholders regarding fingerprint technologies, including providers, managers, and health ministry leaders. The next steps include further refinement of this system and working with key stakeholders to determine its role in supporting national health information systems in Kenya and other countries.

Conclusions

Fingerprint biometric technology offers an improved patient identification mechanism compared with traditional deterministic and probabilistic techniques. Accuracy can be greatly improved when more than one finger is captured during enrollment because this captures more minutiae. The technology is also acceptable to patients in resource-limited settings. However, large-scale deployment should take ethical, legal, and social implications as well as security issues into consideration.

Acknowledgments

This work was supported in part by the Norwegian Programme for Capacity Development in Higher Education and Research for Development program (Norwegian Agency for Development Cooperation: Project #QZA-0484, Health Informatics Training and Research in East Africa for Improved Health Care project). Abstract

Background: High expectations have been set for the implementations of health information systems (HIS) in health care. However, nurses have been dissatisfied after implementations of HIS. In particular, poorly functioning electronic health records (EHRs) have been found to induce stress and cognitive workload. Moreover, the need to learn new systems may require considerable effort from nurses. Thus, EHR implementations may have an effect on the well-being of nurses.

Objective: This study aimed to examine the associations of EHR-to-EHR implementations and the sufficiency of related training with perceived stress related to information systems (SRIS), time pressure, and cognitive failures among registered nurses. Moreover, we examined the moderating effect of the employment sector (hospital, primary care, social services, and others) on these associations.

Methods: This study was a cross-sectional survey study of 3610 registered Finnish nurses in 2020. EHR implementation was measured by assessing whether the work unit of each respondent had implemented or will implement a new EHR (1) within the last 6 months, (2) within the last 12 months, (3) in the next 12 months, and (4) at no point within the last 12 months or in the forthcoming 12 months. The associations were examined using analyses of covariance adjusted for age, gender, and employment sector.

Results: The highest levels of SRIS (adjusted mean 4.07, SE 0.05) and time pressure (adjusted mean 4.55, SE 0.06) were observed among those who had experienced an EHR implementation within the last 6 months. The lowest levels of SRIS (adjusted mean 3.26, SE 0.04), time pressure (adjusted mean 4.41, SE 0.05), and cognitive failures (adjusted mean 1.84, SE 0.02) were observed among those who did not experience any completed or forthcoming implementations within 12 months. Nurses who perceived that they had received sufficient implementation-related training experienced less SRIS (F_1=153.40, P<.001), time pressure (F_1=80.95, P<.001), and cognitive failures (F_1=34.96, P<.001) than those who had received insufficient training. Recent implementations and insufficient training were especially strongly associated with high levels of SRIS in hospitals.

Conclusions: EHR implementations and insufficient training related to these implementations may endanger the well-being of nurses and even lead to errors. Thus, it is extremely important for organizations to offer comprehensive training before, during, and after implementations. Moreover, easy-to-use systems that allow transition periods, a re-engineering approach, and user involvement may be beneficial to nurses in the implementation process. Training and other improvements would be especially important in hospitals.

Introduction

Registered nurses form the largest group using health information systems (HIS) in health care. Therefore, the successful implementation of new HIS highly depends on nurses. High expectations have been set for the implementation of HIS in health care, for example, regarding increased efficiency. Indeed, a previous study shows that the implementation of intensive care unit information systems decreased the time nurses spent on documentation by over 30% and increased the time spent on direct patient care [1]. However, the outcomes of implementations may not always meet the high expectations [2]. Failure to understand users' needs and support workflow are some reasons why implementations may fail [3].

Registered nurses' work is often stressful and cognitively burdensome, and difficulties with HIS may induce extra stress and time pressure. Nurses have been found to prefer electronic health records (EHRs) over paper charts and think that EHR usage enhances nursing work but increases demand on work time and decreases the quality of care [4]. Among nurses, difficult-to-use EHRs have been associated with high time pressure and distress [5], and cognitive workload [6,7], which in turn have been associated with cognitive failures as well as lower patient safety [8].

Even though registered nurses are competent users of EHRs [9], the new systems that are implemented may be difficult and complicated to use especially in the beginning, thus becoming additionally demanding. This may lead to information chaos [10], which has been shown to result in decision-making errors and increased mental workload [10,11]. A previous study showed substantially increased cognitive workload related to new EHR implementation for nurses [6]. Nurses have been found to be most dissatisfied approximately 9 months after implementation, whereas their perceptions appeared to be more balanced after 18 months [12]. In another study, nurses reported greater acceptance of the EHR 12 months after implementation than after 3 months [13].

Education and training are essential prerequisites for successful HIS implementation [14]. The intricacies of new systems and changing functionalities may require nurses to allocate time and effort if they wish to master the new systems. However, the demands and pressures of care may not always afford nurses time to learn the new systems, and it is possible that not enough training and time have been allocated to this process [15,16]. Therefore, it may be a burden for nurses being forced to learn how to use the new systems effectively and efficiently, especially if they are not offered sufficient implementation-related training. Indeed, it has been found that HIS implementation may increase nurses' workload if they receive insufficient training before implementation [14]. Training has even been shown to have a positive impact on the perceived work environment as well [17].

Stress is an ambiguous concept with many definitions; for example, it has been defined as a relationship between a person and the environment that is appraised as important for an individual and exceeds coping resources [18]. Poorly functioning and constantly changing information systems may elicit this kind of stress appraisal, which can be designated as stress related to information systems (SRIS). For example, information systems have emerged as one of the highest stress-inducing factors among Finnish physicians alongside time pressure and patient-related stress [19-21]. Previous findings show that SRIS has increased in the 21st century among physicians [19,21], and the usability of EHRs has an effect on its levels [22]. However, SRIS is less studied among nurses and more information is needed. For example, nurses themselves have proposed that training could be one way to reduce nurses' SRIS levels [23].

As mentioned previously, studies show that nurses are dissatisfied after HIS implementations and challenges with HIS are associated with stress, time pressure, and cognitive burden [5-7,12,13,24]. Previous implementation studies have often focused on implementations involving transitions from paper-based systems to EHR systems [6,12]. However, many developed countries have already reached or will soon reach a saturation point where almost all health care organizations use EHRs. For example, in Finland, the EHR coverage has reached a saturation point of 100%, and many different brands of systems are in use [25]. Thus, more information is needed, especially on the effects of transitioning from one EHR system to another and implementation-related training on the stress levels and well-being of nurses. Therefore, our interest was on implementation of new brands of EHR systems, that is, the changes experienced when transitioning from one EHR to another.

Finnish nurses use many different EHR system brands; for example, in public hospitals, the 7 most popular brands are used by approximately 92% of nurses, and in primary care, the 4 most popular brands are used by 94% of nurses [26]. The most commonly used EHRs among nurses in Finland are Lifecare, Uranus, Pegasos, Apotti (system brand: Epic), Effica Healthcare, Mediatri, Esko, DynamicHealth, and DomaCare [26]. For example, large-scale implementations of Apotti were in progress in different areas of Helsinki and the Uusimaa region from 2018 to 2020.

This study examined the associations between EHR implementations and the sufficiency of training related to implementations with perceived SRIS, time pressure, and cognitive failures among Finnish registered nurses. Moreover, previous studies show that the employment sector, such as whether a person is employed in a hospital or a primary care center, plays an important role in health professionals' perceptions of EHRs and how they affect professionals' stress levels and well-being [22,27,28]. Therefore, we additionally examined whether the employment sector would have an effect on these associations.

Methods

Sample

The data were collected during the spring of 2020 through an internet-based Webropol survey. The link to the survey was sent via email by the Finnish Nurses Association, Tehy (The union of health and social care professionals in Finland) and the National Professional Association for the interests of experts

and managers in health care (TAJA) to their members under 65 years of age, including 58,276 nurses, midwives, and public health nurses representing 72% of the eligible population [29]. One reminder was sent to those who did not respond. A more detailed description of the study can be found elsewhere [29]. Altogether, 10,094 registered nurses opened the link and 3912 responded. Of those who responded, 302 answered that they did not perceive themselves as fit to answer the questionnaire because they had not worked as registered nurses for a long time. Thus, the final sample included 3610 respondents (93.1% women) aged between 22 and 65 years (mean 45.7, SD 11.0) [29]. The sample was representative of the eligible population in terms of the regionality and employment sector. Women were slightly overrepresented, and those under 40 years of age were slightly underrepresented [29]. According to a power analysis conducted using WebPower, an internet-based tool [30], the study had more than 95% power to detect small effects (f=0.1) with an α level of .05 in a 2×4 analysis of variance (ANOVA). Ethical approval for the study was provided by The Finnish Institute for Health and Welfare (THL/482/6.02.01/2020).

Measures

The questionnaire items used in the present study can be found in Multimedia Appendix 1.

Dependent Variables

SRIS was measured with the mean of 2 items, framed in 1 question that asked how often (during the last 6 months) the respondent had been distracted by, worried about, or stressed about (1) constantly changing HIS and (2) difficult, poorly performing information technology (IT) equipment or software. The answers were rated on a 6-point scale ranging from 1 (never) to 6 (constantly). The scale's reliability (Cronbach α=.74) was established in the present sample. This measure was developed in Finland when examining the health and well-being of physicians. [19-21]. It has previously been associated with, for example, experience in using information systems, cognitive workload, distress, and EHR usability [19,22].

Time pressure was measured with the mean of 2 items (α=.94) measuring how often (during the prior half-year period) a person had been distracted by, worried about, or stressed about (1) constantly being in a hurry and time pressure coming from unfinished work tasks and (2) having too little time to do work properly. The items were rated on a 6-point scale ranging from 1 (never) to 6 (constantly). This measure has been widely used previously and associated, for example, with the nurses' perceptions on the poor usability of EHRs [5].

Cognitive failures can be defined as "cognitively based errors that occur during the performance of a task that a person is normally successful in executing" [31]. They were measured with 3 items (α=.6) derived from the Workplace Cognitive Failure Scale (WCFS) [32,33]. Our survey included 1 item from each of the 3 dimensions of the WCFS: failure of memory, failure of attention, and failure of action. The chosen items have previously shown the highest loadings for their dimensions [33]. Participants were asked to rate how often they have faced situations at work where they (1) have not been able to remember work-related passwords, sets of numbers, etc. (memory failure); (2) have not fully listened to the instructions or requests they have received (attention failure); and (3) have accidentally started or closed the wrong device, system, or program (action failure). Items were rated on a 5-point scale ranging from 1 (never) to 5 (several times a day).

Independent Variables

EHR implementation was measured with a question asking whether the respondent's work unit had implemented or will implement a new EHR. The response options were (1) yes, within the last 6 months, (2) yes, within last 12 months, (3) no, but within the forthcoming 12 months, and (4) no past or forthcoming implementations within 12 months.

Training was assessed with a question asking whether the respondent had received sufficient training related to the required changes in work practices (such as new electronic documentation and care practices) due to HIS implementations. The answer options ranged between 1 (completely disagree) and 5 (completely agree). This question also included the answer option "cannot answer," which was coded as missing. The responses were coded as 0=insufficient training (answer options 1-3) and 1=sufficient training (answer options 4-5).

As control variables, gender, age, and employment sectors were also included in the survey. Employment sectors were coded as 1=hospital, 2=primary care, 3=social services, and 4=other.

Statistical Analysis

The associations of the implementation phase and training with the dependent variables were analyzed with analyses of covariance (in separate analyses for each dependent variable). The analyses were adjusted for age, gender, and employment sector. The interactions of the employment sector with the implementation phase and training for the dependent variables were examined with analyses of covariance adjusted for age, gender, and primary effects (in separate analyses for each interaction and dependent variable). Respondents who had missing data for a given variable were excluded from the analyses of that variable. Thus, due to missing information in some variables, n varied between 3525 and 3610.

To further examine the validity of our dependent variables, we conducted principal components analysis (PCA) through direct oblimin rotation with the items of the dependent variables (SRIS, time pressure, and cognitive failures). Moreover, the analyses of covariance were repeated for analyzing sensitivity using the principal component scores resulting from these analyses as the dependent variables.

Results

Demographics

The characteristics of the study population are given in Table 1. Approximately 25% (834/3610) of the respondents had experienced EHR implementation within the preceding 6 months, 13% (476/3610) within the preceding 12 months, and 20% (714/3610) reported forthcoming EHR implementation within 12 months. More than half of the respondents (1894/3573) reported insufficient training regarding changes required in the way of working due to HIS implementations.

Table 1. Basic background characteristics of the study sample (N=3610[a]).

Characteristic	Value
Gender, n (%)	
Women	3340 (93.1)
Men	249 (6.9)
Employment sector, n (%)	
Hospital	1903 (52.7)
Primary care	795 (22)
Social services	445 (12.3)
Other	467 (12.9)
EHR[b] implementation phase, n (%)	
Yes, within the last 6 months	834 (23.1)
Yes, within the last 12 months	476 (13.2)
No, but forthcoming within the next 12 months	714 (19.8)
No	1586 (43.9)
Training related to implementation, n (%)	
Insufficient	1894 (53)
Sufficient	1679 (47)
Age,[c] mean (SD)	45.68 (10.97)
Stress related to information systems,[c] mean (SD)	3.7 (1.13)
Time pressure,[d] mean (SD)	4.54 (1.12)
Cognitive failures,[e] mean (SD)	1.88 (0.5)

[a]Due to missing information in some variables, n varies between 3573 and 3610.

[c]Ranged between 22 and 67.

[d]Ranged between 1 and 6.

[e]Ranged between 1 and 5.

Main Effects for SRIS

Table 2 shows the results of analyses of covariance. Age, gender, employment sector, implementation phase, and training were all associated with SRIS. Women had higher levels of SRIS than men. Higher age was associated with higher levels of SRIS. The highest level of SRIS was in hospitals and the lowest was in social care. As observed in Table 3, those who had experienced EHR implementation within the preceding 6 months perceived the highest levels of SRIS, whereas those who did not have to experience forthcoming or prior implementations within 12 months perceived the lowest levels of SRIS. Those who perceived that they had received sufficient training had lower levels of SRIS compared to those who perceived that they had not received sufficient training.

Table 2. Associations among explanatory factors with stress related to information systems, time pressure, and cognitive failures (analysis of covariance[a]).

Variable	SRIS[b]		Time pressure		Cognitive failures	
	F test *(df)*	*P* value	*F* test *(df)*	*P* value	*F* test *(df)*	*P* value
Age	15.47 (1)	<.001	30.31 (1)	<.001	4.96 (1)	.03
Gender	9.50 (1)	.003	20.57 (1)	<.001	0.21 (1)	.65
Sector	24.14 (3)	<.001	1.77 (3)	.23	1.36 (3)	.25
Implementation	118.43 (3)	<.001	3.05 (3)	.03	5.36 (3)	.001
Training	153.40 (1)	<.001	80.95 (1)	<.001	34.96 (1)	<.001
R^2	0.165	N/A[c]	0.033	N/A	0.015	N/A

[a]Due to missing information in some variables, n varies between 3525 and 3546.

[b]SRIS: stress related to information systems.

[c]N/A: not applicable.

Table 3. Estimated marginal means[a] of stress related to information systems, time pressure, and cognitive failures according to implementation phase.[b]

Implementation phase	SRIS[c]		Time pressure		Cognitive failures	
	Mean	SE	Mean	SE	Mean	SE
Within the last 6 months	4.07	0.05	4.55	0.06	1.87	0.03
Within the last 12 months	3.76	0.06	4.45	0.06	1.94	0.03
Forthcoming within the next 12 months	3.44	0.05	4.45	0.06	1.86	0.03
No implementations	3.26	0.04	4.41	0.05	1.84	0.02

[a]Adjusted for age, gender, employment sector, and training.

[b]Due to missing information in some variables, n varies between 3525 and 3546.

[c]SRIS: stress related to information systems.

Main Effects for Time Pressure

Age, gender, implementation phase, and training were associated with time pressure. Women had higher levels of time pressure than men. Higher age was associated with lower levels of time pressure. Those who had experienced EHR implementations within the preceding 6 months had the highest levels of time pressure, whereas those who did not have to experience forthcoming implementations or postimplementation outcomes within 12 months had the lowest levels of time pressure, as indicated in Table 3. Sufficient training was associated with low levels of time pressure.

Main Effects for Cognitive Failures

Age, implementation phase, and training were associated with cognitive failures. Higher age was associated with lower levels of cognitive failures. Those who had experienced EHR implementation within the preceding 12 months had higher levels of cognitive failures compared to other groups (Table 3). Those who perceived that they had undergone sufficient training had lower levels of cognitive failures compared to those who perceived that they had not had sufficient training.

Interactions With the Employment Sector

The interaction between the implementation phase and employment sector was significant for SRIS (F_9=4.32, P<.001). As observed in Figure 1, implementation in hospitals within 6 months is associated with higher SRIS levels than other sectors (n of the different groups varied between 49 and 715). Moreover, the interaction between training and the employment sector was significant for SRIS (F_3=10.18, P<.001). SRIS levels in hospitals were particularly high if insufficient training was perceived, as shown in Figure 2.

The interaction between training and the employment sector was significant for time pressure (F_3=4.18, P=.006). In primary care, sufficient training was not so strongly associated with time pressure, whereas in all other sectors, time pressure levels were low if training was perceived to be sufficient, as observed in Figure 3. The interaction between the implementation phase and employment sector was not significant for time pressure.

The interactions of the employment sector with the implementation phase and training were not significant for cognitive failures.

Figure 1. Interaction between implementation phase and employment sectors for stress related to information systems (*P*<.001). SRIS: stress related to information systems.

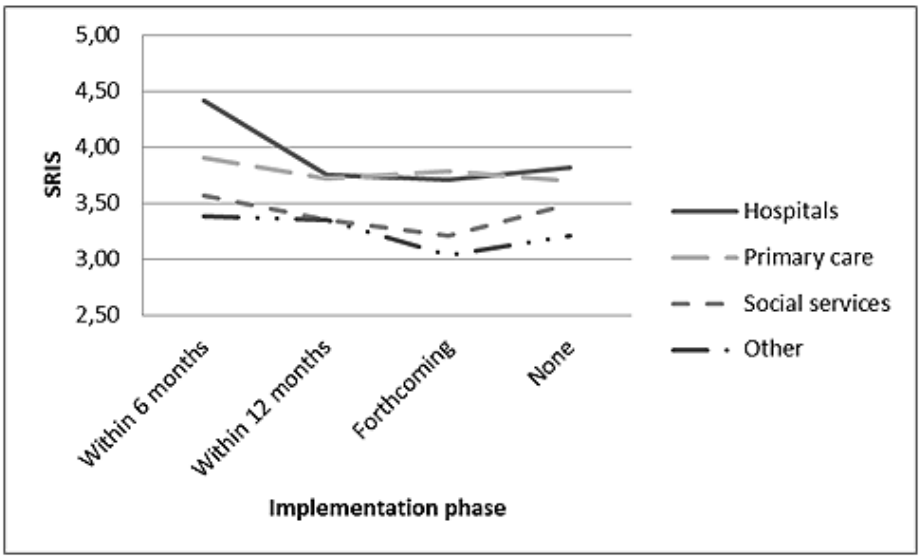

Figure 2. Interaction between training and employment sectors for stress related to information systems (*P*<.001). SRIS: stress related to information systems.

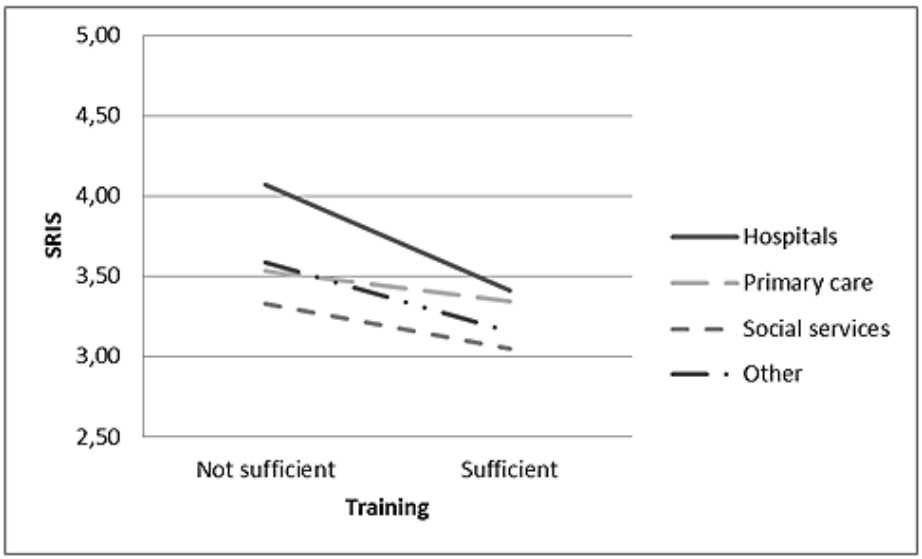

Figure 3. Interaction between training and employment sectors for time pressure (*P*=.006).

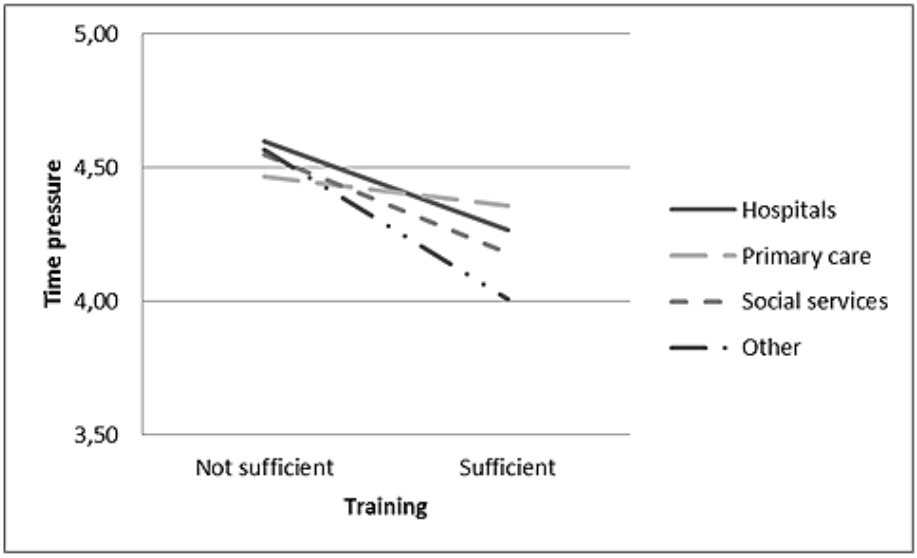

Sensitivity Analyses

The results of PCA are given in Multimedia Appendix 2. Results showed that the principal components resulting from the analysis were similar, as the original measures used (SRIS, time pressure, and cognitive failures) and the items loaded well with these principal components. ANOVA conducted with the principal component scores resulting from PCA as the dependent variables showed results corresponding with the analyses conducted using original variables (see Multimedia Appendix 3). Moreover, the interaction results with the principal components scores were congruent with the results from the original analyses.

Discussion

Principal Results

Our results show that EHR implementations have the potential to decrease the well-being of registered nurses. More specifically, we found that the highest levels of stress related to poorly functioning information systems and time pressure were experienced among those who had experienced EHR implementation within the preceding 6 months. In particular, recent implementations were strongly associated with high levels of SRIS in hospitals. The highest levels of cognitive failures were instead experienced among those who had experienced EHR implementation within the preceding 6 to 12 months. The lowest levels of SRIS, time pressure, and cognitive failures were experienced among those who did not have any past or forthcoming implementations within 12 months.

Sufficient training related to implementations appears extremely crucial for nurses and is associated with improved well-being. Those nurses who perceived that they had received sufficient training related to the changes required in work practices due to HIS implementations experienced less SRIS, time pressure, and cognitive failures. The highest levels of SRIS were among those nurses who worked in hospitals and did not receive sufficient training.

Limitations

We used self-reported measures, which always poses a question related to problems associated with an inflation of the strengths of relationships and common method variance. The reliabilities of our scales were good, except that the reliability of the cognitive failures scale was 0.6, which can be considered low. However, this reliability can still be considered acceptable because the scale included only 3 items [34]. Moreover, we used cross-sectional survey data; thus, causal inferences cannot be drawn from our results. It is possible that nurses who are more competent in using EHRs also learn to use the new system more quickly and are also more likely to perceive that they have received sufficient training.

In addition, a major limitation of this study is the low explanatory strength of the independent variables used for time pressure and the cognitive failures variables, which can be seen in the low R^2 values of the analyses of covariance regarding these variables. Consequently, our results should be interpreted with caution and future studies with high-quality validated measures are still needed on this subject. However, even the small effect size may be noteworthy, and it has been suggested that even though the size of the effect in psychological research would be very small, it may potentially be very consequential in the long run [35]. The effect size was larger when explaining the SRIS variable, which is logical given that when a new EHR is implemented, the strain and stress observed among nurses are not surprising.

Moreover, although we adjusted our analyses for age, gender, and employment sectors, the possibility of residual confounding cannot be totally eliminated. For example, it is possible that some unknown third variable may have an effect on the stress and perceived training level and consequently explain the relationship between training and our dependent variables.

Finland is a country with universal health care for all residents and one of the forerunners in the digitalization of health care [36]. Therefore, we must be cautious in generalizing our findings to countries with dissimilar health care systems or HIS.

We used a rather large sample of registered nurses (3610 nurses), which was obtained from the registers of academic associations and trade unions and may have affected the representativeness of the sample. The email invitation to participate in the survey was sent to 72% of the eligible population and our sample represented the eligible population in terms of the regionality and employment sector but included a slightly disproportionate cohort of women and those over 40 years of age [29]. The data were collected in the spring of 2020 (March to April) at the time when the COVID-19 pandemic gained prominence in Finland. The most stringent restrictions so far were implemented in the middle of March 2020. Therefore, only 1 reminder was sent to those who had not responded to the invite. These circumstances may have had an effect on the results, especially in those hospitals that were most strongly affected by the pandemic.

Comparison With Prior Work

Our results show that EHR implementations may endanger the well-being of nurses. This is congruent with previous findings showing that EHR implementation is associated with decreased interdisciplinary communication, a high demand on work time, and low perceived quality of care among nurses [4]. Correspondingly, nurses have been found to experience stress due to added work, along with concerns about security and encountering poor cooperation in the early stage after the implementation of the nursing information system [15]. It has also been shown previously that implementation seems to induce stress, frustration, and feelings of incompetency, especially among those nurses who have problems with tasks requiring digital skills [37].

According to our results, recent implementations occurring especially within the preceding 6 months seem to induce SRIS and time pressure. Previous studies have also obtained congruent findings [6,12,13]. The dissatisfaction seems to be the greatest soon after implementation and then declines, moving toward greater acceptance 12 months after implementation [12,13]. However, we found that cognitive failures were the highest from 6 to 12 months after implementation. A previous study has found that cognitive workload among nurses is the highest just after the EHR implementation and then returns toward baseline after 4 months [6]. There are many possible reasons for our finding that cognitive failures were the highest 6 to 12 months after implementation. For example, it may pertain to implementation-related support from vendors and organizations. It is also possible that nurses are protected from other cognitively burdensome tasks immediately after implementation.

Our findings show that besides implementation aspects related to the change from paper-based documentation to EHRs, implementation factors regarding the change from one EHR to another EHR may affect employees' well-being. Traditionally, the focus of previous studies has been on the effects of transitioning from paper-based documentation to EHRs [4,6,12]; however, studies focusing on the effects of transitioning from one EHR to another are emerging [13]. In future, we may expect research findings focusing on the transition from one EHR to another, given the widespread use of EHRs in developed countries.

Our results suggest that organizations should implement measures to decrease the negative impact of implementations. A meta-analysis suggested a re-engineering approach to better integrate HIS implementation in health care workflows [3]. During re-engineering, organizations should examine and consider restructuring their work processes related to operational factors and infrastructure in a manner that could enable them to optimally use HIS functions. Moreover, improving the usability of systems would support the implementation, decrease the need for training, and improve employee well-being [22,38,39]. The users should be allowed a transition period, giving them time to understand and appreciate the outcome of the system implementation [3]. Further, user involvement, strong leadership, project management techniques, and standards are important in ensuring successful implementation [3,39,40]. To improve the experience of nurses in the beginning stage, it would be important to commit the nurses to the system design early on [15].

Our findings highlight the importance of proper training related to implementations. According to our findings, it may be possible to decrease the negative ramifications of implementations on nurses' well-being and cognitive functioning with sufficient training. However, training is insufficient in many cases. In our study, 53% reported that training was insufficient. In another study, 62% of health care staff reported that they had not received enough training related to inpatient portal implementation [16]. Moreover, nurses have indicated in focus groups that they had insufficient training related to the nursing information systems [15].

Our results showed some variations according to the employment sectors. In hospitals, the stress levels associated with implementations were the highest and the training related to systems was especially important. This finding effectively reflects the previous findings among physicians showing that attitudes toward EHRs are most critical in hospitals [41-43]. It is also possible that hospitals especially experience insufficiencies in IT support, given that nurses in hospitals often also work outside of office hours. A previous study has suggested that in addition to training, organizations should also identify and appoint champions who could learn more thoroughly and teach others how to use different systems [44].

In primary care, it seems that sufficient training is also inadequate to buffer against time pressure. In Finnish primary care, one of the reasons for time pressure among nurses is that primary care involves accessibility problems and long waiting times [45]. A previous study among Finnish nurses showed that technical problems and poor user-friendliness of the EHRs are associated with high time pressure [5]. Thus, in primary care, tackling the problems associated with the usability of the systems that are implemented might be important in terms of time pressure.

Our results show that sufficient training related to implementations is highly important. It might be beneficial to offer training and other support during the whole implementation

period, that is, before, during, and after the implementation [46,47]. The amount of education has been found to be positively correlated with nurses 'attitudes and behaviors toward the implemented IS; thus, it is important that organizations provide quickly and easily accessible in-house support and proactive training in the use of HIS [48]. In addition, evidence indicates that it is important to consider which training methods would best support professionals in developing the necessary skills and using the systems. Adequate education and training encourage employees to use HIS, which are prerequisites for benefiting from implementations [3]. According to our results, training related to changing work practices due to HIS implementations is particularly important. Additionally, training featuring improvements such as keyboard entry skills, redesigning workflow, and improving interdisciplinary communication are considered necessary [15].

We suggest that training should be planned carefully in advance, including basic training at least 2 to 3 weeks before implementation. After implementation, training should continue for several weeks, following which the authorities must assess whether more training is needed. Moreover, it is important to provide time for nurses to learn to use the systems in practice.

Conclusions

The present study shows that EHR-to-EHR implementations and insufficient training related to the implementations may impair nurses' well-being and even lead to cognitive failures. Thus, it is crucial that organizations implement measures to decrease the negative ramifications of implementations on their employees. This would be very important in all sectors, but especially in hospitals.

Acknowledgments

This study was supported by the Ministry of Social Affairs and Health (project 414919001) and the Strategic Research Council at the Academy of Finland (projects 327145 and 327147). Abstract

Background: Acute kidney injury (AKI) develops in 4% of hospitalized patients and is a marker of clinical deterioration and nephrotoxicity. AKI onset is highly variable in hospitals, which makes it difficult to time biomarker assessment in all patients for preemptive care.

Objective: The study sought to apply machine learning techniques to electronic health records and predict hospital-acquired AKI by a 48-hour lead time, with the aim to create an AKI surveillance algorithm that is deployable in real time.

Methods: The data were sourced from 20,732 case admissions in 16,288 patients over 1 year in our institution. We enhanced the bidirectional recurrent neural network model with a novel time-invariant and time-variant aggregated module to capture important clinical features temporal to AKI in every patient. Time-series features included laboratory parameters that preceded a 48-hour prediction window before AKI onset; the latter's corresponding reference was the final in-hospital serum creatinine performed in case admissions without AKI episodes.

Results: The cohort was of mean age 53 (SD 25) years, of whom 29%, 12%, 12%, and 53% had diabetes, ischemic heart disease, cancers, and baseline eGFR <90 mL/min/1.73 m^2, respectively. There were 911 AKI episodes in 869 patients. We derived and validated an algorithm in the testing dataset with an AUROC of 0.81 (0.78-0.85) for predicting AKI. At a 15% prediction threshold, our model generated 699 AKI alerts with 2 false positives for every true AKI and predicted 26% of AKIs. A lowered 5% prediction threshold improved the recall to 60% but generated 3746 AKI alerts with 6 false positives for every true AKI. Representative

interpretation results produced by our model alluded to the top-ranked features that predicted AKI that could be categorized in association with sepsis, acute coronary syndrome, nephrotoxicity, or multiorgan injury, specific to every case at risk.

Conclusions: We generated an accurate algorithm from electronic health records through machine learning that predicted AKI by a lead time of at least 48 hours. The prediction threshold could be adjusted during deployment to optimize recall and minimize alert fatigue, while its precision could potentially be augmented by targeted AKI biomarker assessment in the high-risk cohort identified.

KEYWORDS

acute kidney injury; artificial intelligence; biomarkers; clinical deterioration; electronic health records; hospital medicine; machine learning

Introduction

The clinical burden of acute kidney injury (AKI) worsens globally with the increasing complexity of cardiovascular diseases, anticancer therapy, and aging population [1-3]. AKI develops in 4% of patients admitted to our institution and involves more than 3000 patients annually [4]. A total of 39% of AKI cases develop during hospitalization following clinical deterioration and multiorgan dysfunction [4,5]. Additionally, 15% of patients who receive antimicrobials or chemotherapy of nephrotoxic potential develop drug-induced AKI [6,7]. Iodinated contrast administered for angiography contributes to AKI in 10% to 40% of patients with chronic kidney disease [8,9]. Once AKI develops in patients, however, the management remains supportive with control of its underlying triggers. AKI portends a poor patient prognosis with high mortality, prolonged hospitalization, and sustained deterioration of kidney function, with a significant risk of kidney failure in the long term [10,11].

Management strategies for high-risk patients may prevent AKI or reduce its downstream complications should AKI still develop. These measures must be implemented promptly, which requires the diagnosis of AKI in the subclinical phase, way before its onset. As the onset of AKI is highly variable during a patient's stay, it is unclear how best to time biomarker surveillance for kidney injury concerning the patient's clinical progress. The advent of electronic health records (EHRs) now provides us with real-time clinical data from routine patient care, built into millions of data points for analytics. These, along with AKI being defined by a numerical measure using serial serum creatinine, allow for an AKI prediction algorithm that is reproducible on a large scale. Machine learning with recurrent neural network–based techniques could improve the accuracy of analytics over traditional biostatistics [12]. These could be enhanced by capturing the relative feature importance temporal to AKI; that is, certain clinical covariates or trends (ie, features) would factor with increasing (or decreasing) importance in the time leading up to the onset of AKI. In this study, we would apply a novel machine learning technique that analyzes patient-related features in the form of routine hematology and biochemistry and their interaction with time to accurately predict AKI in hospitals by a lead time of 48 hours.

Methods

Dataset

The data source was our institution's EHR in 2012, which recorded clinical and laboratory data from 68,832 case admissions in that year. Our institution is a 1200-bed academic hospital that provides complex tertiary care services including cardiothoracic surgery, transplantation, and cancer management. The Institutional Human Research Ethics Committee approved the study (NUHS-DSRB 2018/00169) and waived the need for informed consent given the use of deidentified data for analytics with secured institutional governance.

Study Design and Participants

We performed an observational longitudinal study of the prospectively acquired EHR data from hospitalized patients in 2012. The exclusion criteria were (1) patients discharged within 48 hours of admission; (2) patients with community-acquired AKI, as inferred from onset of AKI within 48 hours of hospitalization [13]; (3) patients with stage 5 chronic kidney disease by Kidney Disease: Improving Global Outcomes (KDIGO) criteria, both dialysis, and nondialysis [14], inferred from diagnosis codes (Systematized Nomenclature of Medicine–Clinical Terms) for "end-stage kidney/renal disease," an admission estimated glomerular filtration rate (eGFR) of less than 15 mL/min/1.73 m^2 by Chronic Kidney Disease Epidemiology Collaboration equation [15], or procedural codes for peritoneal dialysis catheter insertion, arteriovenous access creation, or fistuloplasty; (4) patients with procedural codes for "**dialysis," "**filtration," or "**diafiltration" previously who failed to recover kidney function to a current admission eGFR of at least 30 mL/min/1.73 m^2; or (5) patients with no available laboratory results for analytics.

Definition of AKI

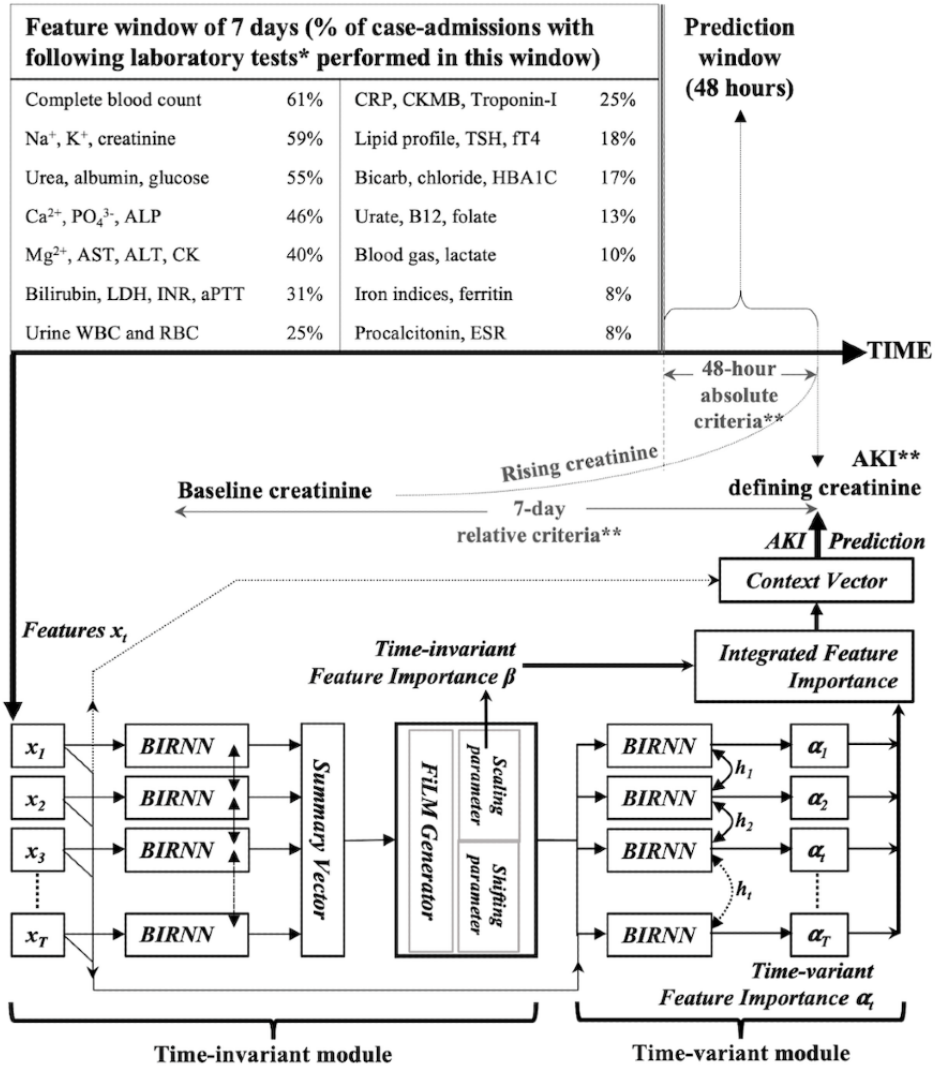
The binary event measure was AKI, as defined by the KDIGO 2012 criteria using serial serum creatinine levels during the index hospitalization [16]. These included the relative criterion of at least 1.5 times an increase in serum creatinine level within a 7-day window; the absolute criterion was an increase in serum creatinine of greater than 26.5 μmol/L (0.3 mg/dL) within 48 hours. The reference serum creatinine within the corresponding 7-day or 48-hour window for either criterion was taken as the baseline creatinine. The AKI-defining creatinine level and the extent of elevation over baseline were used to grade the initial

KDIGO AKI staging severity. Creatinine was measured using the ADVIA 2400 (Siemens AG) enzymatic method traceable to isotope dilution mass spectrometry standard. We did not apply the oliguria criterion for AKI.

Features Used for Analytics

Features (or covariates) were sourced from time-series laboratory results. The data source was our institution's EHR, Computerized Patient Support System version 2 (Integrated Health Information System Pte Ltd). The results were integrated from comma-separated value files using common masked identifiers and ported onto our institution's artificial intelligence discovery platform, an EHR analytic module. Data with the date and time stamps were selected as features to predict the event. These included all serial hematology, serum biochemistry, and urinary investigations (Figure 1). We did not include disease diagnosis codes or medication records.

Figure 1. Prediction logic and features included in analytics. *: Serum biochemistry or hematology unless otherwise stated (eg, urine WBC and RBC); **: AKI defined by KDIGO criteria; x: features entered in model; t: time windows; β: time-invariant feature importance of which influence is shared across time windows; alpha-t: time-variant feature importance; ht: time-variant hidden representation; WBC: white blood cell; RBC: red blood cell; AKI: acute kidney injury; KDIGO: Kidney Disease: Improving Global Outcomes; BIRNN: bidirectional recurrent neural network; FiLM: feature-wise linear modulation.



Analytics

Patient profile was compared between unique patients who developed AKI and those who did not. Parametric variables were reported as mean and standard deviation and compared using Student *t* tests; nonparametric variables were reported as median and IQR and compared using Wilcoxon rank-sum tests. Categorical variables were reported as frequency and percentage and compared using chi-square or Fisher exact tests where appropriate. A 2-tailed *P* value of <.05 was taken as the measure of statistical significance.

We sectioned the dataset by date and time for predictive analytics. Every case admission was taken as one sample. The first AKI episode that occurred in corresponding case admissions was analyzed. The AKI-defining creatinine served as the reference time point; the immediately preceding 48 hours was made the prediction window, and the feature window included the time up to 7 days before the prediction window (Figure 1). For case admissions with no AKI episodes, the corresponding

reference time point would be the final serum creatinine level and likewise preceded by a 48-hour prediction window and a further 7-day feature window. Features performed within the feature window were used to predict AKI, a bivariate event, by a lead time of 48 hours. The feature window was further sectioned into daily serial time intervals for time-series modeling, temporal to the event. For each time interval, we averaged the values of the same feature, followed by normalization of the corresponding result x to generate a normalized x^1 as the input for analytics, where $x^1 = [x - \text{minimum}(x)] / [\text{maximum}(x) - \text{minimum}(x)]$.

We proposed a novel time-invariant and time-variant (TITV) model to facilitate more accurate and interpretable analytics in AKI prediction based on the collaboration of 3 modules [17] (Figure 1). In the time-invariant module, an abstract representation was calculated with the data in the entire feature window, denoting each feature's importance shared across time (ie, time-invariant feature importance). This time-invariant feature importance guided the modulation of input in the next module, the time-variant module. In this second module, we applied a bidirectional recurrent neural network to process sequential data and capture the dynamic behavior both forward and backward in time temporal to the event, as guided by the computed time-invariant feature importance from the time-invariant module. Additionally, we differentiated the influence of features across time windows leading to the event by applying the self-attention mechanism on top of the output of the bidirectional recurrent neural network; the output after the self-attention mechanism represents each feature's importance in the corresponding time window (ie, time-variant feature importance in this time-variant module). Finally, in the prediction module, both the time-invariant and the time-variant feature importance were aggregated to calculate the final prediction (ie, risk of AKI). Meanwhile, the influence of each feature (in each time window) on the final prediction was also derived from the TITV model.

We performed a random shuffling of the entire cohort and arbitrarily partitioned the samples into 80% training, 10% validation, and 10% testing datasets. In the training process, we selected the hyperparameters that achieved the best performance in the validation dataset and applied them to the testing dataset for reporting of the experimental results [18-20]. We examined the reporting performance using the area under the receiver operating characteristic curve (AUC), as well as the respective sensitivity (recall) and positive predictive values (precision) that corresponded with the varying model prediction thresholds for AKI. Precision represents the proportion of predicted cases that truly had AKI; recall represents the proportion of actual AKI cases successfully identified by the prediction model. The AKI prediction threshold that provided the most optimal statistical balance between precision and recall was inferred by the highest computed F1 score. A high model recall gives rise, however, to more false positives (ie, poorer precision), and these permutations were further examined to demonstrate their clinical relevance to AKI diagnostics. These results were compared with the corresponding performance using traditional logistic regression and baseline recurrent neural network models. We applied zero imputation for missing data. Analysis was performed using Python (version 3.8.2, open source for Mac OSX).

Results

Patient Profile

We studied 20,732 case admissions in 16,288 unique patients, of which 1971 patients were younger than age 18 years (Figure 2). The mean age of the final cohort was 53 (SD 25) years, and 52.2 (8510/16,288) were males; 28.9% (4701/16,288) had diabetes, 35.0% (5699/16,288) had hypertension, 11.7% (1898/16,288) had ischemic heart disease, and 11.7% (1899/16,288) had either solid organ or hematological malignancy. Near half (7214/16,288, 44.3%) of patients had a baseline eGFR<90 mL/min/1.73 m^2. More patients with AKI (258/869, 29.7%) had a baseline eGFR<60 mL/min/1.72 m^2 compared to those without AKI (2738/15,419, 17.8%; P<.001; Table 1).

Figure 2. Study flow diagram. AKI: acute kidney injury; CKD: chronic kidney disease; CKD-EPI: Chronic Kidney Disease Epidemiology Collaboration equation; eGFR: estimated glomerular filtration rate; ESKD: end-stage kidney disease; RRT: renal replacement therapy.

[b]eGFR: estimated glomerular filtration rate by Chronic Kidney Disease Epidemiology Collaboration equation.

[c]A total of 1446 non-AKI patients had missing baseline eGFR.

[d]Not applicable.

[e]KDIGO: Kidney Disease: Improving Global Outcomes.

Evaluation Outcomes

AKI developed during 4.4% (911/20,732) of case admissions in 869 unique patients at a median of 6 (IQR 3-10) days from admission; 74.9% (651/869) of AKI patients were diagnosed based on KDIGO relative criterion, and 80.7% (701/869) were of initial KDIGO stage 1 in severity. Patients who developed AKI were older with more comorbidities including diabetes, hypertension, cardiovascular diseases, chronic kidney disease, chronic liver disease, and cancers compared with non-AKI patients (all $P<.001$). The median hospital days per admission and cumulatively in 2012 in AKI patients versus those without were 14 (IQR 8-26) days versus 5 (IQR 3-7) days, and 23 (IQR 13-44) days versus 5 (IQR 3-9) days, respectively (all $P<.001$; Table 1).

Analytics for AKI Prediction in the Hospital

The 7-day feature window was divided into daily time windows, giving a total of 7 time windows and 709 features in the analysis. Figure 1 shows the laboratory variables included in the feature window in order of their corresponding test prevalence by categories. Complete blood count was the most common investigation, performed in 61.3% (12,709/20,732) of all case admissions in the analysis; this was followed by serum electrolytes, urea, and creatinine at 46% to 59%, and liver function markers at 30% to 41%. In comparison, acid-base parameters and serum lactate contributed less (2146/20,732, 10.4%) to the analysis.

The cohort was partitioned into the training (16,585 cases), validation (2073 cases), and testing (2074 cases) datasets; AKI rates in the 3 datasets were 4.5%, 3.9%, and 4.3%, respectively. Table 2 summarizes the AUC of respective analytic modules in the final testing dataset as well as the precision and recall corresponding with the AKI prediction threshold with the highest F1 score. The AUC for AKI prediction by the multivariate logistic regression and recurrent neural network/time-series models were 79% and 80%, respectively. The AUC was 81% after we applied the TITV module with comparable precision and recall compared with the former models; these and the highest F1 score were achieved at an AKI prediction threshold between 15% and 20%. The respective AUCs and corresponding area under precision-recall curves for the training and testing datasets are illustrated in Figure 3.

Table 3 shows the breakdown in our TITV module precision and recall according to the varying probability thresholds for AKI prediction.

A low prediction threshold detected a very high number of predicted AKI cases that scored high in recall but poor in discrimination between true and false positives. Conversely, a high prediction threshold detected a low number of predicted AKI cases but with high precision. A 15% AKI probability threshold implied that 699 cases were predicted to be diagnosed with AKI; 33.3% (233/699) of predicted cases did subsequently develop AKI, while 25.6% (233/911) of eventual AKI cases were successfully predicted. Reducing the probability threshold to 5% led to 3746 predicted AKI cases with much higher false positives but with successful prediction of 60.0% (547/911) of eventual AKI cases. Figure 4 illustrates the confusion matrix plots at AKI prediction thresholds of 5% and 15%. Further details on TITV performance metrics are provided in Table 4.

In addition, our TITV model generated representative interpretation results specific to each AKI case. Figure 5 illustrates the relative feature importance to AKI in 8 case examples, which demonstrated the range of inflammatory, cardiac, drug-specific, or hepatic functional markers in association with AKI, specific to each case. The source codes for our predictive algorithm are available online [21].

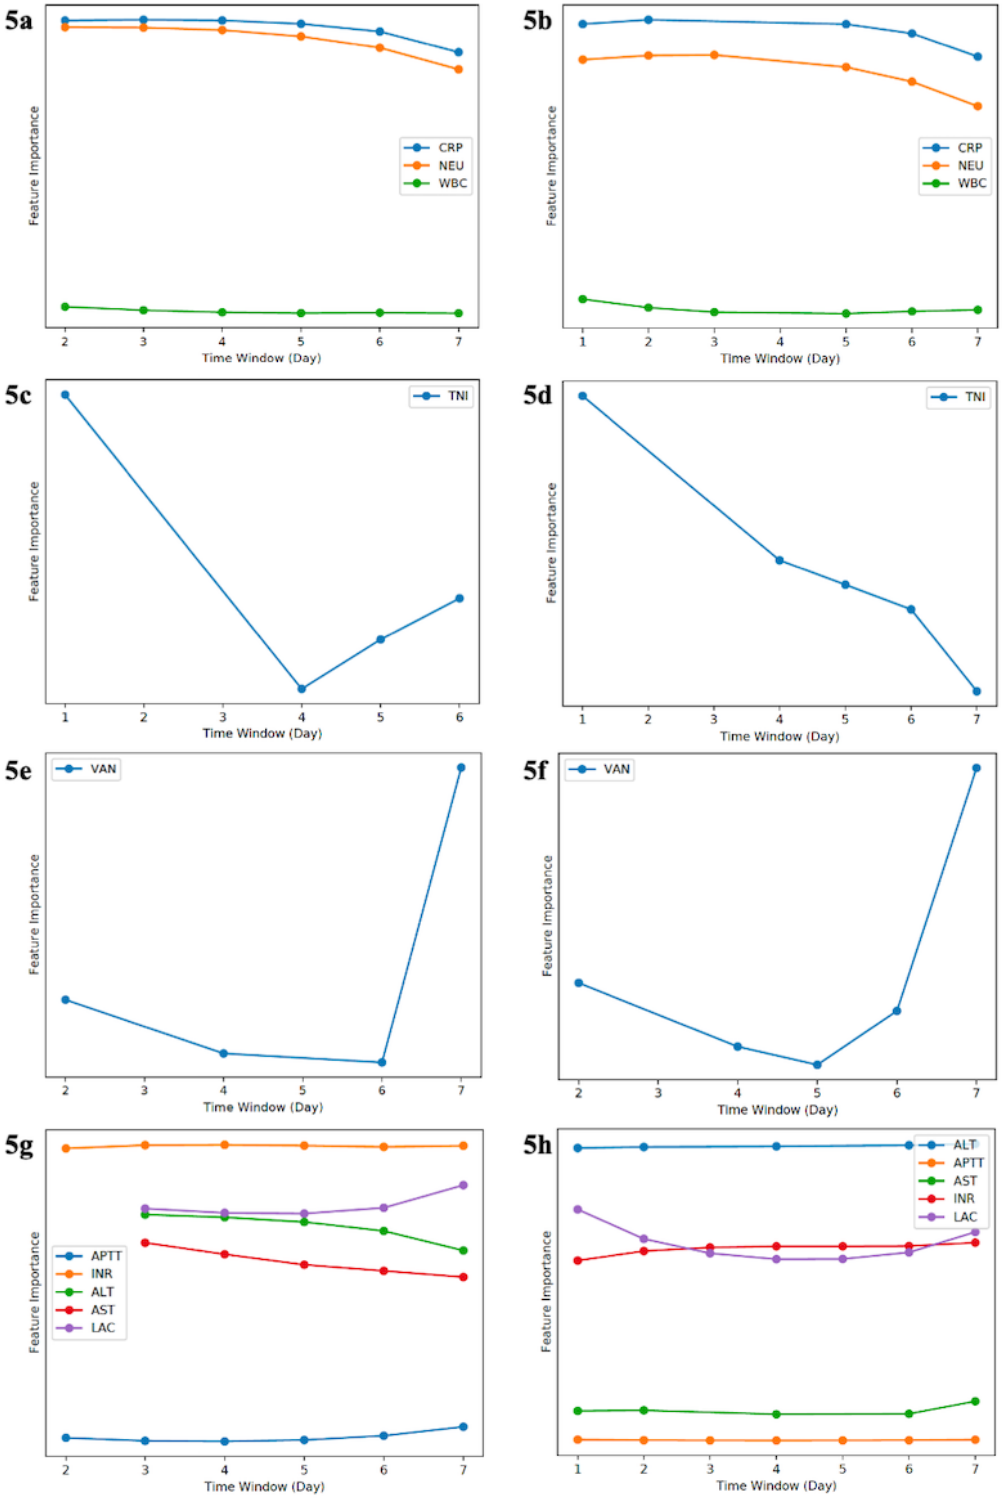
Subtotal	911	19,821	20,732
15% prediction threshold			
TITV predicted (positive)	233	466	699
TITV predicted (negative)	678	19,355	20,033
Subtotal	911	19,821	20,732

[a]AKI: acute kidney injury.

[b]TITV: time-invariant and time-variant module.

Figure 5. Case examples of relative feature importance in acute kidney injury (AKI) prediction. Time-window: refers to feature window of 7 days in AKI prediction; Y-axis: features highly associated with AKI would rank high in relative feature importance; a-b: C-reactive protein, neutrophils featured prominently over days, which suggested infection and inflammation were associated with subsequent AKI; c-d: troponin-I featured prominently initially, which suggested cardiac disease in association with AKI, although its relative importance waned in subsequent days; e-f: vancomycin levels rose in feature importance proximate to AKI, which strongly suggested vancomycin nephrotoxicity; g-h: lactate, liver enzymes, international normalized ratio, and activated partial thromboplastin time featured strongly, which suggested hepatic or multiorgan dysfunction in association with evolving AKI.



Discussion

Principal Findings

We have used structured but heterogeneous biochemical data from 20,732 case admissions in the prediction of hospital-acquired AKI by a 48-hour lead time. We enhanced the recurrent neural network model with a novel analytic module that took into account the temporal interactions in serial laboratory parameters that inferred disease trajectory leading up to AKI [17]. At the optimal statistical operation point as indicated by the highest F1 score (Table 2), our module generated 3 false positives for every 2 true AKI cases, and clinicians would need to act on just 600 predicted AKI alerts of 20,732 case admissions yearly; however, 3 of 4 true AKI cases would be missed. It may be more desirable for our module to successfully predict at least 3 of 5 true AKI cases, but this is counterbalanced by 6 false positives for every 1 true AKI case, and more than 3000 predicted AKI alerts yearly (Table 3). We suggest that our AKI prediction threshold should be low to identify more patients at risk of AKI daily. This narrows the entire hospital cohort to a more manageable patient number for closer monitoring, in whom further assessment could be augmented by AKI biomarkers to reduce false positives [22]. These include urinary clusterin, kidney injury molecule–1, tissue inhibitor of metalloproteinase–2, and insulin-like growth factor binding protein–7, for which levels rise in 12 to 48 hours before a significant rise in serum creatinine [7,23].

Comparison With Prior Work

Our methodology differs from machine learning techniques that used a quasi-random selection of variable prediction points relative to AKI [24]. It resembles models that adopted structured feature and prediction windows relative to AKI that facilitate the deployment of our prediction algorithm in real time [25]. Importantly, we expanded the prediction window to a minimum of 48 hours. Such improved lead time may be necessary for any AKI preventive strategies to make a meaningful change in clinical outcomes. Preemptive interventions may include more detailed patient reviews, timely treatment of infections, precise volume management [26], preferred use of balanced electrolyte over chloride-rich solutions [27], admission to high-dependency or intensive care unit for detailed monitoring, and reduction in or cessation of nephrotoxic medications [28]. These measures, when implemented in a timely fashion and supported by a responsive EHR platform for AKI alerts, may reduce the hospital days and AKI duration in affected patients [29,30].

The performance of any analytic module depends strongly on the appropriate feature selection. Our model was built from objective laboratory test results that would be similar in data structure across institutions [31]. Our algorithm used routinely performed hematology and biochemistry without disease diagnosis codes; these included complete blood count, common electrolytes, acid-base parameters, and liver and cardiac enzymes, and these remain relevant for current AKI prediction even with the changing health care landscape. As our analysis was limited to available investigations performed before a mandatory 48-hour prediction window, the laboratory indices analyzed in the feature window might not be comprehensive. This could compromise the model performance, and the prediction should otherwise improve with features performed at higher frequency and more proximate to AKI [25,32]. Despite this, we demonstrated an AUC that exceeded 80% for AKI prediction in our testing dataset. Certain indices like blood gas, serum lactate, cardiac enzymes, and drug levels should increase in frequency and importance toward the onset of AKI, since AKI serves as a marker of clinical deterioration from nosocomial infections, decompensated cardiovascular diseases, major surgery, or nephrotoxicity [33,34]. Varying significance of these time-sensitive features in association with evolving AKI may be seen among subsets of patients with sepsis, cardiac failure, or cardiac surgery [35-37]. Our TITV module can provide patient-level interpretation of the feature importance, as suggested by our representative interpretation results in unique AKI case examples (Figure 5). These could provide insightful patient-specific trends to aid the evaluation of AKI etiology [17].

Strengths and Limitations

Our study has several strengths but is not without limitations. We have studied a large and diverse population with a comprehensive range of medical and surgical conditions not confined to critical care, which improves the generalizability of our analytic module to hospital practice. We excluded patients with more advanced chronic kidney disease, and our 4% incidence of AKI in the hospital was lower than the 8% reported in prior studies that used similar EHR methods [33,38]. The lack of precise urine output in ward patients could reduce the model accuracy, but oliguria often develops in 24 hours proximate to AKI and may not fulfill our requirement for a 48-hour prediction window. We have normalized the variables for standardized comparison across different tests. Our novel TITV module provided fine-grained interpretability of the prediction results and achieved accurate prediction simultaneously; this facilitates high-quality health care analytics. Being single center in nature, our AKI prediction module needs to be applied and validated in external health care systems to demonstrate reproducibility. The prediction algorithm could be ported to run on platforms that use similar EHR data architecture, but this naturally limits its deployment to institutions with available technology. Nevertheless, our model could be applied for rolling AKI predictions daily if coupled with a real-time feed of laboratory data. While forward application of the algorithm would naturally encounter model degradation due to concept drift, novel techniques could achieve concept drift detection, understanding, and further adaption from contemporaneous data [39,40]. Furthermore, our algorithm was based on laboratory test results less subjected to case-mix shift over time as compared with disease diagnoses or medication records [41]. We had used zero imputation for missing data, unlike the previously described method of imputing preexisting values in time or median value [38]; zero imputation has been widely adopted in machine learning techniques and has achieved state-of-the-art performance in analytics [42,43]. Finally, the subcohort with “false-positive AKI” might be analogous to that of patients with subclinical AKI that may also be associated with adverse long-term outcomes; these were not explored in our study.

Conclusions

We have presented a feasible and enhanced EHR analytic module that captures time-sensitive interactions in laboratory investigations and predicts hospital-acquired AKI by a 48-hour lead time. The AKI prediction threshold could be varied to allow the clinically relevant balance in model precision, recall, and predicted AKI numbers that are compatible with patient service load in health care institutions. With a compromised precision in favor of the better recall, our model serves to risk stratify ward patients for detailed clinical or biomarker assessment for true AKI risk. Its real-time deployment is expected to greatly facilitate our upstream efforts to prevent AKI or its complications in hospitalized patients.

Acknowledgments

This study was supported by a grant from Artificial Intelligence Singapore (100 Experiments Grant), a program supported by the National Research Foundation and hosted by the National University of Singapore. The granting body was not involved in the review or approval of the manuscript for publication. The publication was supported by the Data and Technology Office, National University Health System, Singapore. We thank our institution's EHR data managers, Mr Khong-Hai Wang and Mr Mohammad Shaheryar Furqan, and administrator, Ms Mar Mar Win, for their invaluable support.

Authors' Contributions

HRC, AV, KYN, and HYT conceived the study concept. HRC, KZ, KYN, KA, and BCO planned the methodology and obtained the ethics approval. HRC, KZ, KYN, KA, and BCO retrieved the EHRs. HRC, KZ, AV, HKY, LL, HYT, AM, GM, and SLL preprocessed and curated the data. KZ and BCO applied the machine learning techniques and analyzed the data. HRC, KZ, AV, HKY, LL, HYT, AM, GM, and SLL performed the interim review of analytics. HRC, KZ, and BCO wrote the manuscript. All authors were involved in revising the manuscript and take responsibility for the data presented.

Abstract

Background: Inadequate physical activity is a substantial cause of health loss worldwide, and this loss is attributable to diseases such as coronary heart disease, diabetes, stroke, and certain forms of cancer.

Objective: This study aims to assess the potential impact of the prescription of smartphone apps in primary care settings on physical activity levels, health gains (in quality-adjusted life years [QALYs]), and health system costs in New Zealand (NZ).

Methods: A proportional multistate lifetable model was used to estimate the change in physical activity levels and predict the resultant health gains in QALYs and health system costs over the remaining life span of the NZ population alive in 2011 at a 3% discount rate.

Results: The modeled intervention resulted in an estimated 430 QALYs gained (95% uncertainty interval 320-550), with net cost savings of 2011 NZ $2.2 million (2011 US $1.5 million) over the remaining life span of the 2011 NZ population. On a per capita basis, QALY gains were generally larger in women than in men and larger in Māori than in non-Māori. The health impact and cost-effectiveness of the intervention were highly sensitive to assumptions on intervention uptake and decay. For example, the scenario analysis with the largest benefits, which assumed a 5-year maintenance of additional physical activity levels, delivered 1750 QALYs and 2011 NZ $22.5 million (2011 US $15.1 million) in cost savings.

Conclusions: The prescription of smartphone apps for promoting physical activity in primary care settings is likely to generate modest health gains and cost savings at the population level in this high-income country. Such gains may increase with ongoing improvements in app design and increased health worker promotion of the apps to patients.

Introduction

Inadequate physical activity is a risk factor for coronary heart disease (CHD), diabetes, stroke, and certain forms of cancer [1,2]. The World Health Organization recommends that adults aged 18 to 64 years should complete at least 150 minutes of moderate-intensity aerobic physical activity, at least 75 minutes of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic physical activity each week [3]. Approximately 25% of adults do not meet the recommended level of physical activity worldwide, and it has been estimated that as many as 5 million deaths could be averted each year if the global population were more active [3].

In New Zealand (NZ), >40% of adults are estimated to be insufficiently physically active [4]. CHD, stroke, and diabetes are among the leading causes of health loss in NZ [5], and noncommunicable diseases contribute to marked health

inequalities, with Māori (Indigenous population), Pasifika, and low-income New Zealanders at higher risk for important health conditions [5,6]. Strategies to increase physical activity at the population level are needed to help address this public health concern and reduce health inequalities.

In recent years, the use of mobile health (mHealth) tools to increase physical activity has risen [7,8]. Furthermore, the widespread use of mobile phones has made mHealth interventions scalable to a broad population [9,10]. Although there are a number of different mHealth tools and services available, smartphone apps may be a particularly popular approach to increasing physical activity.

In 2017, there were >325,000 health apps available from major app stores and approximately 3.7 billion app downloads worldwide [11]. The most popular health apps tend to be for diet, physical activity tracking, weight management, and adherence to medication [7,12,13]. Smartphone apps are generally considered easy to use and can enhance physical activity interventions through technological features (eg, accelerometers) [9]. Moreover, apps have been shown to be effective at increasing physical activity levels [10,14], although there is substantial variability in quality and effectiveness between the many available apps [15,16]. Physical activity apps also tend to be inexpensive or free of charge [10]. For example, in NZ, the Ministry of Health–supported web-based Health Navigator app library contains a number of different mHealth apps and specifically includes links to free and low-cost physical activity apps [17].

The prescription of physical activity apps during a primary care visit is a plausible intervention in the NZ context, as some general practitioners (GPs) already *prescribe* exercise as part of a green prescription program [18], although it is unclear whether there is substantial uptake of the program, and there are no requirements for physical activity levels to be assessed as part of standard care by GPs. Such a program could theoretically include smartphone app prescriptions. Clinicians and GPs already frequently recommend apps and other web-based resources during consultations [19,20], and the Royal New Zealand College of General Practitioners supports the adoption of such technology [21]. In addition, some NZ GPs recommend pedometer use for certain patients [22] and would presumably recommend the mHealth equivalent.

Given this background, this study assesses the health impacts, health system costs, and cost-effectiveness of the prescription of smartphone apps for the promotion of physical activity in primary care settings in NZ, a high-income country.

Methods

Modeling Methods

An established proportional multistate life table (PMSLT) model was used to estimate the health impact and health system expenditure of the prescription of smartphone apps for the promotion of physical activity in primary care [23,24]. Physical activity was measured as the change in the metabolic equivalent of task (MET) minutes per week of moderate and vigorous activity. The PMSLT model simulates the entire NZ population alive in 2011 (N=4.4 million) until death or the age of 110 years. Future all-cause morbidity and mortality and incidence and case fatality rates for 5 diseases related to changes in physical activity were projected. Specifically, the model included breast cancer (women only), colorectal cancer, CHD, type 2 diabetes, and stroke.

Health gain was measured in quality-adjusted life years (QALYs) [25], whereas, for costs, a health system perspective was used, and the outputs were the difference in total health system costs between business-as-usual and the modeled intervention and included the cost of implementing the intervention. We also disaggregated the results by period and presented the impact of the intervention after 10 years and 20 years. Calibration and validation of the epidemiological aspects of the PMSLT are described in a web-based technical report [23]. A Monte Carlo simulation (2000 iterations) was used to estimate the uncertainty intervals for the key results.

QALYs and costs were discounted at 3%, with results for 0% and 6% discount rates presented as scenario analyses. We also ran the results applying an *equity adjustment* that set background all-cause morbidity and mortality rates for Māori to non-Māori values [26]. This technique is often used to avoid the undervaluation of health gains and identify potential health equity impacts for Māori. Scenario analyses included higher percentages of the eligible population being screened for the intervention (ie, 25% and 50%), a reversed ratio of GP to practice nurse (PN) consultation time, and maintenance of the intervention impact for 5 years.

Full details of the model are published elsewhere [23,24,27].

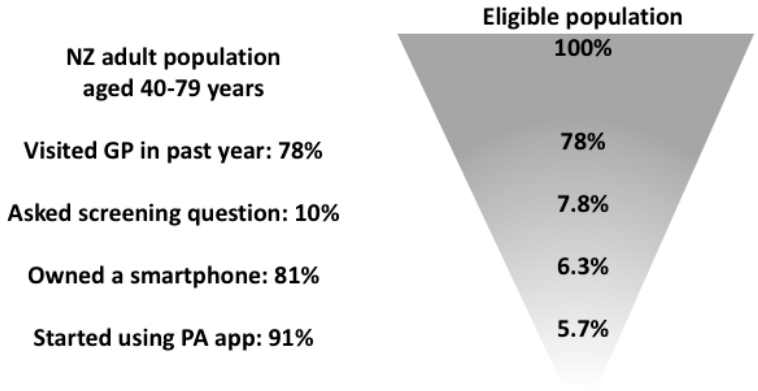
Intervention Specification

Rapid reviews of the literature on physical activity apps and referral schemes (ie, green prescription programs) were conducted to parameterize the intervention for modeling purposes. The modeling parameters used and the justification for their use are presented below (Tables 1 and 2).

As shown in Figure 1, during a GP visit, people with insufficient physical activity were identified using a screening question as per the one used by the NZ Health Survey [28]. For practical reasons and because it might be inappropriate to ask on some occasions, the screening question was assumed to only be asked during a proportion of such visits (10%, with 25% and 50% presented as scenario analyses). For those with insufficient levels of physical activity (defined as <300 MET minutes per week), the GP or PN then provided a printed physical activity prescription form that included specific instructions to exercise and information on how to download and use a physical activity smartphone app. The patient then chose a physical activity app, possibly with input or recommendations from the provider, from the Health Navigator app library. The Health Navigator app library is a repository of apps reviewed by experts, which contains links to a number of independently reviewed exercise apps [17]. It was assumed that individuals would use an app that was already developed and free to download. Furthermore, it was assumed that the app would be available at zero cost for as long as the participants chose to use it. However, adherence to the intervention was expected to decrease relatively quickly;

therefore, long-term availability of the app would not be relevant for most participants. In addition to the prescription, GPs or PNs referred patients to service providers (eg, a regional sports trust or primary health organization in the NZ context) who provided support over the phone, including a comprehensive consultation, 2 brief follow-up calls, and technical support to use the app within the first year after the initial consultation and prescription.

Figure 1. Flowchart of base-case intervention conceptualization for prescribed smartphone apps for physical activity promotion in primary care. GP: general practitioner; NZ: New Zealand; PA: physical activity.



We included direct costs attributable to the intervention (ie, intervention costs) and indirect costs attributable to changes in health system use resulting from the intervention [29]. Intervention costs were applied to everyone who received an initial consultation, even if they did not start using a physical activity app. In addition, it was assumed that all costs would be incurred in the first year following the initial consultation (ie, follow-up calls and technical support would occur in the same year as the intervention). Furthermore, it was assumed that those adults who were sufficiently active or who did not own a smartphone would require less than a minute of the GP's time to screen; therefore, costs associated with such interactions were minimal and not quantified.

Current evidence indicates that physical activity interventions would likely provide minimal chronic disease reduction benefits to adults aged <40 years in NZ [24,27]. Therefore, the age range for the intervention was restricted to 40 to 79 years. Individuals aged ≥80 years were excluded because of low smartphone ownership and use, as well as the relatively high prevalence of comorbidities (eg, arthritis) that could limit participation in physical activity. Although the intervention was only applied to those aged 40 to 79 years, the model followed the entire NZ population alive in 2011 over their remaining life span. Therefore, participants could age into the intervention over time (eg, someone who was aged 38 years in 2011 could still become eligible for the intervention in 2013 when they turned 40).

On the basis of evidence in the literature (Table 1), it was assumed that 91% of eligible patients who were active smartphone users would start the intervention and that physical activity would increase by an average of 410 moderate to vigorous physical activity MET minutes per week. After 1 year, the intervention effect was assumed to be maintained by 36.5% of people, with a decay rate of 55% applied.

Parameters

Tables 1 and 2 contain additional details on the base-case intervention parameters.

Table 1. Modeling input parameters for the prescription of smartphone apps for physical activity promotion in primary care.

Parameter and key source	Supporting evidence and notes	Value (UI[a]; beta distribution unless otherwise indicated)	Resulting percentage (alternate scenarios)
Visited GP[b] in the past year			
Ministry of Health [30]	According to the NZ[c] Health Survey (NZHS), 78% of NZ adults (aged ≥15 years) visited their GP in the past year [30]. The uncertainty intervals are an assumed percentage (±10%).	78% (68%-88%)	78%
Asked screening question			
Croteau et al [31]	A national survey on physical activity and nutrition in NZ by Croteau et al [31] found that only 3% of the survey population (n=235) reported receiving a green prescription from a GP or PN[d]. In addition, the study reported that those aged ≥45 years were significantly more likely to have received a green prescription. On the basis of the findings from Croteau et al [31] and survey data from the NZHS, which indicated that 49% of people who visit their GP have insufficient levels of physical activity [30], it was back-calculated that only approximately 10% of the eligible population would be asked the physical activity screening question during any of their GP visits within a year (ie, the estimate for NZ adults who visited their GP in the previous year [78%] multiplied by the estimate for those asked the screening question [10%], the estimate by Croteau et al [31] for insufficient physical activity [49%], and uptake of the app [81%] equals 3%, which is the percentage of the eligible population that would be expected to receive a green prescription from a GP or PN). However, several alternate scenarios with higher percentages of the eligible population being asked the screening question are also considered in scenario analysis. Although no other evidence was found to support parameter selection, incomplete screening was still included for several reasons. For example, the patient may not be able to exercise because of an existing health condition. In addition, it may be inappropriate to ask the screening question during a consultation about an urgent and critical other matter, and the GP may not have the time for noncritical care provision.	10% per year (alternate scenario 1: 25%; alternate scenario 2: 50%)	7.8% of the eligible population (alternate scenario 1: 19.5%; alternate scenario 2: 39%)
Smartphone ownership			
DataReportal [32]	Using recent metrics on NZ smartphone ownership (based on Google Consumer Barometer data), it has been reported that 81% of NZ adults own a smartphone [32]. The uncertainty intervals are an assumed percentage (±5% of the point estimate).	81% (77%-85.1%)	6.3% of the eligible population (alternate scenario 1: 15.8%; alternate scenario 2: 31.6%)
Uptake of the smartphone app			
Glynn et al [33]	On the basis of an RCT[e] of physical activity apps prescribed in primary care in Ireland, 91% of eligible patients who were active smartphone users were assumed to start the intervention [33]. The uncertainty intervals are an assumed percentage (±10% of the point estimate).	91% (81.9%-100%)	5.7% of the eligible population (alternate scenario 1: 14.4%; alternate scenario 2: 28.8%)
Increase in physical activity			
Glynn et al [33]	On average, mHealth[f] physical activity interventions result in an increase in physical activity, at least in the short term [10,14,34]. As a result of the intervention, it was assumed that physical activity would increase on average by 410 MVPA[g] MET[h] minutes per week. This total was taken from an RCT studying a GP-prescribed physical activity app and follow-up support [33]. The study reported a 2017-step increase per day after accounting for differences between the intervention and control groups. Steps per day were converted to MVPA MET minutes per week using the method outlined in a web-based report [35]. The *Steps to MVPA Conversion* section of this report also has further details about the formula used. The uncertainty intervals are an assumed percentage (±10% of the point estimate).	Increase by 410 (369-451) minutes of MVPA MET minutes per week; normal distribution	—[i]
Adherence at 1 year			

Parameter and key source	Supporting evidence and notes	Value (UI[a]; beta distribution unless otherwise indicated)	Resulting percentage (alternate scenarios)
Allman-Farinelli et al [36] and Damschroder et al [37]	After 1 year, the intervention effect was assumed to be maintained by 36.5% of people. This was based on the average of estimates for 2 app+ (ie, a smartphone app in addition to follow-up texts, calls, or emails) intervention studies (see below), which typically fall between the estimates for traditional green prescription programs and app-only physical activity interventions in retention and adherence. The uncertainty intervals are an assumed percentage (±20% of the point estimate). The first RCT for the prevention of weight gain in young adults in Australia found that an app+ intervention that targeted both dietary behaviors and physical activity generated a 40% response rate to follow-up SMS text messages at 9 months [36]. The second RCT for physical activity in US veterans reported a 33% retention rate at 12 months for an app+ group that received follow-up phone calls [37].	36.5% (29.2%-43.8%)	—
Decay rate of intervention effect after 1 year			
Gc et al [38]	A recent modeling study of brief physical activity interventions also used a similar methodological approach and assumed that the interventions had an effect for the first year and then applied a 55% decay rate every year afterward [38]. This was in line with several previously reported physical activity modeling studies (ie, Over et al [39], Cobiac et al [40], and Jacobs-van der Bruggen et al [41]) that assumed similar base-case decay rates, varying between 50% and 55%. The uncertainty intervals are an assumed percentage (±20%).	55% (35%-75%)	—

[a]UI: uncertainty interval.

[b]GP: general practitioner.

[c]NZ: New Zealand.

[d]PN: practice nurse.

[e]RCT: randomized controlled trial.

[f]mHealth: mobile health.

[g]MVPA: moderate to vigorous physical activity.

[h]MET: metabolic equivalent of task.

[i]Not available (does not change % of eligible population).

Table 2. Cost input parameters for the prescription of smartphone apps for physical activity promotion in primary care.

Parameter	Key source	Supporting evidence and notes	Value (95% UI[a])
Ratio of GP[b] to PN[c] consultations	Research New Zealand [42]	Approximately 73% of consultations were assumed to be GP-run and the rest were run by PNs. These proportions are based on the referral sources reported by the NZ[d] Green Prescription Patient Survey [42].	73% GP, 27% PN; however, in a scenario analysis, this ratio was reversed.
GP consultation parameters			
GP consultation time	Elley et al [43]	On the basis of an RCT[e] studying the NZ Green Prescription Program [43], 7 minutes of GP time were spent on the physical activity advice and prescription part of each consultation. Although it is likely that the overall consultation will typically be longer, only the physical activity–specific part has been quantified. Other studies have reported a longer duration [38]; however, NZ-specific data were used for this parameter. It was assumed that there would be additional GP time available for the intervention and, therefore, all other patient concerns would still be covered in the appointment, and no adverse effects would arise from the GP consultation. The uncertainty intervals are an assumed percentage (±10% of the point estimate).	7 minutes (6.3-7.7)
Cost of GP consultation in 2011	Association of Salaried Medical Specialists [44]	The cost of 7 minutes of a GP consultation was assumed to be NZ $15.38 (US $10.35), or NZ $2.20 (US $1.48) per minute. The midpoint of a GP annual salary scale in 2018 was taken from the Wellington Union Health Services Collective Agreement [44]. An hourly rate of NZ $94.15 was then calculated using this estimate. With 50% overheads, this equates to NZ $141.20, or NZ $131.85 in 2011 adjusted for inflation [45]. For 7 minutes of a consultation at an hourly rate of NZ $131.85, the physical activity part of the GP consultation would cost NZ $15.38 per consultation. By comparison, the NZ government agency PHARMAC estimated that the cost of a GP practice visit was NZ $80 per consultation in 2018 [46]. This equates to NZ $73.73 per consultation in 2011 [45], and NZ $33.73 once a patient copayment of NZ $40 is removed. If 7 out of 15 minutes were allocated to physical activity advice and prescription, the cost would be approximately NZ $15.74, which is close to the estimate above. The final costs have been presented as 2011 NZ $. The baseline year of the model was 2011, and cost parameters were consumer price index–adjusted to the 2011 NZ $ to reflect this. With the exception of costs, other parameters in this table are more current, so they produce more relevant outputs.	NZ $2.20/minute (US $1.48/minute)
PN consultation parameters			
PN consultation time	Elley et al [43]	A PN was assumed to spend approximately 13 minutes on the physical activity app consultation based on the results of an RCT on the NZ Green Prescription Program [43]. It was assumed that there would be additional PN time available for the intervention and, therefore, all other patient concerns would still be covered in the appointment, and no adverse effects would arise from the consultation. The uncertainty intervals are an assumed percentage (±10% of the point estimate).	13 minutes (11.7-14.3)
Cost of PN consultation in 2011	Elley et al [47]	The cost of a 13-minute consultation was assumed to be NZ $8.27 (2011 US $5.57), consumer price index–adjusted to the 2011 NZ $, or NZ $0.64 (US $0.43) per minute. A PN hourly wage was NZ $19.12/hour in 2000-2001 [47], equivalent to NZ $25.42 in 2011 [45]. This equates to NZ $38.16 per hour with overheads (as per the GP calculations) and NZ $8.27 for a 13-minute consultation. By comparison, the midpoint of the Practice Nurse Collective Employment Agreement pay scale was NZ $24.36 per hour [48]. This is similar to our hourly rate before adjusting for overheads.	NZ $0.64/minute (US $0.43/minute)
Additional costs[f]			

Parameter	Key source	Supporting evidence and notes	Value (95% UI[a])
Cost of additional resources in 2011	Elley et al [47]	The cost of follow-up phone calls and additional resources was assumed to be NZ $90.10 (US $60.63) per individual. As per the structure of the NZ Green Prescription Program, the intervention was assumed to also include phone calls and additional resource use. After consultation, the intervention would include 3 follow-up phone calls, the first a comprehensive consultation and then 2 brief follow-up calls. The phone calls would include general advice on physical activity and technical support to use the app. Additional resources would include educational material dissemination, such as an email with a link to a website with responses to frequently asked questions. Similar services were estimated to cost NZ $69 per person in 2001-2002 based on the results of a PhD thesis on the NZ Green Prescription Program [47]. This NZ $69 in 2001 equates to NZ $90.10 (US $60.63) in 2011 [45]. The uncertainty intervals are an assumed percentage (±10% of the point estimate).	NZ $90.10 (US $60.63; 81.09-99.11)

[a]UI: uncertainty interval.

[b]GP: general practitioner.

[c]PN: practice nurse.

[d]NZ: New Zealand.

[e]RCT: randomized controlled trial.

[f]It was assumed that individuals would use an app that was already developed and was free to download from the Health Navigator website (ie, zero cost for the app); it was also assumed that there was zero cost for promoting the app to primary care workers.

Results

The prescription of smartphone apps for physical activity promotion in primary care resulted in an increase of 430 QALYs (95% uncertainty interval 320-550) over the lifetime of the 2011 NZ population. This was equivalent to 0.13 QALYs gained per 1000 population (95% uncertainty interval 0.01-0.16; Table 3) or 0.23 QALYs gained per 1000 adults aged 40 to 79 years. Of the total, 150 QALYs and health system cost savings of NZ $174,000 (US $117,000) were accumulated in the first 10 years following intervention implementation, and 160 QALYs and cost savings of NZ $1,961,000 (US $1,320,000) were accumulated in the 20 years following implementation.

The modeled improvements in health came with net cost savings of NZ $2.2 million (US $1.5 million). The intervention was cost-saving for all age-sex-ethnicity subgroups, except for non-Māori women aged 40 to 59 years.

On a per capita basis, QALY gains were generally larger in women than in men, larger in Māori than in non-Māori, and largest in the 60 to 79 years age group. Health gains for Māori increased with the application of the equity adjustment (ie, non-Māori morbidity and mortality rates used for Māori; Table 4).

In the first 10 years after the intervention was implemented (2011-2020), the total health gain was 148 QALYs, with net cost savings of NZ $174,000 (US $117,000) for the health system. After 20 years (2011-2030), the total health gain was 158 QALYs, with net health system cost savings of NZ $1.96 million (US $1.32 million).

The impact of selected changes to model specifications on the results was explored (Table 5). Changing the discount rate had the expected impact on the overall results, with a 6% discount resulting in smaller health gains and cost savings and a 0% discount (ie, undiscounted) resulting in larger health gains and cost savings. Increasing the percentage of primary care patients who were asked the screening question for the intervention also had the expected impact on the overall results, with higher screening rates resulting in higher health gains. However, the cost savings were larger for the scenario in which 25% of patients were asked the screening question (ie, cost savings of NZ $3.3 million [US $2.2 million]) than for the scenario in which 50% were asked (ie, cost savings of NZ $2.6 million [US $1.8 million]) because of the cost of intervention implementation. Dominant provision by PNs (reversing the ratio of GP to PN consultation provision) resulted in a small increase in cost savings (NZ $148,000 [US $100,000]) over the base case scenario. Assuming that the intervention impact would be maintained for 5 years following the intervention (rather than for 1 year), the health gains were estimated to be >4 times higher than in the base-case analysis and would result in much higher cost savings (NZ $22.5 million [US $15.1 million]).

Finally, we examined the contribution of individual intervention parameters to the uncertainty in the modeled results. Uncertainty in health gains and health system cost impacts was primarily driven by the decay rate and the uptake of the smartphone app (Figures 2 and 3).

Table 3. Health gains and health system costs of the prescription of smartphone apps for physical activity promotion in primary care by age, sex, and ethnicity (lifetime gains and 3% discount rate). 2011 NZ $1=2011 US $0.67.

Sex, ethnicity, and age group	Health gain, QALYs[a] (95% UI[b])	QALYs/1000 population (95% UI)	Health system costs, 2011 NZ $ million/2011 US $ million (95% UI)
All sexes and all ethnicities			
All age groups	430 (320 to 550)	0.13 (0.10 to 0.16)	−2.16[c]/−1.45 (−4.49 to −0.11)
40-79 years	430	0.23	−2.16 /−1.45

Discussion

Principal Findings and Interpretation

The potential impact of the prescription of smartphone apps for physical activity promotion in primary care settings in NZ was modeled using published estimates of uptake, effectiveness, and adherence [33,36,37]. The total health impact was modest, with 430 QALYs gained over the remaining life span of the population, albeit up to 1750 QALYs if the intervention effect was maintained for 5 years. The intervention was also likely to be cost saving for the health system and provide larger per capita health gains for Māori than for non-Māori. Given the higher per capita health gains for Māori than for non-Māori, it is plausible that this intervention could play a role in reducing health inequalities if implemented equitably. Although there is strong evidence that physical activity levels can be improved and maintained in the short term through individual-level physical activity interventions, a cumulative meta-analysis of the effects of physical activity interventions found that additional research is needed to identify interventions that are the most cost-effective [49]. This study provides additional modeling evidence of the cost-effectiveness of physical activity promotion in a primary care setting.

Comparison With Prior Work

When compared with selected health interventions in NZ, according to methodologically compatible modeling studies, we found that the prescription of smartphone apps for physical activity promotion in primary care was likely to provide larger health gains and cost savings for the health system than a mass media campaign for physical activity apps [27], a mass media campaign for weight loss apps [50], or weight loss counseling by nurses in primary care [51] in NZ (Table 6). However, the intervention was less effective than a mass media campaign to promote a smoking cessation app in NZ [52]. It was also less effective on a per capita basis than a traditional *green prescription* program to promote physical activity in Australia [40], although this may be due in part to underlying differences in physical activity patterns and epidemiology across different populations. We also note that the health gains of these individual-level interventions are orders of magnitude lower than upstream interventions (eg, tobacco control endgame interventions [53] and switching driving trips to walking and cycling [24]). Implementing the prescription of smartphone apps for physical activity promotion in primary care alongside other such interventions may help maximize health gains.

Table 6. Comparison of the impact of various health interventions in New Zealand according to methodologically compatible epidemiological and health economic modeling (lifetime perspective and 3% discount rate).

Intervention	Health gains, QALYs[a]	Net health system costs, NZ $ million[b]	Cost per QALY gained (incremental cost-effectiveness ratio), NZ $[b]
Prescription of smartphone apps for physical activity promotion in primary care (this study)	430	−2.2	Cost saving
Mass media campaign to promote physical activity apps [27]	28	2.2	81,000
Mass media campaign to promote weight loss apps [50]	29	2.9	79,700
Weight loss dietary counseling by nurses in primary care [51]	250	38.8	138,000
5-year mass media campaign to promote smoking cessation app [52]	6760	−115.0	Cost saving
Enhanced green prescription program among women aged 40-74 years [54]	—[c]	—[c]	687[d]

[b]2011 NZ $1=2011 US $0.67.

[c]This study did not use the same modeling approach but calculated cost-effectiveness ratios.

[d]Program cost per person made *active* and sustained at 12 months.

Study Strengths and Limitations

A strength of this study was the use of an established PMSLT model for physical activity [24,27], which is based on high-quality disease-specific epidemiological and costing data for a whole country. The modeling framework has been widely used in Australia and NZ to assess different health interventions, including several different mHealth interventions [27,50,52], allowing for comparisons across studies. However, a limitation of the PMSLT approach is the assumption of disease independence, although the model does account for the relationship between type 2 diabetes and CHD and stroke, given that type 2 diabetes is a risk factor for these conditions. The model also does not account for potentially beneficial health impacts via the reduction of obesity, anxiety, or depression (or, conversely, health loss via an increase in these conditions because of musculoskeletal injuries associated with physical activity). Another limitation of this study was the use of a health system perspective for costs and benefits. Such a perspective does not allow for the estimation of societal-level costs and benefits outside of the health system, such as impacts on household spending or reduced greenhouse gas emissions from transport mode shifts.

There are also limitations associated with the parameter estimates used. For example, app uptake likely varies and could be increased with improved app design. In addition, adherence estimates in the literature range widely. We examined estimates from green prescription programs, stand-alone app interventions, and app+ interventions (ie, a smartphone app in addition to follow-up texts, calls, or emails). We chose an adherence estimate between those for green prescription programs and app-only interventions, which was in line with app+ interventions in which there would be some level of follow-up with the intervention participants. We assumed that all of the intervention parameters presented in Tables 1 and 2, including intervention uptake and adherence, would be the same across population groups (ie, men and women and Māori and non-Māori). However, it is possible that for certain parameters, there may be significant variations across population groups that may impact the effectiveness of the intervention. For example, it is unclear whether currently available apps adequately cater to the needs of diverse population groups.

Potential Implications for Research

Additional research is needed to optimize interventions that can lead to sustained increases in physical activity levels over the long term [48] and identify the forms of follow-up (eg, phone calls vs emails) that maximize adherence to physical activity interventions. App improvements may also encourage adherence. Evidence suggests that apps are most effective when they incorporate self-monitoring of physical activity, reminders for app use, and social interaction with peers [7,55]. Gamification (eg, providing point-based rewards for frequency or consistency of app use) may also improve outcomes for app-based interventions [56]. Other factors that may influence app use include simple app interfaces, easy navigation, and automatic or simplified data entry [57]. Such features help increase user engagement, which promotes positive behaviors [7]. Advancements in app design merit additional research to assess their impact on adherence.

Potential Implications for Policy

There are indications that such a program would be best administered by PNs rather than GPs, given the larger cost savings associated with the scenario in which PNs are the dominant deliverers of the consultation. In addition, the literature suggests that GPs are often particularly time-limited [58]. Our scenario analyses suggest that larger health gains would be achievable if a higher percentage of patients were asked the screening question (ie, 25% or 50% asked the screening question). If GPs are unable to ask the screening question as frequently as PNs because of time constraints, then it may be both more effective and a better use of staff resources to routinely have PNs deliver such a program. This may also have implications for the administration of the ongoing green prescription program in NZ. However, the ratio of GP to PN consultations was only included in the model as a cost parameter, and we did not assess potential differences in effectiveness between GP and PN administration of the program.

We also note that, in the context of high levels of unmet need for health care (eg, 13.3% of NZ adults did not visit a GP because of cost barriers in 2019-2020 [59]) and differential access to smartphones and the internet, additional strategies to ensure that any app-based intervention does not exacerbate existing health inequities are warranted.

With the widespread use of smartphones, mHealth interventions such as this have a large potential for scalability to a broad population [9,10]. As part of a range of interventions to address insufficient physical activity, governments should consider investing in the promotion of physical activity smartphone apps, along with additional research to improve app effectiveness and uptake. The intervention should ideally be tailored to the country context, which may include examining existing structural inequities that may influence intervention success and co-designing strategies with relevant population groups.

The promotion of smartphone apps may also complement other strategies to promote physical activity (eg, investments in walking and cycling infrastructure [60]) to support long-term behavioral changes. Although our results suggest that the promotion of physical activity smartphone apps in primary care is likely to be effective and cost-saving in NZ, these results are also likely generalizable to other high-income countries with similar chronic disease epidemiology, physical activity levels, and other population characteristics.

Conclusions

In this modeling study, the prescription of smartphone apps for physical activity promotion in primary care in NZ yielded modest health gains and was cost saving for the health care system. The scope for this type of mHealth intervention is expanding with the increase in smartphone ownership and the availability of easy-to-use and effective apps. This intervention should be considered by policy makers in NZ and also be considered by other high-income nations with similar characteristics.

Acknowledgments

The authors gratefully acknowledge Tony Blakely and Linda Cobiac, who helped with other aspects of building the physical activity model used in this study. This study was funded by the Health Research Council of New Zealand (program grants 13/724 and 16/443). The funder had no role in the study design, analysis or interpretation of the data, writing of the report, or the decision to submit the paper for publication.

Abstract

Background: Worldwide, the internet is an increasingly important channel for health information. Many theories have been applied in research on online health information seeking behaviors (HISBs), with each model integrating a different set of predictors; thus, a common understanding of the predictors of (online) HISB is still missing. Another shortcoming of the theories explaining (online) HISB is that most existing models, so far, focus on very specific health contexts such as cancer. Therefore, the assumptions of the Planned Risk Information Seeking Model (PRISM) as the latest integrative model are applied to study online HISB, because this model identifies the general cognitive and sociopsychological factors that explain health information seeking intention. We shift away from single diseases and explore cross-thematic patterns of online HISB intention and compare predictors concerning different health statuses as it can be assumed that groups of people perceiving themselves as ill or healthy will differ concerning their drivers of online HISB. Considering the specifics of online HISB and variation in individual context factors is key for the development of generalizable theories.

Objective: The objective of our study was to contribute to the development of the concept of online HISB in 2 areas. First, this study aimed to explore individual-level predictors of individuals' online HISB intention by applying the postulates of PRISM. Second, we compared relevant predictors of online HISB in groups of people with different health statuses to identify cross-thematic central patterns of online HISB.

Methods: Data from a representative sample of German internet users (n=822) served to explain online HISB intentions and influencing patterns in different groups of people. The applicability of the PRISM to online HISB intention was tested by structural equation modeling and multigroup comparison.

Results: Our results revealed PRISM to be an effective framework for explaining online HISB intention. For online HISB, attitudes toward seeking health information online provided the most important explanatory power followed by risk perceptions and affective risk responses. The multigroup comparison revealed differences both regarding the explanatory power of the model and the relevance of predictors of online HISB. The online HISB intention could be better explained for people facing a health threat, suggesting that the predictors adopted from PRISM were more suitable to explain a problem-driven type of information-seeking behavior.

Conclusions: Our findings indicate that attitudes toward seeking health information online and risk perceptions are of central importance for online HISB across different health-conditional contexts. Predictors such as self-efficacy and perceived knowledge insufficiency play a context-dependent role—they are more influential when individuals are facing health threats and the search for health information is of higher personal relevance and urgency. These findings can be understood as the first step to develop a generalized theory of online HISB.

online health information seeking behavior; Planned Risk Information Seeking Model; health status; theory building; personal survey

Introduction

Relevance of Focusing on Online Health Information Seeking Behavior

The internet occupies an increasingly important site for health information in many regions of the world [1,2]. For instance, in the United States, 80.2% of the population search for health-related information via the internet [2]. In Germany, using the internet to seek health-related information is also of increasing relevance. A national survey showed that 72% of the population use the internet to seek information on health issues [3]. The internet provides an active, problem-oriented opportunity to find a high volume and variety of online health information available virtually anywhere and anytime. That information can be used to guide individuals' health-related decisions, help to cope with uncertainties, and find strategies for living with health threats. Online health information seeking behaviors (HISBs) give individuals more control over their health care and greater knowledge about their condition [4,5]. Doing so, online HISB is a "key facilitator for promotion, maintaining, and returning to health" [6]. Research on why people seek health information online can identify which specific groups can be reached using online sources for health interventions [7]. Therefore, it is important to learn more about the online search for health information and to understand individuals' choices that determine their online HISB.

A wide range of theories has been applied or used as guidance to examine online HISB, with each model integrating a different set of predictors [5,6,8-12]. Thus, a common understanding of predictors of online HISB is still missing [13]. To learn more about the dominant predictors of online HISB, this study aims to explore individual-level influencing factors that lead people to seek health information online. Further, we adopted the Planned Risk Information Seeking Model (PRISM; [14]) as the latest integrative model for the online domain and test its applicability. Another shortcoming of the theories explaining HISB and online HISB that our study aims to address is that most existing models, so far, focus on very specific health contexts such as cancer or diabetes [9,15-18]. Contrary to this focus, a trend in information seeking research follows Case's [19] call to shift away from single diseases [14,20,21]. In response to this requirement, we aim to explore cross-thematic patterns of online HISB. We use health status as a comparative dimension because it can be assumed that groups of people perceiving themselves as ill or healthy will differ concerning the personal relevance of online HISB and its drivers [21-23]. Considering variations in individual context factors is the key for the development of generalizable theories because it helps to identify both context-specific determinants and cross-contextually important predictors that would emerge as the core of online HISB [6].

To sum up, the objective of our study was to contribute to the theoretical development of the concept of online HISB concerning 2 areas. First, we aimed to apply the PRISM to online HISB to analyze predictors of online HISB in general. Second, we compared the relevant predictors of online HISB in groups of people with different health statuses to identify cross-thematic central patterns of online HISB.

Approaches and Challenges of Health Information Seeking in the Online Domain

HISB is a complex, often multistage, process that can be conceptualized by its triggers, channel selection, search strategy, types of information sought, and outcomes [24]. Johnson and Case [6] describe the selection of a channel as the most basic decision individuals can make regarding information seeking. According to the assumptions of a goal-directed selection of information channels, the specific characteristics of a channel influence the intention to turn to it [25-29]. Even though the combined use of multiple channels for information seeking is prevalent [14,19,30], we argue that a comprehensive understanding of the different channel-specific processes of HISB is needed. Therefore, we consider internet-specific capabilities, attitudes, and norms as access points for further theory development [8,31]. Compared with other channels, the internet offers permanent, 24-hour access to extensive, multifaceted, in-depth, and latest health information. Furthermore, the active and goal-oriented options to search for health information online allow a high degree of customizability [11,12,32]. It is also suitable to seek sensitive information in contexts where anonymity is of high relevance [33]. Beyond channel characteristics, explanations for why people go online have been found in specific predictors. Powell and colleagues [34] described the characteristics of online HISB identifying certain motivations, such as the desire for reassurance, a second opinion, and better understanding of information. However, information with varying quality raises the importance of certain abilities and perceived internet self-efficacy to find reliable and accurate health information increases [12,32,35]. In sum, existing theory and research on HISB should be extended by taking channel characteristics of the internet into account and modeling online HISB.

Modeling Online HISBs

The high importance of the internet for HISB has motivated a large number of studies, most of which aim to describe and explain internet use for health-related purposes [36]. Because of the wide range of theories and predictors used to examine online HISB [8,9], it remains unclear which predictors are the dominant or universal ones for online HISB. A specific model of online HISB is missing; thus, in our study, a well-established model of HISB serves as a foundation for modeling online HISB to take past theoretical progress in general HISB into account to allow progress. The assumptions of the PRISM [14] are adopted to study online HISB because this model identifies the general cognitive and sociopsychological factors that motivate HISB. Variables considered in PRISM were already applied to

examine online HISB [13], but the whole model was not examined regarding online HISB so far.

The PRISM was developed with a general health reference and aimed at explaining information seeking intention in light of individual-level factors across different risk- and health-related issues that are valid for multichannel HISB [14]. PRISM is an integrated model postulating the importance of 7 distal and proximal factors applied from models such as the Theory of Planned Behavior [37], the Risk Information Seeking and Processing Model (RISP; [22,23]), and the Comprehensive Model of Information Seeking [8,26]. It is often viewed as an expanded iteration of the RISP that has incorporated additional models to explain general information seeking intentions as an outcome [30]. Because of this comprehensiveness, we deemed the PRISM particularly suitable for our approach.

Based on the Theory of Planned Behavior, the PRISM posits that the intention to seek information is the result of attitudes toward information seeking, subjective seeking-related norms, as well as perceived seeking control. Attitudes toward information seeking capture an individuals' evaluation of the information-seeking behavior. Subjective norms consist of perceived expectations or social pressure of one's social surroundings to seek information (injunctive norms) as well as seeking behaviors perceived in one's social surroundings (descriptive norms). The perceived behavioral control is understood as an individual's ability to seek information [14]. Further, adopted from the RISP, the PRISM includes an individual's perception of his/her state of knowledge and knowledge insufficiency as well as health-related risk perception and affective risk response [21-23] as factors that influence the intention to search for information. Knowledge and knowledge insufficiency depict the assumption that the desired level of confidence in an individuals' knowledge motivates information seeking [14,21]. Knowledge insufficiency is the gap between what an individual knows and what he or she needs to know to feel confident [23,30]. Risk perception refers to the susceptibility and severity of risks to one's health, whereas affective risk response describes a negative affective reaction induced by the health risk [14,21]. All predictors are postulated to be positively related to the HISB intention.

Kahlor [14] postulated that the predictors integrated into the PRISM are valid across channels, but the claim has never been empirically tested and the individual explanatory power of the predictors remains uncertain. Particularly, some past studies including review and meta-analysis indicated that the power of the predictors of online HISB differs from that of offline sources [8,31,38,39]. Therefore, Wang and coauthors [13] concluded that there is a need to refine the PRISM for online HISB.

Concerning attitudes toward seeking and subjective norms, a meta-analytical review [13] showed that the relation between both predictors and online HISB is understudied. About the attitude, recent research postulated a positive association between attitudes toward online HISB and online HISB intention [13], suggesting that the postulates of the PRISM apply to the online context. Comparing source usage regarding the association with norms, the first findings are mixed. Although studies support that subjective norms are a critical antecedent of online HISB [40], others found that normative influences of family and friends motivate the choice of interpersonal and mass media channels but not the internet [39]. Accordingly, the results at least call into question whether norms are among the strongest predictors of online HISB, as presumed for HISB [21].

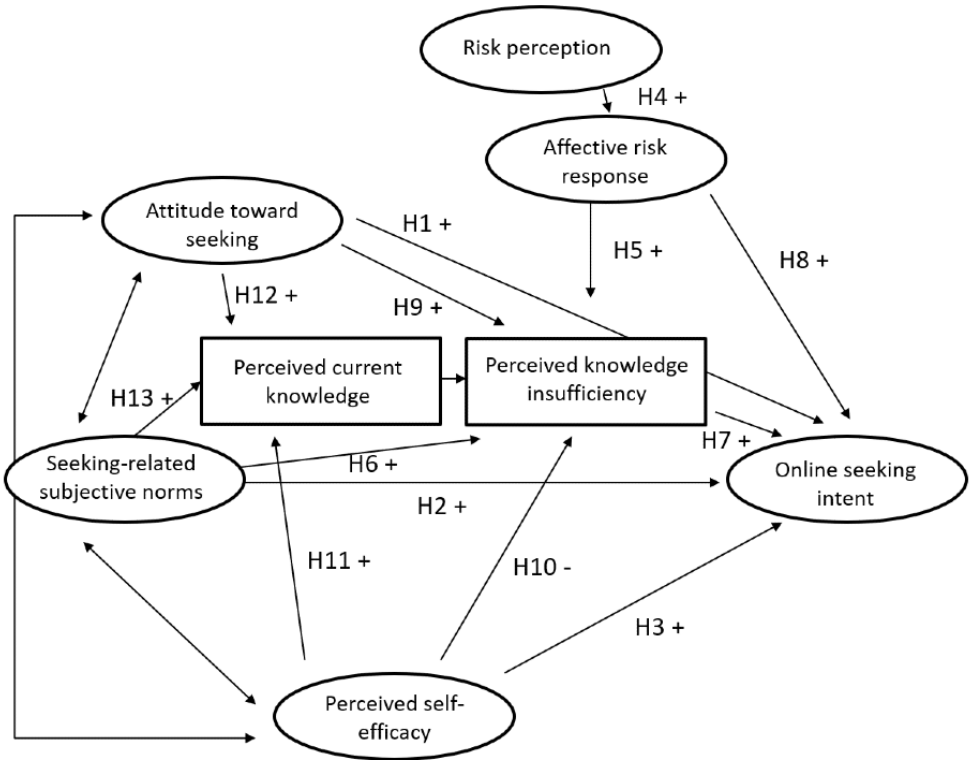
Besides, recent studies stressed that particular (perceived) abilities gain importance for health-related internet use compared with other sources [13,31]. Instead of perceived seeking control that is considered in the PRISM [14], perceived self-efficacy is often theorized as a factor influencing internet use [8,13,35]. The terms are sometimes used synonymously, or self-efficacy is understood as a dimension of seeking control [20,41]. However, although perceived seeking control includes internal abilities and external capabilities such as the accessibility of information, self-efficacy is predominantly based on internal control factors referring to beliefs in one's capabilities to execute a certain course of action such as online HISB [42]. Therefore, we categorize perceived self-efficacy as a part of perceived seeking control [43]. Because more than 90% of German residents possess access to the internet [44] and Germany is characterized by a high information and communication technology development index, external barriers to information acquisition are perceived as low, whereas own capabilities might be a relevant predictor of online HISB. In line with studies showing that self-efficacy is a well-confirmed predictor of internet use [35], we aim to focus on perceived internal control factors of those residents having access to the internet. Acquiring health information online is understood as a behavior that requires many unique capabilities from learning how to use the internet or search engines to gather health information, locating different perspectives or high-quality information, and evaluating the quality of health websites. The need for corresponding abilities underscores the importance of efficacy perceptions to perform online HISB, as self-efficacy is known to determine how much effort an individual is willing to invest to perform a certain course of action such as online HISB [35].

The multichannel comparison of Yang et al [39] highlighted that risk perception and affective risk responses as well as current knowledge and knowledge insufficiency had different impacts on HISB depending on the channel used. For online HISB, risk perception, current knowledge, and knowledge insufficiency were shown to be of low relevance for online HISB [39]. For negative affective risk responses, a weak but a significant positive association with online HISB was supported, whereas negative responses were not associated with turning to interpersonal or other media sources [39]. Given past findings that the internet often serves as a channel for a second opinion [11,35,45], prior use of other sources might result in higher perceived knowledge or higher awareness of knowledge insufficiency as predictors of online HISB and influence the risk perception and affective risk responses, which might influence the selection of the internet.

Overall, these findings indicate that established factors of HISB such as social norms, informational self-efficacy, risk perception, affective risk response, and knowledge insufficiency are of relevance for online HISB and increase the intention to seek health information online. However, the dominance of the predictors might differ in comparison to HISB in offline

channels. Therefore, it is indicated to test whether the general assumptions of the PRISM can be applied for explaining online HISB. Our first research question (RQ1) is as follows: *Can the PRISM be applied to explain online HISB intention?* The single hypotheses (H1 to H13) reflect the predicted relationships of PRISM, whereas the single predictors were transferred to online HISB. The single hypotheses are shown in Table 1 and illustrated in Figure 1.

Figure 1. Predicted relationships of the Planned Risk Information Seeking Model applied to online health information seeking behavior. H: hypothesis.



Health Status–Related Importance of Predictors of Online HISB

Aiming to explain online HISB beyond single disease contexts, we consider the personal relevance of health topics [39] distinguishing between routine (ie, driven by a general interest) and nonroutine information seeking (ie, triggered by a specific health challenge; [23,33,46]). This context factor of online HISB is considered by exploring differences in the importance of predictors of online HISB between a generally healthy population and people who are facing current health issues. Current research considering health-related context factors of online HISB mainly considered health status as a predictor of online HISB frequency but did not distinguish predictors of online HISB depending on different health-related contexts [1,4,9,10,42]. However, the PRISM and RISP have already been tested concerning different communities and different risks, that is, across differing health-related contexts [16,23,39,47-50]. Findings revealed the consistency of factor importance across different risks [23,51] but showed first indications of differences between populations with limited versus high personal relevance of a health topic [39]. More detailed findings of Yang et al [39] suggested that in the general population, higher perceived risks increased online HISB, whereas among patients with cancer, risk perception caused a decrease of online HISB. Furthermore, people's sense of knowledge insufficiency varied based on health status, and normative beliefs had a stronger impact on online HISB in the general population than that among patients with cancer [39,51,52]. Further, the attitudes toward seeking information online can be determined by health status as they are associated with the salience of perceived channel characteristics [28] and the perceived utility of the internet [8]. As perceived health threats may reduce the self-ascribed ability to succeed in online HISB [1,53], it is conceivable to posit a context-dependent role of self-efficacy to use the internet for health-related purposes. Recent research has suggested that health status may result in different influence patterns of online HISB, which might contradict the cross-channel universality of the PRISM. To substantiate this assumption, a comparison of the empirical importance of predictors in groups of individuals with different health statuses is required. Thus, our second research question (RQ2) is as follows: *Do the direct and indirect predictors of online HISB intention differ between people who face a health threat and people who perceive themselves as healthy?*

Methods

Recruitment Procedure and Participants

We conducted a standardized personal survey with a representative sample of 1001 German individuals. The fieldwork was conducted by a German market research company using quota sampling intended to guarantee representative population data. Because we aimed to explain online HISB, our analysis included only people with internet access (822/1001, 82.1% of the respondents). The respondents were aged between 18 and 88 years (mean 47.08 [SD 16.29] years), and more than half of the participants were females (459/822, 55.8%).

Regarding school education, the largest proportion of participants had a secondary school leaving certificate (371/822, 45.1%). Approximately 28.6% (235/822) of respondents had less than a secondary school leaving certificate, 14.8% (122/822) had graduated from high school, and 11.4% (94/822) had university degrees.

Measures: Online Seeking Intention

Based on Kahlor's study [14], 3 out of 5 items were applied to the internet that, on the one hand, express a different strength of intention ("I intend to look for health information on the internet in the near future;" "I will look for health information related to my personal health and risks to my health in the near future") and, on the other hand, aim at intensifying the search for information in the future ("I intend to find more information about my health on the internet soon"). A global query that refers to the internet as a whole seemed justified, as recent studies [45,54] and our survey confirmed that search engines were central (mean 3.36 [SD 0.96]; frequency measured on a 5-point Likert-type scale ranging from 1 "never" 1 to 5 "very often"), while direct access to specific online communities (mean 1.68 [SD 0.95]) or health websites (mean 2.04 [SD 1.01]) was rarely practiced. Further, in the United States, 77% of online health seekers reported using a search engine to begin a search, whereas only 13% began at a site that is specialized in health information [54]. The 3 items were rated on a 5-point Likert-type scale ranging from strongly disagree (1) to strongly agree (5) (α=.920; mean 2.45 [SD 1.13]).

Measures: Predictors

Attitudes Toward Online Information Seeking

We adopted the measurement from Kahlor [14] and instructed our participants to describe their attitudes toward online HISB with seven 5-point semantic differential pairs (eg, bad/good, unhelpful/helpful; α=.944; mean 3.29 [SD 0.90]).

Seeking-Related Social Norms

To measure injunctive and descriptive norms, we used single items adopted from Kahlor [14]: "My family and friends expect me to seek information on health-related topics and risks" (mean 2.75 [SD 1.15]; injunctive norm) and "People in my life whose opinions I value seek information on risks and health-related topics" (mean 3.37 [SD 0.98]; descriptive norm). Both items were evaluated on a 5-point Likert-type scale: strongly disagree (1) to strongly agree (5). Since injunctive and descriptive norms are theoretically conceptualized as 2 dimensions of social norms [52,55,56] and their correlation is mediocre (r=0.38; *P*=.01), we decided to treat them as distinct concepts.

Perceived Health-Related Internet Self-efficacy

Internet self-efficacy was assessed based on a scale of Eastin and LaRose [57], which was adapted and applied to online HISB by Rains [35]. The measure consists of 8 items describing different tasks (eg, evaluating the quality of health websites, finding high-quality health information) asking for respondents' perceived abilities in using the internet to acquire health information. Participants' applicability to the statements was measured on a 5-point Likert-type scale (α=.947; mean 3.51 [SD 0.97]).

Risk Perception and Affective Risk Response

Following Kahlor [14], we measured risk perception asking for the susceptibility ("How likely are you to become ill in the next year?") and the severity of an illness (eg, "If you were to become ill in the next year, how serious do you think it would be?"). All items for risk perception were measured on a Likert-type scale ranging from 1 (not at all) to 10 (extremely; α=.863; mean 3.14 [SD 1.89]). As affective responses to perceived health risks, we assessed the extent to which the participants felt worried, scared, or uncertain (α=.963; mean 3.32 [SD 2.21]). The items that capture affective risk response were measured on a Likert-type scale ranging from 1 (not at all) to 10 (extremely).

Perceived Knowledge and Knowledge Insufficiency

In line with Kahlor [14], we assessed knowledge and knowledge insufficiency on scales from 0 to 100. First, we asked the respondents to rate their current state of knowledge about health-related topics (mean 57.69 [SD 23.01]). Second, they were asked to rate their needed level of knowledge to cope with health-related topics (mean 73.49 [SD 19.7]).

Health Status

Health status was measured in 2 different ways [58]. First, respondents were asked to rate their health status (mean 3.35 [SD 0.85]) on a 5-point scale from "poor" (1) to "excellent" (5). Second, we asked whether the participants perceived themselves as currently completely healthy, acutely slightly ill, acutely seriously ill, or chronically ill [58]. Additionally, we provided the option to refuse to answer this question. To have a sufficient group size for comparison, the answers "acutely slightly ill" (154/822, 18.7%) or "acutely seriously ill" (16/822, 1.9%) and "chronically ill" (59/822, 7.2%) were merged (see RQ2). For this purpose, 2 groups—people perceiving themselves as healthy (n=564) or ill (n=229)—were built (see Multimedia Appendix 1, Table S1). Of the 822 participants, 29 (3.5%) refused to answer the question about their health status and were not considered for the group comparison (see RQ2). To validate this measurement, the relationship between both measurements of health status was assessed showing a rather strong association (r=0.53; *P*=.01).

Statistical Analysis

To answer our research questions and test our hypotheses, we used latent-variable structural equation modeling in R (version 3.4.2). We used two-step modeling to verify all measurement models before testing the structural model. The data fit of all measurement models was evaluated as satisfying (see Multimedia Appendix 1). In response to the second research question, we conducted a multigroup analysis to test the PRISM applied to online HISB intention in a group comparison for healthy and ill internet users. Therefore, measurement and structural invariance were evaluated. The results for measurement invariance are shown in Multimedia Appendix 1. The invariance appeared problematic but justifiable in single cases (see Multimedia Appendix 1). The structural invariance was determined by comparing the unconstrained and constrained model using χ^2 and fit statistics.

Results

RQ1 asked if the PRISM predictors can be applied to explain online HISB. The model fit indices showed a satisfactory model fit (χ^2_{335}=846.5, P≤.001; comparative fit index [CFI]=0.962, root mean square error of approximation [RMSEA]=0.043, standardized root mean square residual [SRMR]=0.054; [59,60]). Since the other indices had very satisfactory levels, the significant χ^2-test was attributed to the sample size [61,62]. The model accounted for 31.8% of the variance in online HISB intention. Besides, the model explained 21.9% of the variance in perceived knowledge insufficiency, 5.3% of the variance in perceived knowledge, and 68.5% of the variance in affective risk response. The results of the hypotheses tests (standardized beta coefficients and their significance) are reported in Table 1 and Figure 2. Overall, 7 of the 13 hypotheses were confirmed. Paths that could not be confirmed applied to online HISB were associated with the distinction between injunctive and descriptive norms. Only influences of injunctive norms were found. Injunctive norms were positively related to online HISB intention (see H2) and perceived knowledge (see H13) but negatively related to perceived knowledge insufficiency (see H6). Additional relationships that could not be supported for online HISB intention included the paths between affective risk response and perceived knowledge insufficiency (see H5), between perceived self-efficacy and perceived knowledge insufficiency (see H10), and between attitudes toward seeking and perceived knowledge (see H11). In contrast to previous studies focusing on HISB [14,47,50], the path between perceived knowledge insufficiency and online HISB intention was confirmed (see H7).

Table 1. Overview of the hypotheses and outcomes.

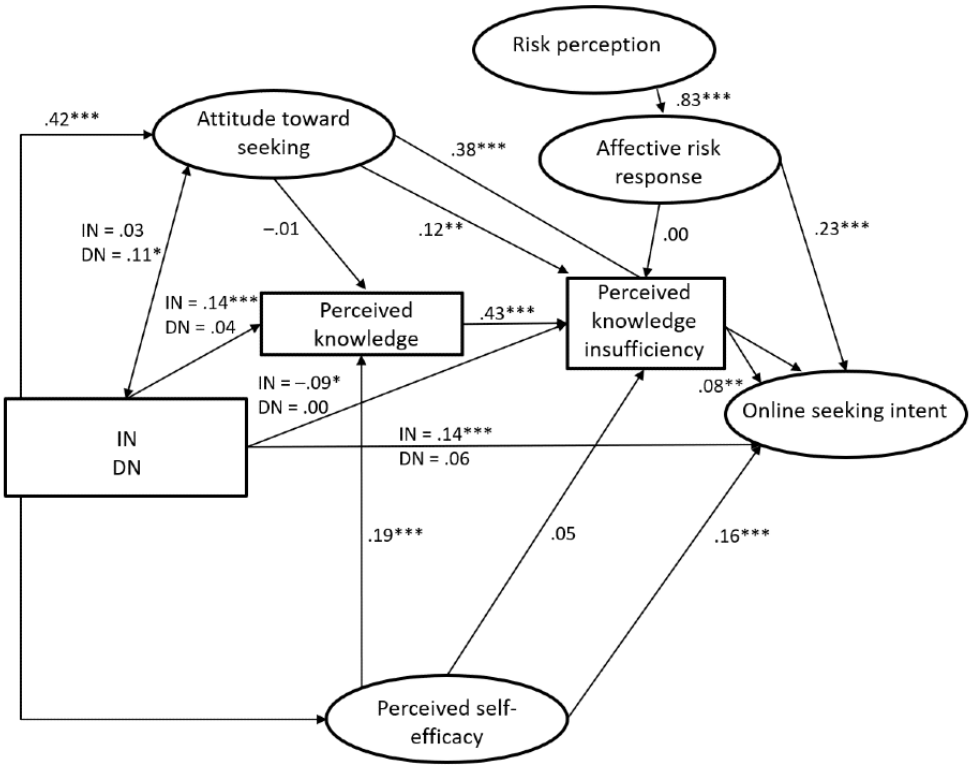
[a]PRISM: Planned Risk Information Seeking Model.

[b]IN: injunctive norm.

[c]DN: descriptive norm.

Figure 2. Planned Risk Information Seeking Model applied to online health information seeking behavior intention. The results of the hypotheses tests are shown as standardized beta coefficients and their significance. DN: descriptive norm; IN: injunctive norm. *P<.05, **P<.01, ***P<.001.



RQ2 asked for differences of predictors of online HISB between groups of people perceiving themselves as healthy or ill. Comparing the unconstrained and constrained model showed that both models fit the data fairly well (unconstrained: χ^2_{686}=1295.0, P≤.001; CFI=0.958; RMSEA=0.050; SRMR=0.061; constrained: χ^2_{726}=1295.0, P≤.001; CFI=0.949; RMSEA=0.051; SRMR=0.065), but the χ^2 difference test indicated that the models are not equivalent ($\Delta\chi^2$=101.1, Δdf=40; P≤.001). The unconstrained model was superior, implying that path coefficients vary among groups. The comparison of the power of the model for healthy and ill people showed that the model accounted for a higher level of variance for ill people with regard to online HISB intention (healthy people: R^2=0.273 vs ill people: R^2=0.437; ΔR^2=0.164), the affective response to perceived risks (healthy people: R^2=0.550 vs ill people: R^2=0.693; ΔR^2=0.143), and perceived risks (healthy people: R^2=0.058 vs ill people: R^2=0.074; ΔR^2=0.016). In turn, the model explains more variance in perceived knowledge insufficiency for healthy people (R^2=0.229) in comparison with ill people (R^2=0.193; ΔR^2=0.036).

Looking at single paths (see Figure 3 and Figure 4), we found different influences from social norms (see H2 and H13). While in the healthy group, injunctive norms had weak to mediocre but significant effects on seeking intention (healthy: β=.18; P<.001; ill: β=.08; P=.20), on perceived level of knowledge (healthy: β=.19; P<.001; ill: β=.01; P=.91), and on perceived knowledge insufficiency (healthy: β=–.12; P=.01; ill: β=–.04; P=.55), these paths were not significant or weaker in the group of ill people (Figure 4).

For the group of ill people, the intention to seek information was significantly influenced by descriptive norms (healthy: β=.02; P=.61; ill: β=.13; P=.047) rather than injunctive norms. Furthermore, perceived internet self-efficacy had a significant and stronger influence on the online HISB intention (see H3; β=.09; P=.07 vs ill: β=.30; P<.001) and the perceived level of knowledge among ill people (see H12; healthy: β=.11; P=.049 vs ill: β=.28; P<.001). The association between self-efficacy and attitudes toward seeking was stronger in the group of healthy people compared with people facing health threats (healthy: β=.47; P<.001; ill: β=.30; P<.001). Other differences related to the relationships between perceived knowledge insufficiency and health information seeking intention (see H7; healthy: β=.05; P=.19; ill: β=.17; P=.01) and between the attitudes toward seeking information online and knowledge insufficiency (see H9; healthy: β=.05; P=.31; ill: β=.18; P=.01). In both cases, only the path for the group of people perceiving themselves as ill was significant.

Figure 3. Online Planned Risk Information Seeking Model comparing healthy and ill people (group of healthy individuals). The results of the tests are shown as standardized beta coefficients and their significance. DN: descriptive norm; IN: inductive norm. *P<.05, **P<.01, ***P<.001.

Discussion

Specifics of the Predictors of Online HISB Intention

As the internet is a frequently used channel for health-related purposes, we applied the PRISM [14] to the internet to provide a theoretically sound analysis of predictors of online HISB intention and refine the PRISM for the online context (RQ1). Our results reveal PRISM to be an effective framework for explaining online HISB intention. For online HISB, attitudes toward seeking health information online provide the most important explanatory power followed by risk perceptions and

affective risk responses. These factors are identified as most essential for online HISB intention and can be understood as the cross-contextual core or dominant predictors of online HISB [6,13]. Further, perceived health-related internet self-efficacy, injunctive norms, and perceived knowledge insufficiency influence a higher online HISB intention. However, they seem to be of secondary importance to explain the intention to turn to the internet. For self-efficacy, our findings do not confirm the postulated higher importance for online HISB [31]. This may be attributed to the fact that our respondents perceive internet use for health-related purposes as less challenging than assumed. As the analyzed sample consists of internet users only, it would be a valuable supplement to compare users with nonusers. However, this was not the aim of this study but should be considered in the future. Regarding the rather weak impact of social norms, our findings are in line with the results of Yang et al [39]. Social norms seem to be less important for online HISB in comparison with HISB in general [14,16]. This is particularly evident for descriptive norms, which have neither an effect on the intention to seek information nor on perceived knowledge insufficiency and the current state of knowledge. The rather weak effect of perceived knowledge insufficiency should be assessed against the background of previous studies that found no relation between knowledge insufficiency and seeking intention [14,50]. This raises the question about the importance of perceived knowledge as a relevant predictor of seeking intention [21]. Our results indicate that the PRISM is a fruitful base to explain online HISB intentions and demonstrate that the process of online HISB rests partially on influencing factors other than offline HISB [21,39]. Thus, more research comparing online HISB with HISB in other channels is needed to determine the differences between channels and to develop a robust generalizable theory of online HISB.

Impact of Health Status on Online HISB

RQ2 addressed the difference between predictors determining online HISB intentions for groups of people perceiving themselves as healthy or ill. The multigroup comparison revealed differences both regarding the explanatory power of the model and the relevance of different influencing factors of online HISB. In general, the causal assumptions were confirmed with greater effect sizes in the subsample of ill people than that in the healthy subsample. Accordingly, the online HISB intention can be better explained for people facing a health threat, suggesting that the influencing factors adopted from PRISM are more suitable to explain a problem-driven type of information-seeking behavior [33,46,63]. These findings call for improving the theoretical understanding of online HISB intentions by healthy people who do not feel immediate pressure to acquire health-related knowledge even though they might perceive their knowledge as insufficient. At the same time, these results indicate that the internet is a particularly important source for ill people [3,45,64], which is important to consider in efforts of distributing health information.

Referring to the single predictors, attitudes toward seeking and risk perception are identified as important in both groups. Although attitudes toward seeking have a stronger influence in the group of healthy people, risk perception and affective risk response show a stronger association for people facing health threats. This contrasts with the findings of Yang et al [39], who identified a positive effect of risk perception on internet use for healthy people and a negative effect for patients with cancer. The severity of a disease could be responsible for this difference. It should be pointed out that the group of people facing a health threat surveyed in this study covers very different health statuses; hence, it is impossible to address differences related to diseases with different degrees of severity and susceptibility. Specific influencing patterns are plausible, and non-HISB coping strategies such as information avoidance are more likely in the case of highly severe diseases such as cancer [65].

Beyond the cross-contextual factors of online HISB, social norms, internet self-efficacy, and perceived knowledge insufficiency are observed as context-specific influencing factors of online HISB intentions. The results regarding the role of social norms are in line with the findings of Yang et al [39] and complement them. They confirm that injunctive norms are a more important predictor for healthy than for ill people. Besides, our data show a higher relevance of descriptive norms for people perceiving health threats. Thus, the individual adherence to injunctive and descriptive norms indicates that healthy people are more strongly influenced for online HISB by perceived expectations held by people in their social environment, while higher intentions among people perceiving themselves as ill are more strongly influenced by the perceived behavior of relevant others. This can be traced back to the fact that affected individuals observe others as role models in a challenging situation; adopting information-seeking behaviors they perceive others to apply in similar situations may provide a solution for the individual search for help, while the perceived pressure from others appears less important in this situation. The context-dependent role of self-efficacy shows that online HISB intention is only directly affected by self-efficacy for people facing health threats that might result from a higher pressure to search for health-related information in the case of illness. For healthy people, the perception of being capable to gather information appears less relevant as their search for health information lacks urgency. However, self-efficacy has a stronger effect on positive attitudes toward seeking information online. This might indicate that healthy individuals assume that they can benefit from the search for information if and when the corresponding needs arise [66]. Another difference between individuals in contexts of health versus illness was found regarding the influence of perceived knowledge insufficiency on the intention for online HISB. This influence is only significant in the group of ill people, which indicates that sufficient knowledge is particularly perceived relevant when problems occur and information might help; so far, this path has not been confirmed in many studies [14,50]. Besides, the influence of attitudes toward seeking health information on perceived knowledge insufficiency was only apparent for the group of people facing health threats. This suggests that health threats are raising awareness of knowledge insufficiency [39]. Overall, the results suggest that the relative importance of predictors of online HISB differs depending on the individual's health status. Therefore, considering health status is a valuable extension of theory-based explanatory modeling of online HISB.

Limitations and Resulting Tasks for Future Research

Although this study informs about the necessity to adjust theoretical models for online HISB, the limitations of the study need to be considered. First, it should be mentioned that information seeking rarely involves only one channel [19,28,29]. Future studies should therefore map the influences of other sources on selecting the internet for health information and compare individual selection factors for different channels. A second limitation is that our study is based on cross-sectional data; therefore, no causality statements can be derived. To ensure a deeper understanding of the processes of information search, longitudinal designs are required in future research. Furthermore, there is a need for cross-cultural studies because the use of the internet to search for health-related topics varies between cultures and countries. We already know that people in the United States are overall more likely to use the internet for health purposes than Europeans [1,2,67]. This suggests that HISB should be systematically compared in terms of cultural context. Third, it should be critically reflected that the categorization of respondents as healthy or ill is unspecific and only based on self-perceptions. Owing to the comparatively small number of cases, differences between acute and chronic illness could not be considered, and different degrees of severity and courses of diseases could not be mapped separately. It can be assumed that, depending on different diseases and different indicators of being or feeling more or less healthy or ill, intentions of HISB will vary [39,66,68]. It should also be noted that the health status variable used to compare the model between contexts of health and illness is closely linked to risk perception as a component of the model. The state of health represents the actual state and can be understood as a predictor of risk perception directed toward the future. Instead of comparing groups of people with different health statuses, further research should integrate health status as a predictor influencing risk perception. Another limitation is associated with the not sufficiently complex measurement of intention to seek information online, as there are manifold types of message forms and contents that can be accessed online (eg, dedicated websites, social media, streaming services, video platforms with user-generated content). Future research should thus consider the diversity to use the internet. Likewise, injunctive and descriptive norms were measured as single items, which should be improved in follow-up studies as well.

Conceptual Perspectives: Advancing Theorizing on HISB

To sum up, our results indicate that attitudes toward seeking health information online and risk perceptions are of central importance for online HISB across different health statuses. The importance of social norms is generally low for online HISB. Further, predictors such as self-efficacy and perceived knowledge insufficiency play a context-dependent role—they are more influential when individuals are facing health threats and the search for health information is of higher personal relevance and urgency. These findings can be understood as the first step to develop a generalized theory of online HISB. In general, the findings from invariance tests indicate that some of the applied measurements such as risk perception may have limited equivalence in health and illness contexts. This points to limited generalizability of the PRISM, which seems to reach greater explanatory power for ill people who are facing more immediate information needs than for healthy people whose inclination to seek and acquire health-related information is not that much energized by situational circumstances [33,46]. This conceptual challenge also holds implications for measurement and testing the PRISM. Although items should be used that are independent of specific health status, the common way of measuring appears not to be optimal for application across different groups with different health statuses. Thus, further studies are needed to show the extent to which the differences found are valid for different health statuses and different information sources to advance model development and increase understanding of the processes of HISB in more detail.

Application Perspectives

Effective disseminating of health information in the online domain can benefit from these findings, as the obtained importance of predictors in health and illness conditions allows to characterize target audiences with greater precision. One striking example of such possible benefits is the observation that internet-related self-efficacy makes a substantially greater difference for online HISB among the ill than among the healthy respondents. Providers of information on a specific illness should thus be aware that online platforms may fail to reach out to relevant parts of the target group who are affected by the illness, as only those with higher self-efficacy are likely to access the online information. Additional (channel) strategies beyond online services are thus advised to avoid information underserving of those patients who do not believe in their ability to find and acquire online health information. In contrast, providers of general or prevention-related health information should consider that motivation of healthy individuals to access their content online is primarily influenced by a positive attitude. Thus, although internet resources have low access barriers and are (seemingly) easy to find and acquire, population segments who do not find online HISB desirable are unlikely to make use of the offered information. Hence, among healthy people, the availability, importance, and usefulness of preventive health information on the internet need to be precisely triggered to increase information pull; besides, general health information should still be transported through mass communication channels such as billboards or television that reach out to nonsearching audiences even in times of nearly permanent internet availability and use.

Abstract

Background: Mobile health (mHealth) as an innovative form of information and communications technology can efficiently deliver high-quality health care by enhancing communication and health management, reducing costs, and increasing access to health services. An individual's internal health locus of control (HLOC) is found to be associated with the behavioral intent to adopt mHealth. However, little is known about the underlying mechanism of this association.

Objective: The primary objective of this study was to test the mediation influence of the Unified Theory of Acceptance and Use of Technology (UTAUT) on the relationship between internal HLOC and the behavioral intention to use mHealth.

Methods: A total of 374 responses were collected from Malaysian adult users of mHealth, using convenience and snowball sampling methods. Partial least squares structural equation modeling was used to analyze the data. Data were collected for variables, including demographics, internal HLOC, and modified UTAUT constructs (ie, performance expectancy, effort expectancy, and social influence).

Results: The results showed that there was no direct relationship between internal HLOC and the behavioral intention to use mHealth (β=−0.039, *P*=.32). The indirect relationship between internal HLOC and the intent to adopt mHealth was supported, indicating that the UTAUT constructs performance expectancy (β=0.104, *P*<.001), effort expectancy (β=0.056, *P*=.02), and social influence (β=0.057, *P*=.002) mediated this relationship. The results showed full mediation, with total variance explained at 47.2%.

Conclusions: This study developed an integrative model, where a health-related disposition (internal HLOC), mHealth-related beliefs (performance expectancy and effort expectancy), and normative pressure (social influence) were combined to explain the underlying mechanism of the behavioral intent to adopt mHealth. The results showed that the intention to adopt mHealth is mediated by the influence of UTAUT factors, while HLOC has no direct effect on adoption intention. The findings provide insights into augmenting mHealth adoption among the public by enhancing the perceived benefits of mHealth, helping design more effective and user-friendly mHealth tools, and capitalizing on social normative influence to adopt mHealth. This study utilized the constructs of the UTAUT model to determine the intention to use mHealth. Future research should focus on other health- and technology-related theories to ascertain other possible factors influencing the behavioral intent of mHealth adoption.

Introduction

Background

Over the past decades, health care systems in most countries around the world have experienced tremendous changes because of the rapid advancement in information and communications technology (ICT). Mobile health (mHealth), as an innovative form of ICT, is one of the most prominent services with remarkable effects on the development of the health care system [1]. According to the Global Observatory for eHealth, mHealth is defined as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [2]. mHealth has the potential to enhance the quality of health care systems by improving communication, efficiency, treatment adherence, and health/disease management; reducing costs; and increasing access to interventions and health services [3-6].

The popularity of mHealth programs has grown worldwide as evidenced by a Statista report in 2017 regarding the estimated number of mHealth app downloads, which has exponentially increased from 1.7 billion in 2013 to 3.7 billion in 2017 [7]. A global survey undertaken by the World Health Organization in 2011 showed that 114 countries have established mHealth initiatives, with health call centers, emergency toll-free telephone services, management of emergencies and disasters, and mobile telemedicine being the 4 most frequently reported initiatives in many countries [8]. Malaysia in Southeast Asia has started restructuring its health care policies and encouraging more start-ups to use disruptive technology to solve key medical challenges [9]. As Malaysia has a high smartphone usage (78% in 2018 [10]), mHealth adoption in the country can be a new and effective approach to empower people in health management and transform the attitude toward health care from reactive to proactive [11].

The importance and implications of mHealth have inspired researchers to investigate the factors in the adoption of mHealth. A cluster of studies viewed mHealth as a perceived technology–driven behavior and attempted to find the correlates of such behavior using technology adoption theories [12-14]. Another stream of studies attempted to explain mHealth from health-related perspectives and examined health factors as predictors of mHealth adoption [15]. While the former has been widely researched, the latter has received less attention.

Among health-related factors, the belief that health events are caused by one's own actions is one of the major predictors of health behaviors such as greater engagement in health/disease management, healthier lifestyle, and better physical and mental quality of life [16,17]. Those who believe that they have an active role in one's own health, also known as internal health locus of control (HLOC), are more likely to take responsibility toward their health and engage in health behaviors [18]. Given that individuals' health-related dispositional factors are significant antecedents of health behaviors [19], including the use of health technologies [20-22], very limited studies have examined the relationship between internal HLOC and the intent to adopt mHealth [23].

Although the direct relationship between internal HLOC and behavioral intention to use mHealth provides a noteworthy tenet to knowledge, little is known regarding the underlying mechanism of this relationship. Focusing on mediating factors, which facilitate the relationship between internal HLOC and the intent to use mHealth, can provide a better insight to Malaysian health policy makers and health care professionals for embedding mHealth use in daily life and promoting mHealth functions (such as health/disease information seeking, communicating for health-related purposes, and downloading and using any health-related apps) for health management and more importantly active participation in disease prevention, thus reducing the need for health care services and consequently the toll on the Malaysian health care system.

Therefore, this study aims to contribute to the literature by introducing 3 constructs of the Unified Theory of Acceptance and Use of Technology (UTAUT) (ie, performance expectancy, effort expectancy, and social influence) as mediators between internal HLOC and the intention to use mHealth, which, to the best of our knowledge, has not been examined thus far. The UTAUT is one of the most widely accepted technology adoption theories with a wide applicability and a high explanatory power to predict the intent to adopt technology [24]. By integrating the UTAUT constructs as mediators in the association between internal HLOC and the intention to use mHealth, a mediation model has been developed to explain the mechanism that underlies the relationship between internal HLOC and behavioral intent to adopt mHealth. Therefore, the objectives of this study are to investigate (1) the relationship between internal HLOC and behavioral intent to adopt mHealth; (2) the relationship between the constructs of the UTAUT (ie, performance expectancy, effort expectancy, and social influence) and the intention to adopt mHealth; (3) the relationship between internal HLOC and the constructs of the UTAUT; and (4) the mediation effects of performance expectancy, effort expectancy, and social influence in the relationship between internal HLOC and the intent to adopt mHealth.

Literature

HLOC and Technology-Related Behaviors

Locus of control (LOC) is a psychological construct that is derived from the social learning theory of personality [25]. Wallston et al [18] developed a multidimensional HLOC scale, which denotes how much individuals believe they are in control of their current and future health. HLOC can be measured as an internal or external HLOC [18]. Internal HLOC posits an active role in one's own health and taking responsibility toward health, whereas external HLOC is divided into 2 parts, with one referring to powerful others and the other referring to chance, luck, or the influence of religion [18].

In general, higher levels of internal HLOC are more likely to drive healthy behaviors and more successful changes in health behaviors and preventive health behaviors, whereas higher levels of external HLOC are not. Stronger internal HLOC orientations were found to be related to greater engagement in health-enhancing behaviors (such as exercise and diet) [16,26,27]; better mental and physical quality of life [16]; lower rates of smoking and excessive drinking [28,29]; better

medication adherence [30]; lower levels of stress, depression, and anxiety [16,31]; longer survival time after surgery [32]; and better health rehabilitation and care [33,34]. Moreover, individuals with internal HLOC tend to actively use coping strategies that focus on solving problems [17] and show greater beliefs in the ability to control the risk of disease [35,36]. Conversely, those with high chance HLOC believe that there is nothing much they can do to influence their health outcomes, and consequently, they are less likely to engage in health behaviors [37]. Additionally, those with higher external LOC are more likely to report higher levels of stress [38] and have worse mental health, as they use more emotion-focused strategies [17].

Research into technology adoption has relied on LOC as a construct that explains adoption behavior. Empirical studies provided support for the association between LOC and higher propensity of adopting technology in an array of technologies where differences in internal and external LOC tend to differentiate the behaviors between these 2 groups [39-42]. Individuals with internal LOC tend to use technology in a goal-directed manner; they are more likely to adopt problem-solving stances to change the environment compared with externals [43]. Internals are more likely to have higher utilization of the technology [44,45]. They are early adopters of technology, are more satisfied with their skills to use technology, and are more comfortable with technology [43], and they perceive difficulties in using technology as associated with their own lack of abilities [46]. Given the rising technology use across all demographic groups, an emerging cluster of scholarly works has been devoted to internal HLOC to predict the intention to adopt mHealth [23].

The Mediating Effect of UTAUT Constructs

Limited research on the relationship between internal HLOC and behavioral intent to adopt mHealth calls for further investigation into the possibility of other variables that could underlie this relationship. Therefore, this study intends to suggest the mediating effect of UTAUT constructs to test the indirect relationship between internal HLOC and the intention to use mHealth. Venkatesh et al developed a unified model that has an overall comprehensive explanatory power to conceptualize and predict acceptance behavior, known as the UTAUT [47]. Numerous UTAUT studies have verified that 3 core constructs (ie, performance expectancy, effort expectancy, and social influence) can affect the intention to adopt technology [48-54]. Performance expectancy refers to “the degree to which an individual believes that using the system will help him or her to attain gains in job performance” [47]. Effort expectancy is defined “as the degree of ease associated with the use of the system” [47]. Social influence is defined “as the degree to which an individual perceives that important others believe he or she should use the new system” [47]. Performance expectancy, effort expectancy, and social influence have direct effects on behavioral intention, which in turn predicts use behavior [47].

Since its emergence, the UTAUT has been empirically tested across domains [53-55], including eHealth and mHealth [56,57]. Past studies have shown that performance expectancy, effort expectancy, and social influence are significantly associated with the intention to use eHealth and mHealth in elderly people and citizens dealing with a health problem [12,52]. Application of the UTAUT to examine the intention to use eHealth and mHealth among clinicians and health care professionals has also been endorsed in a handful of studies [14,56]. It is understood that the target population in most past studies was mainly older adults, people with a health problem, and health professionals. This study attempts to investigate the associations between the 3 constructs of UTAUT (ie, performance expectancy, effort expectancy and social influence, and intention to use mHealth) among Malaysians aged 18 years or above. Evidence showed that although most Malaysians have limited knowledge about mHealth, they reported having a positive attitude toward mHealth [58]. Likewise, a favorable affective feeling was also reported toward telemonitoring systems by patients [59], telemedicine technology by health providers [60], e-counseling by counselors [61], and internet usage for health-related purposes (such as health information seeking and communication) by women [20].

Individuals who score high in internal LOC, also known as internals, cherish innovative ideas [62], tend to be early adaptors of innovative products [44,63], and perceive technology as useful [41,42,46], thus showing a stronger tendency toward technology adoption [64]. They also master their learning environment using more proactive approaches and believe that using technology is free of effort [65]. Internals are characterized by high self-efficacy, which is the impetus to overcome difficulties in using technologies [55]. They are more likely to demonstrate a positive attitude toward computers [65,66], and greater confidence and lower levels of anxiety in using computers [67]. Internal LOC has also been empirically found to be associated with social influence [68,69]. Individuals with higher internal LOC tend to be less likely to be influenced by others [70].

In light of the above literature, we would expect internal HLOC to predict UTAUT constructs, which may, in turn, predict behavioral intent to adopt mHealth. In other words, instead of a direct relationship between HLOC and mHealth, we would expect an indirect relationship that could provide an underlying mechanism to explain how those high on internal HLOC are disposed toward mHealth use. Individuals who tend to assign the cause of health outcomes to their internal characteristics rather than to outside forces are more likely to perceive that mHealth is useful and easy to use. However, they may not use mHealth because of social influences as they do not believe that external forces, such as others, can motivate them to use mHealth. Because of their belief in mHealth usefulness and ease of use, they may have an intention to adopt mHealth. However, their resistant to social influence may hinder them from adopting mHealth. Hypotheses and justifications for the hypotheses are presented in Textbox 1.

Textbox 1. Hypotheses and justifications for the hypotheses.

Hypothesis 1: Internal health locus of control (HLOC) has a positive relationship with the intention to adopt mobile health (mHealth).

Justifications for the hypothesis

- It was found that there is a relationship between locus of control (LOC) and technology adoption in developing agriculture [39], online games [40], and online learning [41,42].
- Individuals with oropharyngeal head and neck cancer with a high propensity for an internal HLOC orientation showed their support toward telepractice models of care telerehabilitation [22].
- A cross-sectional study revealed that the amount of control college students believed they had over their health predicted willingness to use health apps and online health trackers [23].

Hypothesis 2: Performance expectancy has a positive relationship with the intention to adopt mHealth.

Hypothesis 3: Effort expectancy has a positive relationship with the intention to adopt mHealth.

Hypothesis 4: Social influence has a positive relationship with the intention to adopt mHealth.

Justifications for the hypotheses

- In a study to examine the intention of elderly people aged 57 to 77 years to use eHealth apps, expected performance and effort were highly related to the intention to use eHealth while social influence was not [52].
- A study revealed that Unified Theory of Acceptance and Use of Technology factors, namely effort expectancy, expectancy performance, and social influence, were significant determinants of the intention for mHealth adoption behavior in citizens like diabetic patients who were taking traditional health care services repeatedly from any medical hospital for diabetes, blood pressure, and cholesterol monitoring in the United States, Canada, and Bangladesh [12].
- A study on the intention to use a mobile electronic health record (MEHR) system in a sample of health care professionals (doctors and nurses) showed that the intention to use the MEHR system was indirectly influenced by effort expectancy and performance expectancy through attitudes toward the MEHR system, while social influence was found to be directly associated with the intention to utilize the MEHR system [14].
- Venugopal et al [56] examined clinical staff's perspectives on the usage of telemedicine and electronic health records in hospitals and found that performance expectancy, effort expectancy, and social influence have a significant impact on intention, which in turn impacts the usage behavior of electronic health records and telemedicine.

Hypothesis 5: Internal HLOC has a positive relationship with performance expectancy.

Justifications for the hypothesis

- Individuals with high internal LOC are more likely to seek new information when the information is personally relevant, and obtain valuable knowledge and skills to enhance their performance [65,71].
- Internals commonly display a favorable attitude toward technology [66].

Hypothesis 6: Internal HLOC has a positive relationship with effort expectancy.

Justifications for the hypothesis

- Individuals with internal LOC attributed perceived difficulty toward technology to their own abilities and attempted to use technology more effectively [46].
- Internals have more experience in using technologies and find technology, such as e-learning, easy to use [41,42,72,73].

Hypothesis 7: Internal HLOC has a negative relationship with social influence.

Justifications for the hypothesis

- Individuals with higher internal LOC are resistant to social influence as they feel they have more self-control and self-reinforcement over their life and things that happened to them [71].
- They are not easily persuaded and do not conform to others' influence [68].

Hypothesis 8: Performance expectancy mediates the positive relationship between internal HLOC and the intention to adopt mHealth.

Hypothesis 9: Effort expectancy mediates the positive relationship between internal HLOC and the intention to adopt mHealth.

Hypothesis 10: Social influence mediates the positive relationship between internal HLOC and the intention to adopt mHealth.

Justifications for the hypotheses

- Performance expectancy and effort expectancy were found to be positive and significant mediators among website design, customer service, and customer's intention to adopt internet banking [74].
- Performance expectancy and effort expectancy were found to be linked to user adoption in context awareness and Alipay, a third-party mobile and online payment platform [75].

- Fong et al [55] explored the mediating role of effort expectancy and perceived risk in the relationship between internal LOC and the intention to reuse mobile apps for making hotel reservations.

Methods

Participant Profiles

Among 374 participants in this study, there were 145 males and 229 females. The participant age ranged from 18 to 68 years (mean 28.01 years, SD 11.10). Almost 45% (166/374, 44.4%) of the participants were Chinese, and 40.7% (152/374) were Malays. In terms of health status, 47.4% (177/374) of the participants perceived their health status as good, 27.5% (103/374) perceived it as fair, and 18.2% (68/374) perceived it as very good. Participants were also asked whether they had an ongoing or a serious health problem that included heart disease, arthritis, or a mental health condition requiring frequent medical care, such as regular visits to doctors or daily medications. The majority (315/374, 84.3%) of the participants indicated that they did not have any ongoing or serious health problem, while 12.0% (45/374) reported that they did not know of any serious health problems. A small percentage (14/374, 3.7%) of participants had an ongoing disease or serious health problem. Lastly, regarding mobile phone usage experience, 40.4% (151/374) of the participants had 8 to 10 years of experience, 39.0% (146/374) had 4 to 7 years of experience, 15.0% (56/374) had more than 10 years of experience, and 5.6% (21/374) had 1 to 3 years of experience. Table 1 shows the demographic profile of the respondents.

Table 1. Demographic profile of the respondents.

Background variable	Value (N=374), n (%)
Gender	
Male	145 (38.8)
Female	229 (61.2)
Ethnicity	
Malay	152 (40.7)
Chinese	166 (44.4)
Indian	47 (12.5)

Mobile phone usage experience	
1-3 years	21 (5.6)
4-7 years	146 (39.0)
8-10 years	151 (40.4)
>10 years	56 (15.0)

Research Design and Procedure

This study used a questionnaire-based cross-sectional design to collect the required data. A total of 400 questionnaires were distributed to Malaysian adults residing in Kuala Lumpur, Malaysia. The subjects for this study were drawn from mHealth users. A screening self-report question was included in the survey to identify mHealth users. Participants were asked if they have ever used their smartphones for any health-related purposes, such as seeking health- and disease-related information online, texting messages for health-related purposes (such as reminders/alerts for appointments, taking medications,

and consultations), and downloading and using any health-related apps (such as fitness apps, and apps for health tracking and medication tracking). Participants who reported having used their smartphones at least for one of these purposes were included in the analysis.

The questionnaire comprised an informed consent form, demographic profiles, and questions related to internal HLOC and the modified UTAUT constructs for mHealth use. Data were collected using convenience and snowball sampling methods. A research assistant was recruited for data collection. Participation was voluntary where confidentiality was ensured, and respondent consent was obtained before commencing the survey. Participants were given an absolute right of withdrawal at any time and without giving any reason. The protocol of the study (including the research procedure, the rights and safety of the participants, and the method of data collection) was approved by the review board of Xiamen University Malaysia to ensure compliance with research ethics. The approval number is REC-1911.01.

The following 2 rules of thumb are used for choosing the sample size when partial least square is to be used for model analysis: (1) "10 times the scale with the largest number of formative (ie, causal) indicators (note that scales for constructs designated with reflective indicators can be ignored)," and (2) "10 times the largest number of structural paths directed at a particular construct in the structural model." [76]. This study did not have any formative indicator. Therefore, the first rule of thumb was not applicable for this study. According to the former rule of thumb, the minimum sample size for this study is 70, as the largest number of structural paths in the research model is 7, which is related to the behavioral intent to adopt mHealth. Further, recent developments suggest that researchers should determine sample size through power analysis [77,78]. Power analysis determines the minimum sample size by taking into account the part of a model with the largest number of predictors [79]. Therefore, we used G*Power to determine the required sample size. Based on G*Power, the adequacy of sample size was computed using the statistical tests recommended. For a mediation model, the input information was as follows: test family: "F tests," statistical test: "linear multiple regression: fixed model, R2 deviation from zero," type of power analysis: "a priori: compute required sample size–given α, power, and effect size," with effect size=0.15, α=.05, power=0.90, and number of predictors=4. G*Power showed that the minimum sample size required for the mediation model is 108, with an actual power of 0.90. Therefore, the number of responses collected for this study was sufficient for analysis.

Measurements

Internal HLOC

In measuring internal HLOC, 6 items were adopted from the Multidimensional Health Locus of Control scale developed by Wallston et al [18]. Respondents were asked to rate items on a 5-point Likert scale from 1 (strongly disagree) to 5 (strongly agree).

Performance Expectancy, Effort Expectancy, Social Influence, and Intention to Use mHealth

Items to measure performance expectancy, effort expectancy, social influence, and intention to use mHealth were directly extracted from the original UTAUT model [24,47] and modified to make them consistent with mHealth use behavior. Participants were requested to rate the items on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree).

Questions related to internal HLOC and the modified UTAUT constructs for mHealth use are included in Multimedia Appendix 1.

Results

Data Analysis

In this study, partial least squares structural equation modeling (PLS-SEM) was used to examine the proposed conceptual framework using SmartPLS software. By using PLS-SEM, the direct and indirect effects of multiple independent and dependent variables can be tested simultaneously, which provides greater statistical power. PLS-SEM is also able to accommodate a study with a small sample size despite the complexity of the models [79]. After excluding incomplete questionnaires, 374 responses were included in the analysis. The results consisted of a 2-stage analytical procedure, which involved a measurement model and structural model, to validate the model and test the hypotheses developed for the purpose of this study.

Measurement Model

The first step in the analysis concerning the measurement model was to examine the factor loading. In this study, the factor loadings of the items varied from 0.632 to 0.945 (Table 2). All items were retained as the factor loadings were above the recommended value of 0.6 [80]. Second, composite reliability, which measures the internal consistency of the constructs, was used to measure the reliability of the variables. According to Hair et al [79], the minimum value of composite reliability is 0.7. Table 2 shows that all the constructs yielded good composite reliability ranging from 0.873 to 0.954. Third, convergent validity was assessed using average variance extracted (AVE). Hair et al [79] mentioned that the minimum acceptable value for AVE is 0.5 or higher, which indicated that 50% or more of the items were explained by the construct. In this study, all the constructs exceeded the acceptable value, which indicated that all the constructs obtained good convergent validity (Table 2).

Table 2. Assessment results of the measurement model.

Constructs and items	Loading	CR[a]	AVE[b]
Internal health locus of control		0.873	0.535

[a]CR: composite reliability.

[b]AVE: average variance extracted.

Lastly, discriminant validity was determined using the heterotrait-monotrait (HTMT) ratio of correlation as recommended by Henseler et al [81] because it is more suitable for discriminant validity assessment compared with the Fornell-Larcker criterion and cross-loading assessment. In order to achieve discriminant validity, Henseler et al suggested that a threshold value of 0.90 or below is required [81]. As shown in Table 3, all the study variables met the criterion to establish discriminant validity where the HTMT values were below 0.90.

Table 3. Discriminant validity using the heterotrait-monotrait (HTMT) ratio.

Construct	Internal health locus of control	Performance expectancy	Effort expectancy	Social influence	Behavioral intention
Internal health locus of control	N/A[a]	0.390	0.373	0.212	0.213
Performance expectancy	0.390	N/A	0.886	0.687	0.745

[a]N/A: not applicable.

Structural Model

Multicollinearity is assessed using the variance inflation factor (VIF). In this study, all VIF values were below 5, which indicated no violation of the multicollinearity assumption. The structural model was assessed using R^2, beta, and *t* value, which were obtained via a 5000 resampling of the bootstrapping procedure. The direct, total indirect, and specific indirect effects are shown in Table 4.

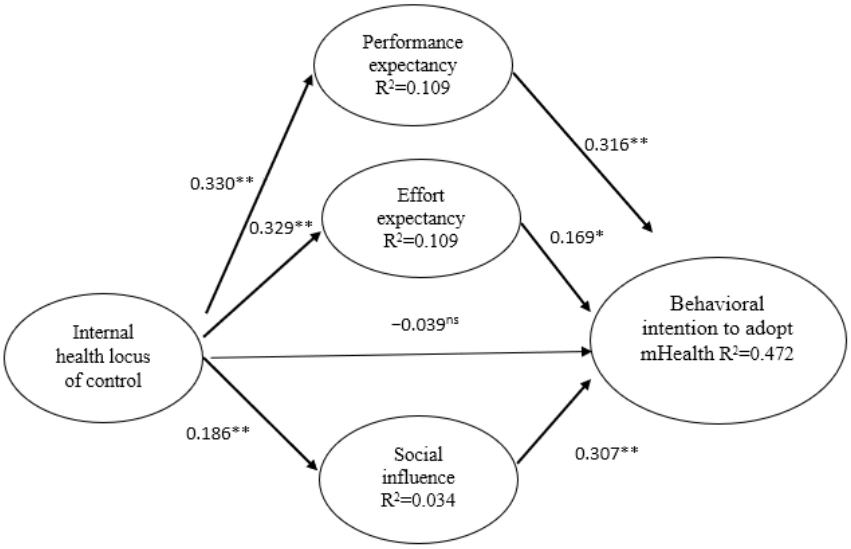
Table 4. Direct, total indirect, and specific indirect effects.

Path	R^2	Beta	*t* value	*P* value
Direct effects				
Behavioral intention	0.472			
Internal health locus of control → behavioral intention		−0.039	0.999	.32
Performance expectancy → behavioral intention		0.316	4.859	<.001
Effort expectancy → behavioral intention		0.169	2.672	.008
Social influence → behavioral intention		0.307	5.715	<.001
Performance expectancy	0.109			
Internal health locus of control → performance expectancy		0.330	6.522	<.001
Effort expectancy	0.109			
Internal health locus of control → effort expectancy		0.329	7.020	<.001
Social influence	0.034			
Internal health locus of control → social influence		0.186	3.621	<.001
Total indirect effects				
Behavior	0.472			
Internal health locus of control → behavior through performance expectancy, effort expectancy, and social influence		0.217	5.554	<.001
Specific indirect effects				
Internal health locus of control → performance expectancy → behavioral intention		0.104	3.813	<.001
Internal health locus of control → effort expectancy → behavioral intention		0.056	2.389	.02
Internal health locus of control → social influence → behavioral intention		0.057	3.123	.002

Based on the structural model, hypothesis 1 was not supported because internal HLOC (β=−0.039, *P*=.32) was not significantly related to the intention to use mHealth. Performance expectancy (β=0.316, *P*<.001), effort expectancy (β=0.169, *P*=.008), and social influence (β=0.307, *P*<.001) had a significant and positive relationship with the intention to use mHealth, which supported hypotheses 2, 3, and 4 (Figure 1). Hypotheses 5, 6, and 7 were also supported where results showed that internal HLOC had a significant positive relationship with performance expectancy (β=0.330, *P*<.001), effort expectancy (β=0.329, *P*<.001), and social influence (β=0.186, *P*<.001).

Overall, the results supported the model of this study where the total indirect effect was significant (β=0.217, *P*<.001). All the study variables explained 47.2% of the variance in the intention to use mHealth. Three specific indirect paths were generated to test hypotheses 8 to 10. Hypothesis 8 was developed to test the mediating effect of performance expectancy on the relationship between internal HLOC and the intention to adopt mHealth. The results showed that the direct effect of internal HLOC on performance expectancy and the direct effect of performance expectancy on the intention to use mHealth were significant, while the direct effect of internal HLOC on the intention to use mHealth was not significant. This indicated that performance expectancy fully mediated the relationship between internal HLOC and the intention to use mHealth with a significant indirect effect (β=0.104, *P*<.001), supporting hypothesis 8 (Figure 1).

Figure 1. Path coefficients of the structural research model. mHealth: mobile health; ns: not significant. *P<.01, **P<.001.



For hypothesis 9, effort expectancy as the mediator for the relationship between internal HLOC and the intention to adopt mHealth was tested. The direct effect from internal HLOC to effort expectancy and the direct effect from effort expectancy to the intention to use mHealth were significant, but the direct effect from internal HLOC to the intention of adopting mHealth was not significant. This indicated that effort expectancy fully mediated the relationship between internal HLOC and the intention to use mHealth (β=0.056, P=.02). Thus, hypothesis 9 was supported (Figure 1).

In Figure 1, the results showed support for hypothesis 10, where social influence significantly mediated the relationship between internal HLOC and the intention to use mHealth. The significant indirect effect (β=0.057, P=.002) revealed that internal HLOC impacted social influence, and social influence in turn affected the intention to use mHealth. Based on the findings of the mediation tests, it can be seen that the mediating effect of performance expectancy on the relationship between internal HLOC and the intention to use mHealth was the strongest, followed by social influence and effort expectancy.

Discussion

Previous studies have demonstrated the role of LOC in the tendency to use technology [39-42,55]. Since research on mHealth behavior is limited and little is known about how LOC could influence the intention to adopt mHealth technology, this study aimed to find out the factors that could explain users' behavioral intent in mHealth technology. Drawing upon 3 constructs of the UTAUT, this study attempted to provide insights on how internal HLOC delineates the intention to adopt mHealth.

In this study, internal HLOC was not found to be significantly related to the intention to use mHealth (hypothesis 1). This result is inconsistent with previous research providing evidence that individuals with internal LOC beliefs tend to utilize health apps [23]. Some studies showed a negligible relationship between HLOC and health behaviors [22,82,83], thus leading to inconsistent findings about the significance of HLOC in driving health behaviors. Calnan [84] suggested that health behaviors may not be associated with beliefs regarding control of health but rather with concerns over risky health behaviors. The absence of a relationship between internal HLOC and behavioral intent to adopt mHealth could also be attributed to potential confounding factors, such as health literacy, that could influence HLOC, which in turn affects the intention to use mHealth. Health literacy was found to be an effective factor in predicting internal orientations [85]. Individuals with higher levels of health literacy are more likely to report higher scores of internal HLOC than those with lower levels of health literacy because their capacities to obtain, process, and understand health information and services in order to make appropriate health decisions are positively associated with their belief that they have control over their health and health behaviors [86]. Another possible confounding factor that may affect internal HLOC is the participants' economic status. Research has found that individuals with lower socioeconomic status engaged in fewer health-promoting behaviors and had different expectations about their ability to influence their own health [87]. People living in economically deprived circumstances may, as a result of their experiences, also learn that they have less control over their own lives and health status [88].

The UTAUT constructs, namely performance expectancy, effort expectancy, and social influence, were found to be significant predictors, with a positive relationship for the intention to use mHealth (hypotheses 2, 3, and 4), lending support to past studies that consistently showed the association between UTAUT determinants and eHealth and mHealth adoption [12,52,56,57]. All these findings unfailingly corroborate the UTAUT model, where if users perceive mHealth as useful, easy to use, and accepted as well as suggested by important others, they will be more likely to adopt the technology. Among these 3 constructs, performance expectancy and effort expectancy have equal contributory impact on mHealth adoption, followed by social influence. These results are consistent with the findings in the study by Tavares and Oliveira [57]. They found that performance expectancy and effort expectancy predict the same variance in the use of online services such as electronic health

record portals. It suggests that usefulness and ease of use are equally central for users when evaluating mHealth services [57]. Besides, the power of important others should not be neglected in technology adoption behavior. Research has found that social influence is an essential source of motivation to utilize hospital electronic information management systems [56]. In contrast, normative pressure was found to be an insignificant force to patient portal use behavior among the elderly [89]. These contradicting results can lead us to an inference that social influence is more likely to be a driving force for technology adoption behavior among young individuals rather than older people because "older people do not follow the bandwagon effect" [90].

To further explore whether internal HLOC can be suitably applied in the UTAUT model, the relationships between internal HLOC and 3 constructs of the UTAUT (ie, performance expectancy, effort expectancy, and social influence) in the mHealth context were postulated in this study (hypotheses 5, 6, and 7). The results showed that internal HLOC had a significant positive effect on performance expectancy, effort expectancy, and social influence in mHealth use, which suggests that the more internal the users are, the higher the perceived usefulness and ease of use they will have and the more likely they will conform to important others. These results are in line with the findings of previous studies that showed the significant influence of LOC on perceived usefulness and ease of use for mobile learning adoption [40,41]. In addition, Fong et al [55] found that internals are characterized by high self-efficacy, a trait that helps individuals to overcome difficulties. Hence, they perceive higher ease of use for new technology products compared with externals [72]. As opposed to the negative association hypothesized between internal HLOC and social influence, this study found a positive relationship between these 2 constructs. This could be due to the individual differences in tendencies to conform for informational reasons but not for normative reasons [73].

In testing the mediating role of performance expectancy, effort expectancy, and social influence, this study found that these 3 constructs fully mediated the relationship between internal HLOC and the intention to use mHealth, supporting hypotheses 8, 9, and 10. Internal HLOC was positively related to the intention to adopt mHealth through performance expectancy. Effort expectancy had a mediating effect on the relationship between internal HLOC and the intention to use mHealth (hypothesis 9), similar to the results found in previous research [55]. Individuals with internal HLOC are more likely to overcome difficulties in using new technology products. They prefer to adopt mHealth because it is easy to use. Moreover, social influence was found to significantly mediate the relationship between internal HLOC and the intention to use mHealth (hypothesis 10). Internals use mHealth partly because of the perception that important others may suggest to employ mHealth. Individuals' beliefs in their own efforts and abilities to control their health drive perceptions toward mHealth, which in turn contribute to mHealth adoption. UTAUT dimensions are central to our understanding of the association between internal HLOC and the intention to adopt mHealth. The mediation results of this study are consistent with the findings in the study by Ahadzadeh et al [20]. The authors found the centrality of perceived usefulness and perceived ease of use in the relationship between health factors and internet use for health-related purposes. A strong mediating effect of health app use efficacy was also identified in the effect of health information orientation and eHealth literacy on health app use [91].

The findings of this study have several implications. Theoretically, this study has contributed to mHealth literature by investigating the direct and indirect relationships between internal HLOC and the intention to use mHealth. The indirect relationship provided a more multifaceted understanding of mHealth adoption behavior, where both health and technology come into play in the adoption decision process. Moreover, the results attested the robustness of the UTAUT in mHealth adoption. To the best of our knowledge, this study is the first attempt to examine the indirect effect of internal HLOC on the behavioral intent of mHealth. The results of the effect of UTAUT dimensions on the intention to adopt mHealth have significant implications for health providers seeking methods to enhance mHealth engagement behavior. They can leverage cognitive and normative factors related to technology (ie, performance expectancy, effort expectancy, and social influence) to increase individuals' preferences to use mHealth for health purposes.

The limitations of this study can be attributed to the urban sample concentrated in the most developed part of Malaysia. A more representative sample should be considered in future studies. Nonprobability sampling methods (ie, convenience and snowball) employed for the sample selection and the unbalanced gender makeup of the sample can jeopardize the generalizability of the results. The cross-sectional design used in this research does not provide definite information about cause and effect relationships. Moreover, social desirability bias can be a problem with self-report measurements used in this study. The framework proposed in this study predicted 42.7% of the variance in mHealth, while a more extended model encompassing more cognitive factors can augment the prediction power of the model. Given the absence of a significant association between internal HLOC and the intent to use mHealth in this research, replication studies are suggested, which can include a broader framework of multiple health-related factors (such as perceived health susceptibility, perceived health severity, perceived health status, and health consciousness) and personality factors in order to advance the frontier of knowledge regarding HLOC and technology adoption, since technology will become even more important in the future with "Industrial Revolution 4.0." Moreover, incorporating perceived health risk factors along with HLOC will enable researchers to determine whether mHealth is a proactive/preventive health behavior, a reactive behavior, or both.

Abstract

Background: Goal-oriented care is being adopted to deliver person-centered primary care to older adults with multimorbidity and complex care needs. Although this model holds promise, its implementation remains a challenge. Digital health solutions may enable processes to improve adoption; however, they require evaluation to determine feasibility and impact.

Objective: This study aims to evaluate the implementation and effectiveness of the electronic Patient-Reported Outcome (ePRO) mobile app and portal system, designed to enable goal-oriented care delivery in interprofessional primary care practices. The research questions driving this study are as follows: Does ePRO improve quality of life and self-management in older adults with complex needs? What mechanisms are likely driving observed outcomes?

Methods: A multimethod, pragmatic randomized controlled trial using a stepped-wedge design and ethnographic case studies was conducted over a 15-month period in 6 comprehensive primary care practices across Ontario with a target enrollment of 176 patients. The 6 practices were randomized into either early (3-month control period; 12-month intervention) or late (6-month control period; 9-month intervention) groups. The primary outcome measure of interest was the Assessment of Quality of Life-4D (AQoL-4D). Data were collected at baseline and at 3 monthly intervals for the duration of the trial. Ethnographic data included observations and interviews with patients and providers at the midpoint and end of the intervention. Outcome data were analyzed using linear models conducted at the individual level, accounting for cluster effects at the practice level, and ethnographic data were analyzed using qualitative description and framework analysis methods.

Results: Recruitment challenges resulted in fewer sites and participants than expected; of the 176 target, only 142 (80.6%) patients were identified as eligible to participate because of lower-than-expected provider participation and fewer-than-expected

patients willing to participate or perceived as ready to engage in goal-setting. Of the 142 patients approached, 45 (32%) participated. Patients set a variety of goals related to self-management, mental health, social health, and overall well-being. Owing to underpowering, the impact of ePRO on quality of life could not be definitively assessed; however, the intervention group, ePRO plus usual care (mean 15.28, SD 18.60) demonstrated a nonsignificant decrease in quality of life (t_{24}=−1.20; *P*=.24) when compared with usual care only (mean 21.76, SD 2.17). The ethnographic data reveal a complex implementation process in which the meaningfulness (or coherence) of the technology to individuals' lives and work acted as a key driver of adoption and tool appraisal.

Conclusions: This trial experienced many unexpected and significant implementation challenges related to recruitment and engagement. Future studies could be improved through better alignment of the research methods and intervention to the complex and diverse clinical settings, dynamic goal-oriented care process, and readiness of provider and patient participants.

Introduction

Background

The rising population of older adults with multimorbidity and complex care needs requires that health systems adjust to meet this new demand [1,2]. Complex care needs of patients go beyond multimorbidity alone, as these individuals will experience biopsychosocial challenges and barriers that make it more difficult for them to manage their multiple chronic physical and mental illnesses [3,4]. Increasingly, digital health solutions are being adopted to support this patient population through tools that enable medication management [5], information sharing [6], care planning [7], chronic disease management and monitoring [8,9], and virtual care tools, particularly since the onset of the COVID-19 pandemic [10]. Of particular use to older adults with complex care needs are solutions that enable person-centered and holistic care delivery to better address their multiple health and social care needs [3,11-17]. Although a person-centered approach has been identified as a priority [16], organizations and providers continue to struggle with how to put the vision of person-centered care into practice [18].

Person-centered care may be operationalized by adopting a goal-oriented care (GOC) approach that involves eliciting patient-identified goals to drive care planning and decision-making [13,14,19,20]. Effectively, this model of care shifts from asking a patient "What is the matter with you?" to "What matters to you?" [21] From a patient perspective, GOC represents a more meaningful and holistic approach to care and decision-making [22]. Emerging studies of GOC report reduced treatment burden for patients with multiple chronic conditions [23] and reductions in acute inpatient days and mortality [24]. The pragmatic trial of the Health TAPESTRY program, a digitally enabled, community-based GOC program, evaluated the program's impact on goal attainment, self-efficacy, quality of life, optimal aging, social support, empowerment, physical activity, falls, and access. The Health TAPESTRY trial demonstrated a shift from reactive to proactive care [25]; however, similar to many other studies of person-centered care [26,27], Health TAPESTRY did not demonstrate an impact on patient outcomes.

Among the challenges in evaluating an approach such as GOC, in particular a digitally enabled GOC model, is that it is a complex intervention that is delivered to a complex patient population within a complex system. Conventional methods, such as randomized controlled trials, that apply rigid methods and rely on assumptions of linear cause-effect perspectives [28] may result in *controlling* for the variables that we need to capture [29]. Greenhalgh and Papoutsi [28] instead suggest methods that adopt a systems mindset that allows for adaptability, iteration, and design-thinking better suited to capturing "changing interrelationships between parts of the system." The evaluation presented in this paper adopts this systems mindset to evaluate the electronic Patient-Reported Outcome (ePRO) tool, a novel mobile device and a linked portal system that enables GOC delivery to older adults with complex care needs receiving care in interdisciplinary primary care practices. This evaluation is the latest iteration of a multiphase developmental evaluation of ePRO that took place in Ontario, Canada, from April 2018 to June 2019.

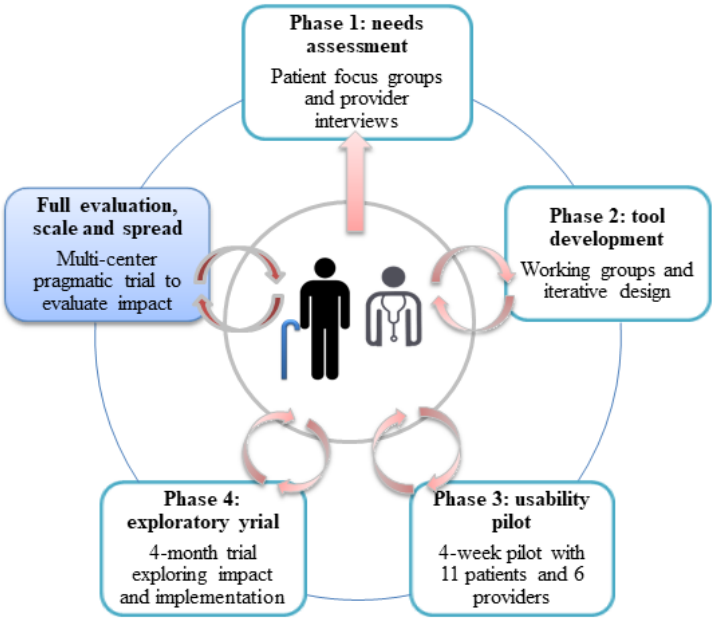
Objective and Research Questions

This developmental evaluation incorporates a pragmatic, stepped-wedge, cluster trial with embedded ethnographic case studies, building on previous stages of design, development, and testing [30-33] (see Figure 1 for a visual representation of how this work builds on previous stages). This study expands the findings from our exploratory trial [33] as a means to engage in what Tsoukas terms "conjunctive theorizing to generate rich pictures of complex phenomena by drawing together different kinds of data from multiple sources" [34]. This work was guided by the following research questions:

1. Does ePRO improve quality of life and self-management in older adults with complex needs?
2. What mechanisms are likely driving observed outcomes?

Regarding the first research question, it is hypothesized that the ePRO tool will have a positive impact on quality of life and patients' ability to self-manage.

Figure 1. electronic Patient-Reported Outcome (ePRO) co-design steps.

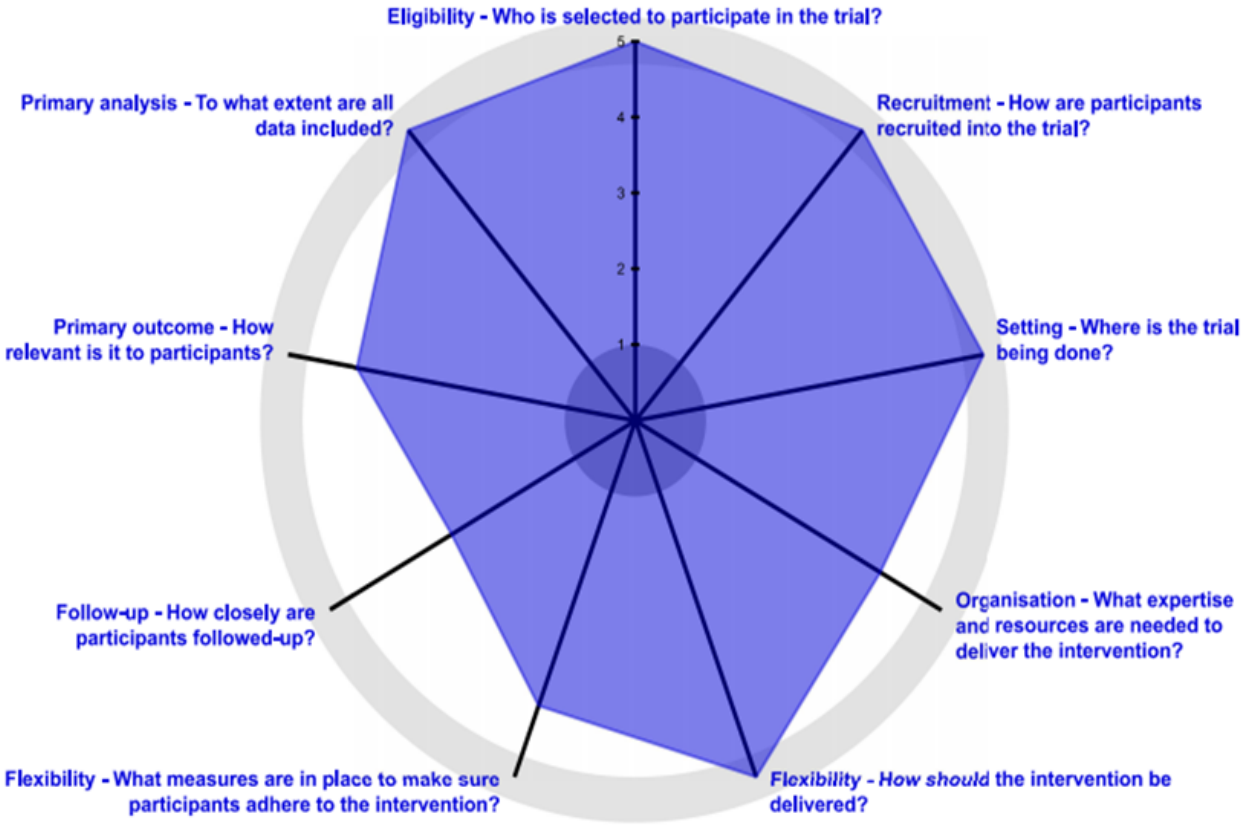


Methods

Design

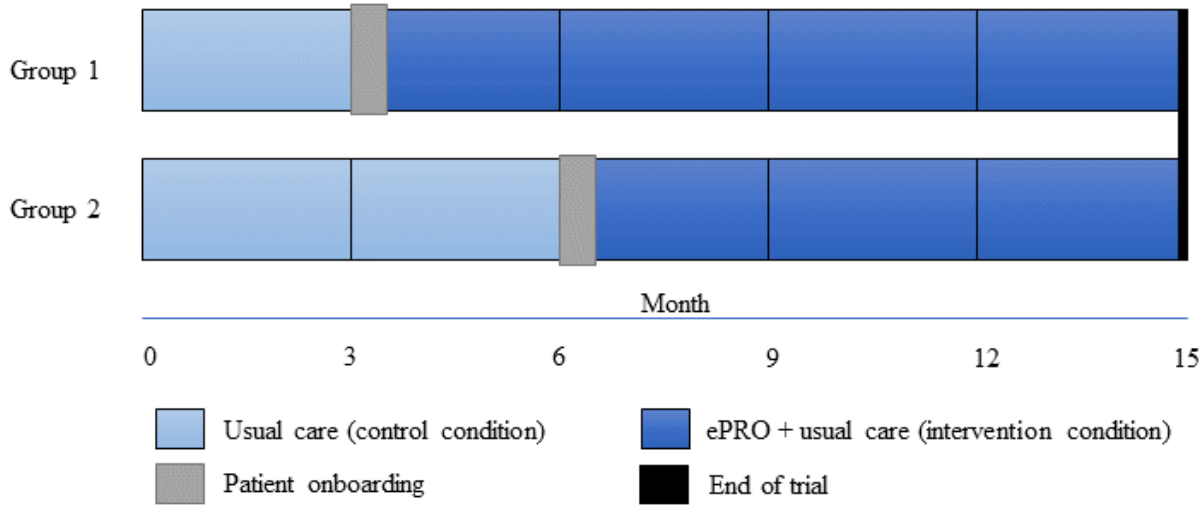
Aligned with Medical Research Council guidelines for evaluating complex interventions [35], a developmental evaluation approach was applied to collect outcome, process, and context measures to support decision-making and technology modifications [36]. A pragmatic, stepped-wedge, cluster randomized trial design was used to assess the effectiveness of the ePRO tool [37]. The Pragmatic Explanatory Continuum Indicator Summary (PRECIS-2) wheel in Figure 2 (see Multimedia Appendix 1 for description of the wheel domains as related to this trial) describes the degree to which the trial represents a pragmatic design. This design was the most feasible and appropriate approach given the nature of the intervention, time, and resources available [38] and the desire to complete in a real-world setting [39]. An embedded ethnographic case study was included, aligned with the methods outlined by Greenhalgh and Swinglehurt [40] for evaluating complex technological innovations. The case studies offer rich contextual and process information that accounts for complex interrelationships between variables that are missed by looking at outcome data alone.

Figure 2. PRECIS-2 (Pragmatic Explanatory Continuum Indicator Summary) Wheel for electronic Patient-Reported Outcome (ePRO) trial.



The trial was conducted in 6 comprehensive primary care practices called Family Health Teams (FHTs) across Ontario, Canada, over a 15-month period. Following the stepped-wedge design, all FHT sites started in the control period where all recruited patients received usual care (no change to their care delivery from the primary care team). A random number generator assigned sites to either the early intervention (n=3 sites) or late intervention (n=3 sites) groups. The early intervention group (group 1) was assigned to the intervention for 12 months after the initial 3-month control period. The FHTs in group 2 were switched to the intervention group for 9 months after a 6-month control period. Figure 3 shows a diagram of the stepped-wedge design.

Figure 3. Stepped-wedge design for electronic Patient-Reported Outcome (ePRO) evaluation.



Intervention: The ePRO Tool

The ePRO tool was developed via multiphase user-centered co-design methods and represents an important divergence from many available systems that are focused on a single disease or are built to enhance existing provider-led models of care. The tool is designed to encourage a shift in the care process toward a person-centered model by enabling the full GOC process, including goal elicitation, ongoing monitoring, and goal modification [41]. Consistent with co-design methods, the tool was iteratively developed with input from patients with complex care needs, caregivers, and a multidisciplinary primary care team [30,31]. The tool has undergone usability testing [32] and an exploratory trial [33]. Findings from these studies were used to update and adapt the tool to user needs and different primary care settings. At the time of the trial, the ePRO tool did not connect to other existing technology systems, such as electronic medical records (EMRs) or other available platforms; however, the system was built so interoperability would be possible (see Multimedia Appendix 2 for wireframes).

Population and Setting

A 2-stage sampling strategy was implemented, first recruiting FHTs, followed by complex patients within each FHT. FHTs in Ontario are similar to Patient-Centered Medical Homes in the United States in that they both seek to provide comprehensive primary care services through a physician-led multidisciplinary team [42]. Working in collaboration with the project's decision-making partner, the Association of Family Health Teams of Ontario (AFHTO; representing all 184 FHTs in Ontario), a multipronged FHT recruitment strategy was pursued, including (1) email invitations sent to AFHTO member sites, (2) a webinar session with AFHTO quality improvement specialists who could identify eligible sites, and (3) an information booth at the annual AFHTO conference (October 2016 in Toronto, Ontario) where study information was shared with delegates. From these avenues, 29 sites expressed interest to be assessed for eligibility, with 6 FHTs agreeing to participate (see the Figure 4 CONSORT flow diagram of site recruitment). As FHTs are geographically diverse, there is no chance of cross-contamination of providers across different sites. The characteristics of the participating sites, as compared with FHTs across Ontario, are summarized in Table 1, and the population densities of the regions are depicted in Figure 5. As can be seen in Figure 5, sites A and F were in rural settings, sites D and E were in urban settings, and sites B and C were medium urban as consistent with Statistics Canada definitions of rurality [43]. Approximately 36% (59/165) of FHTs are located in rural settings.

Providers eligible to participate in the study had to be provided care to patients rostered at the FHT. Providers can be employed full-time, part-time, or casual.

Figure 4. CONSORT (Consolidated Standard of Reporting Trials) flow diagram–Family Health Team (FHT) recruitment.

Patient Recruitment and Eligibility Criteria

Patient recruitment followed exploratory trial procedures, using practice EMRs to identify patients aged ≥60 years with ≥10 visits to the FHT within the previous 12 months. This number of visits has been identified as an indicator of complexity in previous studies [44] and guided the recruitment strategy for the exploratory trial [33]. Age 60 years was chosen as a cut-off over 65 years as the study's site leads and primary care knowledge user partners identified that many individuals, particularly those living in rural settings, experience complex care needs at an earlier age. EMR-generated patient lists were given to providers to assess whether these individuals met the additional eligibility criteria: (1) perceived willingness to engage in GOC conversations, (2) ability to use a smartphone or tablet in English or have a caregiver who could do this on their behalf,

(3) capable of providing consent to participate, (4) willing to complete surveys every 3 months thereafter until the trial concluded. Previous studies have identified that the provider knowledge of the patient is often necessary to identify complexity given the high degree of patient variability [38].

Posters describing the study were hung in waiting rooms at sites, and the study was presented at chronic disease management programs that targeted patients with chronic disease and complex care needs for patient self-identification. Some patients self-identified as eligible after presentations at the programs, but none came to the study via posters. Recruitment materials and processes were built on what was learned from the exploratory trial and were reviewed and modified by the project's patient partner. Recruitment occurred during a scheduled office visit or by phone by a research coordinator assigned to that site. Patient and provider consent was obtained before randomization.

The minimum sample size required for the recruitment of sites and patients was determined using closed-form analytic formulas with a power of 80% based on a minimal clinically important difference of our core measure of quality of life (the AQoL-4D) of 0.06 [45], an expected SD in assessment of quality of life (AQoL) of 0.22 [46], an expected intraclass correlation coefficient (ICC) of 0.01 (calculated based on total primary care use over a 1-year period among a 10% sample of the Ontario population, which served here as a proxy measure for patient outcomes), and an expected attrition rate of 10% (rated based on previous studies in similar population groups using similar technology [47]). A minimum sample size of 176 patients was calculated, with a target of recruiting 29 patients per site.

Technology Training

Providers and patients were trained on the tool before switching from the control to the intervention during an onboarding session. Training for providers was done at the clinic level, where groups of providers were presented the technology by a research team member who walked through the technology by setting up goals for a mock patient. Patients were trained one-on-one with a research team member on how to use the mobile device and platform just before their onboarding visit with the provider. Providers and patients were also provided with user manuals [48] and contact information for the research team for technology support.

Data Collection

Context, process, and outcome data were collected via patient-reported surveys, interviews, ethnographic observations, and chart audits. Survey and chart audit data were collected across all 6 sites, whereas qualitative data were collected at the 3 case sites (sites A, E, and F). In total, 4 of 6 agreed to participate as case sites, and 1 dropped out as a case site because of low patient recruitment.

Patient-Reported Surveys

The primary outcome for this study was health-related quality of life measured using the Assessment of Quality of Life–4 Dimensions (AQoL-4D) [49]. The AQoL-4D is a 12-item questionnaire that addresses the activities of daily living, mental health, relationships with others, and physical aspects of a patient's quality of life. AQoL-4D responses were aggregated to generate a raw, continuous score with higher scores indicating a greater quality of life. The secondary outcome, self-management, was measured using the 13-item Patient Activation Measure (PAM), which measures the extent to which a patient is activated in their own care [50]. PAM is considered a valid and reliable metric of patient self-management for older adults with multimorbidity [50-52]. PAM generates a score from 0 to 100, with higher scores indicating greater activation (patients are better able to manage their care) [53]. Outcome data were collected at baseline and every subsequent 3 months until the end of the trial. For 3 patients in group 2 who were enrolled in the study late, outcome data were collected between October 2018 and June 2019 (Multimedia Appendix 3).

Patient and provider demographic information were collected at baseline. A chart review was conducted posttrial to collect missing data in the patient demographic forms, particularly the number of types of chronic conditions and medications.

Interviews

Semistructured interviews were conducted with patients, providers, and managers at case sites at the midpoint (6 months for sites A and E and 4.5 months for site F) and end of the trial. Interviews were conducted by research team members trained in qualitative data collection, with initial interviews conducted in pairs to ensure consistency in the approach. The interview guide was developed to capture the experiences of patients, providers, and managers using the tool or engaged with the trial. Probes were used to delve into implementation factors found to be important to the intervention in the exploratory trial, for example, patient-provider relationships and team environment [33] (Multimedia Appendix 4). Interviews were conducted in person (with one follow-up midpoint interview conducted over the phone), lasted between 20 and 60 minutes, and were audio-recorded and transcribed verbatim.

Ethnographic Observation

Ethnographic observations of case sites occurred at multiple points throughout the study, mainly when conducting other activities such as training, patient onboarding, and interviews. At these points, a member of the research team would observe the clinic visits between the patient and provider. Providers were also encouraged to inform the team when patients were coming in for visits so that additional *ad hoc* observations could be conducted; however, no such invitations occurred. Field memos were taken during and immediately after the observation periods. Field note guides helped research staff attend to contexts and processes anticipated to be relevant based on findings from the exploratory trial. Observations were conducted by research coordinators who had graduate training in qualitative health services methods or were provided training by the project lead in the approach. For coordinators, newer to the method observation debriefs and field memo reviews were conducted by the lead to provide ongoing training and skill building.

Use Logs

Use logs from the ePRO tool were used to track tool use and the types of goals set by the participants. Goals were categorized

into types using qualitative content analysis. Tool use was determined by the number of interactions defined as any log-in or data entered into the system; participants completing one interaction in a given month were considered *active* that month. The total number of active participants was calculated monthly to categorize participants into long-term (using the app for 3 or more months), short-term (using the app for <3 months), or nonuser (participants who did not use the app after initial onboarding) groups. The 3-month cut-off was consistent with previous mobile health (mHealth) clinical trials [54]. Use categories helped to interpret the qualitative and quantitative findings.

Data Analyses

Statistical Analysis

Descriptive statistics were calculated for the cohort stratified by groups of FHTs using counts and mean (SD) values for categorical and continuous variables, respectively. To estimate the degree to which the ePRO tool plus usual care affects health-related quality of life and self-management relative to usual care alone, linear models were fitted with exposure identified by a fixed-effect ordinal variable of calendar time (accounting for staggered implementation) and adjusting for clustering at the FHT site level [55]. The primary effect estimates are summarized as the mean differences for continuous outcomes. Each comparison was evaluated using a 2-sided test at a nominal significance level of α=.05. Statistical analyses of outcome data were performed using the intention-to-treat principle. All descriptive analyses and multilevel modeling were completed using Stata 15.1 statistical software (StataCorp LLC). Owing to the size of the data set, mixed effects models that included covariates such as age, sex, income level, rurality, chronic disease management, and number of chronic conditions could not be included in the modeling.

While missingness in cluster randomized trials in primary care can be handled via multiple imputation methods, using any such imputation to estimate the absence of data points in the cohort was deemed inappropriate owing to the high degree of missingness [56,57]. Aligned with the intention-to-treat approach, individuals were not excluded from the analysis based on their nonresponses to the survey; only variables were excluded, not individuals.

Interview and Observation Data

Interview and observational data were used to address the second research question and were analyzed using inductive qualitative descriptive [58] and narrative descriptive methods [59], with separate analyses conducted for patient and provider interviews. Manager interviews were coded with provider data as they were asked similar questions and addressed many of the same implementation constructs. Consistent with this method, codes that described the dominant themes within participant groups were identified. The coding was conducted by researcher pairs trained using qualitative methods to support the validation. Observational memos were coded with patient interviews and were also reviewed as part of the analytic process to provide context information where appropriate to guide interpretation. All team members involved in qualitative data collection and analysis were trained to attend to reflexivity in their approach and all kept fulsome analytic memos to track their own positionality with regard to the qualitative analysis.

To support directed analysis for the purposes of this evaluation, a deductive approach was used to map descriptive codes to Normalization Process Theory (NPT) [60] to understand implementation mechanisms. Exploratory trial findings suggest that NPT is a likely theory of change that underpins this intervention [33]. NPT suggests that new processes become embedded as part of actors' routines through the social production of work, enabled through 4 generative mechanisms: coherence, cognitive participation, collective action, and reflexive monitoring (Multimedia Appendix 5 offers descriptions of the concepts). These 4 NPT constructs were applied to descriptively coded patient, provider, and manager interviews and observational data, and cross-referenced with patient user groups (long, short, and non) and case site characteristics to generate insights regarding factors that drove implementation and outcomes. Data coded to relevant themes were extracted and organized using tables using a framework analysis approach [61] to identify patterns and trends. The research team reviewed the tables as part of the qualitative validation (supporting credibility and trustworthiness). NVivo 11 software (QSR International, version 11, 2015) was used to manage data in the initial coding phase, and Microsoft Excel and Word files were used to organize data for the framework analysis.

Integrating Quantitative and Qualitative Data

Integration of quantitative and qualitative data sets followed a *convergent design* that involves collecting all sources of data concurrently, separately analyzing data, and then comparing results through interpretation and discussion of findings [62,63].

Ethics

Research ethics approval was granted by the University of Toronto's Health Sciences Research Ethics Board (#33944) and the ethics committees of all participating practices.

Results

Participant Recruitment

Although the study design target was 176 patients, only 142 (80.6%) were identified as eligible and approached. Of the 142 approached, 46 (32.4%) consented to participate. One participant withdrew before any data collection, leaving 45 (31.6%) participants. This relatively low acceptance rate is an additional challenge. Patient-reported reasons for not participating included perceiving that they did not have complex or chronic conditions, lack of time, perceived conflicts with other life responsibilities (eg, planned vacations and travel), feeling as though they did not have a goal to work on, or were uninterested in this research. In total, 7% (3/45) patients dropped out of the study (1) because of a decline in health condition, making it difficult to participate, and (2) because of loss of interest in participating. Figure 6 shows the CONSORT flow diagram depicting patient recruitment. Figure 7 offers a summary of the number of patient and provider participants per site.

Figure 6. CONSORT (Consolidated Standard of Reporting Trials) flow diagram of patient recruitment arranged by group.

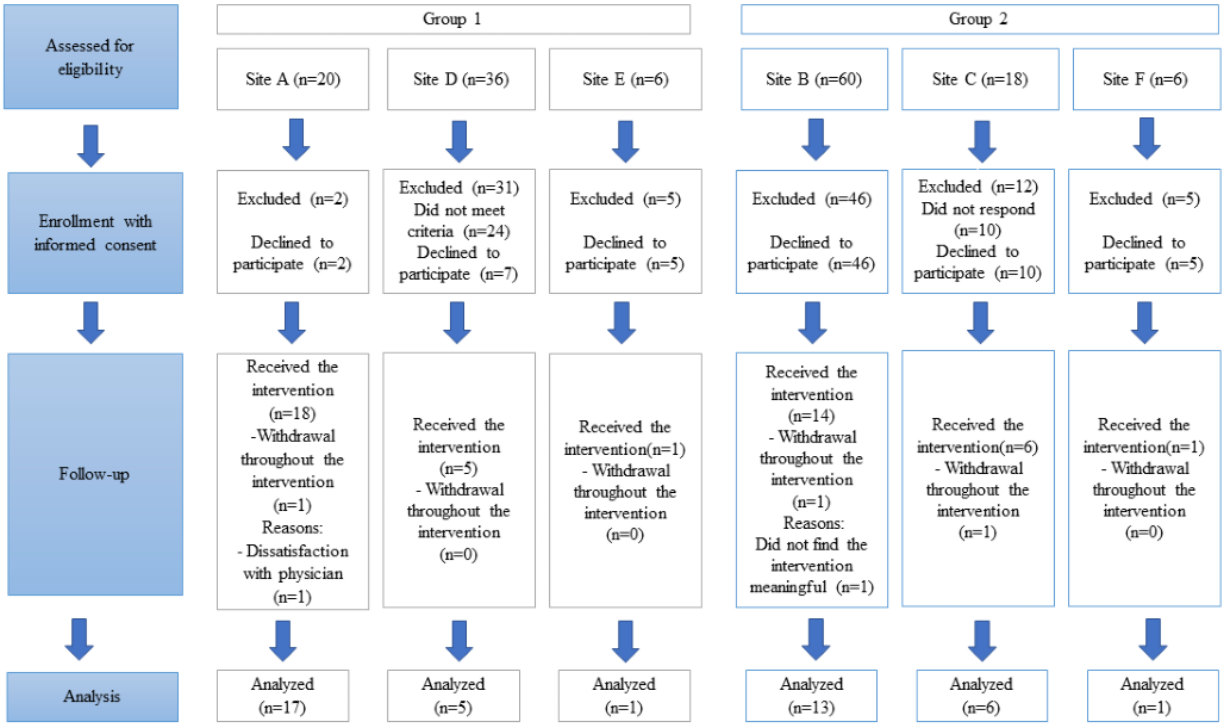

Figure 7. Number of providers and patients participating at each site.

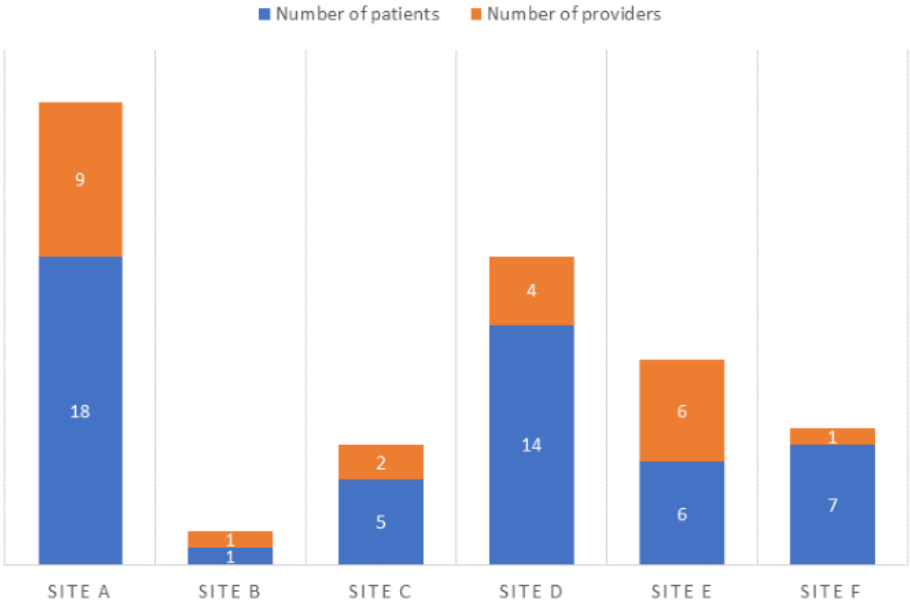

Participant Characteristics and Goals Set

Patient demographics are summarized in Table 2 and presented by randomized groups to allow for between-group comparisons. There was a statistically significant difference in the rurality and socioeconomic status between the groups.

Patients set a variety of goals related to self-management, mental health, social health, and overall well-being and self-care (Multimedia Appendix 6). Patient-provider pairs varied in terms of the degree of specificity of the goals they set, ranging from highly specific goals (eg, walking 20 minutes 3 times per week or losing 10 pounds) to more general goals (eg, reducing meat consumption or getting more sleep).

[a]Balance in the distribution of covariates between group 1 and 2 family health team sites was assessed using the Kruskal Wallis and Fisher exact test. Percentages may not be equal to 100% because of rounding.

[b]Family income before taxes in CAD $. US $1=CAD $1.3.

[c]University indicates individual has either completed a degree or is currently an undergraduate or graduate student.

[d]Missing data not applicable as there were not enough data per individual chronic illness to generate a meaningful *P* value.

[e]Mood disorders (anxiety or depression), multiple sclerosis, acute myocardial infarction, peripheral vascular disease, peripheral neuropathy, and osteoporosis.

Intervention Impact on Quality of Life and Self-management

Missing survey data were substantial, ranging between 14% and 91%, mainly because of nonresponse rather than attrition. There were 2 individuals who withdrew during the trial; therefore, the loss to follow-up was 4.5%.

Tables 3 and 4 present the descriptive statistics of the AQoL-4D and PAM scores from the sites at each data collection time point, where the *gray boxes* represent the control periods. Raw AQoL scores over time suggest that most patients (with the exception of those at site B) started and remained relatively healthy over the course of the study (with a notably wide SD).

After adjusting for the covariate of time in the model, patients with ePRO combined with usual care (mean 15.28, SD 18.60) demonstrated a nonsignificant decrease in quality of life (t_{24}=−1.20; *P*=.24) as compared with usual care only (mean 21.76, SD 2.17). With regard to patient engagement, ePRO combined with usual care (mean 66.5, SD 17.3) demonstrated a nonsignificant decrease in patient activation, t_{27}=−1.41; *P*=.17, as compared with usual care (mean 59.49, SD 9.60).

No patterns were evident when exploring descriptive trends in outcomes related to ePRO user intensity (eg, those who used the tool regularly versus those who rarely used or abandoned it all together). There were fewer completed follow-up surveys in the short term and nonuser groups.

Table 3. Mean (SD) of patient health-related quality of life at each discrete time point[a,b].

[b]Italicization represents the usual care (control) period of the intervention.

[c]Missing data.

Mechanisms Likely Driving Outcomes: Selected Findings From Ethnographic Case Studies

Use log data revealed significant attrition on the tool for both long-and short-term user groups with 46% (21/46) of patients using the tool as intended, 15% (7/46) discontinued use after 3 months, and 36% (17/46) abandoned the app after initial training. Data from the ethnographic case studies are analyzed to provide insights into factors that may drive use and potentially influence outcomes.

Table 5 presents a summary of the data sources, and Multimedia Appendix 5 offers a summary of NPT constructs and analysis.

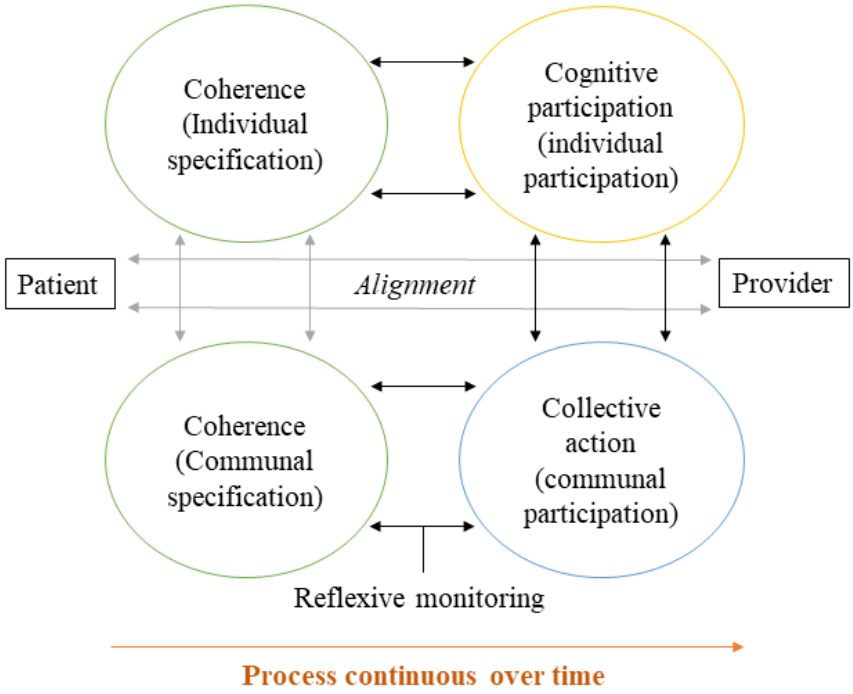
Table 5. Ethnographic data sources.

Case sites	Patient interviews (n=24)	Provider interviews (n=22)	Observations (n=21)
Site A	• 6 midterm • 5 end of project	• 6 midterm • 5 end of project	• 1 onboarding • 5 ad hoc
Site B	• 3 midterm • 3 end of project	• 4 midterm • 3 end of project	• 1 onboarding • 9 ad hoc
Site C	• 2 midterm • 2 end of project	• 2 midterm • 2 end of project	• 2 onboarding • 3 ad hoc

The Role of Coherence, Cognitive Participation, Collective Action, and Reflexive Monitoring

Consistent with findings from the exploratory trial, the meaningfulness of the ePRO tool to patients and providers had a significant influence on how and when it was used. Revealed in this analysis, is that the meaningfulness of the ePRO tool (its coherence to the participants) changed over time, and was reliant on (1) alignment to previously held notions of chronic disease management by providers and patients; (2) alignment to daily work and life activities (enabling cognitive participation); (3) strong relationships between patients and providers (enabling collective action); and (4) consistent positive assessments of the tool's utility (regular reflexive monitoring). An additional challenge is the interactional aspect of the ePRO tool, which means that both individual and collective coherence need to be aligned to the tool, as depicted in Figure 8.

Figure 8. Visual depiction of the normalization process of the electronic Patient-Reported Outcome tool.



The figure offers a simplified illustration of a complex ongoing process, highlighting 2 key drivers of adoption in this study. The first is the need for alignment between how individuals within a shared process understand that process (coherence) and then act on it (cognitive participation and collective action), depicted by gray arrows in the figure. Collective action (the actual use of the tool) proved to be highly influenced by this individual and shared coherence but differed depending on where users were in the process of GOC. For example, the data demonstrate that collective action occurred more toward the beginning of the intervention during goal-setting, when there was better alignment between individual and communal coherence of the intervention. This important time variable is indicated by the orange arrows. Second, the evaluation and assessment of the tool (reflexive monitoring) is continuous and interactive rather than a demonstration of normalization, as originally theorized, depicted in Figure 8 as black bidirectional arrows. As participants moved through participation and action in using ePRO, they consistently reflected on their individual and collective coherence, assessing whether it was worth continuing. Our data suggest that when alignment is high between individual- and group-level coherence, there is a greater likelihood of ongoing collective action; in this case, the use of the ePRO tool. This relationship is not currently depicted in the tool, as it will need to be tested in future studies.

Discussion

Participants and Study Implementation

Only 142 eligible patients of the total 176 patients were identified. The minimum recruitment numbers could not be reached owing to 3 challenges. First, some sites had few provider participants join the study. The usability study and exploratory trial suggested that providers who were just starting with the ePRO tool should manage a maximum of 5 patients at a time to reduce burden. The recruitment strategy required 6 to 8 providers to identify 5 to 10 patients each whom they could manage for the duration of the trial. As such, sites with fewer participants identified fewer patients to participate in the study (sites B and C in particular). Second, the requirement that patients *be ready* to engage in goal-setting proved to be a more significant barrier than at previous stages of ePRO testing. Practice EMRs identified many potential patient participants, but when reviewed by providers, few were identified as *ready.* Related to this point, the stepped-wedge design requires all participants to start an intervention at the same time. This rigid timing created an unanticipated third challenge.

The patient participants also likely represent a *healthier* group overall. Compared with similar patients in Canada, the United States, Australia, and the United Kingdom, patient participants had a lower number of reported chronic illnesses and a higher

level of reported education [64-67]. The AQoL scores of patients were aligned with previously published population norms [68]. Participants PAM standardized scores demonstrate slightly higher activation levels as compared with similar multimorbid populations, for instance, in a validation study of PAM that found a mean score of 56.6 (SD 12.9) [51].

Another important point to highlight is the relatively large number of registered dietitians and nurse practitioners who participated. One systematic review found several examples of dietitian-supported diabetes prevention programs [69], and nurse practitioners have been shown to successfully support digitally enabled chronic disease management programs in outpatient settings [70]. These examples, along with findings from this study, suggest an important role for allied health professionals in the implementation of digitally enabled health interventions for chronic disease populations in primary care settings.

Finally, the nature of the research process itself influenced trial implementation and outcome, as it conflicted with the natural process of delivering GOC. First, providers were exasperated by recruitment challenges, which resulted in delays in the trial start date. Second, while having providers manage few patients' reduced burden, it also meant providers had fewer opportunities to engage with the tool. As time went on, providers began to forget about the tool and why they valued it in the first place. Finally, the stepped-wedge required a time-bounded window for patient onboard. GOC, however, is a fluid approach in which goal-setting needs to occur at a point when patients are ready (as noted in the provider data around coherence). Providers expressed frustration that study parameters limited their ability to onboard patients later identified as individuals who could benefit from the tool.

Principal Findings

Recruitment challenges previously described resulted in the study being underpowered. As such, a conclusion regarding the effectiveness of the ePRO tool cannot be drawn. Analysis of the ethnographic data reveals interrelationships between use patterns, outcome trends, and patient and provider contexts to reveal the underlying mechanisms driving this complex intervention. Many patients and providers perceived the ePRO tool as valuable with the potential to improve engagement and healthy behaviors; however, over time, this excitement waned. Providers reverted to old ways of working, as did some patients. Waning engagement is not unique to digital health and has occurred in other behavior change interventions. Other patients for whom the tool was well-aligned to their values and aimed to manage their health demonstrated long-term adherence. For those *high users* whose coherence of the tool was tied to their interaction and relationship with their provider, they too began to fall away from the intervention as providers became less involved.

These findings uncover 2 tensions that have implications for digital health interventions for patients with complex care needs and multimorbidity in a primary care setting.

Challenge 1: Supporting Engagement in the Intervention Over Time

Engagement with an intervention is a well-documented challenge in primary care. Studies of medication adherence show similar ranges of adherence (40%-60%) [71,72] for chronic disease populations in primary care settings (ePRO adherence was 44%). *Nonadherence* reduces exposure and can lessen the effect of the intervention [73,74]. However, this lens suggests that it is the patient's fault for not doing as they are told, rather than placing a critical lens on the intervention itself. Perhaps a more useful lens is to consider engagement both "(1) the extent (eg, amount, frequency, duration, and depth) of use and (2) a subjective experience characterized by attention, interest, and affect" [75].

The ePRO tool experienced low retention rates typical of many mHealth interventions [76], which are connected to both use and subjective experience. The ethnographic findings suggest that subjective experience is linked to patient coherence and the meaningfulness of the tool. This finding is consistent with other studies that have shown that psychological factors such as motivation, expectations of the app, mental health, cognitive burden, and personal relevance will influence patient engagement [75]. Usability of the technology and tech savviness of users can often act as a barrier to ongoing use [77]. The usability analysis for this trial was too extensive to be included in this study. One key finding from the usability analysis presented in another paper, is that tech savviness and usability issues were moderated by the patient-provider relationship, in that patients with stronger regular connections to their providers were more likely to troubleshoot and work through technology challenges regardless of reported *savviness* [78].

Importantly, in this trial, app burnout occurred for patients *and* providers, for whom attrition was similarly linked to reduced use and subjective experience. Primary care providers have also demonstrated declining engagement with interventions over time, an issue identified in the literature as clinical inertia [79]. With continuous interventions, such as GOC, the ePRO study findings suggest that tapping into coherence consistently may improve engagement by both patients and providers.

Challenge 2: Meaningfulness for the Individual Versus the Group

Alignment of the ePRO tool to what was important and meaningful to patients and providers (coherence) was foundational. The study findings not only lend support for the importance of meaningfulness in technology [80] but also demonstrate how meaningfulness is constructed at both the individual and group levels, as suggested by NPT [60]. The disconnect between how providers and patients approached GOC is likely a contributor to the abandonment of the tool by those patients who sat somewhere between the strongly self-motivated super users and somewhat indifferent nonusers. For patients, GOC was a way to motivate and feel accountable for goals co-constructed with their providers. For many providers, however, GOC was an approach to support patient self-management, which did not require the same amount of ongoing connection and feedback expected from patients. This view is well-represented by the quote from the physical therapist

at site A, as shown in Multimedia Appendix 5, under the cognitive participation domain.

This approach to self-management suggests that a provider plays the role of a consultant, guiding patients through the management of their illnesses [81]. Although there is room for collaborative care and goal-setting in this model, the emphasis is on setting patients up to succeed and then sending them off. The qualitative data from this study suggest patients wanted more of a *coaching* approach with more touch points and interactions to maintain momentum, particularly for patients who started strong but then fizzled out. Theories of volition and self-regulation suggest that "feedback focused on the immediate benefits of behavior may be optimal during the early stages of behavior change" but can be reduced as individuals become more intrinsically motivated and confident [82]. What perhaps happened here is those patients who fizzled out were still at their *early stage* and, as such, required more engagement to keep moving forward. This finding suggests the need to better calibrate coherence when implementing digital health solutions with diverse user groups over time. Future studies should also probe how variation in the degree of goal specification found in this study may also influence patients at different stages of behavior change.

Strengths, Limitations, and Future Research

Similar to comparable studies of digital health interventions in primary care [83], both site and patient recruitment challenges were experienced. In addition, some values in the sample size calculation, such as attrition, were underestimated. Underpowering meant that all confounding variables collected via demographic baseline surveys and chart reviews could not be included in the modeling. In addition, some context data (notably participation in chronic disease management programs) may have changed over time and were only collected once at baseline. The smaller than anticipated sample size did allow for a more robust approach to ethnographic data collection, resulting in a rich, qualitative data set, which is a strength of the study. Future studies in primary care settings should consider both the setting context and the nature of the intervention being tested to better align trial methods to real-world implementation. More flexible adaptive trials or the application of an interrupted time series within the clusters may be more appropriate in these dynamic environments. Further exploration as to the reason why some providers were more successful in identifying eligible patients as compared with others in the study is another potential area of study to better understand this implementation challenge.

The findings may not be widely generalizable to older adults with complex needs, as patients in this study were generally healthier and more educated. However, the high proportion of complex older women living in rural environments in this project addresses a notable gap in the evidence on interventions for this population [84,85]. Relying on provider screening may have led to selection bias, which can reduce generalizability. However, as there is a lack of consensus on the definition of patient complexity, reliance on physician expertise and self-identification has been found to be a viable approach to identify this patient population [86].

Another important limitation is that this study lacks additional data on provider characteristics, such as age, years of experience, and employment status (eg, full-time or part-time). While a baseline demographic survey was deployed to all providers, few remitted these surveys despite multiple attempts to collect the data either via email, phone, or in person. While some key variables, such as comfort with technology, were collected via interviews, the other demographic variables would have aided in interpreting data and supported generalizability to other similar provider groups.

While this study offers a multimethod view of the effectiveness of the ePRO tool, the findings presented here focus on the major themes that emerged in the analysis. Further analyses will explore the interrelationships between NPT constructs and other context variables, in particular how these concepts relate to professional identities, organizational culture, and notions of how best to engage in chronic disease management. An important lesson from this trial is how the nature of GOC and chronic disease management in primary care settings is a fluid and complex process that is often unique to particular settings and provider-patient pairs. Highly adaptive trial designs, which allow the study to align to these contexts more closely, may have greater success in engagement for longer interventions.

Conclusions

Although this study is unable to provide a definitive answer to the effectiveness of the ePRO tool, it did generate novel insights regarding the implementation of digital health technologies in primary care settings. The findings demonstrate the critical role of coherence, or meaningfulness, of an intervention, and the great challenge of aligning coherence across diverse user groups over time. Future work in this area should pay careful attention to how chronic disease management, GOC, and self-management are understood and pursued when implementing digital health technologies to advance these models of care.

Acknowledgments

Funding support for this project was obtained from the Canadian Institutes of Health Research eHealth Innovation Partnership Program operating grant (FN-143559). The co-authors would like to acknowledge and thank the providers, administrators, and patients who participated in this study. The authors are grateful to each of them who gave their time, enthusiasm, and energy. The authors would also like to thank and acknowledge research support from Jasvinei Srinatharan, Tujuanna Austin, Karen Paik, Candis LePage, Janelle Gravesande, Zaki Hyatt-Shaw, and Parminder Hans for their coordination support throughout this study. They also acknowledge the contributions of collaborators Dr Cheryl Cott and Dr Renee Lyons, who offered early guidance in this work.

Conflicts of Interest

Funding for this study was obtained from a Canadian Federal Grant (Canadian Institutes of Health Research, FN-143559), with most co-authors' salaries being funded through their academic and scientific positions at their respective institutions. One co-author, SH, is the co-founder and co-owner of the technology company that hosts the electronic Patient-Reported Outcome (ePRO) tool (QoC Health Inc). While QoC Health Inc owns the platform on which the ePRO tool sits, the tool itself is the intellectual property of the lead author (CSG) in partnership with the Health System Performance Network at the University of Toronto, which is led by WPW (senior author). Any future aims to commercialize the ePRO tool would be done on the foundation of building a research-supporting not-for-profit that would seek to advance the development and evaluation of technologies that support care delivery for patients with complex care needs.

Abstract

Background: There is a general agreement on the importance of health-related quality of life (HRQoL). This type of information is becoming increasingly important for the value assessment of health technology assessment agencies in evaluating the benefits of new health technologies, including medicines. However, HRQoL data are often limited, and additional sources that provide this type of information may be helpful.

Objective: We aim to identify the HRQoL topics important to patients with melanoma based on web-based discussions on public social media forums.

Methods: We identified 3 public web-based forums from the United States and the United Kingdom, namely the Melanoma Patient Information Page, the Melanoma International Forum, and MacMillan. Their posts were randomly selected and coded using qualitative methods until saturation was reached.

Results: Of the posts assessed, 36.7% (150/409) of posts on Melanoma International Forum, 45.1% (198/439) on MacMillan, and 35.4% (128/362) on Melanoma Patient Information Page focused on HRQoL. The 2 themes most frequently mentioned were *mental health* and *(un)certainty*. The themes were constructed based on underlying and more detailed codes. Codes related to *fear, worry and anxiety*, *uncertainty*, and *unfavorable effects* were the most-often discussed ones.

Conclusions: Web-based forums are a valuable source for identifying relevant HRQoL aspects in patients with a given disease. These aspects could be cross-referenced with existing tools and they might improve the content validity of patient-reported outcome measures, including HRQoL questionnaires. In addition, web-based forums may provide health technology assessment agencies with a more holistic understanding of the external aspects affecting patient HRQoL. These aspects might support the value assessment of new health technologies and could therefore help inform topic prioritization as well as the scoping phase before any value assessment.

KEYWORDS

reimbursement decision-making; QoL; health care; quality of life

Introduction

Background

Decisions on the reimbursement of innovative medicines in Europe are most prominently based on the recommendations of national health technology assessment (HTA) agencies. Conventionally, these HTA recommendations are prepared directly after market-authorization of medicines. The starting point for these HTAs is the assessment of (added) therapeutic value, also known as relative effectiveness assessment, and subsequently, cost-effectiveness assessments. In both, relative effectiveness assessments and cost-effectiveness assessments, outcome measures such as the overall survival rate, adverse events (AEs), and health-related quality of life (HRQoL) are considered.

From the perspective of patients, HRQoL is an important outcome measure because it can capture how disease and treatment affect a patient's quality of life [1]. This is especially of interest in diseases such as cancer, where medicines may increase overall survival rates but may cause considerable toxicity. Therefore, HRQoL intends to inform HTA agencies on the relevance and added value of new oncology treatments for patients, for instance, if the medicine improves HRQoL by halting the progression of the disease, or alternatively, decreases HRQoL if toxicity or AEs have a large impact on the patient's well-being.

Although the assessment of HRQoL is becoming increasingly important in different areas of health care, relevant HRQoL data are often unavailable. For instance, patients with severe disease seem less likely to complete HRQoL questionnaires compared with their healthier counterparts [2,3]. The use of complicated HRQoL instruments increases respondent burden and may also lead to lower completion rates. Furthermore, patients might not be motivated to complete HRQoL questionnaires in a research setting if tangible respondent benefits are not delivered. Overall, HRQoL data are currently only sparsely represented in HTA reports for oncological products. More specifically, only in a third of HTA assessments were HRQoL data used [4], leading to a low impact of HRQoL on HTA decision-making despite the general recognition of the importance of HRQoL for patients and society.

In addition to the limited availability of HRQoL data, current methods used to measure HRQoL may fail to truly capture what is most relevant to patients [5], which may result in incorrect overall interpretation. Therefore, there is a continuous search for sources that provide additional relevant information on HRQoL. Social media is a convenient and well-established communication source and therefore presents an obvious potential option. Patients often use social media to gather information on their health condition and treatment options, to share their experiences, and to find social support [6-8]. Previous research has also shown that social media may help identify HRQoL topics of importance to patients, prioritize the topics most relevant to patients, or help in the distribution of HRQoL questionnaires [9-12]. Melanoma is an area of oncology that has seen the rapid introduction of several classes of new therapeutics with new modes of action, increasing the likelihood of existing HRQoL tools failing to capture patient-relevant outcomes [13-15]. Concomitantly, several web-based patient forums for melanoma have been active.

Objectives

To evaluate the potential relevance of social media as a meaningful source of HRQoL information for HTA, we identified the HRQoL topics that are most important to patients with melanoma based on discussions from web-based forums. Following the logic that in an unsupervised setting, patients would bring up topics relevant to them rather than being triggered by, for instance, a questionnaire, we focused on the research question: Which HRQoL topics do patients with melanoma and their caregivers spontaneously discuss on the web?

Methods

Overview

For this study, we focused on public web-based forums that are publicly accessible to anyone, as opposed to private patient communities. These public web-based forums provide peer support for a range of medical conditions, allowing the patients to share their experiences and provide information [16-18]. In a previous study, we collected patient perspectives on HRQoL from private social media sources, including a private Facebook (Facebook, Inc) group for patients with melanoma [9]. Using a different type of social media in this study allows for comparisons between the different sources of social media regarding the HRQoL topics discussed.

Selection of Web-Based Forums

The public web-based forums were identified using 2 internet search engines, namely (1) Google (Google, Inc) and (2) Bing (Microsoft, Inc), which are currently the most popular search engines in the world [19,20]. Searches were conducted in English, with a combination of the search terms *melanoma*, *forum*, *message board*, and *discussion board*. Browser history was cleared before each search because the previous searches might influence the search findings. This forum search was conducted on 5 consecutive days starting June 4, 2019, to account for the websites being unavailable owing to maintenance issues. The search results from the first 2 pages shown by (1) Google and (2) Bing were extracted and assessed for eligibility, and any advertisements or images were excluded.

Forums were eligible for inclusion based on the following three criteria: (1) the website had been active for ≥5 years based on the publication dates of posts, (2) at least 2000 posts had been posted on the forum, and (3) ≥5 new posts had been posted in the past week. We identified 3 forums as eligible for inclusion: Melanoma Patients Information Page (MPIP), Melanoma International Forum (MIF), and MacMillan Cancer Support Online Community for Melanoma Patients. Each forum was informed of our intention to use their publicly available posts for research purposes via email. Both MPIP and MIF are forums based in the United States and MacMillan is based in the United Kingdom. MPIP and MIF focus solely on patients with melanoma, whereas MacMillan provides information to support patients with cancer in general, in addition to having 64

cancer-specific forums (eg, melanoma, Hodgkin lymphoma, pancreatic cancer, and unknown primary cancer) [21-23].

Data Extraction

No login was used to gain access to any of the posts extracted, nor was login required on any of the forums. Each forum thread was sorted by the date of the last post, after which all the threads were collected. A thread is defined as a collection of posts, with an initial post that introduces a specific topic and the subsequent replies posted by one or more members of the forum. We collected the complete threads from each forum using the R package *rvest* (R Core Team) in September 2019 [24]. We collected the following data: title of the thread, text from each post, username of each post, date and time of each post, and whether a post was the original post or a reply. Each username was given a user ID to ensure anonymity.

Data Analysis

We coded the posts using the coding scheme developed in our previous study [9], in which members of the Melanoma Patient Network Europe, an established patient network for patients with melanoma, caregivers, and advocates, were approached via its multiple social media channels to anonymously complete a 25-item web-based survey. In this survey, questions regarding sociodemographic and clinical characteristics and several open questions exploring patient and caregiver perspectives on HRQoL (eg, "What is HRQoL in melanoma for you?", "Name 3 things that deteriorate your/the melanoma patient's HRQoL today?") were posed. Two researchers independently performed inductive content analysis on the responses to the open-ended questions and assigned codes, and any discrepancies in coding were resolved by consensus. As these themes and codes may not have covered all the topics spontaneously discussed in the forums, we created new themes and codes as required. The following themes were added: *alone* and *coping*, and the code *guilt* was added to the theme *certainty*. In addition, we adjusted the coding scheme to be more concise.

We excluded the posts that did not focus on HRQoL or melanoma, provided advice or shared experience, asked a question or provided information, or offered support. We defined HRQoL as the patient's subjective perception of the impact of the disease and its treatment on the physical, psychological, and social aspects of daily life [25,26]. From each forum, a random sample of 100 posts was coded by 4 authors (RRJK, DMJD, WGG and MLB). Agreement regarding the inclusion and exclusion of posts between the coders was 74% for MPIP (RRJK and DMJD), 85% for MIF (RRJK and WGG), and 83% for MacMillan (RRJK and MLB); any disagreements were discussed and resolved by consensus. From this random sample, 44% (44/100) were included in this study from MPIP, 61% (61/100) from MIF, and 63% (63/100) from MacMillan. Subsequently, author RRJK continued coding the posts selected randomly from each forum until 100 posts which referred to HRQoL aspects were included. After this, the posts were coded in batches of 25 until saturation. We defined saturation as not being able to identify a new emerging theme in 2 consecutive batches of 25 posts [27]. Owing to the vast number of posts in each forum, we decided to code until saturation because this was sufficient to identify which HRQoL aspects were relevant to patients with melanoma. When author RRJK was unsure about a specific post or code, the issue was discussed and resolved by consensus among authors (RRJK, DMJD, MLB, and WGG). A total of 72.4% (262/362) posts for MPIP, 75.6% (309/409) for MIF, and 77.2% (339/439) for MacMillan were assessed solely by author RRJK. Coder drift was not assessed in this study, and therefore, poses a potential coding bias.

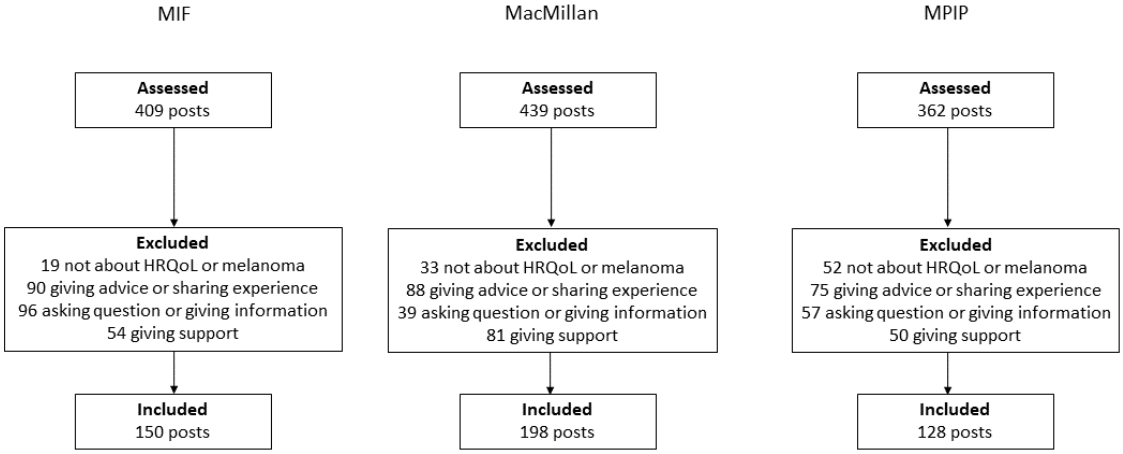
Covering all the posts assessed, we conducted an analysis of the number of threads and reply posts by each unique user to assess how often the same person initiated a thread or replied to an initial post. As a subanalysis, we assessed the subforums available on MIF in more detail. MIF provides separate forums for patients with melanoma with stage I and II, stage III and stage IV, as well as separate forums for newly diagnosed (ND) stage I and II patients and ND stage III and IV patients. This allowed us to evaluate which HRQoL topics were important for patients with melanoma at different disease stages. The results from analyzing the forum posts have been described qualitatively. This study was conducted in accordance with the Standards for Reporting Qualitative Research [28]. All data were collected, coded, stored, and analyzed using R version 3.4.4 (R Core Team) and NVivo (version 12; QSR International) [29,30].

Results

Overview

A total of 14,755, 6798, and 1671 threads were collected from MPIP, MIF, and MacMillan, respectively. This resulted in 88,261, 23,911, and 9551 original posts from MPIP, MIF, and MacMillan, respectively. A total of 409 posts from 189 unique users were assessed from MIF, as were 439 posts from 359 unique users from MacMillan and 362 posts from 243 unique users from MPIP (Figure 1). After the exclusion of irrelevant posts, 150 posts from 112 unique users, 198 posts from 164 unique users, and 128 posts from 96 unique users were included in our assessment from MIF, MacMillan, and MPIP, respectively. We determined how often the same user started a thread and posted a reply (Figure S1 in Multimedia Appendix 1). Some users started 1 thread but did not reply to any other post (46/189, 24.3% on MIF; 130/359, 36.2% on MacMillan; and 71/243, 29.2% on MPIP). Another group of users posted 1 reply, but did not start any threads (99/189, 52.4% MIF; 67/359, 18.7% MacMillan; and 52/243, 21.4% MPIP). Finally, a number of users started 1 thread and posted 1 reply (9/189, 4.8% MIF; 69/359, 19.2% MacMillan; and 32/243, 13.2% MPIP). Overall, 95.8% (181/189) of the users on MIF, 95% (341/359) on MacMillan, and 92.6% (225/243) on MPIP posted ≤5 posts (either as the initial thread or reply post). Only a few users in each forum contributed to a greater extent. Only 2 major outliers can be identified: 1 on MPIP, where 1 user started 45 threads and posted 26 replies, and 1 on MIF, where 1 user started 20 threads and posted 74 replies.

Figure 1. Overview of inclusion and exclusion criteria for forum posts. HRQoL: health-related quality of life; MIF: Melanoma International Forum; MPIP: Melanoma Patients' Information Page.



On all 3 forums, the 2 most often identified themes were *mental health* and *certainty* (Table 1). More than half of the posts mentioned aspects related to *mental health* (85/150, 56.7% MIF; 126/198, 63.6% MacMillan; and 69/128, 53.9% MPIP), and at least a third of the posts mentioned information relevant to *certainty* (63/150, 42% MIF; 80/198, 40.4% MacMillan; and 40/128, 31.3% MPIP). Other often-mentioned themes were *health care communication* (32/150, 21.3%) and *unfavorable effects* (28/150, 18.7%) on MIF, *health care access* (43/198, 21.7%) and *unfavorable effects* (27/198, 13.6%) on MacMillan, and *health care access* (20/128, 15.6%) and *unfavorable effects* (21/128, 16.4%) on MPIP.

Table 1. Total number and percentage of posts mentioning a specific theme on each forum (N=476).

Theme	Total posts per forum, n (%)		
	MIF[a] (n=150)	MacMillan (n=198)	MPIP[b] (n=128)
Mental health	85 (56.6)	126 (63.6)	69 (53.9)
Certainty	63 (42)	80 (40.4)	40 (31.2)
Health care communication	32 (21.3)	21 (10.6)	12 (9.4)
Unfavorable effects	28 (18.6)	27 (13.6)	21 (16.4)
Health care access	16 (10.6)	43 (21.7)	20 (15.6)

[a]MIF: Melanoma International Forum.

[b]MPIP: Melanoma Patients Information Page.

Each theme was constructed from underlying, more detailed codes. Table S1 in Multimedia Appendix 1 shows the codes used for each forum and provides excerpts from posts to provide examples for each code. This provides insight into the construct of each code and displays in more detail which HRQoL aspects the patients spontaneously discussed on the web. Examples of the most-often discussed codes (Table 2) are given below.

Table 2. Total number and percentage of posts mentioning a specific code on each forum (N=476).

Theme and code	Total posts per forum, n (%)		
	MIF[a] (n=150)	MacMillan (n=198)	MPIP[b] (n=128)

[a]MIF: Melanoma International Forum.

[b]MPIP: Melanoma Patients Information Page.

[c]Codes combined as compared with coding scheme used in previous study.

[d]New codes added to the original coding scheme used in previous study [9].

Fear, Worry, and Anxiety

On all 3 forums, the code relating to *fear, worry, anxiety* was most often discussed (Table 2; Table S1 in Multimedia Appendix 1). More specifically, on all forums, users talked about being obsessed over moles and being scared about their diagnosis. Other aspects mentioned included, but were not limited to, being anxious about the results (MIF and MPIP), worrying about recurrences (MIF), and the consequences of stopping treatment (MIF and MPIP).

Uncertainty

The second most frequently discussed topic on MIF, MacMillan, and MPIP was *uncertainty* (Table 2). Users were uncertain about many different aspects, such as whether they had made the right decision, whether the medicines would work, if the diagnosis was correct, and how bad the AEs would be (Table S1 in Multimedia Appendix 1). For example, one user said "[...] any suggestions on [...] how not to worry endlessly about the 'what ifs'."

Unfavorable Effects

On MPIP, MacMillan, and MIF the topic *unfavorable effects* was also discussed commonly (Table 2). This focused on the AEs, the complications and the symptoms that the patients experienced. One specific AE that was most frequently mentioned on MIF and MacMillan was lymphedema (Table S1 in Multimedia Appendix 1). Users also discussed solutions to the AEs and the complications they were experiencing, such as those from the medicines they were prescribed (MIF,

MacMillan, MPIP). Not only were the intolerable AEs, complications, and symptoms discussed, but also those that were manageable. Discussions reflected the different degrees of AE presentation experienced by patients, from manageable to intolerable. For example, 1 user mentioned the following "not the end of the world itching and rash, but it is very maddening and crazy making.", while another indicated "[...] has a terrible rash on his face head and back. We can LIVE with the rash."

Waiting Time and Coping

On MacMillan, next to *unfavorable effects*, both *waiting time* and *coping* were often mentioned (Table 2). Coping was also a topic discussed on the other 2 forums (Table S1 in Multimedia Appendix 1), although it seemed to be discussed to a lesser extent. Users discussed how they coped, for example, with their diagnoses (MIF and MacMillan), with the AEs (MIF and MacMillan), and with their lives in the new normal (MIF and MPIP). Some users indicated how difficult it was to cope with their diagnosis and how they went through denial before being able to accept the seriousness of it all (MacMillan). The long waiting time for appointments and results were also mentioned on all forums (Table S1 in Multimedia Appendix 1). Users expressed this as: *feels like waiting for eternity*, and *the waiting game being the worst*. However, some users on MacMillan also indicated that the waiting time was not as long as anticipated.

Hope

Hope was also a code mentioned in all forums. On MIF, a user expressed the following: "I'm getting to the point where I'm believing I could be ok again!" Users also expressed their hope of having scans that showed tumor shrinkage (MacMillan and MPIP) and their hope for medicines that would work (MacMillan and MPIP).

Health Care

Members shared experiences related not only to their health, but also to their experiences with health care, including access to health care, lack of information, and making informed decisions (Table S1 in Multimedia Appendix 1). On all forums, users talked about good and bad experiences with their health care. For example, one user posted:

> *I was seen by a new (?), certainly very young doctor who had obviously not read my notes as he had no idea that I was on the Avastin trial. In fact he didn't even know what the trial was and even asked me to spell the drug's name for him!!!! Obviously a very well read young man in his specialist field, not!*

However, good experiences with health care were also shared, such as by this user:

> *Had my first PET this week since stage 4 dx, and met with Onc the same day to go over results. She hadn't looked at them yet when we met, so I was pretty nervous. She could tell and just told me these are the first scans and the only bad results would be if there are any new mets that had popped up in kidney, lungs, or any other organs. She said she would be happy with no change, or even if things only grew by a little.*

The subanalysis of MIF subforums (data not shown) showed that fear, worry and anxiety was discussed on all subforums, but most often by patients with stage I or II, with 55.0% (33/60; including ND) of the posts mentioning this topic. Uncertainty was discussed on all subforums to approximately the same extent (17.6% (6/34) - 32.3% (10/31) of the posts discussed this topic). The topic unfavorable effects was more often discussed by stage III and IV patients (25.6% (22/86) including ND) than by stage I and II patients (5.0% (3/60) including ND). ND patients discussed coping more often than patients who were not posting on the ND subforums (17.2% (11/64) vs 3.7% (3/82), respectively).

Discussion

Principal Findings

In this study, we showed that patients with melanoma and their caregivers discussed many different topics related to HRQoL on public web-based forums. Topics related to *fear, worry and anxiety*, *uncertainty*, and *unfavorable effects* were most often discussed. With respect to *fear, worry and anxiety*, some users discussed their worries regarding their moles and diagnosis, which may be most important to patients in the earlier stages of melanoma. Other users discussed aspects related to their fear of recurrence or the consequences of stopping treatment, which may be more relevant to patients in the later stages of the disease. Of note, a caveat of social media is the incomplete information on user characteristics, making it infeasible to determine the disease stage for each user. Many users also discussed aspects related to *uncertainty*. However, this covered different aspects ranging from uncertainty regarding AEs and the effectiveness of the medicines to uncertainty about their diagnosis. Finally, with respect to discussions on unfavorable effects, users shared their experiences with AEs and complications, as well as their solutions.

It is important to realize that the type of social media used may affect the results of a study like ours because social media may be public (anyone may gain access to posts without signing in) or private (where an account is needed before users may gain access to posts). In public sources, users may be less inclined to share personal experiences as compared with private social media sources [31,32]. Previously, we had assessed which HRQoL topics were most important to patients with melanoma and their caregivers on private social media by posting a survey on the private social media channels of Melanoma Patient Network Europe [9]. It was shown that *family* and having a *normal life* were the 2 most important HRQoL topics for patients with melanoma. In this study, patients with melanoma most often discussed topics related to *fear, worry, anxiety, uncertainty*, and *unfavorable effects*. This difference may be because in the previous paper, we actively inquired about the HRQoL aspects most important to patients with melanoma, guiding them through a survey, whereas in the current paper, we merely listened to the topics that patients with melanoma discussed with each other [33,34], the latter being a much more inductive approach.

Another aspect that may influence our study results is the overrepresentation of a specific group of users, such as patients

with a specific stage of disease or their caregivers discussing the topics most important to them and subsequently driving our results. We previously showed using private social media that patients with melanoma with a different stage of the disease find other HRQoL aspects important, as do caregivers [9]. In this study, we confirmed this as our subanalysis of the MIF subforums suggested that different HRQoL topics seemed important to patients with melanoma in different disease stages. Subsequently, melanoma-specific HRQoL questionnaires may benefit from taking these differences into account.

Previous research has shown that disease-specific HRQoL questionnaires do not fully represent what patients find important in HRQoL [9,12,35]. For example, the wording in the questionnaires may be different from how patients describe HRQoL aspects; some topics may seem less relevant to patients and some topics may not be included in the HRQoL questionnaires [9,12,35]. Therefore, we evaluated whether melanoma-specific HRQoL questionnaires represented topics discussed by patients with melanoma on web-based forums. In both the Functional Assessment of Cancer Therapy-Melanoma (FACT-M) and European Organization for Research and Treatment of Cancer (EORTC) QLQ-MEL38, some questions related to the theme *mental health* are present [36,37]. In FACT-M, these questions seem to focus on worrying, losing hope, being sad, and feeling nervous. Although in EORTC QLQ-MEL38, they seem to focus mainly on worrying, including worrying about unfavorable effects. In contrast, web-based discussions seem to focus more on the (overwhelming) fear and anxiety of patients with melanoma. Regarding *uncertainty*, only EORTC QLQ-MEL38 poses one question *Have you felt able to plan for the future?* However, in web-based discussions, other aspects of uncertainty seem to be more important to patients. Several questions related to *unfavorable effects* are posed in both FACT-M and EORTC QLQ-MEL38, including some questions related to lymphedema. This seems to correspond to the web-based discussions among patients with melanoma. Other themes that were often discussed on the web included *health care communication* and *health care access*. It seems that only EORTC QLQ-MEL38 has questions focusing on these themes. Although these melanoma-specific HRQoL questionnaires have been developed with great care, these findings raise questions about the extent to which these questionnaires cover aspects most pertinent to patients. Therefore, HRQoL questionnaires may benefit from ensuring that topics correspond more to patient experiences, such as including more questions on uncertainty.

It is important to note that although aspects related to AEs may be important for reimbursement decision-making, aspects related to uncertainty and coping are less relevant. However, considering the high psychological burden in the early stages of melanoma, which contrasts with the seemingly benign overall survival outcomes, some topics may become increasingly relevant for HTA as melanoma therapies move from the advanced setting into earlier stages of the disease. These insights highlight the importance as well as the burden that these topics present for patients with melanoma across all disease stages, in addition to disease-specific concerns. Health care systems, therefore, should be aware that topics such as health care communication and access to services can critically impact the HRQoL of patients, irrespective of the given treatment.

Limitations

This study has several limitations. First, we focused on web-based forums, whereas other public, social media channels might provide a different type of insight (eg, Twitter, public Facebook groups, or blogs). However, not every social media channel is appropriate for gathering insights on a specific topic. For example, information on AEs is not readily available on Facebook or Twitter [38]. Second, identifying the disease stage for each patient was difficult but has been proven to be relevant as our earlier analysis of stage-specific forums has shown. This could possibly be overcome to a certain degree by using more automated methods of data analysis. In addition, validating authenticity (eg, verifying whether users actually have the disease they discuss) on the web is difficult [11,39,40]. Third, selection bias may be an issue because the patient population present on web-based forums may be different from the patient population that is not using web-based forums. For example, patients using social media are conventionally better educated [40,41], more likely to be female [39,42], and may have a different symptom experience [43]. Finally, web-based forums may update their terms of use at any given time. At the time of collecting the posts, all 3 forums were of public nature and logging in to gain access to the posts was not necessary. However, MIF has changed this and now requires a login to gain access to posts.

Strengths

One of the strengths of this study was the coding of 100 posts from each forum by 2 authors to ensure validity. Analyzing qualitative data can be subjective; therefore, agreement among multiple authors when assigning codes is important. In addition, any uncertainties in the posts that were coded until saturation was reached were discussed and resolved by consensus among the 4 authors to further ensure validity. Another strength was determining how often users posted an initial post and a reply post to assess whether one or more users could possibly drive our results. A total of 94.4% (747/791)of users posted only a few posts (≤5 posts) on the forums, suggesting that our results were not driven by one or more users. It seems highly unlikely that the 2 outliers in MIF and MPIP would drive the results, considering the number of posts assessed.

Implications and Conclusions

Patient involvement is becoming increasingly important in HTA, which is especially appreciated during the scoping phase of HTA and for HTA topic prioritization [44,45]. The scoping phase is conducted at the beginning of an HTA assessment, where the technology under assessment, the reference or comparator technology, the relevant study population, and the relevant outcome measures regarding the effectiveness and safety of the technology under assessment are identified [46,47]. In an ideal situation, several stakeholders, including clinicians and patients, should be involved during this scoping phase. The input from patients or their representatives is, for example, important to choose outcome measures that matter to patients. However, the involvement of patients or representatives may

be limited [48-51]. Social media may allow inputs from a wide group of patients, and may thus provide robust insight into patient experiences. For example, in the scoping phase, social media may be informative in determining which outcome measures would be most important to measure. Social media may not only prove useful in HTA but may also inform health care professionals in their understanding of patient experiences and what is important to patients regarding their treatment and health care [52]. In addition, issues relevant to patients and which they deal with on a regular basis may be uncovered and could lead to identifying issues that might have otherwise gone unrecognized [53]. In addition, in regulatory decision-making, information from social media may help determine which AEs greatly affect HRQoL, are most debilitating to patients, and which AEs are acceptable to patients [39,54,55]. Therefore, social media may be informative for several stakeholders with varying goals. However, this source of information still needs to become part of the regular data extraction practices of stakeholders. Therefore, clear guidelines are needed for the ethical use of social media data, the limitations that are involved, and the purposes for which this information could be used.

To conclude, it is important to realize that web-based forums are a valuable source to cross-reference the relevance of existing tools and help identify gaps in existing procedures. Social media may contribute to improving the content validity of patient-reported outcome measures, including HRQoL measures. More specifically, current melanoma HRQoL questionnaires may potentially improve patient relevance by adding more items related to fear, worry, anxiety and uncertainty. Social media is a readily available source that can provide fast inputs from patients with both rare and common diseases. It can be used passively to listen to what patients discuss on the web and to actively distribute questionnaires. In addition, information extracted from social media may support an evidence ecosystem, where existing evidence is used by several stakeholders for different goals. This information source may contribute to a more holistic understanding of the patient's perspective and highlight external factors affecting patient HRQoL. Social media may specifically provide insights for HTA decision-making during the prioritization of topics as well as during the scoping phase conducted before the value assessment of a new health technology.

Acknowledgments

This study was funded by the Dutch National Health Care Institute.

Conflicts of Interest

MPNE (Melanoma Patient Network Europe) is a volunteer-based network whose activities are funded by balanced support by the following companies: Amgen, BMS, Delcath, Idera, Incyte, Immunocore, MSD, Merck Serono, Novartis, Pierre Fabre, and Roche. Support never includes editorial rights, influence on MPNE's program nor activities. In addition, MPNE is funded by 3 Horizon2020 grants (UMCURE, Share4Rare and iTobos). BR received personal consultancy fees for work in patient affairs from Amgen, AstraZeneca, BMS, Celgene, Clinigen, IQVIA, MSD, Novartis, Pfizer, and Roche.

Abstract

Background: Certain types of artificial intelligence (AI), that is, deep learning models, can outperform health care professionals in particular domains. Such models hold considerable promise for improved diagnostics, treatment, and prevention, as well as more cost-efficient health care. They are, however, opaque in the sense that their exact reasoning cannot be fully explicated. Different stakeholders have emphasized the importance of the transparency/explainability of AI decision making. Transparency/explainability may come at the cost of performance. There is need for a public policy regulating the use of AI in health care that balances the societal interests in high performance as well as in transparency/explainability. A public policy should consider the wider public's interests in such features of AI.

Objective: This study elicited the public's preferences for the performance and explainability of AI decision making in health care and determined whether these preferences depend on respondent characteristics, including trust in health and technology and fears and hopes regarding AI.

Methods: We conducted a choice-based conjoint survey of public preferences for attributes of AI decision making in health care in a representative sample of the adult Danish population. Initial focus group interviews yielded 6 attributes playing a role in the respondents' views on the use of AI decision support in health care: (1) type of AI decision, (2) level of explanation, (3) performance/accuracy, (4) responsibility for the final decision, (5) possibility of discrimination, and (6) severity of the disease to which the AI is applied. In total, 100 unique choice sets were developed using fractional factorial design. In a 12-task survey, respondents were asked about their preference for AI system use in hospitals in relation to 3 different scenarios.

Results: Of the 1678 potential respondents, 1027 (61.2%) participated. The respondents consider the physician having the final responsibility for treatment decisions the most important attribute, with 46.8% of the total weight of attributes, followed by explainability of the decision (27.3%) and whether the system has been tested for discrimination (14.8%). Other factors, such as gender, age, level of education, whether respondents live rurally or in towns, respondents' trust in health and technology, and respondents' fears and hopes regarding AI, do not play a significant role in the majority of cases.

Conclusions: The 3 factors that are most important to the public are, in descending order of importance, (1) that physicians are ultimately responsible for diagnostics and treatment planning, (2) that the AI decision support is explainable, and (3) that the AI system has been tested for discrimination. Public policy on AI system use in health care should give priority to such AI system use and ensure that patients are provided with information.

artificial Intelligence; performance; transparency; explainability; population preferences; public policy

Introduction

Recent developments in artificial intelligence (AI) hold considerable promise for promoting individual health and well-being, and societal flourishing. Taking medical imaging as an example, a recent review showed that although the diagnostic performance of deep learning models is generally equivalent to that of health care professionals, it may outperform such professionals in particular cases [1]. Better diagnosis and early detection may not only enable better treatment but also lead to more cost-effective public spending. However, the performance of AI models comes at a cost. The most successful deep learning models are opaque. The complexity of such models implies (1) that many aspects of the decision-making procedure cannot be fully explicated and scrutinized and (2) that the exact reasoning cannot be replicated step-by-step in real time [2]. Across all types of AI, it seems that at the moment, the better-performing models (eg, deep learning models) are the most opaque [2-8].

The opacity of a medical AI system may concern different groups in the clinical setting. Thus, there are partly dissociable transparency and explainability problems in relation to health care professionals and in relation to patients. If an AI system and its outputs can be made transparent to health care professionals, then patients can potentially rely on the trust they have in those professionals, even if the patients themselves do not understand the system. However, if there is also a significant transparency and explainability problem in relation to health care professionals, both patients and professionals end up in a situation in which the only possible reliance on trust will be on trust in the system. This paper primarily investigates this as seen from a patient perspective.

Opacity is undesirable. The transparency and explainability of AI decision making to the patient are important for psychological, scientific, ethical, and democratic reasons. Psychologically, transparency may increase the understanding of the AI process and may make it easier to cope with AI decisions significantly impacting individual lives (eg, receiving a life-changing diagnosis). Scientifically, transparency may provide insights into hitherto unknown correlations constitutive or suggestive of causal mechanisms. Ethically, transparency may provide a basis for individual self-protection against biased and discriminatory decisions, decisions based on violations of privacy, decisions subjecting individuals to unreasonable risks of harm, etc. Democratically, transparency may unveil the inner workings of the technology used in specific settings by the state or other powerful actors to exercise power over citizens, and thus, it may empower citizens to hold decision makers accountable through the institutions of democracy.

The importance of transparency and explainability of AI is widely recognized. Researchers and research institutions, public committees, and expert groups, as well as private companies, have in recent years issued guidelines for responsible use of AI, emphasizing the value of transparency. A recent systematic review found 84 such guidelines [9]. The authors showed a remarkable global convergence on the importance of transparency, but they also exhibited a significant variation in what transparency is taken to be and requires. The importance of transparency is recognized in the European Union General Data Protection Regulation (GDPR), which in Articles 13 and 14 stipulates that if data subjects are profiled, they have a right to "meaningful information about the logic involved" [10]. A right to "meaningful information" is, however, rather vague. It may be interpreted minimally as simply requiring abstract and generic information about AI involvement in decision making along the lines of "this decision was partly based on recommendations made by an automated computer system." It may also be interpreted maximally as requiring access to all aspects of the AI decision making and the ability to reproduce each and every (significant) step in the decision making. As noted above, a maximal interpretation would entail that some of the best-performing systems of AI cannot satisfy the requirement of transparency.

The need for transparency is also recognized by researchers and developers of AI systems, and "explainable AI" is an active research field, and it is probably unlikely that any system would be implemented in health care without some work having been done estimating the importance of features such as gender, age, and ethnicity on the outputs of the system. This is, however, still not full transparent or explainable.

This paper proceeds from the assumption that there is a real dilemma here. Maximal transparency of AI systems may come at the cost of system performance and vice versa. This is not a conceptually necessary dilemma. New AI architectures may be invented that satisfy all relevant criteria of transparency and explainability and at the same time perform better than current architectures. However, until that happens, there is a balance to be struck between transparency and system performance. We believe that an adequate requirement of transparency should consider individuals' interests and preferences for performance and transparency. We therefore studied the relative importance to citizens of these and other aspects of AI decision making in health care in the Danish population by performing a conjoint analysis survey.

Methods

Initial Focus Groups

In this study, 2 focus group interviews were conducted with 5-6 participants in each drawn from Kantar Gallup´s Danish consumer panel. The participants were a cross section of the public and ranged from age 27 to 75 years. Both interviews were conducted in September 2019, and each interview lasted about 2 hours. The participants were briefly introduced to AI and were subsequently presented with 2 scenarios revolving around the use of AI for decision making in health care. They were asked to discuss each of the scenarios and in particular (1) the importance of being provided with explanations of the AI decision making and (2) the trade-off between the accuracy and performance of AI decision making and being provided with explanations of the decision making. The groups were asked, for instance, how important it is to explain how AI reaches decisions, even if the ability to do so will make the AI decisions less accurate.

All interviews were audio-recorded and transcribed verbatim. The interviews in combination with the literature offered information that was used to identify 6 aspects that play a role in the participants' views on the use of AI in health care: (1) type of AI decision (ie, whether it is used for diagnostics or treatment planning), (2) the level of explanation available, (3) performance and accuracy, (4) responsibility for the final decision, (5) possibility of bias or discrimination, and (6) severity of the disease or condition to which the AI is applied.

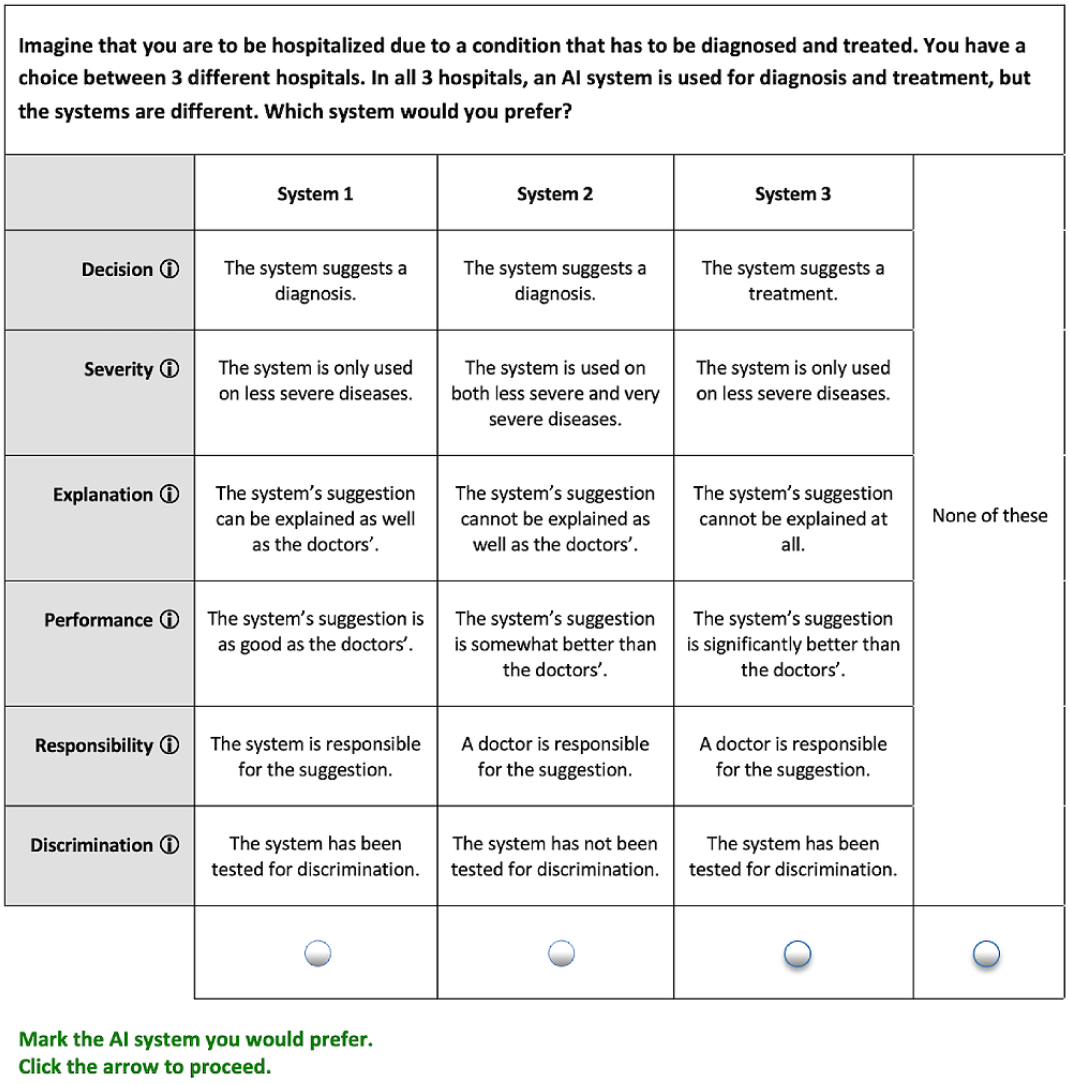
Design of Survey

Conjoint analysis is a discrete choice survey methodology. Respondents are asked to make a choice between 2 or more different options, where each option is described in terms of a number of predefined attributes, each with a number of levels (Figure 1). Given a sufficient number of choices per respondent, it is then possible to statistically estimate the importance of each attribute and level for the choice in terms of part-worth utilities [11].

The 6 aspects mentioned above were chosen as attributes for the conjoint analysis survey. For each attribute, a number of levels were developed based on the literature. In setting the lowest level for performance, it was assumed that any AI system introduced in health care would be known to perform at least as well as a trained health care professional (see also the Discussion section later).

The choice sets were generated using the complete enumeration method in the Sawtooth SSI Web (version 7.0.30) module [12]. The complete enumeration method generates conjoint designs conforming to the principles of (1) minimal overlap of attribute levels within a single choice task, (2) level balance across the set of choice tasks presented to each respondent, and (3) orthogonality (ie, the levels of different attributes are chosen independently). In total, 100 unique sets of conjoint choice questionnaires were generated, each of which was presented to an approximately equal number of respondents. Each set of conjoint choice questionnaires contained 12 choice tasks, where each respondent was asked to choose 1 of 3 options or a "None of these" option.

Figure 1. An example of a choice task with 3 concepts. AI: artificial intelligence.



The choice situation was described as follows:

> *This study is about artificial intelligence (AI). AI is a way of getting digital technologies to solve complex tasks. There is, for instance, AI in self-driving cars, search engines on the web, or the voice assistants in mobile phones. AI is often based on large data sources. You can, for instance, train an AI system to make diagnoses of cataract or melanoma by showing it many different pictures of eyes or skin with moles. You can also train AI systems to make suggestions about treatment of a disease (eg, suggestions for medication). AI systems have shown themselves to be quite good at making diagnoses and suggestions about treatment. However, they also sometimes make errors or differentiate unjustly between patients. In addition, it can be difficult to explain how a diagnosis or a suggestion for treatment has been derived. In what follows, you will therefore be asked about what you would prioritize if an AI system was used in the health care sector to make a diagnosis or suggest a treatment for you. On the next 12-15 pages, you will be shown 3 different scenarios that all involve the use of AI for diagnosis and treatment. On each page, you should choose the scenario that you think is best/you prefer. If none of the scenarios look good to you, there is an option "None of these."*

In addition to the conjoint analysis survey, respondents were asked about demographic data, chronic illness, and recent contact with the health care system; questions about trust in the health care system; and questions about fear and hope in relation to AI in general [13].

Sample

A stratified sample of 1678 potential participants was drawn from Kantar Gallup's Danish consumer panel of 53,000 active members. The sample was designed to be representative of the adult Danish population. Emails were sent to the potential participants, inviting them to participate in the study. After 3, 11, and 29 days, nonresponders (ie, those who had not completed the survey or who had not visited the website hosting the survey) were reminded by email. After 6, 22, and 31 days, nonresponders were contacted by SMS.

Of the 1678 potential respondents contacted, 1441 opened the link to the questionnaire, 1027 completed it fully, and 414 completed it partially. The analysis was based on the 1027 complete answers, giving a response rate of 61.2% (1027/1678). A sample efficiency analysis calculating the overall concordance between the respondents and the desired sample characteristics was performed, considering obtained and desired numbers in relation to gender, age, geographical region, and level of education (sum of squares=33.78, *df*=785, efficiency=88.33%).

Statistical Analysis

The analysis of the conjoint analysis survey deriving the part-worth utilities of the attributes and levels was performed by Kantar Gallup. Part-worth utilities were estimated using Sawtooth CBC/HB (version 5.5.3) to perform a hierarchical Bayes method estimation, running 190,000 burn-in iterations and 10,000 draws per respondent. A detailed description of the hierarchical Bayes method and its implementation can be found in Ref. [14].

The subsequent statistical analysis was performed using IBM SPSS Statistics 25. Demographic data were tabulated and univariate relationships between utilities and respondent characteristics analyzed using ANOVA with Bonferroni correction. Ad hoc trust, fear, and hope scales were formed as simple summative scales from the trust, fear, and hope questions and validated by Cronbach α. All 3 scales had acceptable α values of .74-.79. Univariate relationships between utilities and the 3 scales were analyzed using correlation analysis with Bonferroni correction.

Results

Major Findings

A total of 521 of 1027 (50.7%) respondents were men and 506 (49.3%) women. The average age was 50.3 years (SD 18.1). Of the 1027 respondents, 375 (36.5%) indicated that they had a chronic illness, 830 (80.8%) had visited their general practitioner (GP) at least once during the past year, and 146 (14.2%) had been inpatients in a hospital during the past year. The highest educational level was school or high school for 197 of 1027 (19.2%) respondents, further education for 446 of 1027 (43.4%) respondents, and university or university college for 384 of 1027 (37.4%) respondents.

The part-worth utilities of the attributes and levels are presented in Table 1, the responses to questions about trust in health care and technology, and fear and hope in relation to AI in general in Table 2, and the relationship between respondent characteristics and utilities of attributes in Table 3.

Table 1. Importance of attributes and part-worth utilities of levels.

Attribute	Importance (%)	Level (part-worth utility)
Type	3.0	• Diagnostics (0.123) • Treatment planning (–0.123)
Explanation	27.3	• Equally explainable as physician's decision (1.106) • Not as explainable as physician's decision (–0.270) • No explanation available (–0.836)
Performance	6.6	• System decision significantly better than physician's (0.267) • System decision somewhat better than physician's (0.052) • System decision equally good as physician's (–0.319)
Responsibility	46.8	• Physician responsible for decision (1.900) • System responsible for decision (–1.900)
Discrimination	14.8	• System tested for biased decisions (0.602) • System not been tested for biased decisions (–0.602)
Severity of disease	1.5	• System use only when less severe disease (0.060) • System use both when less severe and when very severe disease (–0.060)

Table 2. Respondent trust and opinions about AI[a] (N=1027).

Opinion	None/not at all, n (%)	Very little, n (%)	Little, n (%)	Some, n (%)	A lot/certainly, n (%)	Don't know, n (%)
Trust						
I have trust in the health care system.	7 (0.7)	35 (3.4)	102 (9.9)	438 (42.6)	424 (41.3)	21 (2.1)
I have trust in physicians.	2 (0.2)	29 (2.8)	72 (7.0)	412 (40.1)	502 (48.9)	10 (1.0)
I have trust in technology.	4 (0.4)	32 (3.1)	129 (12.6)	519 (50.5)	313 (30.5)	30 (2.9)
Fear						
I believe that AI will lead to unemployment.	122 (11.9)	216 (21.0)	251 (24.4)	169 (16.5)	95 (9.3)	174 (16.9)
I believe that AI will cause unintentional harm to humans.	55 (5.4)	206 (20.1)	303 (29.5)	181 (17.6)	67 (6.5)	215 (20.9)
I believe that AI will lead to loss of control to machines.	86 (8.4)	167 (16.3)	249 (24.2)	241 (23.5)	141 (13.7)	143 (13.9)
I believe that AI will lead to increased data collection and mass surveillance.	22 (2.1)	30 (2.9)	106 (10.3)	309 (30.1)	435 (42.4)	125 (12.2)
Hope						
I believe that AI will lead to more jobs.	119 (11.6)	180 (17.5)	300 (29.2)	164 (16.0)	55 (5.3)	209 (20.4)
I believe that AI will lead to longer lives.	69 (6.7)	114 (11.1)	243 (23.6)	284 (27.7)	92 (9.0)	225 (21.9)
I believe that AI will lead to more quality of life.	82 (8.0)	119 (11.6)	279 (27.2)	265 (25.8)	93 (9.0)	189 (18.4)
I believe that AI will lead to peace and political stability.	225 (21.9)	209 (20.4)	232 (22.6)	66 (6.4)	20 (1.9)	275 (26.8)

[a]Numerical data only shown for cells where there is a statistically significant difference.

[b]GP: general practitioner.

[c]Not applicable.

[d]M: male.

[e]F: female.

The results in Table 1 show that the physician having the final responsibility for treatment choice is the most important attribute, with 46.8% of the total weight being allocated to it, followed by explainability of the decision (27.3%) and whether the AI system has been tested for discrimination (14.8%). These 3 attributes accounted for 88.9% of the total weight/importance.

As can be seen in Table 2, the respondents in general trusted health care and technology; did not particularly fear AI, although some did; and in general believed that AI will have positive implications for society.

Table 3 shows that while gender, age, level of education, whether respondents live rurally or in towns, their trust in health and technology, and fear and hope regarding AI did influence the importance they allocated to different attributes, they did not play a significant role in the majority of cases. The data shown for the numerical differences between groups and the correlation coefficients indicate that the statistically significant findings do not reflect large numerical differences or strong correlations.

Discussion

Principal Findings

The results of this study are interesting. First, the study shows that among the respondents, there was a clear order of preference between AI performance and AI explainabillity. Being provided with an explanation was the second-most important factor (27.3%) for the respondents' choice of preferred AI system, while performance carried little weight (6.6%) and was ranked only fourth out of the 6 attributes. However, the study also shows that the population finds a number of different aspects

of AI decisions important for their choice of preferred AI system use. It is not simply a matter of choosing between the performance and explainability of AI. The single-most important factor for their choice is how responsibility for a diagnosis or treatment plan is distributed between physician and AI system. The respondents placed significant emphasis on physicians being responsible for health care decisions (46.8%).

The relatively limited role of AI system performance in the respondents' preferences arguably reflects the chosen levels of the performance attribute. We did not in this study include the possibility that the AI system performs worse or significantly worse than physicians. This would likely have changed the overall weight of performance in the respondents' decisions. Our design was based on what we believe to be the most likely future scenario for the implementation of AI in health care, and this does not include the introduction of AI systems that perform significantly worse than physicians. Implementing such suboptimal systems is likely to be resisted by health care professionals and will in some jurisdictions also be open to legal challenge. Our study specifically shows that in health care implementations with AI systems performing at least as well as physicians, the role of AI system performance in the populations' preferences is limited. They are not particularly interested in getting increased performance if this leads to a loss of other important features of the AI system. On a more speculative note, the choice of a nonnumeric description of the standard of performance ("equally good," "somewhat better," and "significantly better") may be thought to be less informative than providing, for instance, the accuracy of the AI system and physicians as a percentage of correct decisions made, false positives, false negatives, etc. However, providing the information about accuracy in percentage terms may be difficult to understand and may communicate a false sense of precision in our evaluation of how well a system works when implemented in a routine health care setting.

Interpreting the respondents' strong preference for the explainability of AI decisions in health care is difficult. The explainability attribute is stated in terms of the degree of explainability relative to the explanation provided by a physician, and this entails that little can be said about what kind of explanation the respondents want or how they understand explainability. It may be reasonable to assume, however, that this standard would lead the respondents to expect limits to how fine-grained explanations of AI decision making can be made available—just as there are limits to how fine-grained explanations physicians can provide. Thus, providing patients with information about each and every aspect of diagnostics or treatment planning is not the standard of everyday clinical practice for a number of different reasons, including limits to the amount of medical information patients may be able to process and time constraints on the physician-patient encounter. We believe that the relative standard of explainability is the simplest and most meaningful way of introducing different levels of explainability of AI decision making to the respondents.

There are a number of statistically significant findings of relationships between respondent characteristics and the weight given to particular attributes (Table 3). However, when considering the size of the differences in weighting between the highest and the lowest group, it is evident that although these differences are statistically significant, they do not signify a fundamental change in the ranking of the different attributes. The negative finding that there are no significant relationships between the degree of contact with the health service and the weight given to the different attributes is also important since it indicates that there is, broadly speaking, no major differences between patients and nonpatients in their general preferences in relation to AI in health care.

Table 3 contains 2 further key findings. First, that hope in the future benefits of AI certainly is a driver of respondents' views as to the importance of the attributes. The performance of the AI system is of greater importance for the hopeful, whereas testing for discrimination and distinguishing between the use of AI systems for diagnostics or treatment of less severe or more severe diseases is of lesser importance. Second, that the respondents' views concerning the importance of performance are influenced by a number of factors. It is significantly more important for the younger, the educated, the urban, and respondents with fear or hope concerning a future with AI.

Strengths and Limitations of This Study

The response rate of 61.2% is good for a population survey, and the sample efficiency analysis shows that the respondents were similar to the complete sample in relation to the stratification variables. There is therefore reason to believe that the findings reflect the views of the wider Danish population.

The choice situation is hypothetical in 2 ways: (1) The respondents are not in an actual situation demanding a choice between AI systems, and (2) currently, the level of use of AI systems for diagnostic and treatment-planning purposes in Danish health care is not as advanced as the scenarios suggest. The first of these abstractions is a feature of the conjoint choice methodology, and the second is a feature of the current level of penetration of AI in health care. The choice situation is, however, close to a clinical situation of which many respondents will have actual experience. For the purpose of deciding a general policy of transparency of AI health care decision making, we believe it is important to know the wider population's preferences as abstracted from the distress of a real-life choice situation. A general policy should, however, consider the diversity of views and preferences of the general population, including those of patients. Of the 1027 respondents in this study, 375 (36.5%) indicated that they have a chronic disease, 146 (14.2%) had been hospitalized within the past year, and 830 (80.8%) had visited their GP within the past year. Most of the respondents are thus in regular contact with the health care system and are used to being involved in decision making in that context.

Given the rapid developments in AI over the past decade, the general population's familiarity with the potential and actual use of AI systems for diagnostics and treatment planning may be expected to be low. Even those who realize that the voice recognition functionality in their phone or tablet relies on AI processing may not transfer that to the health care context. Asking for views and preferences in relation to hypothetical implementations of AI in hospitals therefore is likely to reflect

more general views and preferences in relation to the implementation of "a new technology" in health care. These views and preferences may or may not change as the familiarity with the technology grows. Potential changes in views and preferences must be monitored and considered in an ongoing adjustment of policies. Such changes do not, however, obviate the need for policy decisions at the current stage of AI development and use in health care.

This entails that it is important that the choice situation be described in a way that does not introduce overt bias, especially in relation to the features of AI that are the attributes of the options in the choice task. There are 2 elements of our choice task that could potentially introduce bias. The first, which we discussed above, is that the performance of AI is compared to the performance of a physician and that choices therefore to some extent depend on the respondents' perception of the typical performance of physicians. The second is our description of the transparency and performance of AI systems. We wrote, "AI systems have shown themselves to be quite good at making diagnoses and suggestions about treatment. However, they also sometimes make errors or differentiate unjustly between patients. In addition, it can be difficult to explain how a diagnosis or a suggestion for treatment has been derived." This is a true description of current and near-future AI systems in health care and is not overtly biased. As all short descriptions, it can be made longer and complete in various ways, but putative proponents or opponents of AI in health care are likely to look for different additions and likely to point to different real-world examples, for instance, in relation to the risk of bias and discrimination. We cannot rule out bias, partly because there is no yardstick for a "neutral description," but we would argue that the risk of bias is low.

This study was conducted in the Danish population and may not be representative of other populations. Further studies are required.

Previous Empirical Research

A number of studies on the broader public's perceptions of automated decision making and AI as such have been conducted in recent years [15-18]. Of particular interest is a recent study on the relative weight of 3 AI features (performance, explainability, and the effort required for implementation/training) for industry experts' choice of a preferred AI decision support system for high-stake maintenance of airplane turbines. The study found that performance is, by far, the most important factor (0.61), whereas explainability (0.20) and effort (0.19) are on a par [19]. Although the study explores the relative weight of AI system features for decisions of a group of experts, it does not report the wider public's perceptions. Moreover, it includes a limited set of features, and it is outside the health care context studied in this article.

Studies of perceptions of AI use in the medical context have taken different approaches. Some have studied the perceptions of AI use among health care professionals [20-23]. We focused here, however, on the public or patient perceptions of AI in the health care context. Overall, the studies on public or patient perceptions report a strong confidence in and acceptability of AI system health care use in the diagnostic context [24-30]. However, most studies also find that the respondents have higher confidence in physician diagnostics and prefer implementations of AI in medical care, with AI playing a decision-supportive role [24,25,27,28]. Several studies indicate that respondents have a strong interest in the performance or accuracy of AI diagnostic systems [28,31]. One study reports a marked difference in respondents' confidence between AI use for diagnostic and treatment decision purposes, with a significant lower confidence in the latter [25]. A study of factors driving the perceived risks of AI clinical device use concludes that perceived uncertainties about performance, concerns about potentially reduced communication with physicians, perceived untrustworthiness of AI, perceived lack of regulatory standards for evaluating the safety and impact of AI, and concerns about liability issues are significant drivers of the perceived risk [31]. Notably, the study also finds that privacy concerns and concerns about social biases and discrimination do not significantly impact the perceived risk of AI clinical device use [31]. Although these previous studies concern perceptions of several features of AI health care use, none of them investigate public perceptions of the importance of AI explainability and perceptions of the relative weight of features of AI decision making in health care. Most of the findings are, however, compatible with our findings.

Policy Implications: The Use of AI in Health Care and Requirements of Transparency

Deciding issues of public policy cannot be done entirely on the basis of individual or population preferences. Various other ethical, legal, professional, and political concerns must be considered. There are, however, at least 2 reasons for considering individual and population preferences. First, the principle of respecting and promoting individual autonomy is usually taken to entail that it counts in favor of an action or a policy if it provides individuals with an opportunity to protect and pursue their interests. Second, the ideal of representative democracy is usually taken to entail that in deciding public policies, decision makers should represent the interests of the people. Designing public policy partly on the basis of population preferences, as mapped in this conjoint analysis survey, is a way of considering individuals' interest at an aggregate level.

This study is of relevance for policies concerning the implementation of AI in health care. The study suggests that AI systems will be found acceptable and can be used for both diagnostic and treatment-planning purposes regardless of the severity of the medical condition if the system has been tested for discrimination, if decisions can be explained to the same extent as physicians' health care decisions, if the physicians are ultimately responsible for the health care decisions, and if the performance of the AI system is at least as good as that of physicians.

The study also has some implications for the question of the transparency of AI decision making in health care. The study clearly shows that a requirement of transparency cannot be dismissed on the grounds that in the eyes of the population, performance is the only significant concern. On the contrary, the population not only takes explainability to be considerably more important than performance, but it also puts significant

emphasis on other aspects of AI decision making. The mere fact that all aspects of the use of AI were considered somewhat important by the respondents could be taken to support the view that the transparency of AI decision making in health care should concern more than the narrow explainability of the AI decision. Transparency should also be a matter of providing patients with information about responsibility and testing for discrimination, performance, and the character of the use of AI.

Taking a more comprehensive approach to transparency fits recent writings on the ethics of transparency of AI use in health care. Thus, it has been argued that transparency in relation to AI-based diagnostics and treatment planning is a matter of providing patients with information that will enable them to effectively contest these decisions [32]. This includes information not only about the key indicators behind an AI-generated diagnosis or treatment plan but also about the performance of AI, bias testing, and the distribution of responsibility between physicians and AI systems.

Conclusion

This paper proceeded from the assumption that AI system performance and AI explainability/transparency are potentially in conflict. Currently, the decision making of the best-performing deep learning models cannot be fully scrutinized or replicated step-by-step. We believe this tension must be resolved in and through appropriate policy making, and we have argued here that an appropriate policy should consider the population's interests in and views concerning AI system features, such as performance and explainability/transparency. The findings of the choice-based conjoint survey reported in this paper are that if an AI diagnostic system does not perform any worse than a physician, then the 3 factors that are most important to the public are, in descending order of importance, (1) that physicians are ultimately responsible for diagnostics and treatment planning, (2) that the AI decision support is explainable, and (3) that the AI system has been tested for discrimination. A policy of AI system use in the health care setting should give priority to AI systems that can meet these requirements and should provide patients with information about the division of labor and responsibility between physicians and the AI system, the key explanatory factors in the AI system decision making, and the bias testing of the AI system. However, this study links the notion of AI explainability to the explainability of physicians' decision making. How AI system explainability can be achieved in a way that makes it relevantly similar to physician decision making is an obvious avenue for further research.

Abstract

Background: Self-monitoring food intake is a cornerstone of national recommendations for health, but existing apps for this purpose are burdensome for users and researchers, which limits use.

Objective: We developed and pilot tested a new app (COCO Nutritionist) that combines speech understanding technology with technologies for mapping foods to appropriate food composition codes in national databases, for lower-burden and automated nutritional analysis of self-reported dietary intake.

Methods: COCO was compared with the multiple-pass, interviewer-administered 24-hour recall method for assessment of energy intake. COCO was used for 5 consecutive days, and 24-hour dietary recalls were obtained for two of the days. Participants were 35 women and men with a mean age of 28 (range 20-58) years and mean BMI of 24 (range 17-48) kg/m^2.

Results: There was no significant difference in energy intake between values obtained by COCO and 24-hour recall for days when both methods were used (mean 2092, SD 1044 kcal versus mean 2030, SD 687 kcal, *P*=.70). There were also no significant differences between the methods for percent of energy from protein, carbohydrate, and fat (*P*=.27-.89), and no trend in energy intake obtained with COCO over the entire 5-day study period (*P*=.19).

Conclusions: This first demonstration of a dietary assessment method using natural spoken language to map reported foods to food composition codes demonstrates a promising new approach to automate assessments of dietary intake.

energy intake; macronutrient intakes; 24-hour recall; machine learning; convolutional neural networks; nutrition; diet; app; natural language processing

Introduction

National recommendations encourage self-monitoring of energy intake to support healthy weight management [1-3]. Mobile phone–based apps are widespread and include features like food imaging and portion guides [4-6]. However, none of the available apps appear to be more accurate or decrease user burden compared with earlier methods [7], and high user burden

combined with limited accuracy are major barriers to routine use. Moreover, high user burden is associated with modifications to usual eating habits that result in atypical energy and nutrient intakes during the measurement period [8].

The use of speech understanding technology for the assessment of food intake is in its infancy but has tremendous potential to reduce the burden of dietary assessment and increase method accuracy, in particular when combined with technologies to map reported foods to their appropriate food composition code for automated nutritional analysis. We have developed an app called COCO (Conversational Calorie Counter) Nutritionist [9], which combines natural spoken language with machine learning to enhance the capture of self-reported dietary intake and map it to food codes in widely used food databases. The primary goal of this study was to conduct a feasibility study evaluating COCO for measurement of energy intake compared to a recommended method [10].

Methods

Overview

This paper describes the first evaluation of COCO for automated self-reported dietary intake. The evaluation was conducted by nutrition research staff at the Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University in Boston, Massachusetts, with data collection and analysis implemented by individuals who had no role in the development of COCO.

COCO Nutritionist

COCO was developed primarily by two members of the research team (JG and MK) in collaboration with the nutrition researchers (SBR, SKD, and CG). A detailed description of the development of the app is provided in Multimedia Appendix 1. Briefly, COCO uses machine learning, specifically deep convolutional neural networks (CNN) [9], to accomplish two tasks: (1) tag each word in a user's natural language description of an eating event as a specific food/drink, with its quantity and brand name and/or description [11]; and (2) map each food item to a matching entity in one of several national food databases [12]. The databases used were the United States Department of Agriculture standard reference and branded foods [13], the University of Minnesota database [14], foods scraped from restaurant websites, and the Nutritionix database [15]. A front-end iOS app [16] makes calls to a back-end Python Flask [17] server that runs the trained CNN models.

Food database measuring units (eg, cup) and amount units (eg, 1, 2) are ranked using string matching. For example, if the user says "cup," it will rank the unit "cup" as the top match. If there are no exact matches, then it defaults to the unit that the user logged for that food item most often previously; if the user never ate that food before, then it defaults to the most popular unit logged by all users. Each user's food logs are stored in a PostgreSQL [18] database on Amazon Web Services [19]. Thus, a user's subsequent logs are customized such that the paired food codes and amounts of user-described foods they have eaten previously are ranked higher or at the top. The input is a spoken or written meal description (eg, "For dinner, I had a bowl of chili with cheddar cheese"). The output is a list of top-15 matching database foods per tagged food item (ranked according to the dot product similarity scores between a vector representing the user's description of the food they ate and a vector representing each food database entry), along with their ranked quantities (ranked according to keyword matching), predicted number amount (eg, 1, if the user logged "a cup"), and corresponding nutrition facts from the selected nutrition database, calculated for each food item. If there are duplicates for foods in different databases, the current system will return both, ranking based on matching the wording in the database versus the user's language.

Participants implicitly confirmed the top-1 food code and food amount proposed by COCO, by not making any changes, or they picked a more suitable food code from the database if the top food code was not the right match, by scrolling through a list of 15 options. If none of the presented options were a good match, participants could delete the food and repeat. A similar process was used for food amounts.

Evaluation of Participants and Informed Consent

Participants and Informed Consent

The research protocol for evaluation of the new COCO app was reviewed and approved by the Tufts Health Sciences Institutional Review Board, and informed consent was obtained from each participant prior to enrollment. In total, 35 participants were recruited using flyers, word of mouth, and emails to a mailing list of individuals requesting to be contacted about nutrition research study opportunities or expressing interest in the app. To be eligible, participants had to be at least 18 years old and generally in good health. Individuals were ineligible if they did not have an iPhone with iOS 10.2 or higher, were unwilling to log their food intake for 5 consecutive days and complete 2 diet recalls, or had a graduate degree in nutrition. Enrollment occurred between June 2018 and June 2019.

Evaluation Protocol

We developed an evaluation protocol for the COCO prototype that was consistent with recommendations for development of new food intake assessment tools [20]. Participants were enrolled in a 5-day study, and completed all components remotely. They were provided with a written overview of the study, including instructions on how to download and use the COCO app, as well as a short video providing tips on use. Participants were asked to use COCO to record the amounts and types of all consumed food and drinks for 5 consecutive days. The recording of intake could be completed using natural spoken language utterances or manual text entry. If a day of recording was missed, they were asked to log an additional day to complete a total of 5 days of entries. A member of the nutrition team (ST) called participants to schedule 2 calls for the 24-hour food recalls (one per day) on day 3 and later. The diet recalls were rescheduled if the previous day's food logging was missed. Each 24-hour dietary recall took approximately an hour to complete. Following completion of both diet recalls, participants were instructed to complete food logging for the remainder of the study.

The diet recalls used the recommended multiple-pass interviewer-administered method [10], and started with an uninterrupted listing by the participant of all foods and beverages consumed the previous day. In addition, the interviewer went through a forgotten foods list, querying the subject on categories of foods that have been documented as frequently forgotten, followed by a final probe listing all the food items consumed, confirming details of the food and serving sizes. A standard food amount booklet [21] was used to assist in portion size estimation of consumed foods. It has eight sections: (1) the forgotten foods list, (2) glasses and mugs, (3) bowls, (4) mounds, (5) circles, (6) grid and thickness blocks, (7) wedges, and (8) shapes and chicken pieces. The 24-hour diet recalls were analyzed using Food Processor (version 10.13.1; ESHA Research Inc).

Demographic questions were also completed by participants, including for age, sex, race, ethnicity, education, weight, and height. A study satisfaction survey on the use of the app was sent to participants to complete at the end of the study, and a US $20 gift card was mailed to their home address.

Analysis

Data from COCO on energy and macronutrient intakes by study day, amounts of information collected via text versus voice data capture, and percentage of food codes proposed by COCO and revised by participants were captured by the Massachusetts Institute of Technology development team without access to the 24-hour dietary recall data, and provided to the Tufts team for statistical comparison of the methods.

Data for the two days when both methods were performed were averaged for each method. Reported mean energy intakes and percent of energy from protein, fat, carbohydrate, and alcohol were compared between the two methods using paired samples *t* tests and Pearson correlations. In addition, for the COCO data obtained over 5 days, the time-distributed effects of energy consumption were evaluated in relation to the sequence of recalls and the day of the week using multiple pairwise comparisons of means with a Bonferroni correction. For comparisons across the number of recalls, we also used multiple comparisons of means, as well as simple linear regression with and without adjusting for weekday versus weekend effects, to examine time series trends in average energy consumption by the numbered recall performed.

All tests were performed for biologically plausible observations, defined a priori as 2-day average energy consumptions <5000 kcals (1 participant was excluded for implausibility). Analyses were performed using STATA (release 15; StataCorp LLC). The significance level was set at $\alpha \leq .05$.

Results

Participants were 25 females and 9 males with a mean age of 28 (range 20-58) years, and mean BMI of 24 (range 17-48) kg/m^2 (Table S1 in Multimedia Appendix 1). When comparing the 2-day averages of COCO and 24-hour recall, we found no significant difference in energy intake (mean 2092, SD 1044 versus mean 2030, SD 687 kcal/d; *P*=.70) or percent energy from protein (mean 16, SD 3 versus mean 17, SD 5; *P*=.54), fat (mean 35, SD 9 versus mean 36, SD 11; *P*=.27), or carbohydrate (mean 50, SD 11 versus mean 50, SD 9; *P*=.89) between the 2-day comparison of COCO and the 24-hour recall method (Table 1).

Table 1. Energy and macronutrient intakes and number of eating events reported with COCO Nutritionist and 24-hour recall (mean of the same two days for each method).[a]

Variables	24-hour recall (N=34), mean (SD)	COCO Nutritionist (N=34), mean (SD)	*P* value
Energy intake, kcal/day	2030 (687)	2092 (1044)	.70
Percent energy from protein	17 (5)	16 (3)	.54
Percent energy from fat	36 (11)	35 (9)	.27
Percent energy from carbohydrate	50 (9)	50 (11)	.89
Number of meals and snacks	4 (1)	4 (1)	.37

[a]Paired *t* tests were used to compare energy and macronutrient intakes across methods.

Mean values were very similar between the methods, as was the number of reported eating events (meals and snacks). On average, there were 4 items in the 24-hour recall that were not reported in COCO (components of composite food items and beverages), and 2 items in COCO that were not reported in the 24-hour recall (snacks, candy, and beverages), reflecting in part the different ways that composite foods (eg, a hamburger, consisting of meat, bread, and other items) were processed by the two methods. There were also significant Pearson associations between 2-day averages of COCO and 24-hour recalls for percent energy from protein (ρ=0.66; *P*<.001), carbohydrate (ρ=0.58; *P*<.01), and fat (ρ=0.38; *P*=.03), with R^2 values of 0.119-0.438 (Figure S1 in Multimedia Appendix 1).

As shown in Figure 1, there was no significant trend over time in reporting of total energy by COCO (*P*=.69), which remained insignificant when controlling for weekend versus weekday effects (*P*=.73). We additionally evaluated how participants entered data, and the accuracy of mapping foods to appropriate food codes. Most foods were logged by typing rather than by speaking (Table 2). Similar ratios of spoken and written descriptions contained mentions of brands or preparation technique, and the percentage was relatively low at ~15%. Spoken meal descriptions were more likely to mention the units of foods (36.1% versus 24.4%). Furthermore, because the editing function of COCO allowed for participant revision of the food type, brand, or description and unit amount (ie, 1, 2, or 3 cups), how often participants revised the COCO-suggested option was

also tracked (8.1% of the time for food name/description/brand and 27.9% of the time for unit amount).

Figure 1. Energy intake reported over 5 consecutive days through COCO Nutritionist (n=34). There was no significant trend in energy intake reporting (*P*=.19).

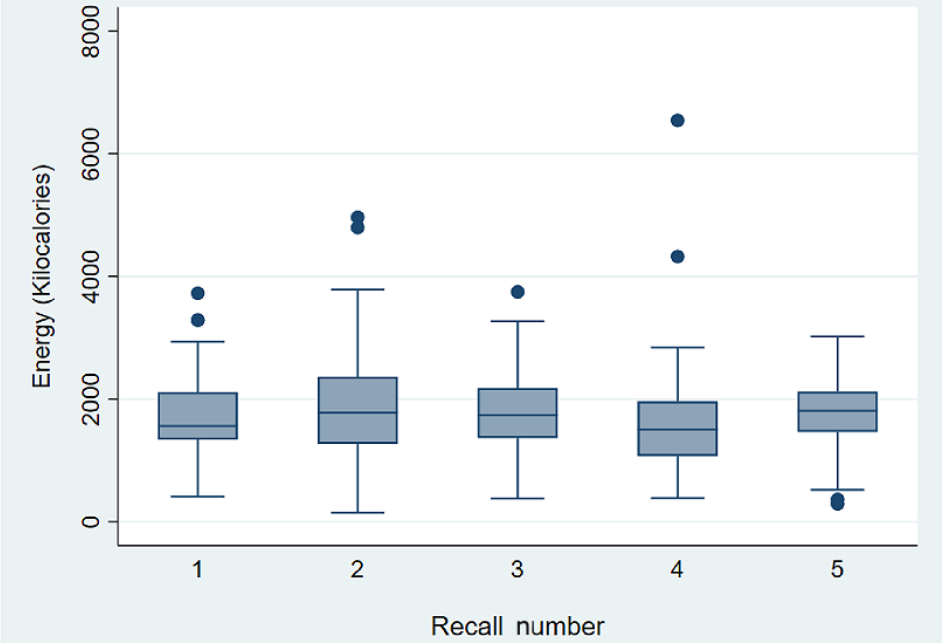

Table 2. Comparison of the food entities logged with spoken versus written natural language in COCO Nutritionist.[a]

Variables	Spoken	Written
Mean number of foods logged per person per day	1.38	7.06
Total of all logged foods, %	28.4	71.6
Mean percentage of foods with specified brands/preparation method	15.6	15.0
Foods with quantities, %	30.7	22.1
Food code identified correctly in default option, %	100	99.9
Food measuring unit (eg, cup) identified correctly in default option, %	83.5	84.1
Food amount unit (eg, 1, 2) identified correctly in default option, %	74.5	84.7

[a]Food code, units, and amounts measured correctly at first try are defined as the user not changing the default.

Discussion

Principal Findings

This study demonstrates that an app using natural spoken language to capture participant self-reports can be combined with automatic mapping of identified foods to information on food composition in national databases to generate estimates of mean self-reported energy and macronutrient intakes—and of the number of meals and snacks eaten—that are not significantly different from those obtained with the gold-standard multiple-pass, interviewer-administered 24-hour recall method. In addition, the lack of any negative trend in reported energy intake by the new COCO app across the 5-day study period was a positive indication that participants were able to complete their reporting without undue burden. To our knowledge, this is the first report of using natural spoken language to collect dietary data in a process that allows for mapping of collected information to food codes to support automated nutrient analyses. Although the data are preliminary, they suggest that this new approach may facilitate accurate, low-cost, and lower-burden methods for dietary tracking for health and weight management.

Comparison With Prior Work

A crucial aspect of this work was demonstration that data collected with natural spoken language can be automatically mapped to a suitable food code in national food databases, something that has not been done previously and allows for automated and instantaneous calculation of dietary intake. This novel feature of COCO will reduce the cost and user burden of dietary assessment, and distinguishes it from previous work using natural spoken language that had a dietician assign food codes to each consumed food [22]. Our demonstration of a relatively low percentage of revisions in the default mapping of collected information to food codes and portion sizes suggests that systems combining voice recognition and writing allow for flexibility in participant use, which may in turn enhance acceptance and sustainable use.

Limitations

Limitations of the study include a relatively small number of features in the COCO app, compared to fully developed apps that include food photography. In addition, the comparator method was self-reported dietary intake by 24-hour recall, which is considered a gold standard for dietary reporting but nevertheless may not reflect absolute dietary intakes. The population sample was relatively small in this first study, and one participant was excluded from data analyses for implausible reporting. Additional work is needed to further refine COCO and to compare collected data with dietary intake of known origin.

Concerning future improvements in COCO focused on making the system as helpful and low-burden as possible, a next step would be to implement a more sophisticated chatbot that can provide personalized food recommendations [23]. For example, the agent could respond if the user asks a question such as "How many calories are in a cup of milk?" or "How many grams of fat have I eaten today?" and recommend foods based on which nutrients the user is missing and their diet preferences. If the user is low in iron, the system could recommend, for example, spinach or steak (both foods high in iron), depending on prior food choices. In addition, taking photos of meals, which is simpler for some users than verbal logging, could provide complementary information to that provided by natural language. Multitask learning research has shown that neural networks trained on multiple input sources and prediction tasks (eg, one side may take an input image, while the other takes an input sentence) have improved performance on both modalities over using each separately [24]. Diet apps use computer vision already; however, to our knowledge, no one has combined language understanding with computer vision.

Summary

Self-monitoring food intake is a cornerstone recommendation in lifestyle interventions for weight management. However, self-monitoring food intake is burdensome with current apps, and frequently inaccurate. This first demonstration of using natural spoken language to map reports of food intake to food composition codes in national food databases and generate automatic assessments of dietary intake demonstrates a promising new approach to substantially reducing user and investigator burden in assessment of dietary intake while supporting the accuracy of reported data.

Acknowledgments

We thank the participants for their participation, and all the Massachusetts Institute of Technology students who contributed to the development of the COCO system, including James Allen, Elizabeth Zhou, Zachary Collins, Rupayan Neogy, Elizabeth Weeks, Liana Reilly, Jiahao Li, Matt McEachern, and Yada Pruksachatkun.

Conflicts of Interest

MK declares that a patent was received for commercialization of the spoken diet tracking algorithm. All other authors declare no conflicts of interest.

Abstract

Background: Academic literature highlights blockchain's potential to transform health care, particularly by seamlessly and securely integrating existing *data silos* while enabling patients to exercise automated, fine-grained control over access to their electronic health records. However, no serious scholarly attempt has been made to assess how these technologies have *in fact* been applied to real-world health care contexts.

Objective: The primary aim of this paper is to assess whether blockchain's theoretical potential to deliver transformative benefits to health care is likely to become a reality by undertaking a critical investigation of the health care sector's actual experience of blockchain technologies to date.

Methods: This mixed methods study entailed a series of iterative, in-depth, theoretically oriented, desk-based investigations and 2 focus group investigations. It builds on the findings of a companion research study documenting real-world engagement with blockchain technologies in health care. Data were sourced from academic and gray literature from multiple disciplinary perspectives concerned with the configuration, design, and functionality of blockchain technologies. The analysis proceeded in 3 stages. First, it undertook a qualitative investigation of observed patterns of blockchain for health care engagement to identify the application domains, data-sharing problems, and the challenges encountered to date. Second, it critically compared these experiences with claims about blockchain's potential benefits in health care. Third, it developed a theoretical account of challenges that arise in implementing blockchain in health care contexts, thus providing a firmer foundation for appraising its future prospects in health care.

Results: Health care organizations have actively experimented with blockchain technologies since 2016 and have demonstrated proof of concept for several applications (*use cases*) primarily concerned with administrative data and to facilitate medical research by enabling algorithmic models to be trained on multiple disparately located sets of patient data in a secure, privacy-preserving manner. However, blockchain technology is yet to be implemented at scale in health care, remaining largely in its infancy. These early experiences have demonstrated blockchain's potential to generate meaningful value to health care by facilitating data sharing between organizations in circumstances where computational trust can overcome a lack of social trust that might otherwise prevent valuable cooperation. Although there are genuine prospects of using blockchain to bring about positive transformations in health care, the successful development of blockchain for health care applications faces a number of very significant, multidimensional, and highly complex challenges. Early experience suggests that blockchain is unlikely to rapidly and radically revolutionize health care.

Conclusions: The successful development of blockchain for health care applications faces numerous significant, multidimensional, and complex challenges that will not be easily overcome, suggesting that blockchain technologies are unlikely to revolutionize health care in the near future.

Introduction

Background

In recent years, distributed ledger technologies commonly referred to as *blockchain* have generated considerable interest and excitement across many industries, including health care, supported by claims of their radically disruptive and transformative potential. Academic literature focusing on blockchain's potential to solve health care problems has proliferated [1-7]. Although scholars have identified many possible applications of blockchain in health care [8], blockchain's perceived value ultimately rests on its potential to create a highly secure, tamper-proof, auditable electronic ledger that can enable responsive, fine-grained, and privacy-respecting access to and sharing of health care data. Accordingly, blockchain is often portrayed as a technological solution that can overcome existing barriers to health information exchange [8], one of the most stubborn challenges that continues to plague contemporary health care [9]. Blockchain advocates claim that these technologies will generate higher quality, more trustworthy, and readily accessible data, which can drive improvements across health care [10]. These improvements would then lead to (1) better quality medical care, including improvements in clinical decision-making and more effective public health management and disease prevention [11]; (2) more efficient, cost-effective, and timely health care administration; and (3) improvements in medical and health care research, resulting from more accurate and secure clinical trial data management and storage [12]. In particular, many believe blockchain will enable fine-grained, patient-controlled access, sharing, and management of electronic health records (EHRs), thereby overcoming existing problems associated with the current *siloed* approach to the storage and management of patient data, which is often regarded as blockchain's *favorite use case* for health care [13,14].

The Blockchain for Health Care Promise: Rhetoric or Reality?

However, expecting blockchain technologies to provide an effective, efficient, patient-centered solution to the multiplicity of problems associated with health care data management and sharing is a tall order. This was one of the expected benefits of EHRs; however, despite their widespread take-up in health care settings, ethically sensitive, lawful, timely, and secure sharing and management of health care data remain a critical but seemingly intractable challenge [9,15,16]. Academic literature concerned with health care applications remains overwhelmingly centered on blockchain's *potential*, focusing on identifying the possible range of benefits that *could* be delivered. However, no serious scholarly attempt has been made to assess the extent to which these technologies have *in fact* been applied to real-world health care contexts and with what consequences, with little attention paid to real-world implementation challenges [17]. In short, academic scholarship remains largely speculative (Multimedia Appendix 1 [1,3,7,18]).

Technical Dimensions of Blockchain Technologies

Overview

To identify what blockchain technologies can and cannot realistically deliver, it is necessary to understand what these technologies are and how they function. Although computer security specialists ascribe a particular technical meaning to *blockchain technologies*, they are understood in a much looser, broader sense for the purposes of this study. In this paper, blockchain technologies refer to a time-stamped database, duplicated across a distributed network of computers (each computer in the network is called a *node*), which is configured such that its technical architecture and operation effectively prevent the rewriting and removal of prior entries. At a basic level, blockchains enable a community of users to record transactions (ie, an interaction between parties) in a shared ledger such that, under the normal operation of the blockchain network, no transaction record can be altered once published. These systems can, as the Bitcoin blockchain demonstrates, enable transactions between strangers without the need for a conventional trusted third-party intermediary, such as a bank or government. Instead, transactions between parties with no pre-existing relationship of trust are enabled by 4 key characteristics of blockchain technologies [19].

Ledger

The technology relies on an append-only ledger to provide a complete transactional history, which, because of its technological design, is almost impossible to amend or alter. This differs from a traditional database in which transactions and entries can be altered or overridden.

Tamper-Proof

Blockchains use cryptographic methods that rely upon mathematical consensus to confirm the consistency and technical authenticity of each transaction's digital record, which is then permanently recorded on the ledger and cannot be altered or deleted. The security and accuracy of the ledger are maintained through the use of cryptographic *keys* and signatures that automatically control who can do what with the ledger. If conflicts between different copies of the database arise (eg, because someone is trying to tamper with the data), the automatic consensus mechanism is designed to ensure that only transactions that are consistent with the earlier, stored version of the database are updated and permanently recorded. Distributed ledger systems that take the blockchain form aggregate transactions into *blocks*, and these are added to a *chain* of existing blocks using a cryptographic signature (hence the name *blockchain*). As the data stored on the ledger can be mathematically attested and cannot be tampered with, it is highly secure.

Shared

A copy of the ledger is replicated and shared across multiple participating nodes, providing transparency across the node participants in the network.

Distributed

As more nodes are added across the network, the ledger becomes increasingly resistant to malicious attacks because it becomes more difficult to interfere with the intended operation of the consensus protocol through which transactions are validated and appended to the ledger. The resilience of the ledger is rooted in its distributed nature. In contrast, conventional databases are based on a centralized, hierarchical design, thus creating a single point of failure.

Blockchain systems can be designed to operate in many ways because of the malleability of the software and protocols through which they are configured. Blockchains may be *permissionless* or *permissioned*, referring to who is entitled to become a network node. Within permissionless blockchain networks, anyone with a computer that has sufficient computing capacity can download the software and participate in the consensus process, storing and updating the shared ledger (referred to as *write* access) without needing permission to do so. As write access is *open* to all for permissionless blockchains, anyone can also *read* or otherwise inspect the ledger. In contrast, permissioned blockchains restrict write access: only those granted advance permission by the relevant authority within the network can participate in the consensus process through which the shared ledger is updated and stored. For permissioned blockchains, the ability of others to *read* and inspect the ledger may be *open* to anyone or can be restricted or *closed* so that only those with authorized access may read its contents. Permissioned blockchains can provide similar functionality to permissionless blockchains but are considerably less computationally demanding. As participating nodes must first be identified and authorized before joining a permissioned network, this provides an assurance of trust across the network, backed by the threat that write access can be withdrawn from misbehaving nodes. As a result, consensus models applied within permissioned blockchains need not provide the same high levels of mathematical and computational security. Therefore, they offer faster performance and are computationally less expensive [19].

The elasticity and malleability of blockchain systems, including the variety of different forms and functionalities that they can offer, has resulted in considerable variation in the way the term *blockchain* is used, particularly in discussions about blockchain for health care. The very broad definition of blockchain adopted here reflects the health care sector use of the term, encompassing any sociotechnical system that uses a distributed, append-only database that relies on cryptographic methods to verify and validate transactions before they are added to the ledger, including both permissioned and permissionless systems, which include distributed ledger technologies that do not aggregate and store data into linked blocks [13].

Aims, Objectives, and Research Questions

The aim of this study is to critically investigate the health care sector's engagement with blockchain technologies to date, analyzing those experiences from a theoretical, cross-disciplinary perspective to ground a more realistic appraisal of the potential benefits, difficulties, and implications of implementing blockchain in health care settings. This investigation was animated by the following research questions:

1. To what extent and in what ways have blockchain technologies been taken up in the health care sector?
2. What are the primary real-world opportunities and challenges that blockchain technology generates in health care contexts?
3. What are the prospects of blockchain take-up and implementation in health care settings to solve real-world problems in the short to medium term?

Taken together, these questions can be amalgamated into a single overarching research question: what does health care's actual experience of blockchain technologies to date reveal about the technologies' *real* revolutionary potential [20]?

This paper proceeds by outlining the study's design, data sources, analytic approach, and theoretical foundations. It then sets out its findings by first providing a qualitative overview and explanation of the extent to which blockchain technologies have been taken up in the health care domain. Second, it offers a critical examination of a series of multidimensional challenges, organized thematically, that constitute (or are likely to constitute) very substantial hurdles that must be overcome if blockchain is to be widely taken up in health care settings. Finally, it discusses these challenges in light of the most promising opportunities for generating real value in health care settings and suggests that the use of blockchain to provide fine-grained patient control over medical records is unlikely to live up to its perceived promise.

Methods

Study Design and Data Sources

The mixed methods study reported in this paper forms the major component of a Wellcome Trust–funded cross-disciplinary project aimed at understanding the challenges, risks, opportunities, and experiences of the health care sector in using blockchain technologies. It took the form of a theoretical investigation, building upon the initial research study by Motsi-Omoijiade and Kharlamov [21] that sought to identify and map evidence of real-world engagement with blockchain technologies in the health care sector, classifying them according to their context of application (as patient care support, administration, or research data management), level of maturity, and the primary geographic region from which the application appeared to originate. The integrated catalog of health care blockchain applications and use cases created in that study provided a snapshot of the state of health care blockchain take-up on November 30, 2019. It identified 128 *applications*, referring to real-world instances in which blockchain technology has been developed into a commercially viable health-related service created largely from a web-based review of English

language websites, gray literature, and academic papers (Multimedia Appendix 2 [21-28]). This study builds on the results of that earlier mapping and classification exercise by drawing on 2 focus group investigations and a series of iterative, in-depth, theoretically oriented desk-based investigations.

Focus Group Workshops

The 2 focus group discussions were organized in which a mix of both academic researchers and blockchain-for-health care sector experts participated. The first workshop, hosted at the outset of the project, was designed to generate insights that could inform and guide the direction of the study's inquiries and help understand the current state of health care sector engagement and experience with blockchain technologies for specific health care purposes. The second workshop occurred toward the end of the study. Its aim was to share the provisional study findings with participants to elicit their critical feedback and provoke discussion. The focus group participants were identified and invited with the aim of bringing wide-ranging, relevant expertise to the discussion, given the project's aim of adopting a multidisciplinary perspective to address the project's research questions. This approach to recruitment reflects a belief that technical, legal, ethical, management, clinical care, and health service industry knowledge and experience would be needed to successfully apply blockchain to real-world settings.

The participant invitation list was compiled from the principal investigator's existing knowledge of academic experts with existing or related interests in blockchain from several disciplinary backgrounds, combined with a light touch review of recent academic and digital health care industry publications to identify key health care sector experts with direct and ongoing experience in seeking to apply blockchain technologies to health care. This initial list was supplemented by the use of snowball sampling techniques (asking each academic and industry invitee to nominate 1 or 2 colleagues) to identify others with relevant expertise. The specific composition of the workshops differed in light of their different objectives and participant availability: the initial workshop comprised more academics than industry experts, whereas the final workshop was attended predominantly by industry experts relative to academics (Multimedia Appendix 3).

Desk-Based Review and Theoretical Investigation

The project's theoretical, desk-based investigations primarily drew on 2 data sources. First, the investigations drew from a wide variety of academic literature from multiple disciplinary perspectives, including computer science, computer security, digital health, organizational management, operations research, medical law, data protection law, medicine, medical sociology, and innovation studies. Given that relatively little information about health-related blockchain projects is publicized via academic journals [29], and existing scholarly literature on blockchain in health care settings has not hitherto been concerned with real-world engagement and experience, relevant academic sources were identified by deductive critical reflection. This entailed developing and refining a series of thematically focused investigations aimed at acquiring a deeper, more fine-grained, cross-disciplinary understanding of the major issues and challenges that would invariably confront those endeavoring to apply blockchain to health care settings. These included matters of data security and integrity, health information technology (IT) implementation, user resistance, internal and external governance, interoperability, organizational management, and data privacy. Second, gray literature (including observations and reflections from those with direct experience of the health sector's engagement with blockchain to date) provided a vitally important source of insight, given that the published scholarly literature represents only a small snapshot of global blockchain activity. This literature included reflections collected from various informal sources, such as guidance and opinion pieces published in various formats, including essay collections [30], blog posts, news articles, newsletters by industry bodies (particularly those published by the Healthcare Information Management and Systems Society [HIMSS]) and key industry experts from organizations offering blockchain for health care consultancy services such as Consensys Health and Hashed Health.

Analytical Approach

This study proceeded from the premise that blockchain's reliance upon cryptographic techniques and networked, distributed computing facilities to provide a highly secure, shared but tamper-proof database means that its foundational value lies in its capacity to facilitate *secure data sharing and collaboration*, particularly between parties in circumstances where a lack of social trust would otherwise inhibit cooperation. So understood, the development, implementation, and scale up of blockchain technologies into health care contexts are likely to pose distinctive and novel challenges because of both its technological design and the health care contexts in which attempts are being made to implement it.

The analysis proceeded in 3 stages. First, it began by seeking to acquire a deeper, more qualitatively oriented understanding of the observed patterns of blockchain for health care engagement mapped from the Motsi-Omoijiade and Kharlamov [21] study. These first-stage inquiries drew heavily on insights and observations contained in industry publications [29], government reports, mainstream media, and initial focus group discussions. The resulting analysis produced a clearer, richer, and more nuanced understanding of (1) how blockchain technologies were intended to provide specific functional capacities across a variety of real-world health care contexts; (2) the range of applications, context-domains, and participants who were expected to engage with and those expected to benefit from these applications; (3) how blockchain was expected to address specific data-sharing problems encountered in health care settings; and (4) the wide-ranging and multidimensional difficulties or *challenges* that have been encountered in the course of these engagements to date or that can be expected to arise if those engagements continue to expand and deepen, particularly if they extend into clinical settings.

The second-stage analysis entailed a critical comparison of the benefits, difficulties, and drawbacks identified in stage 1 against the claims appearing in the academic literature about blockchain's potential benefits and shortcomings (both generally and those specific to health care). This analysis sought to evaluate these claims, which were focused almost exclusively

on the benefits of blockchain, with little mention or consideration of shortcomings, against early-stage experiences with blockchain implementation in real-world health care settings. The resulting mismatch between academic claims and actual experiences of the technology prompted further scrutinization and critical analysis of the implementation problems identified from the first-stage analysis, grouping them together thematically (rather than primarily in relation to specific functional applications or particular kinds of health care data). This grouping was based on recurring difficulties and challenges that have been encountered (or are likely to arise in relation to specific health care applications, particularly those that directly affect clinical practice) in seeking to design, configure, and implement blockchain technologies in health care settings. The encountered challenges were typically multidimensional in character, entailing dynamic interacting and often complex technical, social, regulatory, and organizational difficulties that would need to be addressed successfully before the technology is likely to produce significant value for health care.

The final stage of analysis sought to develop a more theoretically grounded account of the observations generated at the second stage analysis, drawing upon different fields of scholarship, including academic discussions focused on blockchain's *revolutionary* potential; the nature, dimensions, and challenges of innovation more generally; and of health IT implementation in particular (including studies of EHR implementation). The aim was to produce an integrated, theoretically informed, cross-disciplinary understanding of the experience of the health care sector's engagement with blockchain technologies to date, providing a firmer foundation for appraising its prospects by reference to the underlying nature and form of coordination that blockchain technologies currently enable.

Theoretical Frame

The theoretical framework for this study draws primarily on 3 different but complementary perspectives that collectively contribute to addressing the project's overarching research question. First, it draws upon the growing cross-disciplinary literature that has typically emphasized blockchain's *revolutionary* potential to enable novel forms of social cooperation between strangers without the need for a trusted third-party intermediary. Blockchain's potential to enable *trustless* cooperation is ultimately attributable to its underlying technological architecture and distributed operation to produce a shared database that is effectively tamper-proof, enabling the replacement of social trust with computational trust in specific contexts. This has prompted some scholars to describe blockchain as a *truth machine* [31]. More recently, however, a more skeptical strand of literature has started to emerge, drawing attention to a wide range of reasons why the technology may fail to live up to its promise [32]. As these inquiries progressed, it became necessary to look to a wider variety of literature to make sense of these real-world implementation challenges. This led to the investigation of a second body of academic scholarship located within the field of *innovation studies*, a different multidisciplinary strand of work that includes a wide range of industry studies that demonstrate that technologies do not arise in the fully developed form [33-35]. Instead, they find that a period of considerable confusion usually follows the emergence of a new technological invention, with little agreement about what its major subsystems should be or how it can best be put together as a product or service, resulting in significant experimentation [36,37].

Health care's current and ongoing engagements with blockchain can be located within this early experimental phase, situated at the entrance to the so-called *valley of death*. This refers to a *gap* between the development of new scientific knowledge and the establishment of proof of concept but before full development and commercialization [38,39]. Industry estimates suggest that 4 in 5 new inventions are never commercialized because of their failure to overcome numerous *barriers to innovation* encountered during this crucial development phase [40,41]. Innovation studies scholars have identified multiple *valleys of death*, which they have explored from various angles. Some understand the valley primarily as a financing and funding problem that arises after the establishment of a proof of concept. At that moment, significant investment is required to scale up; however, there is considerable technical and commercial uncertainty about its likely success, which thus discourages further investment [34]. Occasionally, this leads to various policy prescriptions, such as government funding initiatives and *translational* centers comprising academic and commercial stakeholders, to help bridge the gap [42]. Others focus on the difficult transition of university research to a product or service brought to market by a commercial firm, particularly in the case of drug development [43].

For the purposes of examining the prospects of blockchain in health care, the most salient strand of this literature is concerned with identifying the *barriers to innovation* that create and contribute to the valley of death. Scholars have classified these barriers as either *internal* to the organization (including factors such as a restrictive mindset, lack of competence, insufficient resources, and an unsupportive organizational structure) or *external* and thus largely beyond the firm's direct control (including factors such as a paucity of external finance; resistance or lack of support from specific actors, such as customer resistance or an unsupportive government; and various factors which result in a restrictive macroenvironment, such as an undeveloped network and ecosystem, technological volatility that narrows the window of opportunity during which an innovation can be introduced, inappropriate infrastructure, and a restrictive local culture) [44]. However, these largely generic, rather abstract, accounts of various obstacles that must be overcome for technological innovations to largely succeed treat the underlying technology as a *black box* rather than engaging with technological design and specific development challenges in seeking to configure and embed the technology into sector-specific social and organizational systems, processes, and practices [45,46].

Rather than treating blockchain in health care as a closed *black-box*, these theoretical investigations drew upon a third set of analytical lenses situated within academic investigations of health care IT system implementations, particularly studies undertaken from a *social practice* perspective [45,47-49]. These studies highlight the critical role of context, culture, and the values that are brought to bear by medical professionals in clinical environments, identifying clinical consultation as a

complex social encounter that occurs within a heavily institutionalized environment [50]. In particular, scholars from these traditions emphasize the role of values in clinicians' understanding of what constitutes and how they seek to practice *excellent care*. Moreover, they stress the nature of clinical knowledge as *tacit, context bound, and ephemeral rather than codifiable, transferable, and enduring* such that the implementation of health IT into clinical settings often departs substantially from those envisaged by system developers and designers [50]. Accordingly, insights of this kind cast significant doubt on the capacity to hard code norms into technological systems in ways that can be seamlessly integrated into clinical environments, especially when these norms concern the sharing of health data, which is typically and legally understood as highly sensitive and worthy of special protection.

Results

Overview

The results of this study are presented in 3 parts, which correspond with the study's analytical approach outlined in previous sections. First, it briefly describes the health care sector's engagement with blockchain technologies to date in the United States, United Kingdom, and at the transnational level. Second, it critically reflects upon a series of 6 challenges that must be overcome and 3 normative trade-offs that must be satisfactorily resolved if blockchain technologies are to cross the *valley of death*, transitioning successfully from *invention* to *innovation* in health care settings. Third, it critically discusses key findings by referring to a selection of wider academic literature concerned with organizational cooperation and radical versus incremental technological innovation and reflects upon the promises of patient-controlled blockchain-enabled EHRs before offering some concluding reflections.

Interrogating Blockchain in Real-world Health Care Contexts

The Motsi-Omoijiade and Kharlamov study [21] revealed that, apart from the Estonian government's eHealth initiative [22], active engagement with blockchain technology in health care began around 2016, primarily in the United States and, to a lesser extent, in Europe, with several recent initiatives occurring at the transnational level. As of November 30, 2019, their study had identified 128 health care blockchain applications (in which a blockchain *application* is defined as providing a specific functional health care purpose so that a single blockchain system might provide multiple applications) from an English-language website review, over half of which were geographically located in the United States (65 applications), with the United Kingdom as the next most popular site of activity (12 applications) [21]. However, less than half of these had a commercially available blockchain product or service, with most still at the experimental or development stage. Of these applications, a substantial minority (50/128, 39.1%) focused on applications to enable user-controlled access to some kind of personal health data, with a significant proportion concerned primarily with using blockchain to facilitate health care administration (34/128, 26.6%) and support for patient care or health management (primarily in facilitating remote care consultations between patient and clinician located elsewhere) or in the form of *wellness* applications to encourage healthy behaviors (31/128, 24.2%) and for medical research data management (13/128, 10.2%; Multimedia Appendix 2).

A closer examination of the technical and contextual dimensions of these applications and their primary sources of funding revealed that, first, the overwhelming majority of blockchain for health care initiatives had used permissioned or hybrid systems, in which the tasks of sharing and updating the ledger are restricted to those authorized to do so. Second, in both the United States and the United Kingdom, private sector investment and funding have been driving these initiatives, although various government programs support blockchain initiatives, including funding support [51,52]. Although some early initiatives sought to generate funding via an *initial coin offering*, including start-up firms claiming specialist blockchain expertise, these have failed to generate positive returns for investors (and a significant number of initial coin offerings generally were merely vehicles for fraud) [23,53]. More recently, investment funding has been provided by venture capitalists, evidencing their confidence in the technology's potential value to the health care sector. The commercial and entrepreneurial expertise that they bring to the sector might help the fledgling industry navigate the fraught and uncertain early development phase [54,55]. Third, the current and ongoing focus of interest in blockchain for health care, at least in the US context, has been predominantly at the intraorganizational and business-to-business (B2B) level rather than being primarily concerned with clinical care provision. Much of this activity has primarily concerned blockchain systems for managing *nonclinical* data, as health care providers explore the capacity to harness blockchain technologies to enhance administrative and operational efficiency. Fourth, by comparison, the UK health sector's experience and engagement with blockchain technology has been far more muted, with only a handful of initiatives, all at the pilot or early-stage implementation phase. These initiatives are primarily for patient care management, with very limited reliance on blockchain functionality. Finally, several promising transnational blockchain initiatives to facilitate medical and health research have been launched in recent years. The following discussion briefly outlines the US and UK experiences (as the 2 most active sites of blockchain engagement in health care) and more recent transnational blockchain initiatives.

The United States

In the United States, ongoing blockchain activity in health care is coalescing at the intraorganizational and B2B level. These applications are intended to facilitate data sharing between business units within the same umbrella health care organization or within recently established consortia of health care organizations seeking to cooperate in the sharing and management of specific forms of health care data stored via a blockchain-enabled ledger [55]. The primary drivers supporting blockchain development to date appear to have focused on its potential to reduce costs and enhance efficiency in health care administration and operations. These applications are broadly concerned with either health care operations management, primarily in the management of supply chains, or administrative data pooling.

Turning first to health care operations management, considerable blockchain activity has occurred either to streamline and automate internal operational processes or to improve the efficiency and verifiability of supply-chain management [29,56]. Examples of the former include the Coalesce Health Alliance consortium's development of blockchain to improve the accuracy and efficiency of patient health care claims management across different entities within the Blue Cross Blue Shield ecosystem [57]. Similarly, the US Department of Health's Office of National Security has built a blockchain providing organizational units with linked, real-time access to a standard set of spend data to improve the department's procurement process, reportedly generating major efficiency gains [58]. In health care supply chain management, significant blockchain activity has occurred to address the potentially serious risks of a compromised health care supply chain [56]. The Food and Drug Administration has actively encouraged these applications by launching a pilot project (announced in February 2019) to encourage drug supply chain stakeholders to develop digital systems to comply with the Drug Supply Chain Security Act 2013, which mandates the creation of an electronic, interoperable system that can trace and identify distributed prescription drugs across the United States. It attracted 26 participants (including several pharmaceutical supply chain stakeholders [59,60]), generating a variety of projects. These include the MediLedger Project, which sought to build a blockchain network around a tamper-proof ledger of pharmaceutical supply-chain transactions to inform responses to product ID verification requests communicated via a permissioned messaging network [61]. The Pharmaceutical Utility Network has taken a different approach, pursuing a *platform first* strategy [61,62] rather than focusing on a specific *use case*. It is developing an open-source blockchain platform that integrates regulatory requirements (such as the Drug Supply Chain Security Act) to enable those involved in the pharmaceutical supply chain (including pharmaceutical manufacturers, distributors, dispensers, and software vendors) to use the platform's services to demonstrate compliance with regulatory requirements, seeking to use blockchain as a form of *RegTech*. [63,64] Other supply-chain management blockchains in the health care sector focus on single use cases, often with some RegTech functionality, such as the Clinical Supply Blockchain Working Group's platform [65], which is now seeking to apply its blockchain-based inventory and event-tracking system to a real clinical trial [66].

Blockchain applications are also being used to facilitate administrative data pooling at the intra- and interorganizational levels. Health care consortia in the United States began emerging in 2018, seeking to use blockchain either to create a single ledger shared between member organizations to serve as a single source of *truth* or to enable network members to create a shared pool of records to which access is controlled and recorded via the blockchain. For example, the Synaptic Health Alliance [67] aims to use a blockchain network to address costs, delays, and inefficiencies in provider directory data (comprising demographic information about physicians and other providers), which insurers are required by federal law to maintain and keep up to date. Each insurer has typically maintained its own directory; however, these often contain inaccurate data, resulting in delayed claims and payment processing. Synaptic's blockchain pilot seeks to create a common source of *truth* for provider directory data created by pooling and comparing each member's directory data to create a complete, accurate shared directory.

Similarly, the Professionals Credentials Exchange (ProCredEx) is a consortium of health care organizations seeking to enhance the efficiency of the physician credentialing process [57]. In the United States, when a new physician is hired or begins working for a new payer's network, the employing health care organization must gather a wide variety of certificates and credentials, a process that takes up to 6 months (sometimes longer), with physicians often required to supply evidence of their professional credentials to a dozen different organizations or more, which must be repeated for all physicians every 2 years by each organization [29]. The ProCredEx blockchain network enables organizations to contribute their credentialing records (essentially, a digital asset) to a shared pool, effectively creating a members-only digital asset exchange so that members can access verified credentials and actively contribute credentials information that other members can acquire. The shared ledger tracks asset ownership, exchange, and use and forms a basis for asset reputation. Buyers of these information assets finance the platform, whereas curators of the assets receive payment for their contributions, as do partners who help facilitate the use of the blockchain network [68,69].

The United Kingdom

In comparison with its US counterpart, interest in blockchain in UK health care has been considerably more limited [70]. The UK blockchain use cases have been directed at patient care management largely outside the clinic, in which secure and auditable data sharing remains the central functionality provided by blockchain technologies. Unlike the United States, UK health care is delivered primarily via a publicly funded National Health Service (NHS), in which NHS hospital treatment and primary care are free at the point of use to UK residents. Decisions about the commissioning of services, including the use of new technologies, are taken primarily at the local level by entities known as clinical commissioning groups or exceptionally at the national level by NHS England, which is informed by guidance issued by the UK's National Institute for Health and Care Excellence [71]. The NHS Long Term Plan states that the NHS will seek to "make better use of data and digital technology" [72] as part of the NHS digital transformation agenda; however, it makes no explicit reference to blockchain technologies. However, the NHS England's Director of Digital Development has been reported as having a general interest in considering blockchain as one of a variety of technologies that the NHS will explore [73].

Nevertheless, NHS England has commissioned Dovetail Labs to develop a novel digital application to enable different members of a multidisciplinary team working with type 2 diabetes patients to share health information. The application operates via a distributed ledger that logs patient consent to share digital data along with user authentication, data access, and transfer records [74,75]. In addition, at least two local clinical commissioning groups have commissioned small-scale

digital applications that are described as using blockchain technology. Hence, a partnership between Guardtime and Instant Access Medical and Healthcare Gateway has produced a comprehensive blockchain-supported personal care record platform (called *MyPCR*). The platform is intended to assist patients in managing chronic long-term health conditions by issuing digital alerts to help them adhere to their personalized treatment plan or personal care pathway via a smartphone app, granting patients complete access to their personal care pathway while generating an automated tamper-proof record of health data provenance and integrity that is compliant with data protection legislation [76]. Similarly, MedicalChain has launched a blockchain pilot enabling patients to create a free wallet to manage access to their digital health records, enable general practitioner video consultations, and enable them to pay for services using cryptocurrency (with users incentivized to pay for telemedicine services with Medicalchain's MedTokens) [77,78].

Transnational Blockchain Systems

At the transnational level, a rather different kind of blockchain application has emerged, which enables network members to run secure but privacy-preserving computational analyses on the data of other members to improve their algorithmic models for research purposes while the data never leaves the host organization [79]. For example, members of the Machine Learning Ledger Orchestration for Drug Discovery blockchain network, comprising 10 large pharmaceutical companies, 5 technical partners, and 2 universities, use blockchain and federated learning to train an algorithm to identify a rare mutation in cancer, enabling pharmaceutical companies to collaborate on therapeutic drug discovery. Each pharmaceutical company can, via the network, run the machine learning algorithms of their academic partners on each other's data sets. The data remain at their local site so that proprietary information from one data set cannot be leaked to another. Nonsensitive algorithmic models are exchanged between the members, which are then collectively consolidated to improve the predictive performance of the algorithmic models by leveraging all the data across the federation. A permissioned blockchain tracks and logs all operations taking place on the federated data using a software framework (Substra) for enabling the execution of distributed machine learning tasks in a secure way. The value of collaboration is particularly evident in attempts to develop drug treatments for rare diseases: each individual organization will have too few patients with a given rare disease to undertake statistically significant analysis; however, by pooling access to their data to enable federated learning, collaboration without data sharing becomes possible. Similarly, the AI Centre for Value-Based Healthcare consortium has created a federated learning network with patient data from 4 hospitals and 3 universities, allowing research partners to train algorithms on the federated data set. Collaborations of this kind, which use blockchain networks to facilitate privacy-preserving, federated data access, offer considerable promise to advance medical research [29]. Health care blockchain industry expert Robert Miller [80] observes the following:

> *Health data is inherently sensitive, and thus demanding of privacy. Yet at the same time health data is inherently statistical, and thus holds within it insights that could improve health for all. The promise of federated learning is to unlock these insights without compromising on privacy. Moreover, federated learning will enable us to assemble more data than ever in federated networks, leading to better algorithms and ultimately better outcomes.*

Challenges for Blockchain Take-up and Implementation in Health Care Settings

Overview

We have seen how the health care sector is beginning to develop viable blockchain applications for specific health care purposes and contexts to establish proof of concept, which are yet to be widely implemented at scale [58]. This invariably invites questions about the prospects of blockchain's sector-wide take-up, implementation, and diffusion, particularly given the limited success of health IT adoption more generally [81]. To begin addressing these questions, a set of 6 interrelated *implementation challenges* associated with seeking to implement and integrate blockchain into real-world health care contexts were identified using the methodological approach described above. Of these, 3 challenges were already being encountered in seeking to use blockchain technologies to facilitate the sharing and collaboration of health care data for administrative and research purposes, namely (1) organizational commitment, (2) interoperability and standardization, and (3) internal governance. A total of 3 additional emerging challenges are likely to be particularly acute if, in the future, sustained attempts are made to introduce blockchain technologies into clinical settings for which only modest experimentation has occurred to date, namely (4) data security and integrity, (5) quality and safety, and (6) truth and immutability (Textbox 1).

In addition to these implementation challenges, 3 further *normative tensions* or value conflicts invariably arise in configuring blockchain technologies to meet specific functional requirements in health care contexts, which were also identified (Textbox 2). Accordingly, acceptable compromises between competing objectives and values must be identified in an attempt to apply blockchain to real-world settings that can be designed into the software and system architecture and implemented into specific organizational contexts [82].

Textbox 1. Blockchain in health care implementation challenges.

Implementation challenges

- Organizational commitment
- Interoperability
- Internal governance and standardization
- Data security and integrity
- Quality and safety
- Truth and immutability

Textbox 2. Normative tensions requiring resolution in applying blockchain to health care.

Normative tensions

- High performance and scalability while providing adequate security
- Providing transparency and accountability while ensuring due respect for privacy and confidentiality
- Establishing computational trust while securing adequate social trust between network participants

Common to each of these challenges and normative tensions is their multifaceted, dynamic, context-sensitive, and complex character, comprising both technical and nontechnical dimensions. Moreover, addressing these challenges typically requires internal organizational adaptations *and* changes external to the organization because of the inherent character of blockchain as a *process* innovation [83], particularly when used to facilitate trustworthy data sharing beyond organizational boundaries. Each of these challenges is outlined below, beginning with 3 near-term challenges, followed by a brief discussion of 3 further challenges that are likely to be particularly acute if blockchain applications are applied in clinical contexts.

Organizational Commitment

The decision by any organization to adopt a new IT system is not made lightly. Making a commitment to experiment with a technology to establish proof of concept as a bounded, time-limited project is likely to be considerably easier for an organization than committing to implementing a novel technology on an ongoing basis, particularly for health care organizations [84]. Difficulties associated with eliciting the funding and commitment necessary to move a technological invention beyond the proof-of-concept stage are one of the characteristic features of the so-called valley of death described above. For organizations, this requires a compelling business case demonstrating that such a move will generate significant, sustainable net gains (such as increased revenues, reduced costs, or better-quality patient care) to justify the substantial investment and risks associated with doing so [85,86]. Given that the nature and magnitude of benefits of blockchain for health care remain largely unproven, and experience has shown that implementing health IT programs involves a great deal of time, money, and effort, making such a case will be difficult [9,81,85,87]. When proposed to support administrative functions, such as supply-chain management, the cost of blockchain adoption and implementation may be difficult for an organization to justify, as the expected benefits take the form of enhanced compliance and, hopefully, lower costs and reduced risk, all of which are difficult to quantify. For example, consider difficulties in quantifying the value gained from using blockchain-enabled pharmaceutical supply chains to reduce the risks associated with the production of fake medicines whose scope and prevalence are not well-known, and alternative cheaper technologies which may be more attractive [29]. Organizations willing to attempt blockchain implementations will also need to join a suitable network of participants willing to align and collaborate over a common interest in a particular kind of health care data via a blockchain network and avoid generating significant user resistance from staff. Neither task is likely to be easy [30,32,88-90].

Nonetheless, the proliferation of health care consortia in the United States, throughout 2019 and early 2020, seeking to develop blockchain-based collaborations over administrative data suggests that a variety of health care organizations increasingly recognize the potential value of blockchain-based data sharing for administrative and research purposes. The use of blockchain-enabled data sharing to support highly labor-and time-intensive administrative processes (such as provider credentialing) could significantly enhance administrative efficiency and reduce workloads. As one leading commentator has observed, almost every insurance company and pharmaceutical company has announced participation in a cooperative data-sharing health care consortium, including health systems, IT companies, and nontraditional health care companies such as PNC Bank and Walmart [91]. However, blockchain applications that have gained the most organizational buy-in have either avoided sharing of patient data, focusing instead on collaboration over administrative data, or have involved research collaborations that share and manage patient data in a privacy-preserving manner.

This points to a further hurdle that is likely to arise in eliciting organizational commitment: the need to ensure that blockchain applications comply with applicable legal and regulatory requirements, which are especially demanding in relation to

clinical applications. Legal requirements that apply to patient-related health care data and the broader regulatory environment in which health care is provided are substantial, complex, and often difficult to navigate, both in the United States and Europe. Accordingly, ensuring that blockchain-enabled *clinical* applications demonstrably comply with applicable laws will be very challenging [9,92]. That said, blockchain advocates place considerable optimism in *smart contracts*—computer programs that automate the verification, execution, and enforcement of certain terms and conditions of an arrangement, built on top of a blockchain system that enables a distributed ledger to function as a distributed computer [8,93-95]. Accordingly, blockchain systems in combination with smart contracts could operate as a form of *RegTech* through which compliance with legal and other regulatory requirements can be *hardwired* to execute automatically. However, whether these technologies will live up to this potential, given the messiness and unpredictability of real-world contexts, remains unknown [96,97]. Overcoming each of these barriers to organizational commitment presents formidable challenges and taken together, generate major obstacles that lie in the path of successful blockchain innovation and diffusion in health care [98].

Interoperability and Standardization

Another significant obstacle that continues to frustrate health care data-sharing efforts is the lack of interoperability within and between health IT systems [99]. This is equally true for blockchain-based data management systems. HIMSS explains that, for the purposes of a health data ecosystem, interoperability is "the ability of health information systems to work together within and across organizational boundaries in order to advance the effective delivery of healthcare for individuals and communities." HIMSS [100] notes that:

> *In the healthcare space, interoperability is important across systems and organizations for information to flow seamlessly between actors like patients, doctors, hospitals, payers, etc. However, it has been one of the hardest challenges healthcare has faced as vendors, providers, policies, payers and patients have, at times, set roadblocks up and created misaligned incentives to achieve true exchange of data between disparate systems. Realizing the benefits of blockchain technology depends on the associated network of healthcare organizations being able to share data and collaborate via the blockchain. These net-new requirements increase the scope of interoperability challenges that pre-dated blockchain. When systems are not interoperable, the cost of verification and networking of the information is very high. The same is true for the cost of settlement and reconciliation of the transactions of information.*

To maximize the capacity for data sharing, *full* interoperability between blockchain systems is needed; however, achieving this remains a very long way off and arguably will forever remain an impossible dream [101]. Interoperability in relation to health care IT can be understood at 3 levels. First, foundational interoperability allows data exchange from one IT system to be received by another without needing the receiving IT system to have the capacity to interpret that data. Second, structural interoperability allows the movement of health care data from one IT system to another such that the clinical or operational purpose and meaning of the data are preserved and unaltered, which is enabled by defining the structure or format of data exchange. Third, semantic interoperability refers to the ability of 2 or more IT systems or elements to exchange information and use the information that has been exchanged [102], requiring both the structuring of the data exchange and the codification of the data (including vocabulary) so that the receiving IT systems can interpret the data. Critical to the achievement of interoperability is the shared use of common standards (that are either mandated or very widely accepted and adopted) at the relevant level. To this end, important and ongoing efforts are being made to establish international standards for health care data and IT architecture to enable all 3 levels of interoperability for health care data sharing, including the work of standard-setting organizations such as Integrating Healthcare Enterprise International [103] and Health Level Seven International [104,105].

The need for interoperability may help explain why the blockchain use cases with the greatest prospects of success in the near term are largely concerned with sharing *back office* functions and associated records, such as credentialing and provider identity verification, and claims management and billing rather than the sharing of patient data for clinical purposes [106,107]. Although these applications entail interorganizational record sharing, which may well be in different formats and structures, the substantive content of the records themselves is likely to have a high degree of *semantic* interoperability that tends to avoid subjective evaluations and is not readily prone to misinterpretation or misunderstanding. For example, the ProCredEx consortia enable the pooling of records concerning whether a particular individual possesses particular professional qualifications; these records can be readily shared between participants without any serious likelihood that the meaning of those records will be misinterpreted by other members [57].

In other words, blockchain-based record sharing among multiple participants is more likely to succeed if the underlying data are highly stable and readily verifiable as evidencing the *truth* of the underlying phenomena that the data purports to represent (eg, such as whether a clinician has obtained a university degree from an approved medical school), and the consequences of an error or data inaccuracy are not safety-critical. However, experts worry that, as multiple blockchains for health care networks emerge supporting a wide variety of applications, they might not be interoperable *with each other*. This could seriously undermine the value and benefits of blockchain-enabled solutions [108,109]. For example, an organization participating in a pharmaceutical supply-chain blockchain may find that it is not interoperable with a clinical trial blockchain network that it also wishes to join, significantly reducing the potential value it might otherwise derive from using blockchain. These anticipated challenges reflect the observations by Greenhalgh et al [98] that a common but significant health care infrastructure challenge in many countries lies in enabling state-of-the-art

individual technologies to interface with (but have often been designed with little awareness of) a legacy infrastructure and restrictive regulatory standards, all in the context of a complex, fast-changing, unpredictable, and underfunded service environment.

Internal Governance

A feature of the growing number of health care consortia seeking to use blockchain technologies to selectively share data and collaborate at the B2B level is that member organizations are often conventionally regarded as competitors [110]. If these novel sociotechnical collaborations are to succeed, a clear set of agreed norms and arrangements to govern the terms of their collaboration will be essential, without which stable cooperation across the network is unlikely to be viable in practice. In open, permissionless blockchains, including Bitcoin and Ethereum, disagreements over proposed changes to the technical architecture have led to highly publicized disagreements, reflecting the different political viewpoints and motivations of participants, which often lead to the fragmentation of the blockchain network in the form of a *fork* in the ledger [111-114]. Although the overwhelming majority of health care distributed ledger technology applications use hybrid enterprise or permissioned systems, they face internal governance challenges that may be no less fraught than those that have arisen in open, permissionless blockchains [115]. However, establishing a durable internal governance framework that commands widespread acceptance by members and participants across the network (including potential new members and participants) will be especially challenging, which is discussed more fully in the following sections in relation to the challenges of *coopetition* [116].

Data Security and Integrity

Although the most promising engagements with blockchain in health care contexts have hitherto largely avoided the clinic, many industry experts believe that as the technology matures, clinical applications entailing collaboration over patient data are likely to emerge [117]. A further 3 challenges are already being encountered within the health care sector in seeking to engage with blockchain technologies, but which are likely to be particularly acute if blockchain applications are applied in clinical contexts. Chief among them are the challenges associated with data security and integrity. For any blockchain-based system, the desired level of data security must be identified, established, and maintained across the system's architecture and operation. For patient data, questions about data security are primarily informed by their size and high sensitivity. Accordingly, it is widely accepted that patient data are best stored *off chain*, for example, in a relational database with the shared ledger merely storing metadata together with pointers to where the actual patient data resides and hash codes to verify the integrity of the off-chain data [82,118]. By incorporating technological mechanisms for identity management and access control into blockchain systems, the on-chain record can also record when, whether, and by whom the relevant linked data are accessed. This approach is reflected in what HIMSS refers to as the principle of *minimal sufficiency* to on-chain data, which it advocates as best practice, stating the following [92]:

> *Blockchain technology was not designed to be a storage mechanism for data and should not be leveraged as such, for security, privacy, compliance and performance reasons. Information added to the chain may be transparent to permitted network participants and difficult to remove without affecting the entire chain. Therefore, we strongly recommend that regulators and policymakers promote that organizations leveraging blockchain-enabled solutions employ a "minimal but sufficient" strategy for the data that should be included on-chain. This strategy should be guided by the use case's data needs, and implementers should keep in mind not only the privacy and security risks but also the performance of blockchain transactions when deciding the amount of data and/or personally identifiable information (PII) included on the chain. Whenever possible, privacy-enhancing technologies should be used to secure private data on the blockchain.*

However, by storing patient data offline, the blockchain ledger cannot ensure data security. Although there are various measures, including encryption, that can enhance off-chain data security, these are separate and distinct from blockchain's technological protections for securing on-chain data. Given that one of blockchain's most significant *promises* lies in the iron-clad security it purportedly brings to on-chain data, the inability to extend that protection to the data stored off chain seriously limits the technology's capacity to deliver on this promise. In addition, a frequently overlooked and neglected issue in the blockchain literature is the problem of *data leakage* or *escape*. Although blockchain offers the technological capacity for fine-grained, auditable data sharing through technological access controls that protect the privacy and confidentiality of stored records, blockchains do not address the possibility that, once data are revealed, those with access will generally be able to copy and extract the data and store it perpetually. As Finck [93] warns, the purposes of blockchain projects can be completely undermined when data escape is possible, particularly in circumstances where data are sold once, and the buyer can then resell or manipulate the data set at will.

Truth and Immutability

A critical feature emphasized by blockchain advocates is the technology's capacity to create a single, immutable, shared authoritative record, reflected in descriptions of blockchain as a *truth machine*. However, the validity of this claim assumes that the data recorded on the blockchain has *integrity*—meaning that they are accurate, up to date, and comprehensive. Although often discussed in terms of providing assurance that the data have not been tampered with or subject to unauthorized alteration [119,120], data integrity also requires that the data faithfully and accurately represent the underlying real-world phenomenon they purport to represent. For example, if a health care record is labeled as representing a particular item, such as an X-ray taken of patient Y on Z date at location P and stored

at an off-chain location Q, then it must represent precisely that. This also requires (among other things) that blockchain consistently keeps transaction information associated with the correct person. Although considerable work is being devoted toward identifying universal identity management solutions for blockchain-based systems, this remains an unresolved challenge. Questions concerning how blockchain can ensure that the records appended to the blockchain ledger are accurately tethered to and reflect the underlying reality that they purport to be associated with remain surprisingly overlooked (or perhaps conveniently ignored) in the existing blockchain literature. In health care, these challenges are particularly acute if data are to have clinical relevance. However, they sit uncomfortably with developers' and entrepreneurs' claims that blockchain will enable the creation of accurate and comprehensive patient records that draw data directly from a patient's wearable device, which is gathered via sensor technologies, without mechanisms that guarantee the accuracy, veracity, and reliability of data thereby collected [21]. Although sensor technologies can help establish direct connections between the digital and physical world in a secure manner, sensors can be easily tricked (even if tamper-proof hardware is used); thus, conventional social trust is needed to trust the veracity of the underlying data. This calls into question the value that blockchain purports to offer in the first place. In the context of supply chain management, Wüst and Gervais [119] refer to the following:

> *The inherent problem of the interface between the digital and the physical world. A human, or some machine under the control of a single writer, typically is required to register that a good has arrived in a warehouse and, if for example, its quality is appropriate. If there is no trust in the operation of these employees, then the whole supply chain is technically compromised as any data can be supplied by a malicious writer. If, on the other hand, all writers are trusted, a blockchain is not needed as a regular database with shared write access can be used instead.*

Although the accuracy of health care administrative data may not always be safety-critical, there is little value in a blockchain that maintains a tamper-proof record of inaccurate or poor-quality data. Accordingly, descriptions of blockchain as a *truth machine* appear somewhat overstated [31]. Data integrity is a necessary prerequisite for establishing trustworthiness and providing a reliable basis for decision-making. Houlder [121] explains the following:

> *Data security is often equated with protecting data confidentiality: but it is data integrity that must be protected – and this requires ensuring that the data is accurate, up-to-date and complete. Blockchain only protects what arrives at blockchain. From an immutability and transparency standpoint, if that data is compromised or of poor quality before it reaches the blockchain you end up with garbage in, garbage out, where you're protecting garbage on the blockchain. Unless the data has the integrity and quality needed, blockchain will not realise its potential.*

The yet-to-be-resolved challenge of assuring data integrity may help explain why the handful of patient-facing blockchain applications offered through the NHS (in partnership with private technology providers) have largely confined blockchain functionality to storing records of patient consent and providing computational assurance concerning when a patient has accessed (and securely copied) his or her NHS records.

In addition, the application of blockchain to health care will entail human interaction and engagement. Even if users are provided with high-quality training, help, and guidance, mistakes will be inevitable. However, identifying and correcting errors generates new challenges, particularly given that blockchain ledgers cannot be retroactively altered. Although blockchain's tamper-proof character prevents certain kinds of mistakes and problems that arise in relation to conventional centralized databases (such as inadvertently overwriting data stored on the database), they will inevitably introduce new ones. This is particularly so given the complex and dynamic nature of health care settings and the multiple intersecting and sometimes conflicting interests, rights and obligations, expectations, and anxieties they typically implicate. In other words, the vagaries of human behavior and decision-making in real-world health care contexts could prevent blockchain's expected benefits from being fully realized.

Quality and Safety

Data integrity is but one element of the larger, multidimensional challenge of ensuring that blockchain systems can be implemented in health care without compromising quality and safety, particularly when they interface with and operate within clinical contexts. Although the safety implications arising from the digital transformation of health care have been well-documented [122], patient safety has received relatively little attention to date, perhaps because of the relative scarcity of clinical blockchain use cases being trialed and implemented. Patient safety issues include the need to ensure that blockchain systems that affect clinical workflows and environments are subject to rigorous testing, validation, and independent evaluation before their introduction into the clinic. However, in the US health care context, no systematic attention appears to have been given to the technical robustness, safety, or ethical dimensions of blockchain implementation. Rather, health care blockchain projects appear to move from proof of concept through to implementation without necessarily being subjected to formal testing and validation to provide assurance of the system's robustness, resilience, or clinical safety. Accordingly, health care blockchain expert Heather Flannery argues that these projects should be understood as experiments to learn and discover the kinds of conditions that produce the desired results; although these conditions are partially technical, in her view, most are clinical, social, economic, legal, ethical, and governance-related. Hence, Flannery argues that these projects should be undertaken as studies subject to proper research protocols as the only ethically viable way to move past the point of experimenting with the technology [123,124]. In contrast, regulatory oversight of health IT systems in the United Kingdom is more developed. Thus, the Health and Social Care Act 2012 requires the development and implementation of clinical risk management processes to ensure patient safety with respect to

the manufacture of new health IT systems, or the modification or decommissioning of an existing system, and their deployment and use [125,126].

Normative Conflict Requiring Satisfactory Resolution

Although the above 6 challenges might be overcome in time, several further challenges rooted in inherent tensions between desirable qualities or functional requirements that arise when configuring blockchain applications may prove more intractable. Although technical blockchain experts have identified various *design trade-offs* when building blockchain systems for specific purposes [82], reflecting the *micropolitical nature of software choices* [98], the following 3 are particularly apposite to health care settings:

Performance and Scalability Versus Security

Ideally, an IT system would provide high levels of security and resilience for the system and the data it stores and generates while offering high-speed performance at scale. However, achieving these objectives in blockchain systems is technically impossible (on currently available technology) because of inherent trade-offs in functionality. There is a loose *trilemma* in the design and configuration of blockchain systems such that they can have at most two of the following three properties: (1) decentralization, (2) scalability, and (3) security. The more computationally demanding and time intensive the consensus protocols for validating transactions [127] before being appended to the ledger and the greater the degree of decentralization across the network, the greater the ledger's security and resilience against attack but the slower the performance in terms of speed and throughput [128]. In addition, as blockchains ledgers are distributed, they entail high storage costs, precluding large data from being effectively stored on the blockchain. As already noted, although blockchain can be used for access control (and auditing), large data must be stored *off chain* [129]. This generates the need to assure off-chain data security; simply using a blockchain to manage access does not thereby offer the security of the stored data, pointing to an inherent tension between the desired values of scalability versus security in their design and operation [130].

Transparency Versus Privacy

The transparency of all transactions appended to the ledger is a critical feature of open, permissionless blockchains, contributing to the ledger's trustworthiness. However, this level of transparency is fundamentally at odds with the private and confidential nature of patient data and other health-related personal information. Accordingly, there is an inherent tension between the need to respect privacy and confidentiality and the design and operation of open blockchain networks that are transparent to the world at large [93]. Under the European Union's General Data Protection Regulation, data collectors and processors must not collect or process personal data without a lawful basis, which includes, but is not limited to, consent by the data subject. In common law systems, additional legal obligations attach to information acquired in circumstances of confidence by clinicians and other care providers, including information communicated by patients to doctors during clinical encounters. At the same time, health care organizations typically seek to keep details of their business records confidential. As already indicated, the *minimum sufficiency* principle of information collection and storage is considered best practice in health care IT design and operation so that health care blockchain systems have hitherto largely taken the form of *permissioned* systems, thereby limiting *read* access to the ledger to those authorized to do so, with health care data being stored off chain and only the hashed metadata stored on chain.

Computational Trust Versus Social Trust

Although the hyperbole associated with blockchain technologies has begun to subside, early industry activity and engagement with blockchain appears largely to have been *technology lead*, arguably motivated by the desire to engage with the latest cutting-edge technology [131] without either a deep understanding of the technology or a desire to meet a specific need that blockchain might usefully address. As the technology has begun to mature, so too have academic investigations, with more recent academic critiques arguing that conventional database structures and systems will often provide cheaper, faster, more sustainable, and scalable approaches to specific real-world data access, management, and storage needs [119,132]. Several scholars have sought to identify the circumstances in which blockchain technologies have a genuine prospect of addressing real-world problems for which conventional centralized, networked databases are inadequate. For example, Wüst and Gervais [119] argue that if either a trusted third party who can verify transactions is always available on the web or if all writers mutually trust others, then a conventional database with shared write access is likely to be preferable. However, if the writers of the ledger do not trust each other, a permissioned blockchain may provide a viable solution. Their insight resonates with, and may help to explain, the recent emergence of consortia of health care organizations who compete with each other in many respects but recognize that they share a limited common interest in relation to specific kinds of data and forms of data sharing. In these circumstances, member organizations may not fully trust each other, and a permissioned blockchain may provide a technological solution to address this trust deficit.

Permissioned systems (including so-called *enterprise* systems) have hitherto been favored in health care blockchain applications. They appear to offer the greatest opportunities for generating value from network effects arising from the creation of a shared, trustworthy transactions ledger between a limited number of authorized participants, enabling members to benefit from effectively sharing elements of a *back office* administrative system (ie, shared records management in a single shared ledger). However, the security and integrity of the shared record will only be as strong as its weakest link, giving rise to what may be called the *computational trust* paradox. On the one hand, the use of computational consensus mechanisms to verify transactions and maintain a single shared ledger across a distributed network of computers obviates the need for each participant to maintain their own ledger and reconcile their ledger with that of other participants, generating significant administrative efficiencies. On the other hand, this means that each participant must trust the integrity, quality, and security of the participant's records, including the accuracy of the

information contained in those records. This relies, in turn, upon the integrity of the practices and processes underpinning the events and transactions that each record purports to represent (subject to those records being validated by the network and appended to the shared ledger). By pooling their records, each participant is thereby exposed to the vulnerabilities of the record keeping and information security practices of their fellow participants. A paradox arises because, although blockchain systems offer the possibility of coordination with others *without* the need for social trust in those others by relying instead on *computational trust*, when these systems take the form of permissioned ledgers, this is likely to *enhance* the need for conventional (social) trust in the practices and systems of other network members. Hence, reliance on computational trust serves, ultimately, to heighten the importance and need for social trust to reap the gains from cooperation [133]. A leading industry expert [121] commented as follows:

> *If you have a consortium of 10 organisations and one of them is a kind of weak link...in terms of they're connecting to the blockchain and pulling information off the blockchain, or in interactions that are enabled by blockchain, and putting information in their own enterprise systems which are insecure and a breach occurs, it impacts everyone...you're not just worried about securing your own organisation, you've got to make sure that everyone connecting to that blockchain is adequately secure.*

Discussion

Overview

The above findings draw attention to the number and variety of formidable, multidimensional challenges that must be satisfactorily addressed if blockchain technologies are to traverse the valley of death. Nevertheless, this study also shows how early engagements with blockchain in health care have begun to demonstrate that these technologies *can* enable and facilitate novel, valuable forms of health care data sharing and cooperation in real-world health care settings under specific circumstances. The following discussion critically reflects upon these key findings by reference to 3 quite different strands of academic literature: first, it examines the character and tensions inherent in these incipient forms of blockchain-enabled cooperation; second, it draws on insights from innovation studies to consider the character of blockchain as *radical* or *incremental* health care technologies; and third, it evaluates the prospects of blockchain for health care's *favorite use case*, that is, to enable *patient sovereignty* over EHRs while overcoming the currently siloed approach to patient data.

The Blockchain in Health Care Promise: Rhetoric, Reality, and Blockchain-Enabled Coopetition

Recent health care blockchain initiatives have successfully demonstrated how technology can facilitate limited, purpose-specific forms of cooperation through the shared pooling of data to solve common problems. These incipient forms of cooperation involving data sharing, which consortia of health care organizations are actively seeking to develop, rely upon interactions that organizational studies scholars refer to as *coopetition*. Although the interaction between firms conventionally focuses on either of 2 contrasting and antagonistic logics—competition (traditionally defined as the conflicting and rivalrous relationship between firms) on the one hand and cooperation on the other [134]—the actual interaction between firms can involve cooperation in some activities while competing in others [135]. As these coopetitive relationships entail 2 diametrically opposing logics of interaction, they are inherently complex, generating tensions between and within organizations [136,137]. In particular, each organization faces conflicting incentives: a desire to cooperate through the pooling of resources to generate shared benefits on the one hand and the incentive to capture private benefits for themselves on the other [137,138]. Several theories have been offered, claiming to predict the effect of coopetition on firm performance [137,139], including transaction cost theories. Transaction cost theories highlight the difficulties of fostering trust between parties in a coopetitive relationship, as each participant has incentives to opportunistically behave while facing high levels of uncertainty [140]. This creates barriers to open collaboration, making it difficult to develop the necessary level of trust needed for common projects to succeed. On the other hand, several scholars have noted that the inherent tension between cooperation and competition arising within coopetitive relationships can, if managed efficiently, create shared value and generate beneficial outcomes for each party [137]. On this view, the key to successful coopetition is effective management of the coopetitive tensions within the relationship that nurtures and maintains an appropriate balance between competition and collaboration. Various insights from this literature help illuminate the challenges likely to arise within health care consortia comprising organizations that would otherwise regard themselves as competitors seeking to share health care data via a permissioned blockchain network. The configuration of access rules within a permissioned blockchain system offers a potentially novel mechanism through which *social distrust* might be replaced by *computational trust*, thereby enabling new forms of cooperation at the B2B level that might not otherwise occur, as the trust gap is too difficult to overcome.

That said, the need for strategies to successfully manage the tension between organizations within the network highlights the importance of a blockchain network's internal governance arrangements, particularly in establishing and maintaining rules concerning changes to the network's architecture, protocols, rules of admission, and incentive mechanisms. Details about the internal governance arrangements that underpin the various blockchain consortia that have emerged in recent years are not publicly available because of the confidential nature of the underlying partnership agreements. Nevertheless, one would expect that formulating and maintaining a set of governance arrangements that will prove durable and resilient over time is likely to be extremely difficult, as the interests of participants are not *wholly* aligned and hence, difficult to settle in advance. These internal governance arrangements must identify how critical decisions about, for example, the structure of economic incentives or rewards for participants to engage in the consensus protocol, how the network will be maintained, and how other changes to the network's structure and operation will be made and by whom. Potentially conflicting interests may not be

readily apparent at the time of the network's inception but may subsequently arise as organizational needs, the larger industry context, and other external factors inevitably change over time. However, perhaps it is only when the *rubber hits the road* in the context of specific disagreement between network participants that the critical need for robust governance structures that command the respect and allegiance of the network's members becomes apparent.

Finding an appropriate but flexible equilibrium between the need for social trust between network participants on the one hand and *hardwiring* computational trust into the technical architecture and operation of the blockchain system will be a very tough nut to crack. It remains an ongoing and continuing challenge for the foreseeable future, at least until blockchain in health care achieves a level of maturity in which a widely shared set of agreed norms concerning the core requirements of good blockchain governance can emerge. Furthermore, these networks are likely to encounter what has been referred to above as the *computational trust* paradox; by seeking to rely on computational trust to provide a basis for enabling cooperation between firms, this may reinforce and accentuate the need to nurture and maintain social trust between the parties in domains in which computational trust cannot be secured.

Permissioned Blockchains in Health Care: Incremental or Radical Innovation?

Early engagement with blockchain technologies in health care contexts has largely used *permissioned* blockchain systems (including so-called *enterprise* blockchains) rather than open, permissionless systems that many blockchain advocates believe will revolutionize social cooperation between strangers without the need for conventional trusted third-party intermediaries, such as banks and governments. Although the blockchain for health care promise has not typically emphasized the role of permissionless blockchains, a significant *revolutionary* narrative is evident in claims that blockchain technology will *disrupt* health care [17]. Within this narrative, blockchain is portrayed as enabling radical patient empowerment achieved via hard-coded access controls, securely facilitating the seamless exchange of patient records currently stored in disparate data silos while enabling patients to exert fine-grained control over who is granted access to those records, wherever located, and on what terms [141,142]. It is blockchain's potential to overcome the many existing technical, legal, and bureaucratic obstacles that obstruct the free flow of health data while preventing patients from exerting control over access to their own health care records that is typically highlighted rather than emphasizing the role of permissionless blockchains in achieving this vision.

The health care sector's focus on permissioned (rather than permissionless) blockchain systems to date will disappoint radical blockchain enthusiasts such as Bruce Schneier, a well-known computer security expert. Schneier claims that permissioned blockchains are "completely uninteresting" as they are no different from centralized databases in relying on conventional forms of trust to facilitate social cooperation [143]. However, his perspective fails to recognize that even open, permissionless blockchains ultimately and invariably rely on social trust to support their internal governance arrangements [112,113]. By enabling participants to rely on computational trust mechanisms to enforce the explicitly agreed terms of their cooperation, permissioned blockchains could facilitate novel forms of cooperation, leading to valuable and potentially transformational change.

The transformational potential of permissioned blockchain systems can be illuminated by reference to a distinction drawn by technology management researchers between *inventions*, which refers to an "idea, sketch, or model for a new or improved device, product, process or system" and *innovations*, which, in the economic sense, arise "only with the first commercial transaction involving the new product, system or device" [144]. Within this literature, a further distinction is commonly made between *incremental* and *radical* innovation. Incremental innovations introduce relatively minor changes to an existing product, exploiting the potential of the established design (although they may entail considerable skill and ingenuity) [145-148]. In contrast, radical innovations are based on different engineering and scientific principles, potentially opening up whole new markets and applications [146,147,149]. This distinction is considered to have important competitive consequences: incremental innovation tends to *reinforce* the capabilities of established organizations, whereas radical innovation forces them to *ask a new set of questions*, draw on new technical and commercial skills, and use new problem-solving approaches [36,146,148,150]. Hence, radical innovation often creates great difficulties for established firms [148,151-153]. As the late Clayton Christensen famously argued, radical innovation can *disrupt* the entire industry as incumbent firms lose out to smaller firms with fewer resources who use these radical innovations to deliver superior functional performance, eventually leading to their adoption by the incumbent's established customers [154].

It is too early to assess whether permissionless blockchains will ultimately form the basic technological architecture underpinning a dominant design for particular kinds of health care applications. It is not possible to reliably predict whether they will come to be regarded as incremental or radical innovations or, indeed, whether they come to be understood as innovations at all or merely just an interesting invention with little real-world utility. However, the preceding insights suggest that we cannot assume that the use of permissioned rather than permissionless blockchains in health care necessarily implies that they cannot subsequently establish themselves as *radical innovations*. Bruce Schneier's dismissal of permissioned blockchains overlooks the possibility that they may offer particular functional properties capable of meeting a very specific sectoral need. In functional terms, permissioned blockchains are something of a hybrid—analogous to centralized databases insofar as participation and access require authorization from a network controller but can mathematically provide the verified security and automated audit functionality of permissionless blockchains without the heavy computational expense. Accordingly, they might prove *radical* in their effects [155], creating shared value by facilitating new forms of coopetitive collaboration between health care organizations while generating significant efficiencies.

Blockchain-Enabled EHRs and the Promise of Patient Data Sovereignty

Mention has already been made of frequent references in both academic and industry literature to the potential of blockchain-enabled EHRs to *revolutionize* health care. According to this vision, blockchain operates as a form of *middleware*, facilitating the flow of data between independent IT systems, thereby integrating disparately located silos of patient health care records while enabling patients to exercise fine-grained but automated control over their EHRs via *smart contracts* that automate the execution of patient instructions or consents [14,109]. In so doing, blockchain is widely portrayed as *solving* the tension between the need to respect the privacy and confidentiality of individual health records and recognizing the tremendous knowledge potential unleashed by pooling and aggregating patient data. Blockchain for health care scholarship has largely taken these claims at face value. Although various blockchain-enabled EHR projects are currently being experimented with, the preponderance of activity appears to reflect the views of industry experts, who advise that blockchain applications focusing on patient care records are best avoided in the early stages of the sector's engagement with the technology because of the demanding and complex legal and regulatory requirements that apply to personal health information. Nevertheless, many believe that these demands can eventually be overcome, so that patient-controlled, blockchain-enabled EHRs will eventually emerge [91,117]. Even if the difficult and complex challenges and tensions identified in the preceding section can be satisfactorily overcome, whether these systems will live up to their promise depends upon the validity of underlying assumptions about their benefits, particularly in clinical contexts.

Academic literature concerned with health IT implementation has hitherto been dominated by the *technology acceptance model* (TAM), which originates from the perspective of health information systems research that studies the systems that support health and medical work [156]. This approach, developed jointly by doctors with an interest in computers and computer scientists with an interest in medicine, adopts a positivist outlook that regards the relationship between technology and their expected benefit as linear and causal [81]. Similar assumptions appear to underpin 2 distinct, albeit related, elements of the vision of blockchain-enabled EHRs offered by their proponents. The first assumption is that blockchain will enable the seamless integration of patient records currently stored in distinct *data silos*, thereby effectively providing patients and clinicians with a single, up-to-date, and comprehensive repository of each patient's medical records over his or her lifetime. The second assumption is that configuring blockchain-enabled EHR systems to enable patients to control access to their records will ensure respect for privacy without impeding the transfer and sharing of patient data for clinical and other legitimate purposes.

In relation to the first assumption, Berg et al [157] highlighted studies of EHR implementation that emphasize the personalized nature of health care work, thus setting "natural limits to the possibilities of IT to revolutionise this work." These studies suggest that the considerable energy and resources thus far devoted to various components of the EHR failed to substantially improve the quality or efficiency of frontline clinical work. Moreover, they argue that EHRs are *unlikely ever* to produce dramatic gains in the quality of care because of the importance of the creative human work needed to bridge the gap between clinical design and technical reality [50]. In contrast, biomedical literature often rests on a TAM model, evoking a belief that IT systems will make clinical information instantly available, implicitly assuming that *meaning* can be transmitted unproblematically along with the data contained in the EHR. This assumption also appears to underpin the *beautiful dream* of blockchain-enabled EHR systems, suggesting that, if properly designed, blockchain will enable more accurate, secure, and timely data access that will drive quality improvements across health care, including clinical care. However, studies from more sociologically informed traditions roundly reject this assumption, providing evidence that clinical data must be interpreted in context and *framed* before they become meaningful, and this is not achieved simply by placing information on an electronic platform that is accessible by multiple users [50]. These studies rest on assumptions that differ from those underpinning the TAM model (including understandings of what counts as *success* for the purposes of evaluating health IT systems), drawing on a wider range of methodological approaches [158]. They highlight the critical role of context, culture, and the values brought to bear by medical professionals in clinical environments, identifying the clinical consultation as a complex social encounter that occurs within a heavily institutionalized environment [50]. In particular, scholars from these traditions emphasize the role of values in clinicians' understanding of what constitutes and how they seek to practice *excellent care* and the nature of clinical knowledge as *tacit, context-bound, and ephemeral rather than codifiable, transferable and enduring* [50]. These studies find that in many *failed* EHR projects, technical designers typically missed these subtleties and produced artifacts that fitted poorly with the situated nature of knowledge and the microdetail of clinical work practices [81].

Conversely, the TAM model assumes that the failure of EHRs to generate their expected benefits can be largely explained by shortcomings in EHR system design and implementation, resulting in user *resistance* to the technology [50], which can be overcome by system design improvements and more sensitive implementation. One of the most significant lessons from studies of EHR adoption is that considerable clinician resistance to these systems has often resulted from the unintended but radical alteration and disruption of clinical workflows and patient interactions accompanying the introduction of EHRs, adversely affecting physician workload [81,122,159]. In addition, the data captured in these records have been described by a legal expert as often error prone, incomplete, unprotected, and dispersed across numerous organizations unknown to the patient [130]. However, if used as *middleware* to support the integration of EHRs across disparate data silos, blockchain technologies should not, in theory, affect clinical workflows or practices, as they operate as a *backend* technology. In other words, blockchain should not exacerbate workload burdens or introduce additional integration work of the kind that has typically accompanied EHR implementation. However, HIMSS [160] warns that:

> *Blockchain technology is meant to operate on the back end and should avoid, where possible, adding additional steps for the end user. If this technology is poorly implemented without a strong federated approach, workflow may be negatively impacted, potentially affecting the quality of care.*
>
> *Adding a blockchain-enabled solution without considering its applicability to a use case, potential value, or relationship with a partnering stakeholder, could add a layer of complexity to an already convoluted health IT ecosystem. Furthermore, if this complexity detracts from the end goal of sound care, ethical and other questions may arise from the implementation of this kind of solution that is not well suited for the coordination and delivery of care.*

This cautious view, offered by one of the health care IT sectors' leading industry bodies, suggests that one cannot assume that implementation of blockchain as a *backend* technology will not add further system complexity simply by avoiding any change to the *front end* experience of users [98].

The second assumption underpinning the promise of blockchain-enabled EHR systems—that they will enable patient data sovereignty and empowerment by providing patients with fine-grained control over who may securely access their health care records and on what terms—resonates with broader societal shifts in favor of *self-service economy* models across many sectors [161]. Blockchain for health care advocates assumes that patient-controlled health care records will resolve dilemmas arising from the tension between ensuring compliance with privacy and confidentiality norms and duties and fostering the aggregation of patient care records for medical research and other legitimate purposes [162]. This assumption is likely to be both mistaken and naive for several reasons. First, although it is essential that patients are enabled to exercise their rights of informational self-determination in relation to health and care information that directly pertains to them [163], some patients will enthusiastically embrace the capacity to control access to their medical records [164], whereas others will not [165]. A significant proportion of patients (including children and those with mental illness or disability) cannot make informed decisions about access to and sharing of their clinical data; therefore, alternative consent models will be needed. Second, there will be circumstances in which patient consent cannot be secured; however, the ability to access that patient's health records will be necessary, particularly in emergency situations. Third, in other circumstances, patient rights to data privacy and confidentiality may be legitimately overridden by compelling public interests, particularly when appropriate technical and organizational measures are taken to safeguard those interests so that patient consent is neither legally nor ethically needed to justify access to their records. For example, the public interest in data sharing and access can, particularly in times of public health care emergency, justifiably override individual rights to privacy and the need for patient consent to data sharing.

Taken together, the vision of *patient data sovereignty* underpinning blockchain-enabled health records exhibits a *techno-solutionist* mindset, reflecting a belief that technological fixes can be used to *solve* complex social problems [166]. Critiques of this kind draw attention to the complex and messy set of interacting norms, practices, and dynamics that arise in the real-world contexts for which simple technological *solutions* are unlikely to be found, which the disappointing experience of EHR implementation has vividly demonstrated. Despite this, the underlying *information as property* paradigm that informs these beliefs appears to hold considerable sway in contemporary debates about data governance, both within health care and beyond [167]. However, as the German Data Ethics Commission points out, supporting and promoting the practical capacity of patients to access their health care records and take an active role in decisions about access to those records does not necessitate a *propertisation* model of data governance, which underpins the views of those who favor the making of micropayments to data subjects in return for access to their personal data [163,168,169].

Apart from unfounded assumptions that technological access controls built into health IT systems can be expected to successfully mediate and resolve the complex interests in patient data, any such shift in favor of patient sovereignty over health care records may reflect an underlying reconfiguration of the ethical basis upon which patients receive care. Rather than characterizing patients as vulnerable individuals and beneficiaries of care provided by an expert clinician who is professionally obliged to act in their best interests, patients may increasingly be expected to *self-manage* their own medical records based on largely unexamined claims that this will *empower* them to exert greater control over their own care [85]. However, if these systems are configured in ways that force adherence to norms that are at odds with the basic cultural and moral norms of contemporary health care settings, this might provoke backlash. This might occur, for example, if systems are designed to shift responsibility for care to patients and away from clinicians and care providers in ways considered contrary to the professional duty and commitment of clinicians to act in the best interests of their patients [170]. Alternatively, if patients are unable to make meaningful decisions about the sharing of their data, they are likely to stick with defaults; however, these might fail to reflect legitimate patient expectations and existing informational privacy and confidentiality norms. These and other similar risks underline the importance of meaningful stakeholder engagement in the design and implementation of blockchain systems, as well as the importance of more critical engagement with the logic of *empowerment* that frequently accompanies their promised benefits [50].

Accordingly, the vision underpinning blockchain for health care's *favorite use case*, which is capable of seamlessly integrating patient-controlled EHRs accessible by clinicians in real time wherever located, is based on problematic and unrealistic assumptions. Their promised benefits are therefore unlikely to be realized in practice. Even if blockchain technologies can operate as *middleware*, enabling organizations to access and retrieve patient health care records stored at different sites in real time, blockchain cannot ensure that the information stored in those records is an accurate representation of the underlying real-world events they purport to reflect. Conferring responsibility for making access decisions on patients themselves will not avoid conflicting and sometimes difficult

trade-offs between respect for patient privacy and other rights and legitimate interests implicated in health care. In other words, the health care *data silo* problem is only one aspect of a much larger, more complex set of needs, rights, and interests associated with medical and health care information, which are likely to continue to defy hard-coded solutions.

However, one of the most valuable insights arising from *technology-in-practice* studies of EHRs for understanding the real value that blockchain-enabled EHRs might create arises from the recognition that there are two conflicting work processes in play with EHRs: immediate clinical care (primary use) on the one hand and tasks such as audit and research, which are one step removed from the clinical encounter (secondary use) on the other. These studies show that when EHRs are used as a formal tool (eg, with structured templates and a requirement for data to be coded), they often slow down and frustrate the clinical encounter but can greatly accelerate secondary uses of clinical data. Accordingly, Greenhalgh et al [50] argue that, rather than promising that the EHR will *save time* or *make clinical care more efficient*, a more honest message would be that creating accurate and complete clinical records requires the sacrifice of time and effort by frontline clinical and admin staff, which is (sometimes) justified by more benefits for efficient business processes (eg, billing) governance and research. In other words, the real value of blockchain-enabled health records might rest in their secondary use, enhancing health care administration and medical research rather than in substantially improving clinical care.

Study Strengths and Limitations

This study has both empirical and theoretical strengths. Its strengths are 3-fold. First, by focusing attention on the health care sector's experience in attempting to use blockchain technologies for specific purposes, it fills an important gap in the existing literature by offering a more grounded, evidence-based but theoretically informed appraisal of blockchain's prospects for transforming health care, unlike the burgeoning academic literature that has focused overwhelmingly on the technology's *potential* to solve health care problems. Second, it identifies and critically examines a series of complex, multidimensional implementation challenges that must be satisfactorily confronted if blockchain technologies are to be widely taken up within health care contexts, illuminating the nature and dimension of these difficulties by referring to a range of theoretical perspectives. Third, the critique offered here contrasts sharply with the considerable hype that accompanied the emergence of blockchain technologies. It provides a more theoretically and empirically grounded appraisal of the oft-proclaimed radically transformative potential of blockchain technologies in a specific domain, notably within complex health care environments that are typically saturated with technologies, many of which are highly sophisticated and often safety-critical.

The limitations of the study rest in the lack of publicly available, authoritative data concerning blockchain uptake in health care. Hence, the snapshot provided by the study of current and ongoing industry engagement and experience with blockchain relies heavily on web-based investigations of gray literature, particularly industry publications, to investigate the focus and tenor of discussions about these technologies in health care and the trajectory of their development. This methodological approach was limited in several significant aspects, insofar as it relied on unconfirmed industry sources publicly available on English-language websites as a substantial source of evidence for understanding the current state of blockchain development and implementation in health care contexts. As the accuracy of claims made on public websites is practically impossible to verify and often fails to provide significant financial information about the level of investment or revenue generated (or expected to be generated), the findings on blockchain take-up in the health care sector are not comprehensive, particularly given the growing interest in developing blockchain applications in non–English-speaking countries (eg, China [171,172] and Japan [173]).

Although significant assurance about the reliability and robustness of the study's provisional findings was obtained by eliciting feedback from industry experts through the second focus group workshop while cross-checking the validity of these provisional findings against the published insights of industry specialists [174-176], the findings concerning the state of industry experimentation and maturity offered here are neither authoritative nor comprehensive. Nevertheless, they provide worthwhile insights into the general state of the health care sector's engagement with blockchain technologies to date, the particular domains and applications in which this engagement is occurring, and the current direction of travel. Accordingly, these findings offer a useful reference point for critical reflection in the context of future investigations of blockchain in health care and beyond.

Conclusions

This paper has demonstrated that the health care sector's engagement with blockchain technology has grown steadily since 2016, with the most promising activity occurring at the intra- and interorganizational level to enable data sharing and cooperation in health care administration and medical research. Although various blockchain initiatives have appeared in response to the COVID-19 pandemic [177], in which the rapid spread of misinformation intensified the importance of ensuring trustworthy health care information management, industry experts suggest that they have not hitherto taken root [178]. Contrary to the focus of the academic literature, the health care sector's engagement with blockchain has not focused primarily on enabling and integrating patient-controlled EHRs into clinical practice. It is in nonclinical contexts that early-stage health care engagement with blockchain is now producing evidence that blockchain-enabled cooperation can create both collective and individual value for network members that is greater than the sum of its parts, generating potentially significant efficiency gains [121]. Accordingly, blockchain in health care cannot currently be dismissed as a passing fad. Although scholars of innovation studies have identified various *barriers to innovation* that arise when technological inventions seek to cross the *valley of death* during the development phase of innovation, this literature has tended to treat technological inventions as a *black box*. In contrast, the analysis offered here highlights the importance of attending to the design and functionality of the technology itself and the particular health care contexts and

fields of practice into which it might be applied in ways that may deepen and enrich innovation studies literature that has tended toward a high level of generality and abstraction.

This study identified 6 complex and multidimensional challenges and 3 normative tensions that must be resolved if blockchain technologies are to be made readily implementable in health care. Negotiating and overcoming these challenges and tensions will require considerable commitment, including time, investment, and willingness by health care organizations to take substantial risks, experiment, learn, and share knowledge across the sector. It suggests that the technology's progress through the development process will be difficult and lengthy. Moreover, as the National Advisory Group on Health Information Technology advised in its 2016 report, "implementing health IT is one of the most complex adaptive changes in the history of healthcare, and perhaps of any industry" [179]. Another leading expert observes that "while policy makers are calling for technology to be implemented rapidly and at scale, the reality is that when dealing with the multiple complexities of health and care, it is extremely difficult to go beyond small-scale demonstration projects" [85].

Even if blockchain succeeds in crossing the valley of death, it does not necessarily follow that these technologies will live up to their promise. The underwhelming experience of health IT offers a sobering reminder, with Kellermann and Jones [180] noting that despite the increased use of health IT in the United States, with aggregate annual national expenditure on health care growing from US $2 trillion in 2005 to roughly US $2.8 trillion in 2013, the efficiency of patient care is only marginally better. In the United Kingdom, 10 years after the launch of the National Program for IT, which promised to revolutionize care in the English NHS [181,182], it was described by the UK Secretary of State for Health as a "huge disaster that became impossible to deliver" despite costing £3.66 billion (US $4.84 billion) [183,184]. These experiences highlight the serious gap between the grand visions of IT's transformative potential in health care and the fraught nature of implementation, given the inherently complex, dynamic, and context-driven nature of health care. They throw into high relief the inherent difficulties associated with seeking to *hard code* norms into complex sociotechnical systems in ways that that can satisfactorily resolve and mediate a wide variety of often conflicting rights, interests, expectations, norms, and risks associated with information sharing in dynamic, complex but safety-critical health care settings.

Although the *blockchain for health care promise* is rooted in a belief that blockchain systems will facilitate secure data sharing while enabling more fine-grained management of health care data, thereby creating *more and better data* that will drive improvements across the sector, real-world engagements and experiences with the technology in health care settings to date suggests that blockchain's core *value proposition* is more nuanced and narrowly framed. Blockchain's value generally (both within health care and beyond) rests primarily on its capacity to provide an automated, mathematically verifiable, highly secure, and therefore, highly trustworthy record-keeping function. It is this functional capacity that supports the technology's nascent potential as *middleware*, facilitating various kinds of health care data sharing and exchange, particularly between health care organizations where a lack of social trust rooted in institutional incentives for opportunistic behavior might be replaced with the computational trust that permissioned blockchain systems can provide. In so doing, blockchain systems may enable new forms of cooperation that generate shared value from the pooling of health care data, although whether these networks can develop governance strategies that can successfully and sustainably mediate the relevant interests of network participants remains to be seen.

However, the difficulties of ensuring that the ledger accurately, systematically, and comprehensively tracks and reflects the real-world phenomenon that it claims to record may mean that the envisaged benefits of blockchain's automated *track and trace* function may not be fully realized. Computer scientists and mathematicians have long recognized the *garbage in, garbage out* problem: the quality of output is determined by the quality of the input. Blockchain technology cannot guarantee that data arriving at and recorded in the ledger is an accurate, complete, and comprehensive record of the underlying real-world events that it purports to track; however, blockchain advocates typically overlook this critical vulnerability. In other words, although blockchain systems can deliver valuable functionality in terms of automatically and securely recording the handling of data items (for example, when a digital record has been viewed by a particular user), they cannot guarantee the integrity of the underlying data.

Nevertheless, blockchain's automated audit function might offer real and significant value because, by creating a highly secure and verifiable record, it offers a vehicle through which organizations can *demonstrate compliance with data handling norms* at scale, thus operating as a form of *RegTech*. In this way, blockchain as middleware can automatically and securely track and record the location and handling of data items. Therefore, it might have real potential to facilitate the *integration* of health data *silos* stored in a variety of locations across multiple organizations using different IT systems [185]. The value of this contribution could potentially be significant, reducing costs and improving efficiency, transparency, and security, and could be widely applied across any sector in which sensitive data generation, processing, and sharing occur in large volumes.

Blockchain is frequently portrayed as offering the potential to deliver radical and positive transformations to many sectors, including health care. This study has identified significant activity within the health care sector aimed at exploring how blockchain technologies might deliver real value. It has been found that the technology is still in its infancy and that the nature and scale of its value to health care remain unproven [29]. Experience of early health care sector engagement has shown that the relevant question is not *how can blockchain be used* in health care settings but *under what conditions can blockchain be realistically expected to provide a viable, scalable and efficient solution to a concrete health care problem in real-world health care settings that would add significant value relative to alternative solutions?* In other words, when considering whether to engage with blockchain technologies, organizations must ask themselves whether a blockchain is really necessary

to solve the problem at hand or whether other alternative approaches are preferable.

This shift in mindset is reflected in the divergence between the *rhetoric* of blockchain-enabled health care data sharing, which focuses primarily on the capacity of blockchain technologies to enable the seamless yet secure sharing of patient records that will enhance clinical decision-making, and the *reality of* engagement with blockchain, which has largely avoided clinical contexts. Instead, the most innovative health care blockchain applications have occurred at the interorganizational level, enabling the sharing of administrative data between health care organizations to improve the efficiency of health care administration. The most recent initiatives are aimed at facilitating shared access to the secondary use of patient data for medical research through cooperative endeavors to train algorithmic models on data sets in a secure, privacy-preserving manner.

However, to succeed in this endeavor, there remain very significant challenges associated with achieving social trust and cooperation, including the need for the effective and legitimate governance of blockchain networks, that no amount of technological sophistication or hard-coded solutions can, on their own, satisfactorily resolve. It remains to be seen whether these and other tensions inherent in these incipient forms of blockchain-enabled *coopetition* between health care organizations will be satisfactorily overcome and whether blockchain applications in health care might be characterized as *radical* or *incremental* technologies. Accordingly, the possibility of blockchain technology precipitating a *revolution* in the delivery of health care of the kind envisaged by blockchain for health care advocates appears to have been exaggerated. Nevertheless, there are real prospects of using blockchain in ways that could lead to genuine health care improvements. However, progress toward this goal is likely to occur slowly, incrementally, and more *by stealth* rather than through radical and rapid *disruption* over a short period and—at least in the first instance—likely to be concentrated across a much narrower range of applications than the blockchain for health care promise suggests.

Abstract

Background: There are limited evidence-based strategies that have been shown to increase the rate at which peer-reviewed articles are cited. In a previously reported randomized controlled trial, we demonstrated that promotion of article links in an online cross-publisher distribution platform (TrendMD) persistently augments citation rates after 12 months, leading to a statistically significant 50% increase in citations relative to the control.

Objective: This study aims to investigate if the citation advantage of promoted articles upholds after 36 months.

Methods: A total of 3200 published articles in 64 peer-reviewed journals across 8 subject areas were block randomized at the subject level to either the TrendMD group (n=1600) or the control group (n=1600) of the study. Articles were promoted in the TrendMD Network for 6 months. We compared the citation rates in both groups after 36 months.

Results: At 36 months, we found the citation advantage endured; articles randomized to TrendMD showed a 28% increase in mean citations relative to the control. The difference in mean citations at 36 months for articles randomized to TrendMD versus the control was 10.52 (95% CI 3.79-17.25) and was statistically significant (*P*=.001).

Conclusions: To our knowledge, this is the first randomized controlled trial to demonstrate how a postpublication article promotion intervention can be used to persistently augment citations of peer-reviewed articles. TrendMD is an efficient digital tool for knowledge translation and dissemination to targeted audiences to facilitate the uptake of research.

Introduction

Citations are a leading indicator of scholarly impact. They measure the spread of new knowledge; acknowledge the contribution of colleagues; and, in many fields, form the basis of tenure and promotion or even direct compensation [1,2]. Citations accrue from research getting noticed and used by authors when creating their own scholarly work. The problem is, there is a growing mismatch between the number of newly published articles and the number of papers an academic can discover and ultimately cite in the creation of their own scholarly work. There are over 8000 new peer-reviewed articles published daily, a figure that is growing exponentially, making it challenging for scholars to sift through potentially relevant

literature [3,4]. As a result, many relevant papers that could be cited are missed by scholars [3]. Accordingly, data suggests that roughly 35% of articles published between 1990 and 2015 remain uncited; a figure that may be increasing [5]. A study published in 2021 found that the increasing enormity of academic literature may be impeding on the rise, progress, and adoption of new ideas; the authors suggest that changes are needed in scholarship dissemination to increase the discoverability of new concepts that researchers may not be searching for [6]. The growing mismatch between the number of articles published and the ability for readers to come across articles that they were not already seeking out has created a pressing need for strategies that augment the discoverability of scholarly content and to target content to potential knowledge users. Postpublication strategies such as promotion of articles in social media and other content distribution networks promise to enhance discoverability, which may increase the chances that the most relevant paper is found and ultimately cited by scholars in the creation of their own work. However, how to target promotional campaigns to the right audience remains an open question, and there is currently limited evidence showing which strategies yield a positive effect on scholarly article impact, such as that reflected by citation counts.

One of the most widely studied strategies examined to increase discoverability, accessibility, and consequential citation counts of scholarly work is publishing content in open access (OA) journals. OA increases visibility and hence can have a positive effect on usage metrics such as the number of downloads [7], but the effect on citations is less clear and likely discipline dependent [8-12]. Since the first carefully designed multivariate observational study in 2006 showed a clear OA citation advantage even when adjusted for possible confounders [8,9,13], several large observational studies have found OA articles accrue between 50% to 200% more citations compared to closed access articles; this is referred to as the "open access citation advantage" (OACA) [8,14]. The OACA, however, has not been universally accepted [7,15,16]. For example, in 2011, Davis [16] completed a randomized controlled trial study showing that making articles free and open did not yield an increase in citation counts over a 3-year period relative to closed access articles. Part of the reason why the OACA has been found in observational data and not experimental data is likely due to residual confounders. Even though the original study suggesting an OA citation advantage was carefully adjusted for multiple confounders [8], selection bias cannot be fully adjusted for and is one of the biggest confounders identified in observational research examining the OACA [17]; more prominent authors are more likely to pay to publish OA articles, and if authors are more likely to provide access to their "highest quality" articles, then OA articles will have more citations than closed access articles [11,18]. Furthermore, as OA content becomes increasingly ubiquitous in the scholarly ecosystem, the OACA, if any, is likely to extinguish, as all articles share the same OA characteristic.

Aside from publishing research in an OA journal, other studies have suggested that the promotion of articles in social media platforms may be used to augment the page views and citations of articles, but this too remains highly controversial. For example, two recent studies [19,20] found that intensive social media promotion significantly increased page views of scholarly articles. A more recent study [21] found that an intensive social media promotion strategy yielded a citation advantage to promoted articles. However, the findings of the Luc et al [21] study have come under considerable scrutiny due to significant methodological flaws that suggests that social media promotion did not yield a citation benefit at all [22-24]. The most significant methodological flaw was the fact that the papers listed in the Luc et al [21] paper may have not matched those described by their methods. Similarly, two rigorous randomized controlled trials [25,26] found that the promotion of articles in social media did not yield any increase in article page views. These results refer to organic tweeting, and an unexamined question remains if promoted tweets, which measurably lead to more visits, also lead to more citations. Taken together, though there are mixed data as to whether social media promotion increases article page views, there are currently no replicated data to suggest that the strategy yields a citation advantage to promoted articles.

Our group previously published studies examining the extent to which the promotion of articles in a novel cross-publisher distribution platform (TrendMD) increases article page views, usage, and citation counts. In a 2014 study, TrendMD article promotion led to an 87% increase in page views relative to the control in a 4-week randomized controlled trial [27]. These data were replicated in in a 3-week crossover trial that found that promotion of articles in the TrendMD Network yielded a 30% and 49% weekly increase in page views relative to the control [28]. In 2017, we completed a 4-week randomized controlled trial that found articles randomized to TrendMD had a 77% increase in article saves on Mendeley relative to the control [29]. These findings were particularly significant because Mendeley saves are not only a robust measure of article usage, but the metric is also strongly correlated to future citations [30-34]. Building on these data, in 2019, we conducted a randomized controlled trial including 3200 articles published across 8 subject areas (eg, medicine, physics, business, and humanities) and found that promotion of articles over 6 months conferred an overall statistically significant 50% citation advantage to promoted articles relative to the control at 12 months [35]. TrendMD promotion increased citations for 3 of 8 disciplines tested, yielding the largest citation advantage to articles published in the subject areas of health, medical, and life sciences. Taken together, results of our studies suggest that TrendMD confers a short-term page view, usage, and citation advantage; however, we do not know whether the measured advantages persist over time or becomes diluted by other factors [36].

In this study, we conducted a follow-up analysis to our 12-month randomized controlled trial to determine whether the citation advantage persists at 36 months. We also sought to determine whether TrendMD's effect on citation counts were specific to particular disciplines or consistent across all disciplines. We hypothesized that the promotion of articles in TrendMD would yield a persistent citation advantage at 36 months. We further hypothesized that this effect would be seen across more disciplines than initially measured at 12 months.

Methods

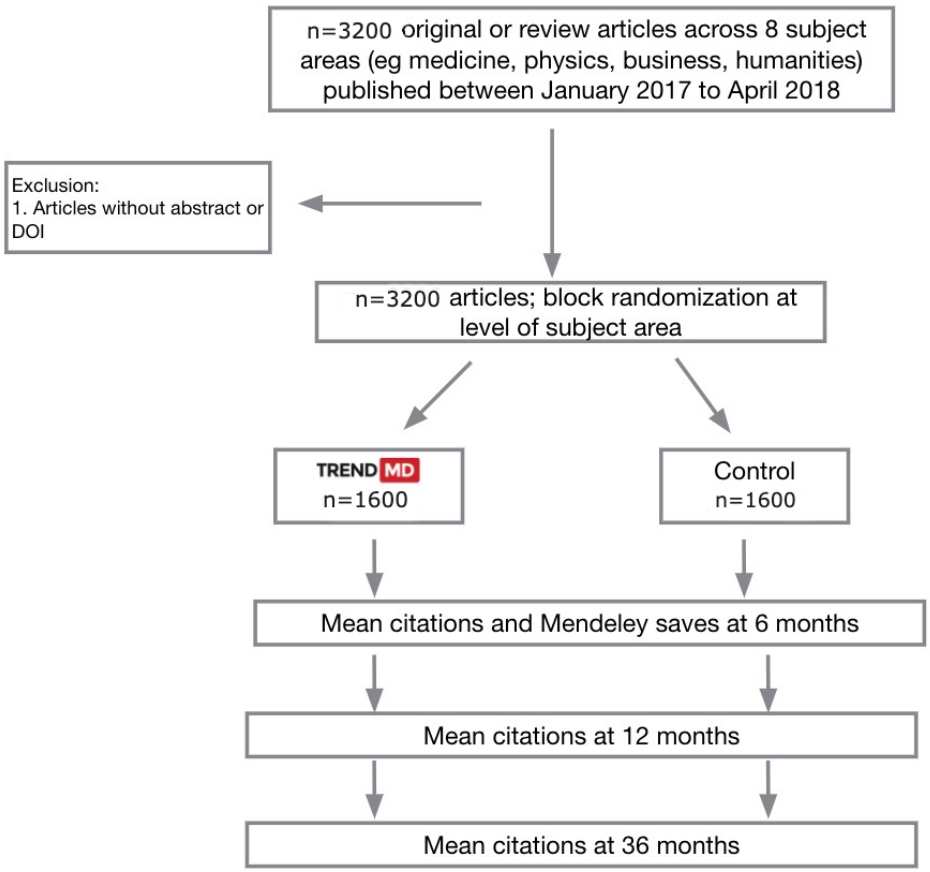
Summary

The majority of the Methods section included herein were copied verbatim from the Methods section we describe in our previously published 12-month randomized controlled trial [35].

We conducted a 36-month randomized controlled trial that included 3200 articles published in 64 peer-reviewed journals across 8 subject areas. The length of the study was 6 months for the intervention and an additional 30 months of observation for a total of 36 months. We published our initial findings at 12 months [35]. We measured citations at 6, 12, and 36 months. The subject areas/categories were selected based on the 8 categories listed in Google Scholar [37]. The categories selected were business economics and management; chemical and materials sciences; engineering and computer science; health and medical sciences; humanities, literature, and arts; life sciences and earth sciences; physics and mathematics; and social sciences. For each subject area, the top 20 journals ranked by Google Scholar's h-5 index were selected (Google Scholar only displays the top 20 journals in each subject area). Please see the supplementary material published in our 2019 study [35] for our rationale for using Google Scholar and the h-5 index in our selection criteria. Eight journals were then randomly selected with a random number generator from the top 20 in each subject area to be included in the study; we did this as opposed to selecting the top journals in each subject area so that our sample would include a randomized mixture of journals of high and lower impact in each subject area. Including both high and lower impact journals was important to our study because we wanted to mitigate the potential confounder that TrendMD promotion is only effective in high impact journals. Journals that were not indexed in Scopus or Web of Science were excluded from the study. Preprint servers such as ArXiv were also excluded from the study.

Starting from April 2018, 50 of the most recently published original articles or review articles in each journal were selected for inclusion in the study. Articles selected for inclusion were published online between January 2017 and April 2018; this includes early view articles. Articles were excluded if they did not contain an abstract or DOI. Block randomization using a random number generator at the subject level was used to randomize articles to either the control or the intervention arm of the study. For each subject area, 200 articles were randomized to the control, and 200 articles were randomized to the intervention. In total, 1600 articles were randomized to the control, and 1600 articles were randomized to the intervention. The overall study design is presented in Figure 1.

Figure 1. Overall study design.



Intervention

TrendMD [38] is a cross-publisher article recommendation and distribution platform that, as of May 2019, was embedded on over 4700 journals and websites from 300 publishers and seen by approximately 125 million readers per month. Roughly two-thirds of the TrendMD Network is related to scientific, technical, and medical (STM) publications; the other one-third is a relatively even split between social sciences, humanities,

and business publications. Participating publishers use TrendMD to distribute their published article links within the article recommendations displayed on articles within their journals (nonsponsored recommendations) or third-party journals within the TrendMD Network (sponsored recommendations; please see Figures 2 and 3). TrendMD's content distribution model is benchmarked to similar services in the consumer web, where the leading networks Outbrain [39] and Taboola [40] generate the "From the web" and "You may like" recommendations seen alongside the content on many popular websites like CNN or BBC [29,35] (please see Figure 4 for reference).

The intervention consisted of the promotion of 1600 articles in the TrendMD Network for 6 months, between May 1, 2018, and November 2, 2018. Articles included in the TrendMD Network are displayed as recommended article links. Links to articles randomized to TrendMD were displayed as sponsored recommended links on publications participating in the TrendMD Network. There was an average of 4300 participating journals and 121 million readers per month during the course of the study. The frequency of sponsored article link placements is determined by a relevancy score based on the following: relatedness (ie, keyword overlap), collaborative filtering (similar to Amazon's "people who bought this item also bought that item"), and user clickstream analysis (the Netflix approach, basing recommendations on the users' interests expressed through their online history) [27-29,35]. As a result of the relevancy scoring system, some articles randomized to TrendMD were both seen more often (ie, accrued more link impressions) and clicked on more frequently than others in the TrendMD Network.

Figure 2. TrendMD: sponsored versus nonsponsored links.

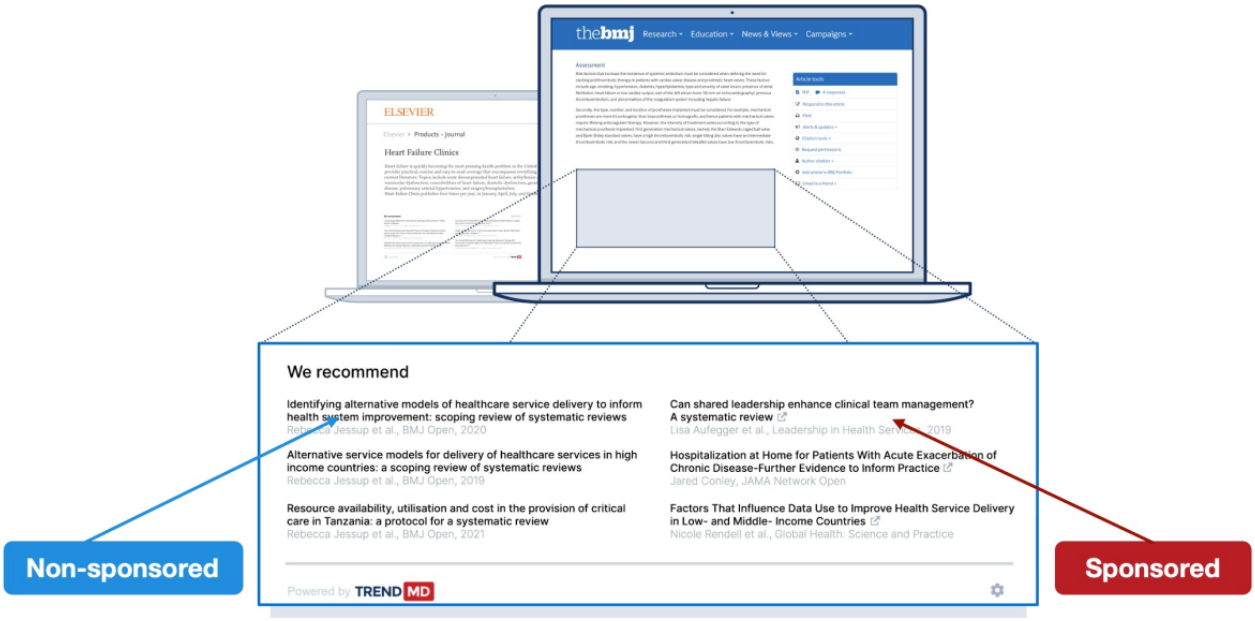


Figure 3. How the TrendMD Network works.

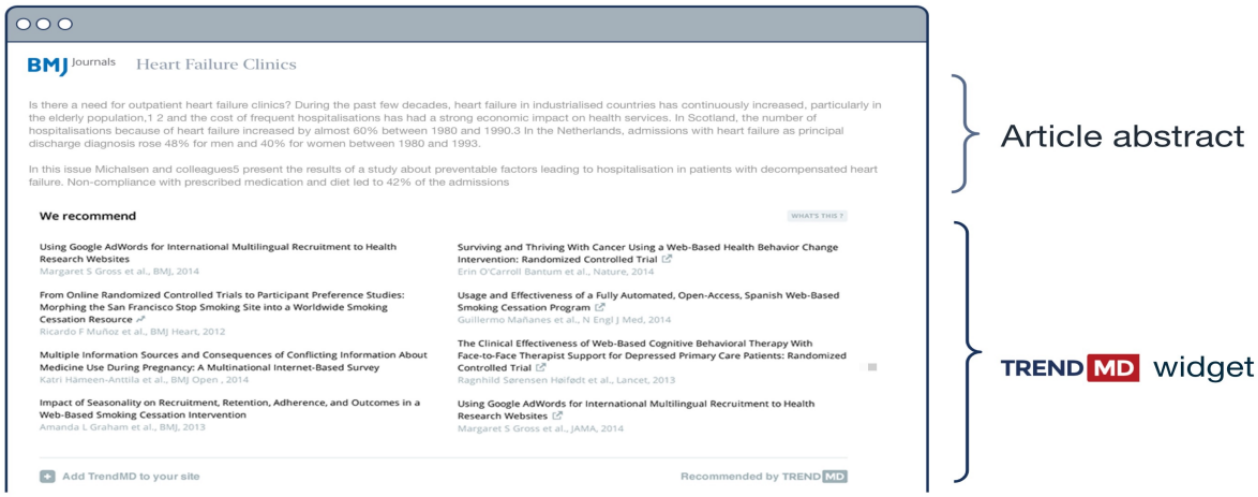
Figure 4. TrendMD widget display.



The sponsored links are displayed in the TrendMD Network as long as they are relevant and the advertiser account balance is greater than US $0. An account in TrendMD was created for this study. The 1600 articles randomized to TrendMD received a maximum total budget of US $9600 at a cost-per-click of US $0.10 for 96,000 sponsored TrendMD clicks. The account was allowed to spend up to a maximum for US $1600 per month, or 16,000 clicks per month, over the 6-month study period for a total of 96,000 clicks. The actual amount spent by the account was US $1600 per month; all clicks were delivered each month throughout the 6-month study. A summary of how TrendMD works and the outcomes measured can be seen in Figure 3.

Control

Articles randomized to the control (n=1600) received no promotion in the TrendMD Network. Articles randomized to the control received traffic by organic means (eg, Google, Google Scholar, or PubMed) and other means implemented by publishers or authors of content outside the context of this study.

Primary Outcome

The primary outcome of our study is the mean citation counts for articles randomized to TrendMD compared to the control at 36 months. Article citation counts at 36 months were extracted through the Scopus application programming interface (API) on March 30, 2021.

Secondary Outcomes

Thirty-six–Month Analysis

Mean citation counts after 36 months were compared for articles randomized to TrendMD versus control for each of the 8 subject areas. This analysis was completed to assess whether the effects of TrendMD promotion were discipline specific. Article citation counts were extracted from the Scopus API on March 30, 2021.

Twelve- and Six-Month Analysis

Mean citation counts after 12 and 6 months were compared for articles randomized to TrendMD versus the control. Article citation counts were extracted from the Scopus API on May 2, 2019, for the 12-month data and on November 2, 2018, for the 6-month data. These data were also published in our 2019 paper and included here for convenience to readers [35].

Statistical Analysis

We performed an a priori power calculation to determine the necessary sample size (n=1600 in each arm of the study) to detect differences in our primary outcome of mean citation counts between groups at 12 months. Please see our previously published paper for how we determined the required sample size in each arm of the study [35]. The study was not powered to detect differences in citation counts at 6 or 36 months nor was it powered to detect differences across the subject area–level comparisons at any of the time intervals. To power a study to detect differences at the subject level, each subject would have required between 1000 to 3000 articles in each arm of the study, which was not feasible for us to conduct for budgetary reasons.

Baseline characteristics of articles at the start of the study were tabulated and compared across randomized arms of the study. We categorized articles by subject area, access type (closed vs OA), Journal Impact Factor, and citations and Mendeley saves. Both the primary and secondary outcomes were analyzed with the two-sample *t* test on log-transformed data (1 + x). In the event that mean differences were statistically significant, we calculated effect sizes using Cohen *d* [41] on log-transformed data. Cohen *d* is defined as the difference between two means divided by a SD for the data. Lastly, we performed a stepwise and backward multivariate ordinary least squares (linear) regression analysis to determine the predictors of citations at 6, 12, and 36 months; we used log-transformed dependent variables in the model. A significance value of 0.1 was used for the removal of variables in our stepwise regression model. Journal Impact Factor, access type (ie, OA vs closed), baseline Mendeley saves and citations, and TrendMD clicks (ie, clicks on promoted article links) and impressions (ie, display of promoted article links) were covariates in the regression model; they were selected as covariates because each of them has known independent effects on citations (eg, Journal Impact Factor is a predictor of citation counts) and do not have issues of multicollinearity. We did not collect data on all possible predictors of citations (eg, number of authors or international collaboration) in our regression model, as this was out of scope

to our analysis; the primary goal of our regression model was to determine if TrendMD clicks and impressions were independent predictors of our primary outcome of citations at 36 months. All regressions adjusted the SEs for clustering of citations using Huber-White SEs; this corrected for heteroscedasticity [42]. Residuals were analyzed for normality using the Kolmogorov-Smirnov test; we also analyzed the residuals using skewness and kurtosis statistical values and compared to SE values.

A 2-tailed $P<.05$ was considered statistically significant. To mitigate the type I error rate, the Bonferroni correction method was used to control for multiple comparisons made for the 8 disciplinary differences in mean citation counts [43]. A 2-tailed $P<.006$ was considered to be statistically significant for mean differences in Mendeley reader and citation counts across subject areas. Arithmetic mean values for Mendeley saves and citation counts are shown with 95% CIs on non–log-transformed data unless otherwise specified. Tests for normality were included in the model. SPSS version 25 (IBM Corp) was used to complete the statistical analyses.

Results

Baseline Characteristics

The following was published verbatim in our previously published randomized controlled trial [35]; these data and discussion are included here for convenience of the reader. Overall, 3200 articles were randomized: 1600 to the TrendMD arm and 1600 to the control arm. The Kolmogorov-Smirnov test of the 6-month Mendeley saves ($P=.61$) and citation count ($P=.13$) data retained the null hypothesis that the distributions were log-normal within the control and TrendMD arms. Tables 1 and 2 show the baseline characteristics of articles randomized to TrendMD versus the control; no statistical tests were used to compare any metrics between groups at baseline according to the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines [44].

Table 1. Overall baseline characteristics [35].

Intervention	Articles, n	Open access, n	Journal Impact Fact, mean (SD)	Mendeley saves, mean (SD)	Citation count, mean (SD)
Control	1600	88	14.77 (15.87)	23.37 (36.33)	0.86 (2.98)
TrendMD	1600	92	15.41 (16.56)	23.79 (39.34)	1.04 (3.37)

Physics and mathematics				
Control	10	7.67 (5.86)	8.90 (14.33)	0.33 (1.09)
TrendMD	11	7.74 (5.85)	9.04 (18.12)	0.31 (1.29)
Social sciences				
Control	9	4.52 (1.08)	15.01 (16.56)	0.36 (1.16)
TrendMD	18	4.51 (1.06)	14.39 (17.27)	0.35 (1.17)

Primary Outcome

Articles randomized to TrendMD (n=1600) showed a 28% increase in mean citations relative to the control at 36 months (Figure 5). The mean citations for articles randomized to TrendMD was 48.05 (SD 113.51), compared to 37.53 (SD 77.36) for articles randomized to the control. The difference in mean citations for TrendMD articles versus the control was 10.52 (95% CI 3.79-17.25) and was statistically significant (P=.001). The effect size of TrendMD on citations at 36 months was small (Cohen d 0.11; Table 3). The cumulative distribution of article citations at 36 months is shown in Figure 6. The fact that the TrendMD cumulative distribution curve is shifted to the right relative to the control indicates the promotion of increased citation rates across the entire distribution of articles; the effect was not limited to just a few outlying articles.

Figure 5. Mean citation count over 36 months: TrendMD versus control.

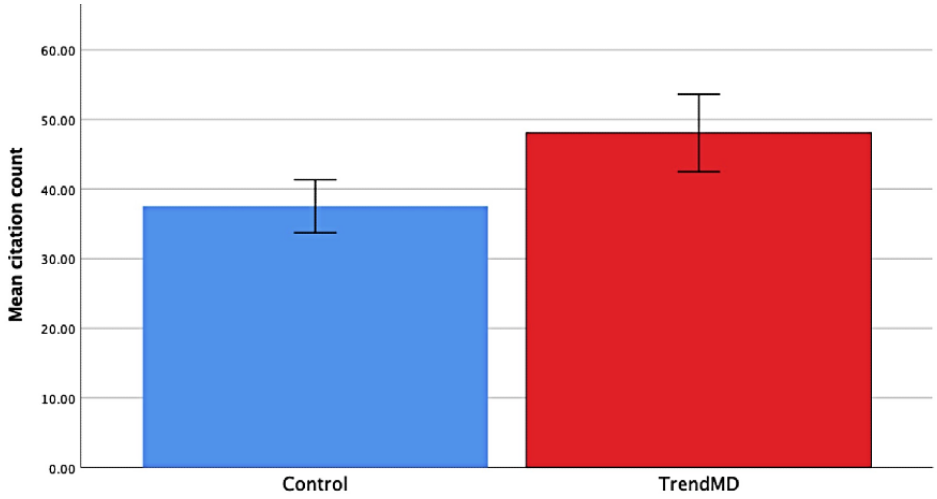

Table 3. Citation counts at 36, 12, and 6 months.

	36 months		12 months		6 months	
	Control	TrendMD	Control	TrendMD	Control	TrendMD
Citations, mean (SD)	37.53 (77.36)	48.05 (113.51)	10.10 (19.09)	15.16 (40.37)	5.12 (10.65)	6.18 (16.10)
Mean difference in citations (95% CI)	N/A[a]	10.52 (3.79-17.25)	N/A	5.06 (2.87-7.25)	N/A	1.06 (0.12-2.01)

Secondary Outcomes

Subject Area Differences in Mean Citations at 36 Months

At 36 months, TrendMD was not found to yield statistically significant increases in citation counts relative to the control in any of the individual subject areas. The largest relative difference in citation counts compared to the control was found to be in the subject area of health and medical sciences (41%); however, it was not found to be statistically significant (see Table 4 and Figure 7 for a breakdown of mean differences for each subject area).

Table 4. Citations at 36 months by subject area.

Category and intervention	Articles, n	Citations, mean (SD)	Mean difference (95% CI)	*P* value
Business, economics, and management			3.95 (–0.66 to 8.56)	.24
Control	200	18.75 (20.45)		
TrendMD	200	22.70 (26.14)		
Chemical and materials sciences			12.68 (–1.84 to 27.20)	.18

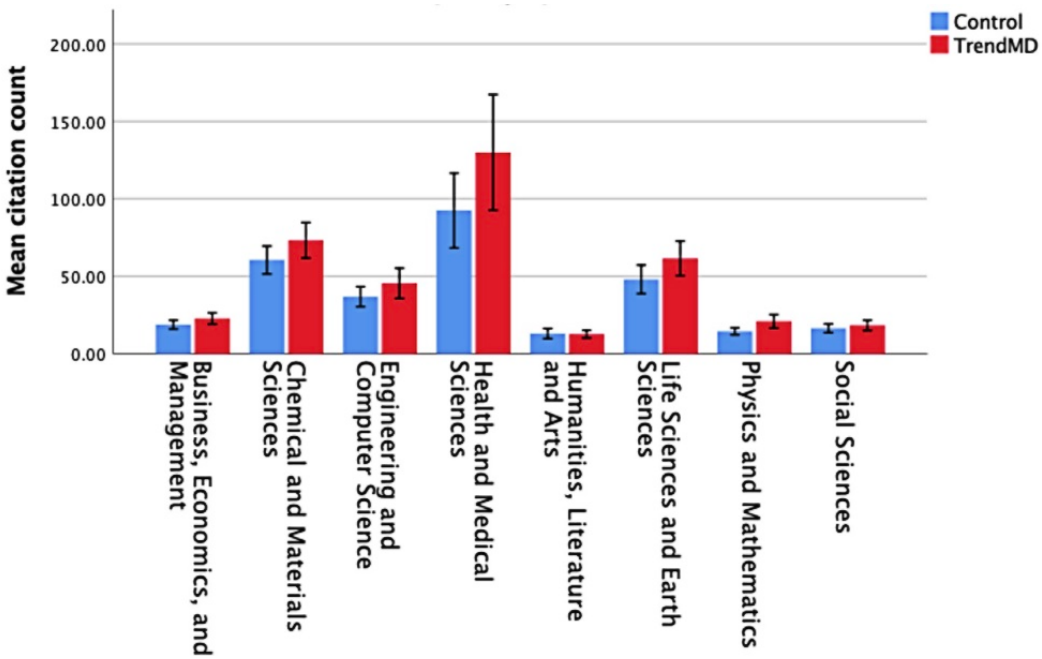
Figure 7. Mean citation counts by subject area over 36 months: TrendMD versus control.



Multivariate Regression Analysis

Overall, our multivariate regression models were a good fit to predict citations in all articles at 6, 12, and 36 months. The Kolmogorov-Smirnov test of the residuals (*P*=.21) were normal; values for skewness and kurtosis in the residuals were both less than 1 SE, which suggests that the residual values were not significantly different from the expected value of zero for a normal distribution. Our models predicted 41%, 43%, and 44% of the variation in citation counts at 6, 12, and 36 months, respectively. Clicks driven by TrendMD were found to be an independent predictor of citations; articles that received the greatest number of clicks from TrendMD had the largest citation advantage at 36 months (see Table 5 for the standardized beta coefficients for each covariate in the model).

Table 5. Multivariate regression model: standardized beta coefficients at 36, 12, and 6 months.[a]

Standardized beta coefficients	36 months	12 months	6 months
Baseline citations	0.286	0.329	0.323
Baseline Mendeley saves	0.209	0.216	0.163
Journal Impact Factor	0.207	0.175	0.222
Access type	NS[b] (0.664)[c]	NS (0.847)	NS (0.721)
TrendMD clicks	0.266	0.182	0.153
TrendMD impressions	NS (0.342)	0.063	0.073

[a]All other variables included in the regression model were significant at *P*<.001.

[b]NS: nonsignificant.

[c]Significance values for nonsignificant variables excluded in the model are included in brackets.

Discussion

To the best of our knowledge, this was the first randomized controlled trial to demonstrate how relatively brief postpublication promotion of peer-reviewed articles over a 6-month period can be used to persistently increase citation rates of those articles after 36 months. The overall citation advantage conferred by article promotion in the TrendMD Network was 28% relative to the control at 36 months, which dissipated from a 50% citation advantage at 12 months. Despite the overall citation advantage observed at 36 months, we did not find a statistically significant increase to citation counts within individual subject areas included in this study. There were, however, larger, albeit nonstatistically significant differences in citation counts measured in certain subjects versus others. For example, health and medical sciences articles saw larger citation increases than articles published in humanities, literature, and arts journals. One possible explanation for this could be because two-thirds of the TrendMD Network are STM journals; therefore, the effect size of promotion is likely to be larger for STM articles rather than humanities-related articles. The other possible explanation for the smaller citation advantages in some subject areas is because of differing publication cycle lengths, which have a direct effect on the speed in which citations accrue overtime. Articles in the fields of medicine, life sciences, and physics, for example, are typically published faster in comparison to articles in the humanities and social sciences [2].

Notwithstanding, our study was not powered to detect differences across the subject area–level comparisons; therefore, the negative findings across individual subject areas are likely due to the small sample sizes and resulting type II errors [45]. Given that we found an overall citation advantage at 36 months and found a Mendeley save advantage in 7 of the 8 subject areas at 6 months, it is reasonable to conclude that studies using larger sample sizes within subject areas over periods longer than 36 months may have shown an increase in citations. Future studies using larger sample sizes within subject areas over longer periods of time are needed to determine whether, and to what degree, promotion of articles in the TrendMD Network confers a citation advantage to individual subject areas.

We initially hypothesized that the overall 50% citation advantage observed at 12 months would increase over time due to the time it takes citations to accrue from manuscripts passing through peer review and onto publication [2]. However, our data suggests the citation advantage conferred to promoted articles dissipated between 12 and 36 months, which could be due to multiple factors affecting article citation rates, such as author credentials, subject matter, and cited references [36]. We do not know the precise timing of the peak of the citation advantage because we only measured citation counts at 6, 12, and 36 months. Future studies are warranted that measure citation rates at more frequent intervals to discern when the citation advantage conferred to promoted articles are at its maximum.

Based on these data, we can speculate on the mechanism in which TrendMD conferred a sustained citation advantage to promoted articles at 36 months. Readers clicking on promoted article links displayed in the widget that they may have not otherwise discovered, saved these articles to their Mendeley reference libraries, and cited these articles while creating their own scholarly work. This pathway is evidenced by the fact that page views (ie, clicks) driven by TrendMD were an independent predictor of both Mendeley saves at 6 months and citations at 6, 12, and 36 months (Table 5).

The findings of our study significantly add to the limited corpus of literature examining the efficacy of strategies to augment citation counts of peer-reviewed research. Though publishing research in OA journals is the most widely studied strategy to

augment citation counts, the extent to which the OACA exists or is confounded by selection bias remains unknown [7,11,12,15,16]. In addition, even if the OACA did exist at some point in time in the past, the more that OA content becomes the standard, the less likely the strategy will yield citation benefits as the effect will be ubiquitous across all articles. Other strategies such as the promotion of peer-reviewed literature in social media platforms for the purpose of enhancing citation counts have similarly yielded inconclusive and, at times, conflicting results [21-23,25,26]. These data presented in our study address a pressing unmet need of authors, publishers, and funders for evidence-based strategies that can be used to enhance discoverability by the right targeted audience, which in turn augments the usage and citations counts of peer-reviewed content.

The research presented here has several strengths. First, the outcome of citation counts is unbiased and objective, increasing the reproducibility of the results. Second, we used a rigorous randomized controlled trial design, which minimizes the likelihood of bias and confounding. Third, our sample size was large, and our study was adequately powered for outcomes of differences in mean citations.

There are, however, several limitations to this research. First, all authors have a conflict of interest with the results presented as creators (PK and GE) or employees (TB) of TrendMD. Risk of bias, however, was mitigated by the randomized controlled trial design. Second, although our study was adequately powered to detect mean differences in citation counts across all articles at 12 months, our study was not adequately powered to detect mean differences in citation counts between disciplines. Third, our inclusion criteria of randomly selecting articles published in 8 out of the top 20 journals with the highest h-5 index in Google Scholar categories may make our results less generalizable to articles published in journals with lower Impact Factors. We attempted to mitigate this possible limitation by randomly selecting 8 of the top 20 journals in each subject. Future studies are needed to determine whether TrendMD still confers an enduring citation advantage to articles published in lower Impact Factor journals. Another limitation and question that stems from these data is whether longer periods of promotion beyond 6 months would yield larger and more enduring benefits to citation counts. Future studies using promotion periods longer than 6 months are needed to determine whether there is a dose-dependent relationship between the length of the article promotion period and the magnitude of citation advantage conferred. Our group has previously completed a study showing that there is indeed a dose-dependent relationship between the intensity of article promotion and page views [28]; however, the degree to which the increase in page views leads to a citation advantage is not known. It is also possible that a longer promotion period of articles may saturate over time as readers are presented with the same article links; future studies are needed to determine whether prolonged promotion of articles lead to diminishing rates of return for citations. Lastly, the number and type of publishers participating in the TrendMD Network may change over time, which may affect the reproducibility of our findings [35]. Past studies indicate that the efficacy of TrendMD promotion is dependent on the number and type of publishers participating in the Network [28,29]. In general, replicated data indicates that the more publishers across subject areas using TrendMD the greater the efficacy of the channel to confer benefits to article visibility and usage [35]. If publishers stopped using TrendMD, the channel is unlikely to be as effective at augmenting citation counts as described in this study. More generally, there are, of course, limitations to citation analyses; citations only reflect activity in academia, and the usefulness of citations as indicators varies greatly between fields [46].

Despite the limitations, this study demonstrates that the promotion of articles in a cross-publisher online distribution channel (TrendMD) over a 6-month period can be used to persistently increase citations of articles after 36 months. Though we did not find a statistically significant increase in citation counts within individual subject areas at 36 months, this was likely due to small sample sizes and insufficient power, which resulted in type II errors. The overall citation advantage conferred to promoted articles was observed at 6 months, appeared to peak at 12 months, and endured, albeit to a lower level relative to the control at 36 months.

Acknowledgments

This research was supported in part by two investment grants made by the Ontario Centres of Excellence (OCE), a Canadian government-funding program. The grants were OCE Market Readiness CC (Grant 22292) and OCE Market Readiness CB (Grant 23811). We also want to thank members of the TrendMD team for help with data acquisition.

Conflicts of Interest

PK is a cofounder and former Chief Executive Officer (CEO) of TrendMD Inc. TB is a full-time employee of TrendMD Inc. GE is a cofounder and former Chief Science Officer of TrendMD Inc. GE and PK currently hold no equity in TrendMD. GE is also founder and CEO of JMIR Publications, where TrendMD was initially tested and developed. The reviewers and editors of this paper were not aware of GE's coauthorship during the peer-review process. JMIR Publications continues to offer TrendMD services to its authors and receives a commission.

This randomized study was not registered, explained by authors with the reason that the study does not require registration due to its nature. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials, because the study is a follow-up on an initial study involving peer-reviewed articles. It does not involve the randomization of people into groups and does not target any behavioural outcomes.

Abstract

Background: Given the ongoing COVID-19 pandemic situation, accurate predictions could greatly help in the health resource management for future waves. However, as a new entity, COVID-19's disease dynamics seemed difficult to predict. External factors, such as internet search data, need to be included in the models to increase their accuracy. However, it remains unclear whether incorporating online search volumes into models leads to better predictive performances for long-term prediction.

Objective: The aim of this study was to analyze whether search engine query data are important variables that should be included in the models predicting new daily COVID-19 cases and deaths in short- and long-term periods.

Methods: We used country-level case-related data, NAVER search volumes, and mobility data obtained from Google and Apple for the period of January 20, 2020, to July 31, 2021, in South Korea. Data were aggregated into four subsets: 3, 6, 12, and 18 months after the first case was reported. The first 80% of the data in all subsets were used as the training set, and the remaining data served as the test set. Generalized linear models (GLMs) with normal, Poisson, and negative binomial distribution were developed, along with linear regression (LR) models with lasso, adaptive lasso, and elastic net regularization. Root mean square error values were defined as a loss function and were used to assess the performance of the models. All analyses and visualizations were conducted in SAS Studio, which is part of the SAS OnDemand for Academics.

Results: GLMs with different types of distribution functions may have been beneficial in predicting new daily COVID-19 cases and deaths in the early stages of the outbreak. Over longer periods, as the distribution of cases and deaths became more normally distributed, LR models with regularization may have outperformed the GLMs. This study also found that models performed better when predicting new daily deaths compared to new daily cases. In addition, an evaluation of feature effects in the models showed that NAVER search volumes were useful variables in predicting new daily COVID-19 cases, particularly in the first 6 months of the outbreak. Searches related to logistical needs, particularly for "thermometer" and "mask strap," showed higher feature effects in that period. For longer prediction periods, NAVER search volumes were still found to constitute an important variable, although with a lower feature effect. This finding suggests that search term use should be considered to maintain the predictive performance of models.

Conclusions: NAVER search volumes were important variables in short- and long-term prediction, with higher feature effects for predicting new daily COVID-19 cases in the first 6 months of the outbreak. Similar results were also found for death predictions.

KEYWORDS

prediction; internet search; COVID-19; South Korea; infodemiology

Introduction

COVID-19 is a new disease entity that has caused a global pandemic, with more than 200 million cases and 4.5 million deaths since it was first reported at the end of December 2020 [1]. In contrast to the previous outbreaks of SARS and Middle East respiratory syndrome (MERS) that spread in clustered countries, COVID-19 exhibited massive disease transmission and longer periods of spread, even with implementation of multiple public health measures. Given this situation, predictions could greatly help in health resource management [2], particularly in terms of human resources and medical equipment deployment [3], as well as in preparing for upcoming future waves [4]. This approach will be beneficial for policy makers and health care managers [2], both in national government and at the level of local authorities [3].

However, as a new entity, COVID-19's disease dynamics seemed difficult to predict [5]. Most existing COVID-19 prediction models are highly dependent on confirmed cases, which may lag behind underlying infections [6]. The number of confirmed cases may only represent the number of people who have sought medical attention due to the occurrence of moderate to severe symptoms [5]. Therefore, external factors need to be included in models to increase the accuracy of these models.

One of the most common emerging external variables included in COVID-19 prediction models is comprised of internet search data. These data are collected during information-seeking activities on Google, NAVER, Daum, Baidu, and other search engines. Studies used information-seeking activities are part of infodemiology studies. The term "infodemiology" was first introduced by Eysenbach [7] in 2002 as an acronym of information epidemiology. This field aimed to analyze online information in terms of its distribution and determinants for public health–related purposes [8]. In addition, infodemiology is a fast-growing field of research that can be assessed both from demand- and supply-side studies [9]. Search engine query data in infodemiology studies are used in demand-based studies, which may have several advantages in the case of the COVID-19 pandemic. An increase in search data has commonly preceded traditional COVID-19 metrics [5,10,11]; as such, these data may provide a real-time indication of symptoms in a population [6]. Therefore, constructed models could possibly detect new waves or peaks at an earlier stage of the outbreak [5].

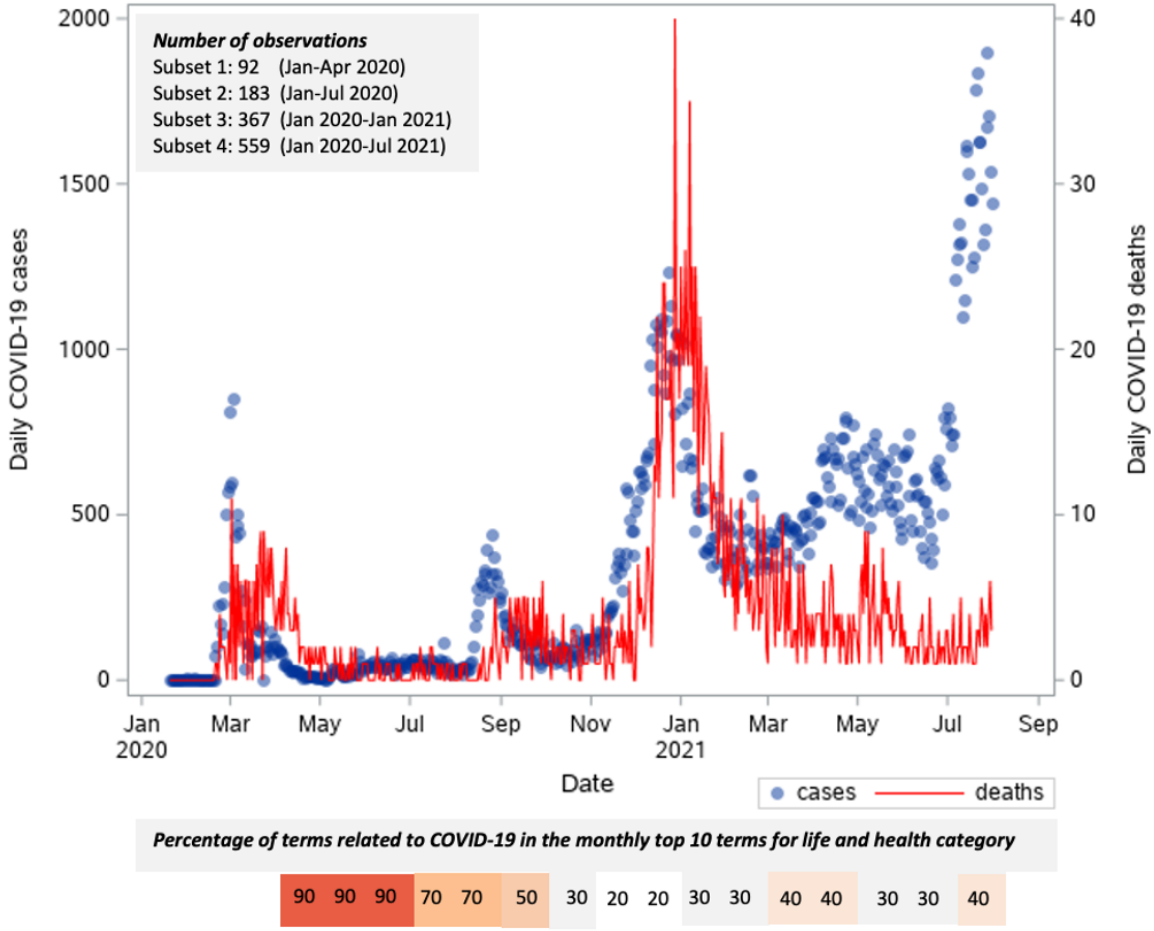
A study by Rabiolo et al [12] found that models that included search data performed better than those that did not include the search volumes in the first month of outbreak prediction. Similar findings were also shown in two previous analyses—one studying data from Iran [13] and another studying data from India, the United States, and the United Kingdom [14]—for periods of 1 month and 3 months, respectively, after the first case was detected. However, other studies conducted in the United States demonstrated low accuracy in model prediction [15] and variability in model performances among states and time periods [16]. Both of those studies were constructed using time series data of less than 2 months. Hence, it remains unclear whether models incorporating online search volumes will lead to better predictive performances for longer periods of prediction of new daily COVID-19 cases and deaths. In this study, we assessed the predictive performance of NAVER search volumes at different pandemic stages in South Korea. Data were aggregated into four subsets: 3, 6, 12, and 18 months after the first case was reported. In brief, this study aimed to analyze whether search engine query data constitute an important variable for inclusion in models for short- and long-term prediction of new daily COVID-19 cases and deaths.

Methods

Data Sets

In this study, we used country-level case-related data, NAVER search volumes, and mobility data from Google and Apple. NAVER search volumes were retrieved from NAVER's website [17] using terms related to COVID-19 and popular terms as of July 31, 2021. Terms in Korean, followed by their English translation, included the following: 코로 나 바이러스 (coronavirus), 코로나 바이러스 테스트 (coronavirus test), 메르 스 (MERS), 마스크 (face mask), 사회적 거리두기 (social distancing), 신천지 (Shincheonji), kf94 마스크 (kf94 mask), 일회용 마스크 (disposable mask), 온도계 (thermometer), 손 소독제 (hand sanitizer), 마스크스트랩 (mask strap), and Kf80 마스크 (kf80 mask). NAVER search volumes were queried in the Korean language, with quotation marks used for terms with more than two words, for all types of searches, genders, and age groups. Mobility data were collected from Google's Community Mobility Reports [18] and Apple's Mobility Trends Reports [19]. In addition to case-based data, daily cumulative COVID-19 cases and deaths were downloaded from the country-level time series data repository from the Center for Systems Science and Engineering at Johns Hopkins University [20]. A detailed description of all data used in this study is given in Table 1. Case-related data were retrieved from January 20, 2020—when the first COVID-19 case was reported in South Korea—to July 31, 2021. NAVER search volumes and mobility data were queried with a lag of 3 days to include more-recent observations in the analysis. Data were then aggregated into four subsets: 3, 6, 12, and 18 months after the first case was reported (Figure 1). Moreover, we also retrieved the monthly top 10 terms in the life and health category from NAVER beginning in April 2020 (Multimedia Appendix 1).

Figure 1. Time series of new daily COVID-19 cases and deaths in South Korea from January 20, 2020, to July 31, 2021. The information at the bottom of the figure describes the percentage of terms related to COVID-19 per month, from April 2020 to July 2021, out of the monthly top 10 terms for the life and health category (N=10). The list of terms is provided in Multimedia Appendix 1.



Statistical Analysis

Explanatory variables (Table 1 [21]) were used to develop models for predicting new daily COVID-19 cases and deaths. The first 80% of the data in all subsets were used as the training set, and the remaining data served as the testing set. In order to determine the best-fitting model in each subset, generalized linear models (GLMs) with three different distributions (ie, normal, Poisson, and negative binomial) were developed, along with linear regressions (LRs) with lasso, adaptive lasso, and elastic net regularization.

Table 1. Data set description.

Data set[a]	Data description	Use
Case-based data	Daily cumulative cases and deaths; used to calculate new daily cases and deaths	Time series graph, correlation, and prediction analysis
Google Community Mobility data	Daily changes in time spent in six categorized places—retail and recreation, grocery and pharmacy, parks, transit stations, workplaces, and residential areas—compared to baseline days; median value from January 3 to February 6, 2020	Correlation and prediction analysis
Apple Mobility Trends data	Daily relative volume of direction requests, in driving and walking situations, in Apple Maps compared to a baseline volume on January 13, 2020	Correlation and prediction analysis
NAVER search volumes	Daily online searches made through NAVER search engines; data ranged from 0 to 100; queries were made based on 12 terms used in our previous study [21] and popular terms related to COVID-19 as of July 31, 2021, from the life and health category; data were retrieved using terms in the Korean language, with quotation marks used for terms of more than two words, for all types of searches, genders, and age groups	Correlation and prediction analysis

[a]All data sets include country-level data.

All analyses and visualizations were conducted using SAS Studio, which is part of SAS OnDemand for Academics (SAS Institute Inc). For the GLMs, proc hpgenselect in SAS was used to develop and test the model performance with stepwise selection and an α level of .05 in selecting variables for the model. Only statistically significant variables (P<.05) were

included in the model. Furthermore, proc glmselect in SAS was used to construct LR models with steps of 25 and with the lowest Akaike information criterion (AIC) values in defining model selection. The 25 model construction steps were chosen in order to provide sufficient steps to define the best model with the lowest AIC value. Root mean square error (RMSE) values were defined as loss functions to assess the performance of models in the four subsets..

Results

Characteristics of New Daily COVID-19 Cases, Deaths, Mobility, and Search Data

The first case of COVID-19 in South Korea was reported on January 20, 2020, as shown in Figure 1. In the first 3 months of the outbreak, the mean number of new daily cases was 116.02. During this period, massive numbers of coronavirus tests were conducted along with the strict implementation of the social distancing policy. On February 7, 2020, the first coronavirus test kit was approved [22], and the first coronavirus drive-through test center was opened on February 23, 2020 [23]. The curve of cases was flattened, which led to an easing of social distancing rules at the national level beginning on May 6, 2020. A contact tracing system called KI-Pass was also introduced during this period [24]. Thus, with implementation of strict public health measures, the average new daily cases in the first 6 months of the outbreak dropped to 75.50, which was lower than that in the first 3 months.

However, a surge of cases occurred in mid-August, which led to a reinstating of level 2 restrictions beginning on August 28, 2020, in conjunction with mandatory mask-wearing. On October 12, 2020, restrictions were eased throughout most of the country, although a huge surge of cases developed as of mid-November. Level 2 restrictions were then tightened again [24]. This wave of cases remained high until the early months of 2021.

The first COVID-19 vaccine in South Korea was rolled out on February 28, 2021 [25]. Through the end of May, more than 700,000 people were newly vaccinated each day, but this number began to decrease by the end of June [26]. In early July, only around 1665 people were being vaccinated each day [27]. During this period, an immense wave of cases occurred that led to implementation of level 4 social distancing rules for the greater Seoul area beginning on July 26, 2021 [28]. The number of cases during this wave was larger than that of the other waves since the first reported COVID-19 case in South Korea. Time series analyses of new daily COVID-19 cases showed that implementation of public health measures heavily impacted the progression of cases. The number of new daily deaths seemed to follow the dynamics of COVID-19 cases, which were relatively higher in the third wave and lower in the fourth wave.

During the four waves of COVID-19 cases in South Korea, searches using various terms related to COVID-19 were captured in the NAVER database. In Figure 1, percentages of terms related to COVID-19 in the life and health category are presented. Due to the limitations of data querying in NAVER, retrospective top searches are only displayed starting from April 2020. A list of the top monthly terms is provided in Multimedia Appendix 1.

Figure 1 shows that a high percentage (9/10, 90%) of COVID-19–related terms were used in searches until June 2020. Afterward, the percentages decreased in the remaining months, with the lowest percentage (2/10, 20%) in November and December 2020. Relatively constant percentages of 30% (3/10) to 40% (4/10) of COVID-19–related terms used in internet searches were found in 2021. These findings reveal a massive use of COVID-19–related terms during online information-seeking activities in the early phase of the outbreak and a decreased pattern during the longer periods of the outbreak. In addition, top searches were mostly related to face masks, along with thermometers in April 2020 and hand sanitizers in August and September 2020.

Furthermore, decreased trends of mobility captured by Google were found to resemble the dynamics of cases and deaths (Figures 2 and 3). This differed from Apple mobility data, which seemed to be higher in the first and second waves and increased as the fourth wave developed. Moreover, increased numbers of searches seemed to precede the surge in cases and deaths.

Figure 2. Time series of new daily COVID-19 cases, mobility data (top plots), and NAVER searches (bottom plots) in South Korea from January 20, 2020, to July 31, 2021.

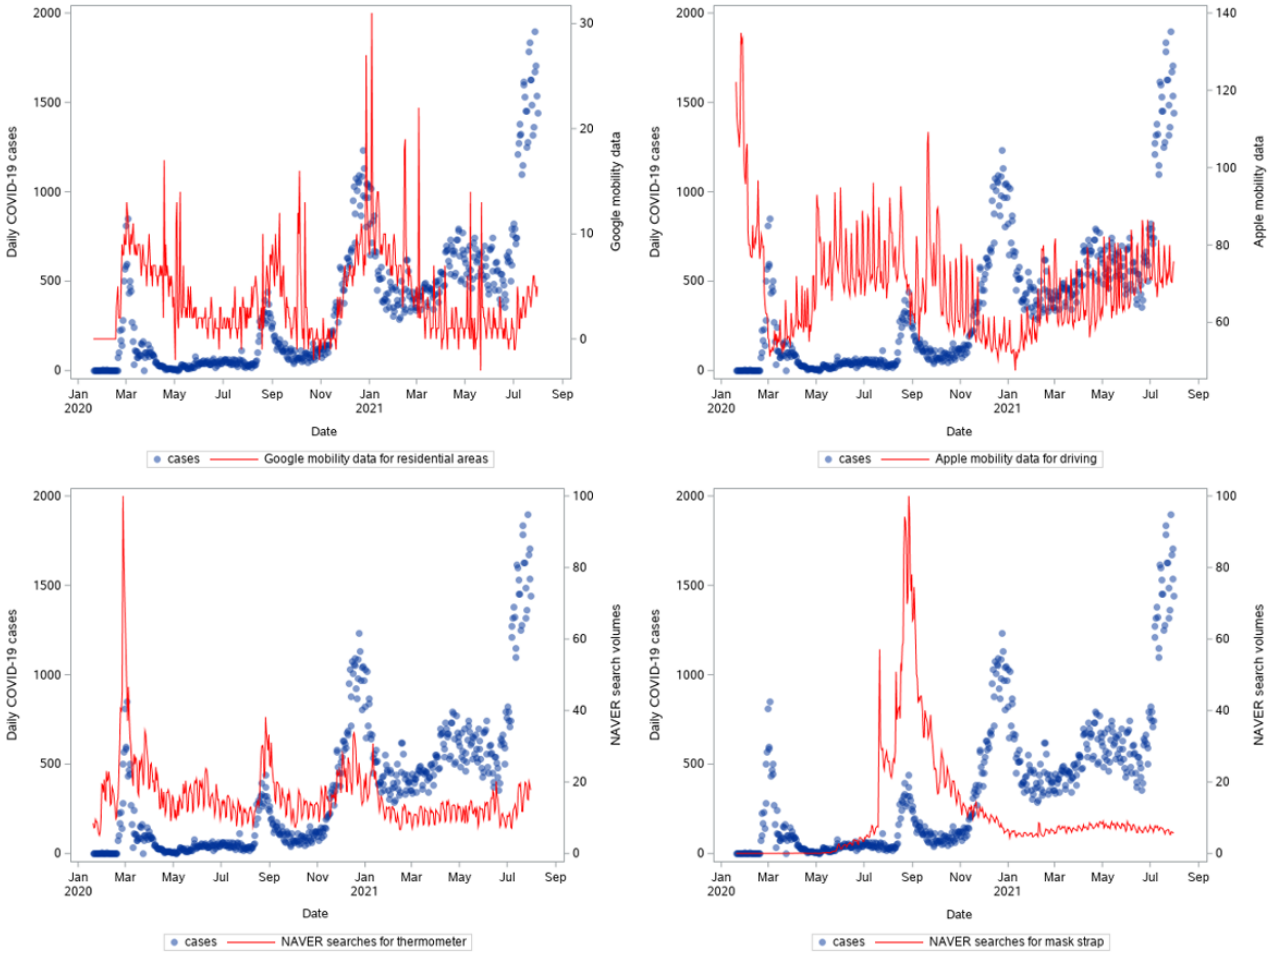


Figure 3. Time series of new daily COVID-19 deaths, mobility data (top plots), and NAVER searches (bottom plots) in South Korea from January 20, 2020, to July 31, 2021.

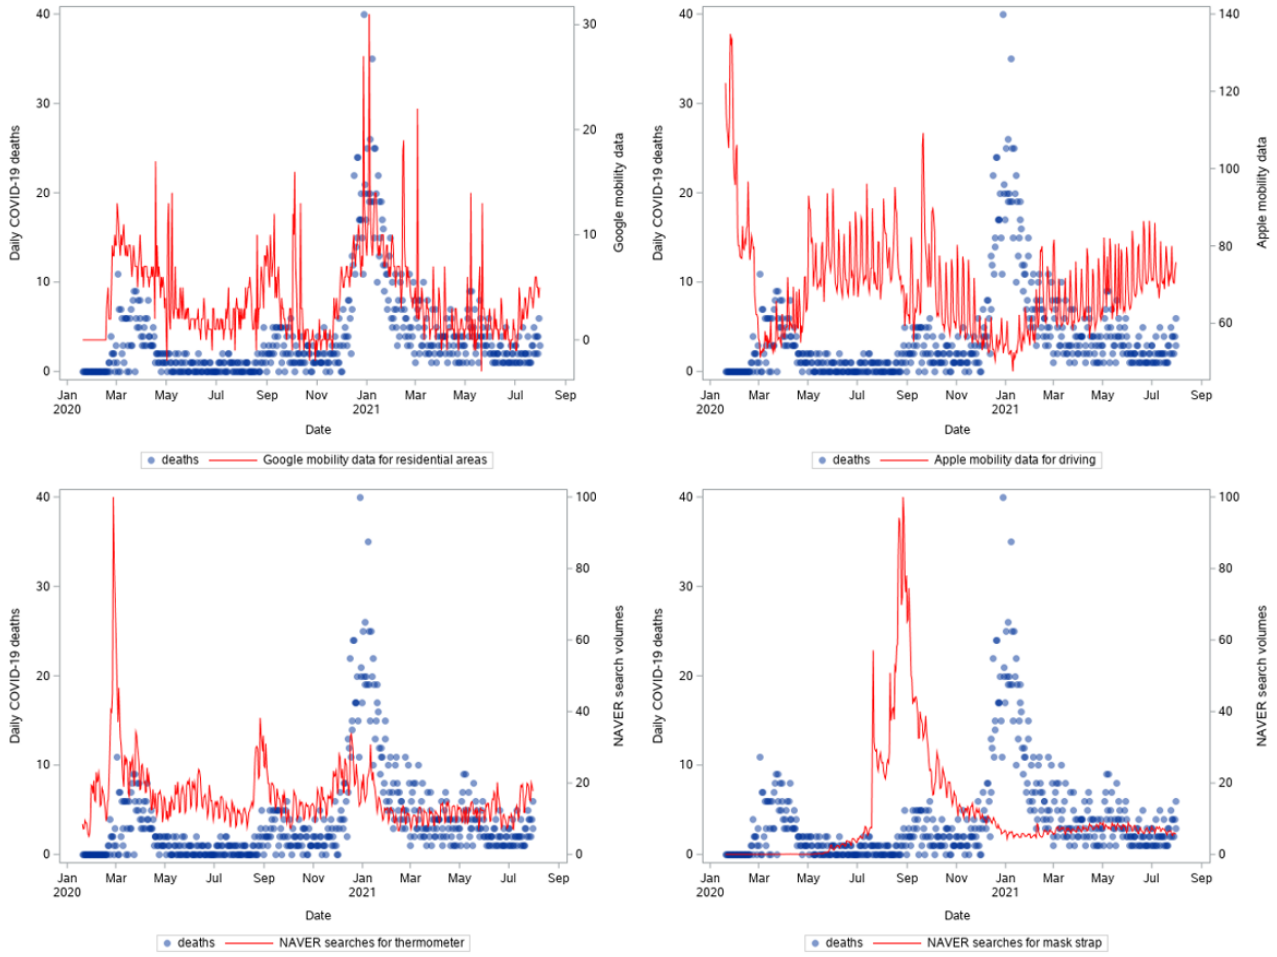

Correlations of New Daily COVID-19 Cases and Deaths With Explanatory Variables in the Training Sets

In the early stages of the outbreak, regarding subsets 1 and 2, new daily cases in the last 3 days (r=0.75, r=0.83), Google mobility data (retail and recreation: r=–0.82, –0.72; transit stations: r=–0.79, r=–0.70; residential areas: r=0.80), Apple mobility data (driving: r=–0.73; walking: r=–0.72), and NAVER search volumes (face mask: r=0.75; Shincheonji: r=0.83; thermometer: r=0.83, r=0.70) were highly correlated with new daily COVID-19 cases (Multimedia Appendix 2). In the third and fourth subsets, high correlations were only found between new daily COVID-19 cases and new daily cases in the last 3 days (r= 0.85, r=0.93). Moreover, moderate correlations were found between new daily COVID-19 cases in the third subset and Google mobility data (retail and recreation: r=–0.53) and between new daily COVID-19 cases in the last subset and new daily deaths in the last 3 days (r=0.62), Apple mobility data (driving: r=–0.62), and NAVER search volumes (disposable mask: r=–0.55). Negative correlations were mostly found between new daily COVID-19 cases and mobility data, which showed a decrease in the public's mobility during the pandemic period, particularly in the early stage of the outbreak. Negative correlations were also observed between new daily COVID-19 cases in the last subset of NAVER search volumes.

For new daily COVID-19 deaths, high correlations were only found for Apple mobility data (driving: r=–0.72; walking: r=–0.73) and NAVER search volumes (social distancing: r=0.72) in the first subset, and new daily cases in the last 3 days (r=0.71) and deaths (r=0.72) in the last subset. Similar to results in new daily COVID-19 cases, most of the negative correlations were found in mobility data in all subsets and NAVER search volumes in the last subset. Only Google mobility data for residential areas were positively correlated in all sets with both new daily COVID-19 cases and deaths. Results of the correlation analysis showed that higher correlations tended to be found in case-based data as the outbreak progressed, while reverse findings were found in mobility and internet search data.

Model Performance

GLMs with a Poisson distribution performed better as compared to the other models in predicting new daily COVID-19 cases in the first subset (Table 2). This finding suggests that at the early stage of the COVID-19 outbreak in South Korea, new daily cases more closely resembled a Poisson distribution. Later, in the second subset, the distribution of cases tended to be normally distributed, leading to a GLM with a normal function becoming the best performing model. GLMs with Poisson and negative binomial distributions resulted in larger RMSE values, which suggest that the distribution of cases in this subset did not follow those distributions that tended to be skewed.

In the third and fourth subsets, the LR without regularization (GLM1) and the LR with regularization (LR1-3) performed very similarly (Figure 4). This finding shows that GLMs performed better in the first 6 months of the outbreak. Over a longer period, LR models with regularization outperformed the GLMs. In addition, better performance of the model was found in predicting new daily deaths compared to new daily cases (Figures 4 and 5). For death predictions, the best performing models were the GLM with a negative binomial function in the first, second, and fourth subsets, and the LR with adaptive lasso regularization in the third subset.

Table 2. Assessment of the performance of the models.

Model	Subset 1[a], RMSE[b]		Subset 2[a], RMSE		Subset 3[a], RMSE		Subset 4[a], RMSE	
	Training set	Test set	Training set	Test set	Training set	Test set	Training set	Test set

Figure 4. Time series of new daily COVID-19 cases in South Korea from January 20, 2020, to July 31, 2021, and predicted values in the generalized linear models (GLMs) and linear regression (LR) models. GLM1: GLM with a normal distribution; GLM2: GLM with a Poisson distribution; GLM3: GLM with a negative binomial distribution; LR1: LR model with lasso regularization; LR2: LR model with adaptive lasso regularization; LR3: LR model with elastic net regularization; RMSE: root mean square error.

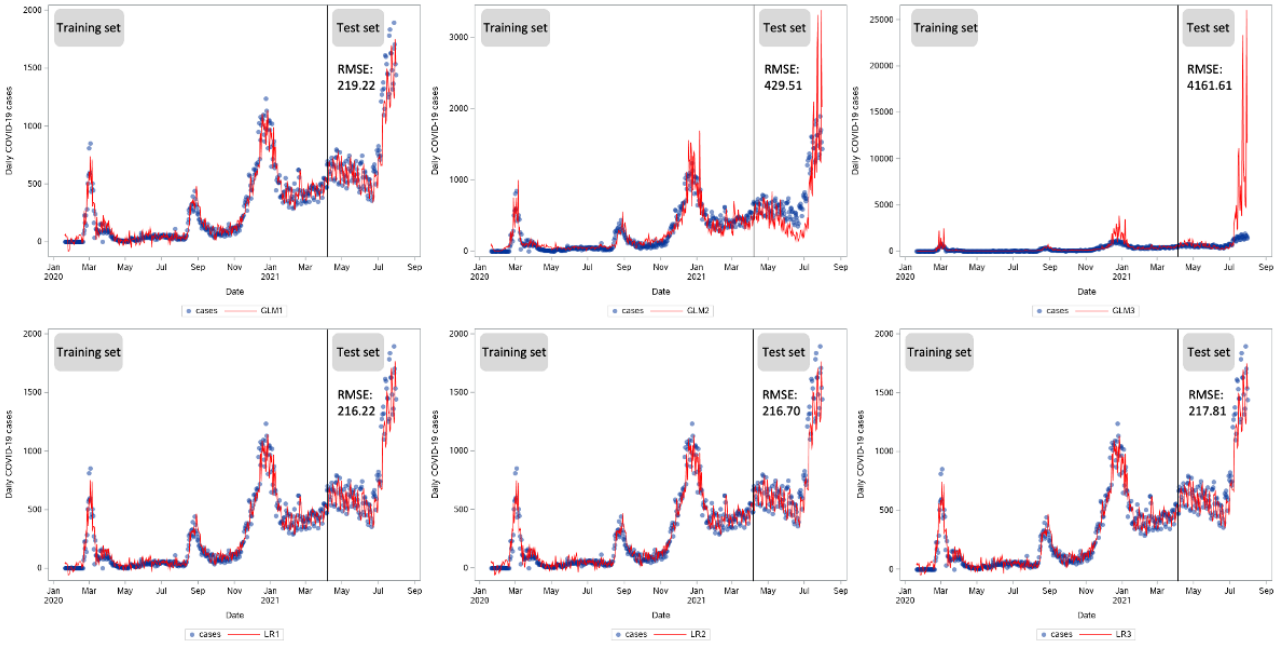

Figure 5. Time series of new daily COVID-19 deaths in South Korea from January 20, 2020, to July 31, 2021, and predicted values in the generalized linear models (GLMs) and linear regression (LR) models. GLM1: GLM with a normal distribution; GLM2: GLM with a Poisson distribution; GLM3: GLM with a negative binomial distribution; LR1: LR model with lasso regularization; LR2: LR model with adaptive lasso regularization; LR3: LR model with elastic net regularization; RMSE: root mean square error.

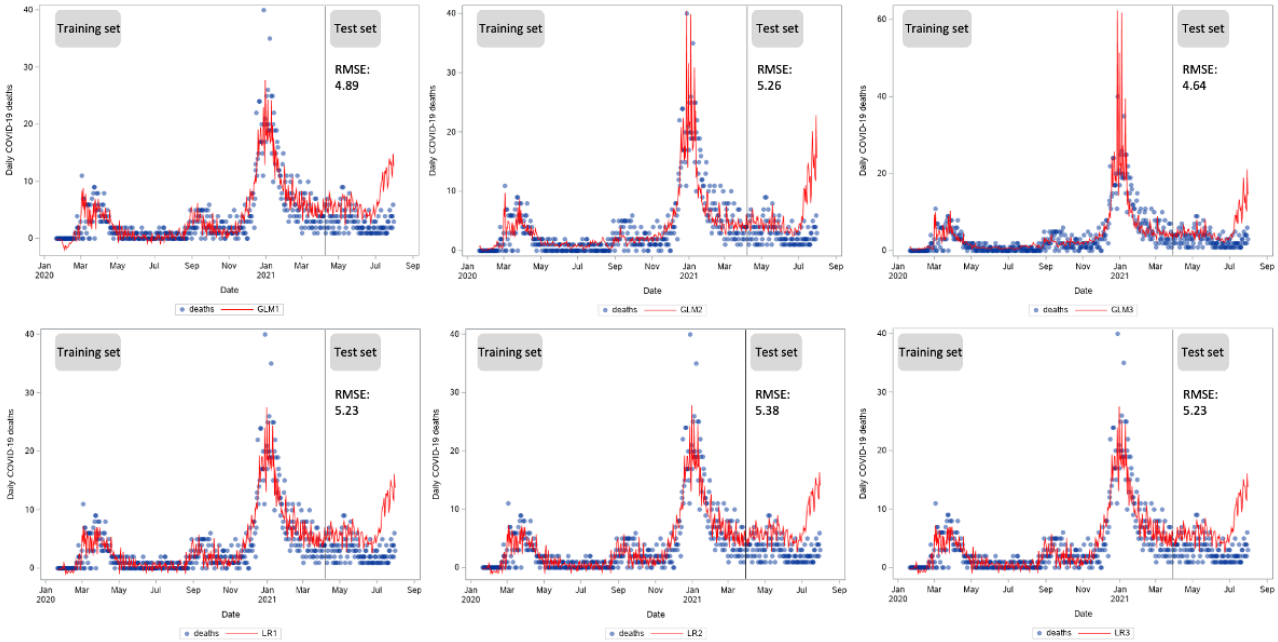

Feature Effects

In terms of the importance of the variables, NAVER search volumes produced higher parameter estimates in the models compared to case-based variables, Google mobility variables, and Apple mobility variables in the first and second subsets (Multimedia Appendix 3) in predicting new daily COVID-19 cases. This finding infers that NAVER search volumes might have affected the model performances to a greater extent and illustrates the usefulness of those variables, particularly searches for "thermometer" and "mask strap." However, parameter estimates of NAVER search volumes tended to have decreased in the third and fourth subsets. Higher parameter estimates were found in Google mobility data (ie, residential areas, transit stations, and workplaces) along with Apple mobility data (ie, driving) and case-based data (ie, new daily deaths in the last 3 days).

In this study, inclusion of NAVER searches for "thermometer" in models with longer periods seemed to be beneficial. In

addition, negative values of parameter estimates were found for most of the mobility data, except for the residential type, in all subsets. Negative parameter estimate values were also found in NAVER searches for "coronavirus," "coronavirus test," "MERS," "face mask," "kf80 mask," "disposable mask," "Shincheonji," and "hand sanitizer" in the third and fourth subsets.

In contrast to the abovementioned results, predictions of new daily deaths showed similar values of parameter estimates for case-based variables, mobility data, and NAVER search volumes (Multimedia Appendix 4). The numbers of variables included in the model were relatively fewer in the first and second sets compared with that in the third and fourth sets. However, most of the NAVER search volume variables were still included in the model, even in the last subset. Negative parameter estimate values were found for most of the mobility data, except workplace and residential types, in all subsets. Similarly, negative parameter estimate values for NAVER searches were also found in all sets. However, positive parameter estimate values were seen in all sets for case-based variables.

Discussion

Principal Findings

This study demonstrated an easy and explainable approach for determining the predictive performance of NAVER search volumes in four different subsets: 3, 6, 12, and 18 months after the first case was reported in South Korea. Subsets were used to create scenarios to analyze whether search engine query data are important variables for inclusion in models for short- and long-term prediction. In this study, we found that NAVER search volumes were useful variables in predicting new daily COVID-19 cases and deaths, particularly in the first 6 months of the outbreak. For longer prediction periods, NAVER search volumes were still found to constitute an important variable, although with a lower feature effect. In addition, this study discussed the role of search engine query data in infodemiology studies during the COVID-19 pandemic.

Short- and Long-Term Predictive Performances

Findings exhibited massive use of COVID-19–related terms for information-seeking activities at the early stage of the outbreak, which decreased over the longer period of the outbreak. This indicated a huge surge in information searches in the early months of the outbreak, as only limited COVID-19–related information was circulating. However, in later periods, extensive amounts of information were available, such as online news and reports by health experts [29]. Thus, these induced decreases in online information-seeking practices, which were observed from search term use. Beginning in April 2020, top searches were mostly related to face masks (Multimedia Appendix 1). A previous study in South Korea [21] showed increased in searches for various keywords concerning national and international events in the first 2 months of the pandemic. Similar results were also found in a worldwide setting [10], Taiwan [30], the Philippines [31], and the United States [32,33]. In addition, changes in the use of terms might indicate public concerns throughout the pandemic stages. In the case of South Korea, searches tended to be more related to logistical needs, including face masks, thermometers, and hand sanitizers for certain months in the longer period of the pandemic.

In terms of the correlation analyses, negative correlations were observed in the last subset for NAVER search volumes, which demonstrated a decline of searches as the number of cases increased. This finding is in line with an earlier study [16]. Moreover, lower correlation coefficients were found in search data as the outbreak progressed. This indicated the public's concern in terms of online information searches related to the ongoing outbreak, which tended to change over time. In addition to the prediction models, GLMs with different types of distribution functions may have been beneficial in predicting new daily COVID-19 cases and deaths in the early stages of the outbreak. Nonnormal distributions of cases and deaths could be better predicted using a Poisson or negative binomial function. Over a longer period, as the distribution of cases and deaths changed more into a normal distribution, LR models with regularization may have outperformed the GLMs. The use of regularization could also be important in preventing overfitting due to increased numbers of possible terms used in the longer period of prediction. This study also found that better performances of models were achieved in predicting new daily deaths compared to new daily cases, as found in a previous study [34]. This finding suggests higher variability of time series components (ie, trend, seasonality, and error) in new daily COVID-19 cases, which affected the prediction performances.

Furthermore, feature effects in the models showed that NAVER search volumes were useful variables in predicting new daily COVID-19 cases, particularly in the first 6 months of the outbreak. Searches related to logistical needs, particularly for "thermometer" and "mask strap," showed higher feature effects in that period. Compared to previous studies [12-14], terms with higher feature effects in the models were varied, from COVID-19–related terms, symptoms, and preventive measures. For longer prediction periods, NAVER search volumes were still found to be important variables, although with lower feature effects demonstrated from values of the parameter estimates. This result suggests that term use should be considered to maintain the prediction performance. This task may be subject to several challenges, since terms selected from top searches might not always perform as important variables in the model. Therefore, extensive keyword queries are needed to ensure that all possible and related terms are included in the model development.

Lastly, NAVER search volumes were also found to be beneficial in predicting new daily COVID-19 deaths, even for longer periods. Negative parameter estimate values for NAVER searches in the models were in line with results of the correlation analyses. This possibly suggests a decline in searches as the number of cases increases, although NAVER search engine query data were still regarded as useful variables for inclusion in the models.

The Role of Internet Search Data in Infodemiology Studies of COVID-19

As the COVID-19 pandemic has emerged, infodemiological studies related to COVID-19 grew exponentially. In general, such studies can be divided into three major subjects: studies

to understand community online search behaviors, preliminary studies to assess possible use of search data for prediction purposes, and prediction analyses. Studies to understand community online search behaviors are mostly aimed at assessing how the public responds in online information-seeking practices during a pandemic situation. Studies conducted by Strzelecki [11], Effenberger et al [10], Springer et al [35], Husain et al [32], and Hu et al [36] are examples of this kind of study. Those studies used search engine query data to understand patterns of information-seeking behaviors, particularly in interpreting public interest toward the ongoing pandemic. Some studies [31,33,37] have also been designed specifically to understand essential health information searched for by the public as cases increased. In addition, these types of studies were also used to assess health risk communication strategies [30] and health risk perceptions [21].

For preliminary studies to assess the possibility of using search data for prediction purposes, most studies found high correlations between COVID-19 cases and online search data [4-6]. Some also exhibited highly correlated patterns in the preceding days [2] and weeks [3]. Therefore, internet searches have become a potential data source for predicting COVID-19–related metrics. However, limited studies are available that assess predictive performances of search volume models. Studies [12-14] conducted in the early months of the pandemic showed that proposed models that included search data performed better than those that did not include the search volumes. However, studies in the United States demonstrated low accuracy in model prediction [15] and variability in model performance among states and time periods [16].

Accordingly, in this study, we assessed the predictive performances of models that incorporated online search volumes. Data were aggregated into four subsets: 3, 6, 12, and 18 months of time series data. We intended to analyze whether search engine query data are important variables for inclusion in models for short- and long-term prediction of new daily COVID-19 cases and deaths. Results demonstrated promising use of NAVER search volumes for prediction tasks with higher feature effects in the first 6 months of the outbreak. Thus, this study provides an overview of using search data for predictive purposes in the context of a pandemic situation.

Limitations

Analyses reported in this study only drew from perspectives of a demand-based infodemiological study. This means that this research examined the information-seeking behavior through search engine queries [9], which potentially reflect sudden changes in users' online behaviors toward the ongoing pandemic [38]. Future analyses may need to take into account the supply-side analysis, incorporate other search engines' data sets, as well as retrieve wider terms in order to capture wider infodemiological patterns in the population. In addition, other dynamic explanatory variables, such as health policy indices, may need to be included in the models to increase the model performance.

Conclusions

NAVER search volumes were important variables with higher feature effects for predicting new daily COVID-19 cases, particularly in the first 6 months of the outbreak in South Korea. For longer periods, NAVER search volumes were still found to be important variables, although search term use should be considered, as more specific terms need to be used. Similar results were also found for death predictions. Likewise, GLMs with different types of distribution functions may be beneficial for use in the early stages of an outbreak. In longer periods, LR models with regularization may outperform GLMs as the number of possible explanatory variables that can be used in the models increases.

Acknowledgments

This work was supported, via grants to ECYS, by the Ministry of Science and Technology in Taiwan (grants MOST109-2221-E-038-018 and MOST110-2628-E-038-001) and the Higher Education Sprout Project by the Ministry of Education in Taiwan (grant DP2-110-21121-01-A-13). This work was also supported, via a grant to ES, by the Basic Science Research Program through the National Research Foundation of Korea funded by the Ministry of Education (grant 2021R1A6A1A10044154). The sponsors had no role in the research design or content of the manuscript for publication. The authors wish to acknowledge the Center for Systems Science and Engineering at Johns Hopkins University for use of their geographic information system dashboard and providing open-access data on daily cumulative COVID-19 cases and deaths in South Korea. In addition, the authors wish to acknowledge Google and Apple for allowing access to freely available data on community mobility, and NAVER for allowing access to the online search volumes.

Authors' Contributions

AH designed the study, performed the experiments, analyzed the data, and drafted and revised the manuscript. ES contributed analytical suggestions and revised the manuscript. AF made analytical suggestions. ECYS conceived the study, designed the experiments, and revised the manuscript. All authors approved the final version of the manuscript.

Abstract

Background: Clinical mobility and balance assessments identify older adults who have a high risk of falls in clinics. In the past two decades, sensors have been a popular supplement to mobility and balance assessment to provide quantitative information and a cost-effective solution in the community environment. Nonetheless, the current sensor-based balance assessment relies on manual observation or motion-specific features to identify motions of research interest.

Objective: The objective of this study was to develop an automatic motion data analytics framework using signal data collected from an inertial sensor for balance activity analysis in community-dwelling older adults.

Methods: In total, 59 community-dwelling older adults (19 males and 40 females; mean age = 81.86 years, SD 6.95 years) were recruited in this study. Data were collected using a body-worn inertial measurement unit (including an accelerometer and a gyroscope) at the L4 vertebra of each individual. After data preprocessing and motion detection via a convolutional long short-term memory (LSTM) neural network, a one-class support vector machine (SVM), linear discriminant analysis (LDA), and k-nearest neighborhood (k-NN) were adopted to classify high-risk individuals.

Results: The framework developed in this study yielded mean accuracies of 87%, 86%, and 89% in detecting sit-to-stand, turning 360°, and stand-to-sit motions, respectively. The balance assessment classification showed accuracies of 90%, 92%, and 86% in classifying abnormal sit-to-stand, turning 360°, and stand-to-sit motions, respectively, using Tinetti Performance Oriented Mobility Assessment-Balance (POMA-B) criteria by the one-class SVM and k-NN.

Conclusions: The sensor-based approach presented in this study provided a time-effective manner with less human efforts to identify and preprocess the inertial signal and thus enabled an efficient balance assessment tool for medical professionals. In the long run, the approach may offer a flexible solution to relieve the community's burden of continuous health monitoring.

KEYWORDS

fall risk; balance; activity recognition; automatic framework; community-dwelling elderly

Introduction

Falls prevail among the aging population, and led to more than $30 billion in direct medical costs in 2015 [1]. Around 55% of unintentional injury deaths among older adults in the United States are due to falls [2]. Falls pose a threat to the physical and psychological aspects of older adults' health [3,4]. It is critical

to identify older adults at the risk of falls and take interventions in advance [5].

Fall risk factors can be grouped into extrinsic (environmental) factors and intrinsic factors (age, health status, and other factors derived from the human). Outpatients and community dwellers usually suffer less from illnesses; consequently, intrinsic mobility and balance are the most discriminative intrinsic indicators of falls [6]. Mobility and balance assessment tools, such as the Balance Evaluation Systems Test (BESTest) [7], the Tinetti Performance Oriented Mobility Assessment (POMA) [8], and the Berg Balance Scale (BBS) [9], have been popular in community and outpatient settings to assess the mobility and balance aspects of individuals [6]. Along with the use of these instruments, a trained health care professional observes the participants' motion(s) as they complete a series of tasks (eg, sit-to-stand, turning 360°, and stand-to-sit) and scores their performance based on medical expertise.

Nevertheless, such assessment tools carry disadvantages that prevent older adults from undergoing frequent fall assessments [10]. First, many mobility and balance assessments, such as the BESTest [7], the Tinetti POMA [8], and the BBS [9], take from 15 to 35 min to complete [6,11], which is time consuming and burdensome to implement on a community-wide scale. Second, traditional assessments heavily rely on observations made by medical professionals [6,10]. Such resource-demanding assessments become unaffordable, which is a phenomenon commonly observed in Hong Kong [12,13]. A review [14] reported that over one-third of elderly services units fail to fill their physiotherapist and occupational therapist vacancies. In short, conducting mobility and balance assessment requires time, human resources, and financial availability, which further discourages older adults from frequently checking their fall risk.

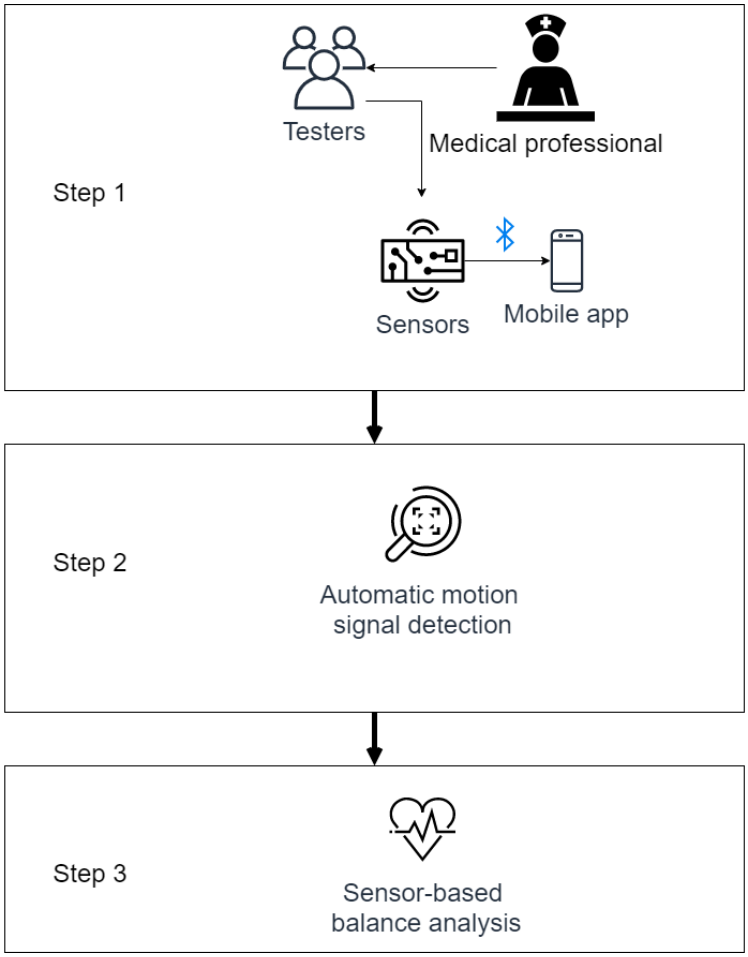
Thanks to the rapid development of information technology, the sensor provides a practical solution to this predicament nowadays. Commercial sensors (eg, accelerometer and gyroscope) are affordable to most community service sites or health care agents [15,16]. These sensors provide an objective measurement of motion that can support health professionals' decision making or act as a preliminary screening tool in the absence of professionals. Current research [17-19] has proven the utility of this approach by validating sensor-based assessments with clinical mobility and balance assessment tools. Researchers [20-25] have quantified and analyzed several sensor features that indicate motion and balance capability insufficiency. Halilaj et al [26] emphasized the importance of interpretability of sensor features and the model in this application for health care professionals and individuals. The majority have adopted statistical models to provide a statistical explanation of the work [10,16,27]. Some recent research [28-30] has argued that though the neural network approach might not be as interpretable as the previous research, it provides an accurate prediction. Sensor technology offers a quantitative method of studying human mobility and balance and coincides with clinical mobility and balance assessments.

Although there are advantages to the use of sensor technology, it is also important to acknowledge the residing problems. Ideally, individuals can perform these sensor-based assessments independently. In practice, irrelevant signals that come before and after performing the testing motion might be recorded. Therefore, an additional process to remove those irrelevant signals becomes necessary. Existing studies have relied on an additional research assistant's manual observations [28,31-33] or crafted features specific to motion [34] for identifying the motion signal, which will be assessed in the sensor-based assessments. In addition, although crafting features and building a heuristic algorithm [34,35] to detect motion provide a scientific solution, it is limited to specific, well-studied activity. This limitation makes detection hard to be generalized and transferred to different motion analyses. The additional manual efforts for identifying sensors or recording signals discourage health care professionals and community users from adopting sensor-based approaches [36].

Human activity recognition (HAR) is a practical remedy to relieve this burden. The majority of developed methods adopt machine learning models [37-39] or deep learning [40-45] to build on and validate renowned public data sets, such as the University of California, Irvine (UCI)-HAR [46] and UniMib SHAR [47], that target healthy adults aged 30 years or less. In contrast, only a few research works [48,49] focus on older adults. These studies [37-39] and reviews [43] claim that HAR techniques can be applied for health care purposes. Nonetheless, to the best of our knowledge, there is no existing work that explicitly delineates the combination of HAR and sensor-based mobility and balance assessments as completely automated assessments.

This study illustrates an automatic sensor-based framework (Figure 1) of motion and balance assessment. We hypothesized that the motion detection method is a solution for better automating sensor-based balance assessments. This framework resolves the requirement of human input in the preprocessing stage and completes the whole automation data pipeline. The developed framework aims to solve a simplified motion detection problem by leveraging the application scenario and a motion evaluation according to the Tinetti POMA-B grading standard. This study embodies this framework with deep-learning motion detection and sensor-based mobility and balance assessment. The major contributions of the proposed method are two-fold. First, few existing studies integrate motion detection and sensor-based balance assessment to form the data analysis pipeline, to the best of our knowledge. Second, the proposed method requires less human effort to identify and preprocess the inertial signal and enable a more efficient sensor-based balance assessment tool for medical professionals. This framework offers a flexible automatic solution to relieve the community's burden during large-scale implementation, such as long-term balance monitoring.

Figure 1. Overview of the developed framework.



Methods

Recruitment

In total, 59 community-dwelling elders (19 males and 40 females; mean age = 81.86 years, SD 6.95 years) participated in our study from September 2019 to December 2019. Participants with behavioral problems (eg, violence), unstable mental status (eg, paranoia), communication problems (eg, dialect), or severe hearing impairment were excluded from the study. Written informed consent was obtained from all participants before performing data collection. The imbalanced gender distribution was a direct reflection of the outnumbered male participants enrolling in community services [50]. Among the participants, six had experienced falls within the past year. A detailed breakdown of the demographics is shown in Table 1. This study was approved by the Research Ethics Committee of City University of Hong Kong (reference no. 3-2-201803-02).

Table 1. Demographics of all participants and group difference according to Tinetti grading items (N=59; 19 males and 40 females; mean age 81.86 years, SD 6.95 years).

Score	Age (years), mean (SD)	Males:females (n)
Sit-to-stand		
<4	86.64 (6.05)	6:8
4	80.37 (6.79)	13:32
Turning 360°		
<2	85.55 (5.88)	6:5
2	81.02 (6.90)	13:35
Stand-to-sit		
<2	87.00 (5.15)	5:9
2	80.26 (6.65)	14:31

The score followed the Tinetti POMA grading guideline [8]. The Tinetti POMA grading guideline is the mobility and balance assessment outcome used in this study. Age affected the Tinetti POMA performance, but gender did not. Age showed a

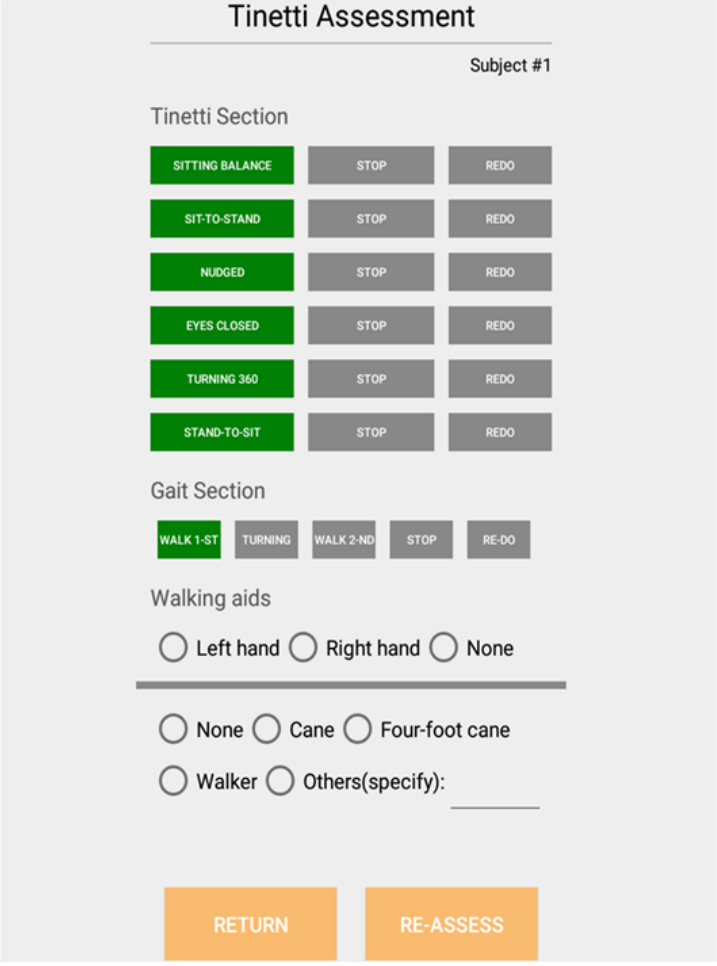
significant difference between the sit-to-stand score=4 and <4 groups (Student *t* test, *P*<.001). Age also showed a significant difference between the stand-to-sit score=2 and <2 groups (Student *t* test, *P*<.001). There was no gender difference in all of these tasks (Fisher exact test *P*=.99, 0.44, and 0.50 for sit-to-stand, turning 360°, and stand-to-sit motions, respectively.)

Experiment Protocol

In this step (Step 1 in Figure 1), balance assessments were conducted with an inertial sensor. Each participant was asked to perform three actions: standing up from an armless chair, turning around, and sitting down in the armless chair. There were 59 recorded inertial signals for each task from 59 participants. The three motions are commonly used in many functional assessments. All the three motions are adopted in the BBS [9], the Physical Performance Test (PPT) [50] and Tinetti POMA [8]; standing up and turning are adopted in the Fullerton Advanced Balance (FAB) [51] and the clinical Gait and Balance Scale (GABS) [52]; standing up and sitting down are adopted in the Postural Assessment Scale for Stroke Patients (PASS) [53], the Sensory Orientated Mobility Assessment Instrument (SOMAI) [54], and the Activity-based Balance Level Evaluation (ABLE) scale [55]. These three motions were considered sufficient to illustrate the idea of motion detection and evaluation in the developed framework.

A commercial inertial measurement unit (Wit-motion JY901B; including an accelerometer and a gyroscope at 3 axes with 16-bit resolution, sampling frequency 40 Hz, and a built-in Kalman filter) was attached on an elastic belt and placed on the L4 vertebra of each participant prior to each task. The inertial signal was transmitted via Bluetooth to the dedicated mobile application. The participants would then listen to the instruction and perform it accordingly. As soon as a participant initiated the task, a research assistant would press the button (green buttons and STOP buttons in Figure 2) on the app to mark the starting time and ending time, as shown in the clock on the mobile device. Figure 2 displays a screenshot of the data collection app.

Figure 2. Screenshot of the data collection app.



Before starting the assessment, each participant was required to perform a trial. Sit-to-stand and stand-to-sit motions were conducted using a straight-backed armless chair. Participants were asked to complete the turning task in a fast yet safe manner according to their judgment. These motions were conducted in line with Tinetti POMA guidelines. Participants were asked whether they needed a break for rest, but none needed it.

Automatic Motion Detection

In this part (Step 2 in Figure 1), we aimed to determine the starting and ending times for a known task from inertial signals containing only a known task (sit-to-stand, turning 360°, and stand-to-sit) and nontask activities. Since some participants needed extra time to comprehend and respond to the instruction, some recordings included pretask records. In addition, it also

took a few seconds for users to stop the recording after the participants completed the motion. Therefore, some sensor signals irrelevant to the motion might be included in the data. Since the motion to be analyzed was known in the prescribed mobility and balance assessment list, we only needed to detect the motion. The developed framework leverages these facts to reduce the complexity of motion detection to a simpler binary classification problem. We built separate classifiers for each task motion, allowing each piece of signal that contained a known task (ie, sit-to-stand, turning 360°, or stand-to-sit) to go through the data pipeline separately, as introduced below.

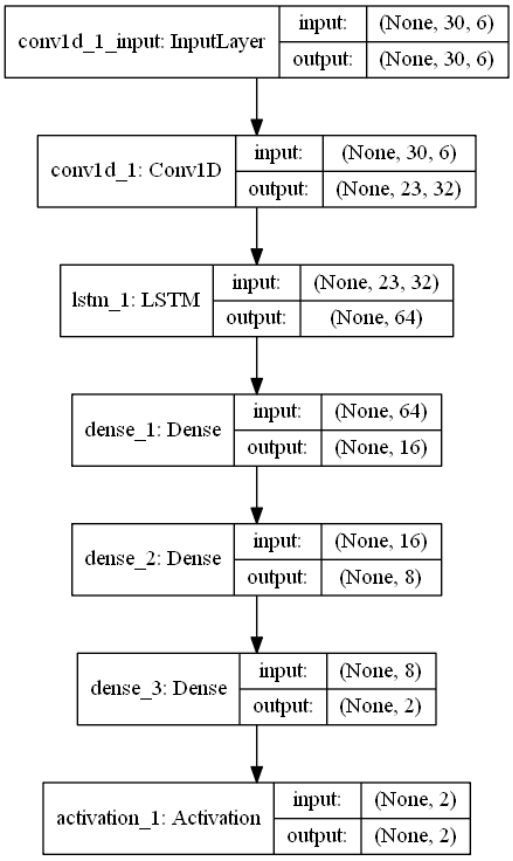
Preprocessing

The acceleration signal was detrended by subtracting the mean of the acceleration at each axis. The gyroscope signal was converted into the angular displacement from the starting point by integration. The gyroscope's drift issue was neglected as each task took less than 30 s to complete, and the drift rate is at 0.05°/s according to the product specification. Subsequently, each task signal was segmented from the preprocessed task signals into 0.75 s sliding windows with a step size of 0.03 s. The different sliding window sizes are examined and discussed in the Results and Discussion sections. The label of the sliding window segment is defined as the percentage of the class it covers. For example, a sliding window segment that contains 0.5 s of a sit-to-stand task and 0.25 s of the nontask motion would be labeled as 0.67 for the class sit-to-stand and 0.33 for the class nontask motion.

Convolutional LSTM Motion Detector

A convolutional long short-term memory (LSTM) neural network was built for detecting the starting and ending times for each task. The motion detection model takes the raw acceleration and angular displacement at three axes in the 0.75 sliding windows as input. The convolutional layers and LSTM layers can extract the temporal human dynamic inertial signals to construct the classification. The overall network structure is shown in Figure 3. This structure was inspired by a previous study [56], which used convolution networks to obtain the feature maps and LSTM structure to learn the temporal pattern.

Figure 3. Structure of a convolutional LSTM used in motion detection. LSTM, long short-term memory.

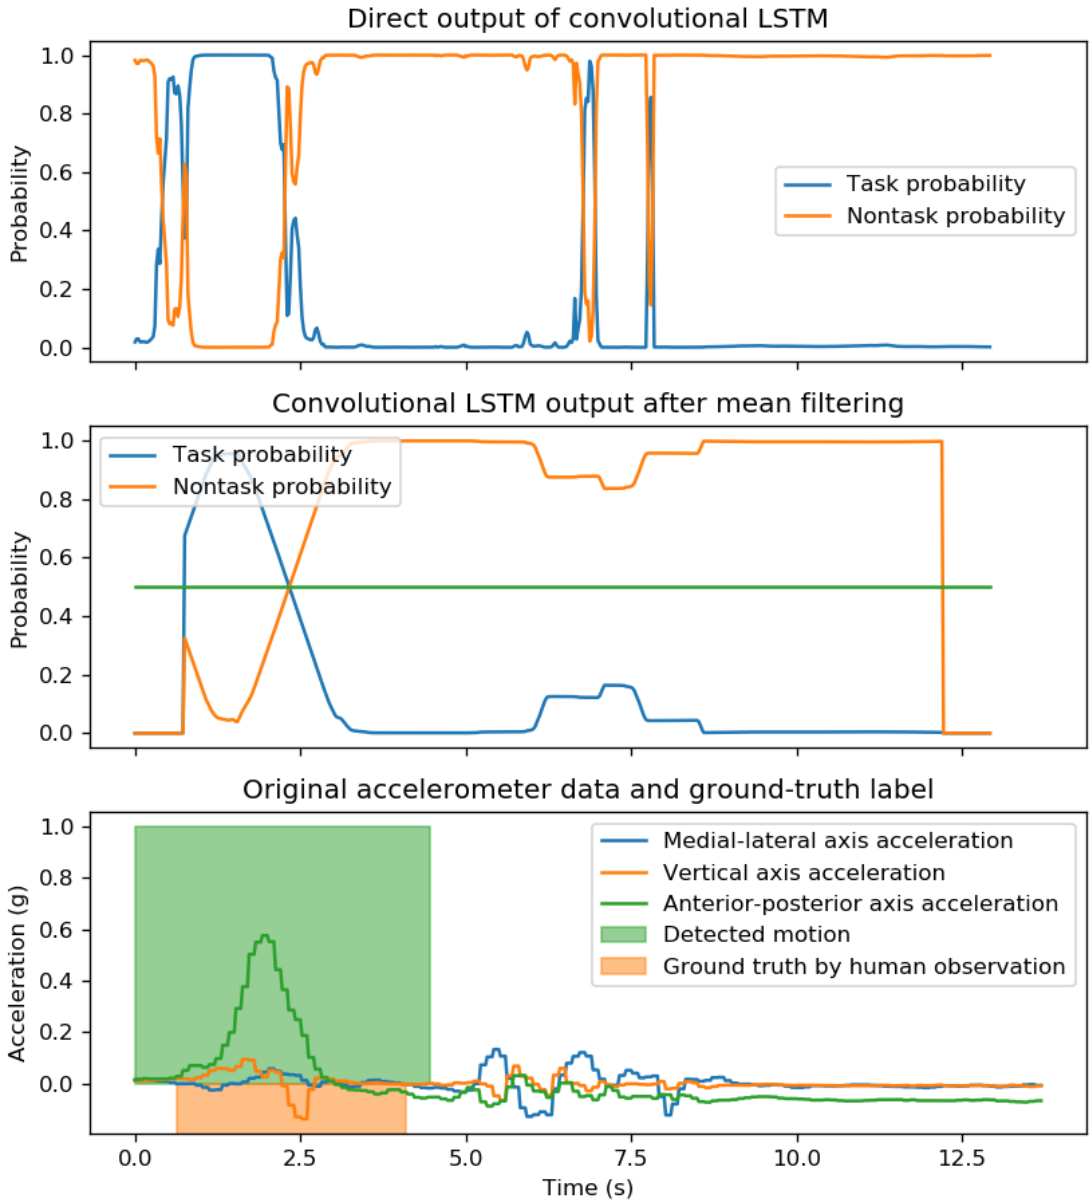


The convolution layer took the preprocessed sliding window segment as input and performed a convolution operation with 32 filters, kernel size 3. The LSTM layer is a specific implementation of the recurrent neural network that takes the previous state information into the current calculation. Finally, the densely connected layer operates by applying the activation function of the dot operation of weights. The first two dense layers did not apply any activation function, and the SoftMax function activated the last dense layer to calculate the percentage of labels containing and not containing the task.

Postprocessing and Labeling

The direct prediction of the convolutional LSTM neural network appeared to be noisy, as shown in the top image of Figure 4. This phenomenon was also observed in a similar network structure in HAR [56]. Therefore, the following postprocessing was performed to determine the beginning and end of the task.

Figure 4. Original signal and output of the convolution LSTM network before and after processing. LSTM: long short-term memory.



A mean filter was used to filter the convolutional LSTM neural network output with window sizes of 1, 1.25, and 1.5 s. These mean filter sizes used in this section are examined and discussed in the Results and Discussion sections. The output is shown in the middle image of Figure 4. Subsequently, the candidate intervals were identified according to the following two rules:

1. Beginning of the interval: The closest peak of nontask probability before the point where task probability starts to be greater than 0.5
2. End of the interval: The first peak of nontask probability after the point where task probability starts to be less than 0.5.

Peak detection was conducted using the SciPy package [57] with 0.5 thresholds.

Typically, only an interval would be identified. If more than one interval was identified, the following rules were applied accordingly to the different tasks. For sit-to-stand and stand-to-sit tasks, the time interval that contained the greatest anterior-posterior (AP) acceleration range was assigned to when the participant performed the motion. For the turning 360° task, intervals with cumulative angular movement from a starting time less than 360° along the turning axis (vertical axis) were selected. The final result is illustrated in the bottom image of Figure 4.

These rules were inspired from the biomechanical point of view for human motion [58], where AP acceleration drastically changes during the sit-to-stand or stand-to-sit motion. The assumption is that only one movement prevails in the signal recordings, as stated previously.

Sensor-Based Mobility and Balance Assessment

After the signal was automatically annotated, sensor-based mobility and balance assessment was performed to evaluate the corresponding motion (Step 3 in Figure 1). Sensor features that have been used in several previous studies were extracted from the detected signal and evaluated in relation to its Tinetti

POMA-B grading items. This part consisted of feature extraction and prediction modeling to achieve the goal.

Feature Engineering

Sit-to-Stand and Stand-to-Sit Tasks

The count of the acceleration peaks along the AP axis was extracted from the labeled data. Peak detection was conducted using the Scipy package [59] with the threshold 45% of the maximum value. A normal sit-to-stand transition usually shows one peak along the AP axis [58]. Multiple peaks imply the possibility that the motion was not smooth or multiple attempts were performed to achieve the task.

Turning 360° Task

The average turning speed along the vertical axis was extracted from the labeled data. Research [60] shows a significant difference in turning speed between fallers and nonfallers.

Prediction Modeling

Participants who did not receive full marks in the corresponding Tinetti POMA-B grading items were labeled as deviating from the norm in performing such tasks in this study. The goal of mobility and balance assessment is to identify older adults with insufficient mobility and balance capability and intervene as early as possible. Therefore, we aimed to identify older adults whose balance evaluation score was different from that of healthy adults (ie, full marks in the balance assessment). The sensor features introduced above were used to predict the corresponding Tinetti POMA-B grading items. A detailed description is presented in Table 2, and the corresponding sensor feature distribution between two populations is tabulated in Table 3.

Table 2. Tinetti POMA-B[a] task, grading items, and deviation from the healthy people criteria.

Task and grading item	Score	Deviation from healthy adults' criteria	Feature
Sit-to-stand		Tinetti POMA-B total sit-to-stand score <4	AP[b] acceleration peak count
Arises from the chair	~0-2		
Attempts to arise	~0-2		
Turning 360°		Tinetti POMA-B total turning 360° score <2	Average turning speed
Turns 360° continuously	~0-1		
Turns 360° steadily	~0-1		
Stand-to-sit		Tinetti POMA-B total stand-to-sit score <2	AP acceleration peak count
Sits down	~0-2		

[a]POMA-B: Performance Oriented Mobility Assessment-Balance.

[b]AP: anterior-posterior.

Table 3. Sensor feature distribution between normal and deviation from healthy participants.

Task	Sit-to-stand AP[a] acceleration peak count, mean (SD)	Turning 360° average turning speed (°/s), mean (SD)	Stand-to-sit AP acceleration peak count, mean (SD)
Healthy people	1.00 (0.29)	58.16 (19.22)	0.98 (0.15)
Deviating from healthy people	2.46 (2.02)	23.46 (13.96)	1.54 (0.75)

[a]AP: anterior-posterior.

A one-class support vector machine (SVM) [59], linear discriminant analysis (LDA), and k-nearest neighborhood (k-NN) from previous research works [31,61,62] were adopted in balance assessments.

Evaluation Metrics

Accuracy and the area under the curve (AUC) were used to evaluate the performance of this work. Accuracy was defined as the percentage of observations classified into the correct class, as (TP + TN)/(TP + TN + FP + FN), where TP is the true-positive class being classified as positive, TN is the true-negative class being classified as negative, FP is the false-negative class being classified as positive, and FN is the false-positive class being classified as negative. The AUC was obtained from the area under the receiver operating characteristic (ROC) curve. The ROC curve plots the sensitivity [TP/(TP + FN)]) against the false-positive rate [1 – (TN/{TN + FP})] at different levels of thresholds.

The agreement between the mobility and balance assessment results using the human-annotated label and the motion detection method was evaluated using the McNemar agreement test. The null hypothesis states that the two results show agreement in classifying the mobility and balance assessment evaluation results. The test statistic was calculated by $z^2 = (n_{12} - n_{21})^2/(n_{12} + n_{21})$, where n_{12} is the prediction result of when the manual label sensor feature shows positive but the motion detection label sensor feature shows negative. In contrast, n_{21} is the prediction result where the manual label sensor feature shows negative but the motion detection label sensor feature shows

positive. The test statistic followed a chi-square distribution with 1 degree of freedom.

Training and Testing Environment

Leave-one-subject-out (LOSO) cross-validation (CV) was used for training and testing. Each time, all the participants' inertial measurements except the i-th participant were used for training the motion detection and sensor-based balance assessment, and the inertial measurements from the i-th individual were used for testing. The convolutional LSTM neural network was built and trained using Keras [63] with TensorFlow [64].

The computer used for training was an Intel E5-2670 CPU with Nvidia Tesla K20 and CUDA version 10.2 on a Linux system. The batch size was set at 200, and the stopping rule was set for no improvement after 20 epochs. The rest of the computation was conducted using SciPy [57] and NumPy [65].

Results

Motion Detection

Our motion detection methods yielded moderate accuracy in detecting sit-to-stand, turning 360°, and stand-to-sit tasks from 85% to 88% at different levels (see Table 4). The difference in classification accuracy did not significantly vary between different mean filter sliding window sizes. The developed motion detection method detected the same motion performed by the participant not observed in the training stage, because the LOSO CV withheld the participant's motion signal as a testing set in each train and validation cycle. The training time and testing time showed that it took more than 1500 s to train the model, but detection was conducted within 0.3 s/participant.

Table 4. Accuracy of the automatic motion detection in different sliding windows.

Task	Accuracy (~Q1-Q3) mean filter 1 s sliding window (%)	Accuracy (~Q1-Q3) mean filter 1.25 s sliding window (%)	Accuracy (~Q1-Q3) mean filter 1.5 s sliding window (%)	Training time (s)	Testing time (s)
Sit-to-stand	87 (~82-95)	86 (~82-94)	85 (~78-93)	1681 (479)	0.21 (0.06)
Turning 360°	86 (~82-94)	86 (~79-95)	85 (~78-93)	2686 (495)	0.26 (0.09)
Stand-to-sit	88 (~85-94)	89 (~86-95)	88 (~83-94)	2186 (512)	0.24 (0.03)

Sensor-Based Mobility and Balance Assessment

The sit-to-stand task motion was well detected and classified using the developed method. The detector had 85%-87% accuracy in detecting sit-to-stand motion that was not previously observed in the training set. The extracted feature, the peak count along the AP axis, exhibited a strong ability to discriminate between normal and abnormal motion in the sit-to-stand task through the k-NN method at 90% accuracy. The high accuracy could be attributed to the fact that multiple attempts to rise generate multiple peaks in the signals [58], which aligns with the Tinetti POMA grading criterion sit-to-stand transition. LDA showed the least discriminative capability because of the Gaussian distribution assumption. The result shows that the developed motion detection method and balance evaluation model can predict abnormal sit-to-stand motion.

The turning 360° task motion was detected using the developed method at an accuracy ranging from 85% to 86%. The classification showed 92% agreement with the professional opinion using k-NN in terms of the Tinetti POMA turning motion outcome. These results indicate that Tinetti grading items may correlate with the turning speed of the participants. Previous studies [66,67] have also reported that the turning speed is correlated with certain clinical mobility and balance assessment tools.

The stand-to-sit task motion was detected at 88%-89% accuracy by the developed method. Compared with the other two tasks, however, sensor-based prediction showed the least accuracy in predicting the functional assessment result, at 86% accuracy using the one-class SVM. This may be ascribed to Tinetti POMA's grading to deduct a mark for participants who completed this task with the assistance of their arm, which occurred in the majority of the cases according to the report. This kind of information may not be revealed from the sensor signal, as the location of the sensor is at the participant's lower back. Consequently, it could result in weaker performance in classifying the category of older adults.

Discussion

Principal Findings

The sensor features from the manual label signal and the motion detection method yielded little difference, which barely affects the sensor-based balance assessment results. Both sit-to-stand AP peak counts and stand-to-sit peak counts showed no statistical difference (Wilcoxon signed-rank test P=.42 and .45, respectively). The average turn speed showed discrepancy (P=.03) with a mean difference of 5.68°/s. In summary, the motion detection label features showed statistically no difference in the sit-to-stand and stand-to-sit motions but a slight difference in turning.

Using the manual label motion signal features or the detected motion signal features showed no statistical difference in classifying the Tinetti POMA outcomes in all circumstances (Table 5). The McNemar test was conducted to determine whether there is a difference in the classification outcome between the manual label and the presented motion detection. The results revealed that there is no statistical difference. The motion detection accuracy was satisfactory enough to ensure that the sensor features were not affected by the detection method. Consequently, practitioners could be comfortable with adopting the motion detection method instead of traditional laborious works. None of the models rejected the null hypothesis

that both labels will yield the same result. This indicates that even though the motion detection method did not fully agree with the manual label, it still captures vital information in the sensor signal to predict mobility and balance assessments.

[d]k-NN: k-nearest neighborhood.

[e]AUC: area under the curve.

Previous research [36] has reported clinician concerns about the real-time application of sensor-based balance assessments. The testing results in motion detection indicated only a little delay in obtaining the results of the developed framework. Therefore, the presented implementation showed acceptance by the clinician in terms of time efficiency. In contrast, a survey [68] reported that most of the Hong Kong community-dwelling older adults perceive motion-analyzing systems as useful. Accordingly, we believe that the framework would receive acceptance from both clinicians and older adults.

Limitations

There are four limitations of our study. First, we only analyzed sit-to-stand, turning 306°, and stand-to-sit motions rather than the complete mobility and balance assessment that covers comprehensive mobility and balance aspects. Nonetheless, motions used in this study have been frequently analyzed in several mobility and balance assessments to assess lower-body strength [69] and dynamic balance [70]. Other popular mobility and balance assessments, such as the Timed Up and Go (TUG) test [71], would be included in our future work. Second, instead of solving a HAR problem, this work leveraged the application scenario and broke it down into a detection problem, which only required an indication of the start and end times for the known task. This assumption helped the model to finesse the large variability in different motions in older adults. Third, we would like to expand the population and observations to enhance motion detection performance and balance assessments. In the framework discussed in this study, motion detection still relied on a certain amount of postprocessing, such as postprocessing after motion detection and feature engineering. This additional processing may become unnecessary with more observations for training. In addition, a greater sample size can also facilitate sensor-based balance evaluation with more complex modeling techniques and a one-off multiclass classifier to detect all the motions like in other works [28,30]. We can also observe that there are more healthy adults in the community than those with deviation from the healthy populations. A large sample size provides more in-depth insights into functional assessment with further complex feature engineering and feature selection methods. The last limitation is that the technology acceptance of this approach was not validated with the users. Though some related work with similar populations has shown good acceptance, as mentioned in the Discussion section, it is worth investigating how this approach can provide better user experience in the future plan.

Conclusions

We presented human motion detection in a large-scale health care assessment. Existing works [72,73] on HAR have achieved satisfactory results in detecting activities from nonmovement validation on public data sets. Nonetheless, most of the public data sets are limited in the subject count and focus on healthy subjects than normal life. The network structure of this study was also inspired by several previous works [56,74] on HAR. This research aimed to provide a sensor-based balance assessment approach to clinical decision support with less human effort. We illustrated a framework using an inertial sensor for balance assessment. The major contributions are two-fold. First, few existing studies have integrated motion detection and sensor-based balance assessment to form the data analysis pipeline, to the best of our knowledge. Second, our

method requires less human effort to identify and preprocess the inertial signal and enable a more efficient sensor-based balance assessment tool for medical professionals. This research examined the applicability of a deep-learning approach to detecting motion in the health care assessment context instead of general daily living.

This research illustrated the idea that functional assessment motions can be detected through HAR models. Therefore, the sensor data collection process can be conducted without additional labor if there is a sufficiently pretrained model in the future. Without the additional labor, the cost of sensor-based functional assessment can be reduced, providing more incentive to conduct large-scale implementation in identifying potential fallers in the community.

Acknowledgments

This work was partly supported by the CityU Provost Project (grant no. 9610406) and the National Natural Science Foundation of China (no. 71901188). The authors wish to thank Welfare Enterprises Association for its support to the study.

Authors' Contributions

YCH, HW, YZ, FC, and KLT were responsible for data collection. HW, YZ, FC, and KLT contributed to the study design and review of the manuscript. YCH conducted the analysis and writing of the report.

Conflicts of Interest

None declared.

Abstract

Background: Noncommunicable diseases (NCDs) constitute a burden on public health. These are best controlled through self-management practices, such as self-information. Fostering patients' access to health-related information through efficient and accessible channels, such as commercial voice assistants (VAs), may support the patients' ability to make health-related decisions and manage their chronic conditions.

Objective: This study aims to evaluate the reliability of the most common VAs (ie, Amazon Alexa, Apple Siri, and Google Assistant) in responding to questions about management of the main NCD.

Methods: We generated health-related questions based on frequently asked questions from health organization, government, medical nonprofit, and other recognized health-related websites about conditions associated with Alzheimer's disease (AD), lung cancer (LCA), chronic obstructive pulmonary disease, diabetes mellitus (DM), cardiovascular disease, chronic kidney disease (CKD), and cerebrovascular accident (CVA). We then validated them with practicing medical specialists, selecting the 10 most frequent ones. Given the low average frequency of the AD-related questions, we excluded such questions. This resulted in a pool of 60 questions. We submitted the selected questions to VAs in a 3×3×6 fractional factorial design experiment with 3 developers (ie, Amazon, Apple, and Google), 3 modalities (ie, voice only, voice and display, display only), and 6 diseases. We assessed the rate of error-free voice responses and classified the web sources based on previous research (ie, expert, commercial, crowdsourced, or not stated).

Results: Google showed the highest total response rate, followed by Amazon and Apple. Moreover, although Amazon and Apple showed a comparable response rate in both voice-and-display and voice-only modalities, Google showed a slightly higher response rate in voice only. The same pattern was observed for the rate of expert sources. When considering the response and expert source rate across diseases, we observed that although Google remained comparable, with a slight advantage for LCA and CKD, both Amazon and Apple showed the highest response rate for LCA. However, both Google and Apple showed most often expert sources for CVA, while Amazon did so for DM.

Conclusions: Google showed the highest response rate and the highest rate of expert sources, leading to the conclusion that Google Assistant would be the most reliable tool in responding to questions about NCD management. However, the rate of expert

sources differed across diseases. We urge health organizations to collaborate with Google, Amazon, and Apple to allow their VAs to consistently provide reliable answers to health-related questions on NCD management across the different diseases.

Introduction

Background

Noncommunicable diseases (NCDs) constitute a significant burden on public health [1,2] and are best controlled through self-management practice [3,4]. For this purpose, digital health technologies have been developed to assist individuals in managing disease in a scalable way and at a low cost [5]. Among other types of support [6], digital health tools can facilitate self-information on an on-demand basis (eg, decision support or information lookup devices).

Voice Assistants for Information Lookup

Commercial voice assistants (VAs) can be employed on both smartphones and smart speakers, which are increasingly present in our daily lives. In fact, in 2018, 76% and 45% of individuals in advanced and emerging economies, respectively, owned a smartphone [7], and 66.4 million Americans owned a smart speaker [8]. Furthermore, although 148 million US adults used voice search for general purposes [9], 19.1 million used VAs for health-related purposes, such as gathering information about symptoms, medication, treatment options, or healthcare facilities [10]. Thus, VAs are not only scalable but also show considerable penetration.

In addition, VAs leverage speech-based interaction, which makes information lookup more efficient and accessible compared to classical methods (eg, desktop web search [11,12]). This is particularly the case in situations in which users have their hands occupied [13-17], lack reading and writing skills [18], or suffer from visual, motor, or cognitive inabilities [19-24] and cannot access information on display devices, such as smartphones, desktops, or tablets. Hence, VAs are a powerful alternative to provide chronic patients with easy access to information about NCD management. The question remains how well they can respond to health-related questions to facilitate NCD management.

Related Work

Previous research investigated VAs' reliability and assessed their ability to provide patients with reliable responses to health-related questions. These included mental and physical health, interpersonal violence [25], sexual health [26], smoking cessation [27], general health and lifestyle prompts [28], vaccines [29], addiction [30], postpartum depression [31], and COVID-19 [32]. The assessment methods varied across studies. Reliability was evaluated in terms of the ability to help with a safety-critical situation [25,28], the information correctness in comparison to official sources [31], the propensity to direct the user to available treatments or treatment referral services upon help seeking [30], or the reliability of the sources behind the responses [26,27,29,32]. All these studies have reported a rather poor performance, which is not surprising as this phenomenon has also been observed in other domains, such as shopping-related questions [9]. However, it is difficult to conclude which VA is the most reliable. For instance, although Google Assistant seems to be more reliable than Apple Siri for smoking cessation information delivery [27], the performance reverses for general lifestyle prompts [28]. Moreover, Google Assistant and Apple Siri are both more reliable than Amazon Alexa for vaccine-related questions [29]. Thus, it is unclear which VA best supports patients with chronic medical conditions in accessing information about NCD management.

Objectives

This study evaluates the ability of common Vas, such as Amazon Alexa, Apple Siri, and Google Assistant, to vocally respond to questions related to NCD management, based on expert web sources. In particular, we measure reliability through *response rate* and *source type*. Based on previous research, we control for the effect of *developer* (ie, Amazon, Apple, and Google) and interaction *modality* (ie, voice-based interaction and multimodal interaction) [28] and compare the measures to web search results [27]. This comparison allows us to relativize the reliability of VAs to the standard consumer-accessible method of information retrieval. Conducting a web search may not always be the best solution, compared to consulting medical professionals [33], but patients are increasingly searching the internet for information [12]. Therefore, we consider web search as the method of reference for health information lookup.

Hence, we seek to answer the following research questions:

1. Is the *response rate* dependent on *developers* and *modality*?
2. Is the *source type* dependent on *developers* and *modality*?
3. Is the *response rate* dependent on *developers* and *disease*?
4. Is the *source type* dependent on *developers* and *disease*?

Methods

Our experiment consisted of a quality assurance evaluation, where experimenters submitted validated questions to VAs and assessed (1) whether an error-free voice response was provided and (2) the category of the referenced web source.

Research Design

We manipulated 3 independent variables: interaction *modality*, software *developer*, and *NCD*. We set a 3×3×6 fractional design with 3 *modalities* (ie, *voice only*, *voice and display*, *display only*), 3 *developers* (ie, *Amazon*, *Apple*, and *Google*), and 6 *diseases* (ie, *lung cancer [LCA]*, *chronic obstructive pulmonary disease [COPD]*, *diabetes mellitus [DM]*, *cardiovascular disease [CVD]*, *chronic kidney disease [CKD]*, *and cerebrovascular accident [CVA]*). For the *display-only* modality, we solely included the developer *Google*. The dependent variables were the *response rate* (ie, percentage of provided voice responses) and the *source type* (ie, *expert*, *commercial*, *crowdsourced*, or *not stated*).

Measures

To measure the reliability of the different VAs, we assessed the *response rate* and *source type*. To assess the response rate, we computed the percentage of error-free speech-delivered responses. Specifically, a response was included if (1) the VA did not manifest an error, such as a system error (ie, a bug in the execution of a command), a natural language processing (NLP) error (ie, misunderstanding of the user's utterance), or an intent error (ie, the user's utterance is understood but leads to an unsupported command or an inappropriate execution), and (2) the response was voice-delivered without prompting the user to access information by interacting with a display device. For instance, if a VA was to reply *Here is what I found* and show results on the screen, we considered this response as not provided. Note that we leverage the use of VA for accessible, hands-free health-related information provision. Thus, we intentionally considered only those responses that could benefit individuals who cannot interact with a display.

In the *display-only* condition, we calculated the *response rate* by including all responses provided in the form of a web search featured snippet. A featured snippet is a unique box presented above the list of Google's search results, containing a text answer to a question-like search query (what, how, when, etc). A snippet contains a title, a summary of the answer, and a link to the web source [34]. We chose this method to compare the ability of VAs to utter a selected response with that of the web search in pulling the best information source answering the question.

The source type was categorized based on the work of Alagha and Helbing [29] and Boyd and Wilson [27] into *expert*, *commercial*, *crowdsourced*, or *not stated*. Table 1 provides a description and examples of these categories. In particular, Alagha and Helbing [29] evaluated the VAs' responses with points and categorized the web sources as *government*, *heath nonprofit*, *commercial*, *crowdsourced*, or *not stated*. If a web source was categorized as *government* and *heath nonprofit* (which they defined as *expert sources*), the response would gain a point and would otherwise get no points. Following this approach, we merged *government* and *heath nonprofit* categories into one that we called *expert* and considered such sources as *reliable* because they consistently assure good quality of information. Furthermore, we verified the reliability by exploring primary websites or by finding third-party sources of reliability evaluation (eg, Verywell Health is described as verified by doctors and collaborating with Cleveland Clinic, or Cancer.net presents patient information from the American Society of Clinical Oncology).

Table 1. Description of source types with examples.

Source type	Description	Examples
Expert	Site from a health organization representing a group of medical professionals, a governmental medical department or agency, a nonprofit medical organization, or a medical journal. These are considered reliable because they consistently provide verified and impartial information.	US Centers for Disease Control and Prevention (CDC), Mayo Clinic, *British Journal of Cancer*
Commercial	Any not nonprofit site that publishes medical information. These may or may not provide verified and impartial information.	WebMD, Medscape
Crowdsourced	Information from a site that is based on the collaboration of a large group of people. This information may or may not be verified and impartial.	Wikipedia, Blurtit
Not stated	The source type was not stated explicitly.	—[a]

[a]Not available.

Selection of Health-Related Questions

Following Kvedar et al [5], we aimed to cover NCDs involving conditions considered the leading causes of mortality. Hence, we selected questions for Alzheimer's disease (AD), LCA, COPD, DM (type 1 and type 2), CVD, CKD, and CVA. Regarding cancer, we decided on LCA as it is the most prevalent type of cancer affecting both sexes [35].

The questions were selected in 2 steps. First, we generated questions by collecting frequently asked questions (FAQs) from health organization, government, medical nonprofit, and other recognized health-related websites (eg, mayoclinic.org, nia.nih.gov, everydayhealth.com, webmd.com). When relevant, we looked for or replicated prevalent general questions across diseases. For instance, as we found the question *IsAlzheimer's disease genetic?* on nia.nih.gov and *Is lung cancer genetic?* on foxchase.org, we searched for equivalents (eg, *Are strokes genetic?* on saebo.com) or arbitrarily created one for other diseases (eg, *Is chronic kidney disease genetic?*). This process allowed us to obtain a more comprehensive pool of questions.

Second, we asked practicing medical specialists to think about their medical consultations with patients suffering from the relative type of chronic disease and to rate the frequency of occurrence of the generated field-related question on a 5-point

Likert scale (ie, 1=never, 2=rarely, 3=sometimes, 4=often, and 5=always). If they deemed it necessary, the specialists were also free to add manually missing frequent questions. For each disease, we recruited 2 specialists, resulting in a total set of 14 evaluations. We intentionally let the medical specialists rate questions in terms of absolute frequency and not ask, for instance, to indicate the *n most frequent questions*, as we wanted to avoid selection biases. The evaluations led us to an insufficient number of questions for AD. This can be explained by the fact that we asked the specialists to select questions that patients would ask their physician, and in the case of AD, information exchange rather happens between the physician and the caregiver, while the patient tends to be less involved [36]. Such tendency was confirmed by unsolicited comments from the specialists. Thus, following an intense discussion among the coauthors, we excluded the questions related to AD.

Next, we included the 10 most frequent questions for all other diseases. If any resulted in a different formulation of the same question, only the question with the simplest formulation was included (eg, we favored *How long can I live with COPD?* over *What is the life expectancy for a COPD patient?*). If the ratings did not result in a clean cut of 10 questions, we defined further selection steps. If there were more than 10 questions, we favored wh-questions (ie, questions requiring an informative answer, rather than yes or no) and removed the most ambiguous questions (eg, we excluded *Why do I have difficulties breathing?* for COPD). If there were less than 10 questions, we included questions with lower ratings, always following the criteria mentioned above. Table 2 shows the number of questions included before and after the validation process (see the complete list of selected questions in Multimedia Appendix 1).

Table 2. Number of questions before validation from medical specialists.

NCD[a]	Questions generated (N=607), n (%)
AD[b]	48 (7.9)
LCA[c]	145 (23.9)
COPD[d]	60 (9.9)
DM[e]	135 (22.2)
CVD[f]	93 (15.3)
CKD[g]	69 (11.4)
CVA[h]	57 (9.4)

[a]NCD: noncommunicable disease.

[b]AD: Alzheimer's disease.

[c]LCA: lung cancer.

[d]COPD: chronic obstructive pulmonary disease.

[e]DM: diabetes mellitus.

[f]CVD: cardiovascular disease.

[g]CKD: chronic kidney disease.

[h]CVA: cerebrovascular accident.

Setting and Apparatus

The experiment took place in a meeting room at ETH Zurich, Switzerland, between February 18 and March 4, 2021. Each VA device was placed on a table and tested separately. Two experimenters sat at the two ends of the table. One experimenter submitted the questions to each device through a text-to-speech conversion program [37] on a laptop (Lenovo ThinkPad X1 Carbon Gen 8, Lenovo Group Limited). After pilot testing, we decided to use a female voice with a speech rate of 150 words per minute. For the questions to be adequately detected by the VAs, we played the questions through a set of 2 speakers (Sony Vaio VGP-SP1, VAIO Corporation) at a distance of ca. 10 cm from the VA device.

The other experimenter took note of the voice responses and the web source through either accessing them on the user accounts (smart speakers) or taking screenshots (display devices). To have a backup of the voice responses, we used an audio recorder (Philips DVT4010, Koninklijke Philips N.V.).

Tested VAs

Based on Kocaballi et al [28], we tested commonly used unimodal and multimodal VAs. To operationalize the variables *developer* and *modality*, we employed the 3 most common Vas (ie, Amazon Alexa, Apple Siri, and Google Assistant) and aimed for the 2 most frequently used devices (ie, smart speaker and smartphone) for each VA [10]. In particular, we used Amazon Echo Dot, Apple HomePod Mini, and Google Nest Mini for the *voice-only* modality and a mix of smart displays (Amazon Echo Show) and smartphones (Apple iPhone 8 with iOS 14.4, Nokia 6.1 with Android 9) for the *voice-and-display* modality. The latter heterogeneity in the devices was due to the unavailability of the Amazon Alexa smartphone application in the authors' country of affiliation at the time of testing.

Moreover, to operationalize the *display-only* modality and our reference method of (health) information retrieval, we included a laptop with the Google Search engine (Lenovo ThinkPad X1

Carbon Gen 6 with Google Chrome). We referred to this condition as the *web search*.

All devices were set to factory settings, and we used new dedicated accounts, whose history was deleted before testing each device. Table 3 summarizes the implementation of the research design.

Table 3. Operationalization of the independent variables.

Modality	Amazon	Apple	Google
Voice only	Smart speaker (Eco Dot)	Smart speaker (HomePod Mini)	Smart speaker (Nest Mini)
Voice and display	Smart display (Eco Show)	Smartphone (iPhone 8, iOS 14.4)	Smartphone (Nokia 6.1, Android 9)
Display only	—[a]	—	Laptop (Lenovo ThinkPad X1 Carbon Gen 6, Google Chrome)

[a]Not available.

Procedure

The selected questions were played in randomized order. In the *voice-only* and *voice-and-display* modalities, upon manual start, the text-to-speech program would play the appropriate wake-up keyword (ie, “Hey Alexa,” “Hey Siri,” or “Hey Google”), followed by a question. In the case of an error (see the Measures section), we first replayed the question and then, if necessary, played the question again using a male voice. In the case of a persistent error, 1 of the experimenters asked the question manually. This protocol allowed us to ensure the ability to respond to a question did not depend on the input quality. If none of those attempts produced a voice response, we considered the response as not provided. In the *display-only* modality, the question was directly entered in the text field of the web search engine.

Ethics

Given the involvement of practicing medical specialists, we validated our research proposal (EK 2020-N-173) with the ETH Zurich Ethics Commission. The procedure was approved without reservation on December 21, 2020.

Statistical Analysis

R Version 1.2 (RStudio, Inc.) was used to compute the frequency and descriptive statistics.

For the sake of comparison, all results (response rate and source type) are shown in percentages.

Results

For each subsection, we first introduce the analysis and then present the results in the form of a table (see also Multimedia Appendix 2 for the complete list of voice responses, web sources, and categorization).

Response Rate Across Developers and Modalities

To understand to what extent the examined VAs could provide an answer at all, we calculated the response rate across developers and modalities. The results are summarized in Table 4.

Table 4. Response rate across developers and modalities.

Response	Display only (N=60), n (%)	Voice and display (N=180), n (%)	Voice only (N=180), n (%)	Total (N=420), n (%)
Amazon				
No	—[a]	14 (23.3)	15 (25)	29 (24.2)

[a]Not available.

Source Type Across Developers and Modalities

Classifying the web sources into *commercial*, *crowdsourced*, *expert*, and *not stated* allowed us to derive the level of reliability of the voice response across developers and modalities. The results are summarized in Table 5.

Table 5. Source type across developers and modalities.

[a]Not available.

Furthermore, we want to point out that all error-free responses involved the synthesis of a meaningful response and none resulted in the VA proposing to use a voice application to answer the question (eg, Alexa Skill or Google Action).

Response Rate Across Developers and Diseases

We aimed to verify whether there was a pattern in the ability to provide an answer depending on the NCD in question. As the effect of modality was minimal, we present the results for the *voice-only* modality. Thus, we calculated the percentage of provided answers across *developer* and *disease*. Table 6 summarizes the results.

Table 6. Response rate by developer and disease.

Source Type Across Developers and Diseases

Calculating the proportion of source types across developers allowed assessing the presence of information reliability patterns among the VAs. We present the results for the *voice-only* modality. Table 7 summarizes our results.

Table 7. Proportion of source type by developer and disease.

Source type	LCA[a] (N=70), n (%)	COPD[b] (N=70), n (%)	DM[c] (N=70), n (%)	CVD[d] (N=70), n (%)	CKD[e] (N=70), n (%)	CVA[f] (N=70), n (%)	Total (N=420), n (%)

Discussion

Principal Results

Google showed the highest response rate and rate of expert sources, leading to the conclusion that Google Assistant would be the most reliable tool in responding to questions about NCD management. However, the rate of expert sources differed across diseases.

Response Rate Across Developers and Modalities

We observed Google Assistant provided the highest response rate, even outperforming the web search results. Apple Siri showed the lowest response rate. This specific advantage of Google Assistant is consistent with previous studies [27,29,32,38,39].

Moreover, Apple Siri often replied *I found this on the web* and presented visually a list of results instead of *voicing* a unique response. This may reflect a tendency to transfer the responsibility of information retrieval to the patients, whereas they are in charge of choosing (the most) reliable information source. As we believe in the potential of VAs in increasing the accessibility of health information by *vocally* interacting with patients having their hands occupied or with disabilities [13-17,19-24], we urge Apple to consider favoring voice responses over lists of results to make the information search more suitable for hands-free interaction.

Source Type Across Developers and Modalities

Similar to the results for the response rate, Google Assistant also answered the most frequently with *expert* sources, without outperforming the web search results. Amazon Alexa showed 13.3% fewer *expert* sources. These results are surprising, given the partnership that Amazon started with the United Kingdom National Health Service (NHS) in 2019, allowing the former to freely access health-related information provided by the latter

[40]. Finally, Apple Siri showed the least *expert* sources, favoring *crowdsourced* sources. Importantly, Apple Siri also showed the highest proportion of missing sources (ie, *not stated*). Alagha and Helbing [29] classified *commercial*, *crowdsourced*, and *not stated* sources as less reliable than *expert* sources. As *commercial* and *crowdsourced* sources may, in some cases, still provide reliable information [41,42], Apple Siri may tend to transfer the responsibility of judging the reliability of the information to the patient. This assumption is also supported by the low rate of voice responses from Apple Siri discussed above.

Response Rate Across Developers and Diseases

When comparing the response rate across diseases, we observed Google Assistant to respond rather similarly across diseases, with a slight advantage for LCA and CKD. Amazon Alexa and Apple Siri showed the highest response rate for LCA. Thus, questions related to LCA seemed to have a general advantage over the other diseases. Both Amazon Alexa and Google Assistant outperformed web search results on both LCA and CKD.

Source Type Across Developers and Diseases

Our results showed Google Assistant to most often use *expert* sources for CVA, while Amazon Alexa did so for DM. Apple Siri showed *expert* sources only for questions about CVA. Thus, there seems to be an advantage of CVA questions in being reliable the most often, except when those questions are asked to Amazon Alexa.

Finally, this slight heterogeneity in results is in line with the diversity in previous research, whereas depending on the condition or disease of interest, reliability varies across VAs [27-29]. Hence, there seems to be a need for systematization of health information search algorithms across the different medical domains.

Limitations

Despite our best efforts, our study presents some limitations.

First, for technical reasons, we employed a smart display instead of a smartphone for Amazon Alexa. The observed similarity in source type proportion between modalities may be explained by the use of 2 types of home devices. This similarity may reflect a consistency in information provision across Amazon Alexa modalities, which is desirable. However, future research should aim to replicate the results by comparing the reliability between the Amazon Alexa app and an Amazon smart speaker. This will support an absence of the effect of interaction modality in Amazon Alexa.

Second, to control for the effect of time on the responses, we aimed to restrict the time window inside which to test the VAs as much as possible. Thus, given the high number of questions submitted (ie, 60 questions per device, resulting in a total of 420 submissions), we did not submit the same questions multiple times. However, we conducted a post hoc test-retest reliability assessment by randomly selecting 1 question per NCD and submitting each one 10 times to all VAs. Our results showed no variation in the voice responses or the source type. Nevertheless, as observed in previous research that VAs do not always provide the same response [29], future research should consider the test-retest reliability of VAs in responding to a more extensive set of questions about the included NCDs.

Third, questions were selected by looking for FAQ pages on health-related websites, but it is difficult to conclude whether all relevant questions were included. As we shared the list of questions (see Multimedia Appendix 1), we hope future research will be able to establish whether additional relevant questions need to be tested.

Fourth, the source type was categorized based on the work of Alagha and Helbing [29] and Boyd and Wilson [27] into *expert*, *commercial*, *crowdsourced*, or *not stated*, whereas *expert* sources represented *government* and *heath nonprofit* sources [29]. We considered such sources as the *mostreliable* because they consistently assured good quality of information. However, although not stating a source of information makes it difficult for a patient to judge the response's trustworthiness, *commercial* and *crowdsourced* sources may, in some cases, still provide correct information. Health-related information coming, for instance, from wikipedia.com (*crowdsourced*) varies importantly in terms of quality [41] and could, in some cases, still provide reliable information. *Commercial* sources may also contain partly reliable information [42], despite presenting a higher risk of bias toward marketing purposes [43]. Future research should investigate directly the reliability of the provided information rather than the mere source type in order to have a more fine-grained landscape of its reliability.

Fifth, the FAQs about AD were evaluated as rather rarely asked by the patients. As information exchange about AD rather happens between the physician and the caregiver, while the patient tends to be less involved [36], future research should include questions from caregivers as well in order to assess the response and *expert* source rates for FAQs related to this disease.

Finally, questions were validated by Swiss doctors and thus may not be representative of the patient's most frequent concerns in other realities. Future research should validate the tested questions with professionals of other countries to ensure their relevance across nations.

Comparison With Related Work

Comparing VAs to Web Search

Our results are partly in line with the work of Boyd and Wilson [27], comparing the ability of Apple Siri and Google Assistant (*voice-and-display* modality only) to provide expert information for smoking-cessation-related questions compared to the web search. Similar to Boyd and Wilson [27], we observed Google Assistant to be more reliable than Apple Siri at providing information from reliable sources (which in their study was defined as web pages of *health agencies with medical expertise*). However, although Boyd and Wilson [27] found the web search to be more reliable better than Google Assistant, our evaluation showed Google Assistant to be slightly more reliable than the web search (in both *voice-and-display* and *voice-only* modalities). The difference may lie in the evaluation of the web search's responses: although we considered featured snippets as the selected response to judge the search engine on, Boyd and Wilson [27] considered the *first non-advertisement link or*

information of the list of results. This criterion may have led the authors to collect more responses from the web search and thus a different distribution of reliable sources. Moreover, Boyd and Wilson [27] were the only ones comparing the reliability of the VAs to a traditional method of health information search, such as browser-based web search. Not comparing the VAs' response rate and information reliability to web search makes it difficult to conclude on their absolute ability to respond to health-related questions. Our results not only show Google Assistant leading in NCD-related information provision, but also that it can even outperform the web search results and quite successfully inform patients about NCD management.

Evaluating Response Source Type

Based on Alagha and Helbing [29], who based their evaluation system on Boyd and Wilson [27], we evaluated the source type and classified the sources as *not stated*, *crowdsourced*, *commercial*, or *expert* (ie, a combination of the *health nonprofit* and *government* sources in Alagha and Helbing [29]). Although the authors observed Apple Siri and Google Assistant responding and providing expert information more frequently than Amazon Alexa (in the *voice-and-display* modality only), our study showed an advantage of Google Assistant, followed by Amazon Alexa. The higher advantage of Amazon Alexa observed in our study may be explained by the time of data collection. More specifically, Alagha and Helbing [29] tested the VAs in 2018, which was before Amazon would instantiate a partnership with the NHS in 2019 to provide reliable health information [40] (see also the Principal Results section). Thus, Amazon Alexa's ability to respond to health-related questions and the reliability of its sources may have increased since then.

Response Reliability Versus Response Appropriateness

Considering our results and the work of Boyd and Wilson [27] and of Alagha and Helbing [29], Google Assistant seems to be the best solution for health-related information lookup and thus for best supporting patients with NCDs. This conclusion may, however, be challenged by studies by Kocaballi et al [28] and Yang et al [31].

Kocaballi et al [28] assessed how frequently Amazon Alexa, Apple Siri, and Google Assistant would provide *appropriate* responses to safety-critical and non-safety-critical questions. Appropriateness was defined as the VA *recommending to get help from a health professional or service and to provide specific contact information* if the question was safety-critical and as *including relevant information to solve the problem* raised in the question if the question was non-safety-critical [28]. The author observed that although Google Assistant often provided a web source with its response, Apple Siri was the one providing the highest number of appropriate responses. Similarly, Yang et al [31], who assessed the *clinical appropriateness* of VAs' responses, observed Google Assistant to provide an *appropriate* response only 21% of the time, while Amazon Alexa performed slightly better, with 29% of *appropriate* responses. *Appropriateness* was defined by 2 physicians comparing the response provided by the VA to the answer present in the American College of Obstetricians and Gynecologists patient-focused FAQs. Although *appropriateness* evaluation is more meticulous because of analyzing the content, it is more subjective. We approached the responses from a *reliability* perspective and assessed them solely on an objective level, that is, by assessing the use of recognized health web sources. Given that, as mentioned above, source type may not be sufficient to evaluate information quality, and future research should combine source evaluation with professional content evaluation to obtain a more complete representation of the VAs' ability to provide patients with reliable information.

Leveraging Speech Interaction

In general, most of the related work presented above [27-29] evaluated VAs' responses by considering both display and voice responses. That is, if the VA was not to vocally synthesize a direct response to the question but to say *Here's what I found* and visually showed a list of results, the first of that list was still considered for evaluation. In our study, we considered only voice responses. The rationale behind this decision is that the use of VAs for (health-related) information lookup is truly advantageous and accessible if it can breach the barriers of lack of literacy [18]; visual, motor, or cognitive inabilities [19-24]; or manual unavailability [13-17]. Only Yang et al [31] reported whether the VAs provided a voice response. Although the differences between VAs were not statistically significant, the authors showed Apple Siri to be the least reliable and Amazon Alexa to be the most reliable. Our results replicate the low voice response rate of Apple Siri but show Google Assistant to respond vocally more frequently than Alexa. Given the small sample of questions and low statistical power in Yang et al [31], future research should evaluate a larger sample and contrast the results to the findings of Yang et al [31] and this study.

FAQ Relevance

Although the questions used in the studies discussed above were based on health-related web pages [27,29,31], none of them verified the questions' relevance for the patients themselves in the real-world practice. In particular, gathering questions from health-related websites ensured including questions that are of most interest to the affected population, that is, not only patients but potentially also their caregivers and close social network. However, we aimed to target questions specifically relevant to the patients, as they are the protagonists of self-management. Thus, we submitted the selected questions to the respective practicing medical specialists and explicitly asked them to rate their frequency, considering the questions coming from the patients. The fact that not all questions were relevant is also supported by the fact that specialists did not select all questions as being "Often" to "Always" asked by patients (see also Multimedia Appendix 1).

Implications

Complications related to NCDs, such as CVD, cancer, chronic respiratory disease, and DM, are among the main causes of mortality, accounting for 71% and 74% of all deaths worldwide in 2016 [1] and 2019 [2], respectively. Preventing those complications or their worsening is, therefore, crucial for survival. Engaging with self-management solutions is the best preventive practice [3,4]. VAs can support self-management through efficient and accessible information delivery by fostering patient's health literacy [44,45] (ie, the ability to

obtain, process, understand, and communicate health-related information to a level that favors positive health behavior [46]). For instance, an individual with a chronic respiratory disease who can ask their VA about smoking cessation strategies and put those into practice has higher chances to stop smoking and mitigate their health conditions. Our results show that Amazon Alexa and Google Assistant are capable of providing reliable health information through pure speech-based interaction, although such ability differs across NCDs.

Conclusion

This study provides evidence of the ability of Vas, such as Amazon Alexa, Apple Siri, and Google Assistant, to provide reliable voice responses to questions related to NCD management compared to the standard consumer-accessible method of information lookup (ie, web search). We validated NCD-related questions with practicing medical professionals, submitted a set of 60 questions to each VA, and assessed the response rate and source type. We answered the first research question (ie, *Is the response rate dependent on developers and modality?*), observing that Google Assistant responded to most of the answers and Apple Siri responded to the fewest. Modality played a minimal role, whereas Google Assistant and Apple Siri responded slightly more often in the *voice-only* modality and Amazon Alexa in the *voice-and-display* modality. Moreover, we answered our second research question (ie, *Is the source type dependent on developers and modality?*), finding that Google Assistant based most of its responses on *expert* sources of information, even outperforming the web search snippets. Furthermore, Amazon Alexa was less reliable but provided *expert* sources more than 50% of the times. Finally, Apple Siri was the least reliable, providing a considerable percentage of *crowdsourced* sources or often not providing a source at all. Across modalities, Amazon Alexa and Apple Siri similarly provided *expert* sources, while Google Assistant did so more frequently in the *voice-only* modality. Thus, the variation seemed to be more influenced by *developer* than *modality*. Finally, answering our third and fourth research questions (ie, *Is the response rate dependent on developers and disease?* and *Is the source type dependent on developers and disease?*), we observed that although there is a slight variation across the diseases, Google Assistant showed a general clear advantage. Nevertheless, although Google Assistant seems to be a good option to ask NCD-related questions, a large number of *commercial* sources was used, in particular for COPD. Providing patients with unverified or non-evidence-based information may be counterproductive if not dangerous. Therefore, we call out health organizations to collaborate with technology companies, such as Google, Amazon, and Apple, to ensure patients with NCDs are provided with openly reliable (ie, expert) information about the management of their condition. Finally, as the algorithms behind the VAs continuously change, future research should establish the temporal consistency of these results.

To conclude, our contributions lie in the following aspects. First, to the best of our knowledge, no previous research assessed the reliability of the 3 most prevalent VAs in responding to NCD-related questions. Second, we tested the selected VAs by submitting questions that we validated with practicing medical specialists in terms of the frequency of occurrence in their medical consultations. Third, we systematically controlled for the effect of visual display by testing both smart speakers and display devices for each VA. Finally, as previous research remains rather preliminary and lacks transparent method reporting [47], we aimed to report our methods as precisely as possible in the hope of stimulating informed future research on the ability of VAs to retrieve reliable information about health-related topics.

Acknowledgments

We would like to thank Dr med. Christoph Globas, Dr med. Dan Georgescu, Dr med. Daniel Franzen, Dr med. Eva Krebs-Roubicek, Dr med. Eva Bühlmann, Dr med. Frank Rassouli, Dr med. Martina Pechula Thut, Dr med. Michael Kiessling, Dr med. Oliver Gämperli, Dr med. Rebekka Gigger, Dr med. Susanne Wegener, Dr med. Thomas Schachtner, Dr med. Thomas Züger, and Dr med. Viviane Hess for validating our health-related questions.

The research was conducted at Future Health Technologies at the Singapore-ETH Centre, which was established collaboratively between ETH Zurich and the National Research Foundation Singapore. This research was supported by the National Research Foundation, Prime Minister's Office, Singapore, under its Campus for Research Excellence and Technological Enterprise (CREATE) program. This work was also supported by CSS Insurance, Switzerland.

Authors' Contributions

CB, EF, and TK were responsible for the study design. CB and ZFK were responsible for the selection of the questions, data collection, and response evaluation. CB was responsible for the first draft of the manuscript. All authors were responsible for critical feedback and final revisions of the manuscript.

Conflicts of Interest

At the time of submission, CB, EF, and TK are affiliated with the Centre for Digital Health Interventions, a joint initiative of the Department of Management, Technology, and Economics at ETH Zurich and the Institute of Technology Management at the University of St. Gallen, which is funded in part by the Swiss health insurer CSS. EF and TK are also cofounders of Pathmate

Technologies, a university spin-off company that creates and delivers digital clinical pathways. However, Pathmate Technologies was not involved in the study described in this paper.
