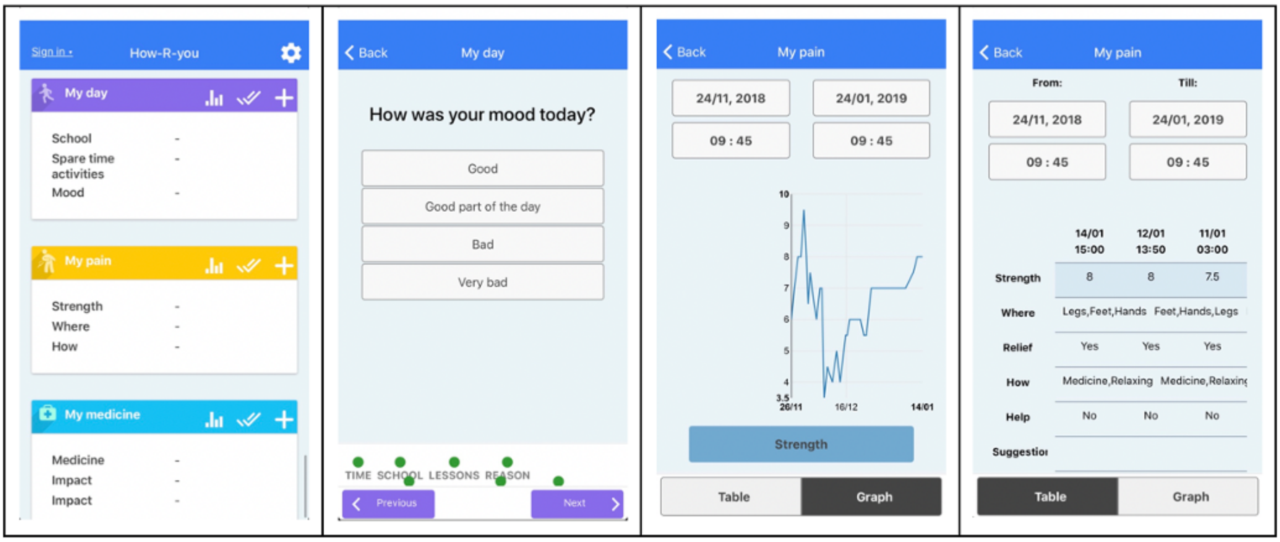
In this paper, we argue that mHealth is sometimes used as a solution to this challenge. mHealth technologies invoke a seemingly unoppressive power because they provide patients the right to speak and be heard, which is perceived as liberating and empowering [42]. They give patients a voice; yet, they are a means to ensure compliance. Specific practices during consultations highlight this point. Thus, we argue that mHealth does not simply liberate patients from being subjugated to power; rather, it reinstalls patients in new power relations, in which their seemingly empowered voice is used to govern them in specific directions. Thus, mHealth governs by ensuring that the patients are, in Rose's terms, "bound into the language of expertise at the very moment they are assured of their freedom and autonomy" [45]. In other words, the patients are paradoxically governed exactly through the freedom that mHealth seems to provide them. In the following analysis, we argue that How-R-you is constituted as a power technology. Although it seems liberating, it also organizes consultations to ensure patient compliance according to medical recommendations. Thus, it is invested with a governmental rationale.

How-R-you

How-R-you was chosen for this study because it was developed with a focus on empowerment and strengthening of patients' voices. The app was developed by Business Academy Aarhus with input from patients, health care professionals from Aarhus University Hospital, and researchers from Aarhus University. The app was commissioned by physicians to gain a better understanding of patients' everyday lives with chronic diseases and the symptoms they experience. How-R-you allows patients to continuously report on their health and monitor their well-being using PRO data. Specifically, the app enables 4 of 7 self-management activities [46] in patients' everyday life (drug management, communication with health care professionals, social support, and symptom management) by allowing patients to track drug use and monitor symptoms, and by supporting communication with both health care professionals and other stakeholders, especially parents [47]. How-R-you is organized into modules that contain health questions. The modules are "My medicine," "My pain," "My day," and "My night" (Figure 1).

Figure 1. How-R-you modules, question, graph, and table examples.



How was your mood today?

	14/01 15:00	12/01 13:50	11/01 03:00
Strength	8	8	7.5
Where	Legs,Feet,Hands	Feet,Hands,Legs	
Relief	Yes	Yes	Yes
How	Medicine,Relaxing	Medicine,Relaxing	
Help	No	No	No
Suggestion			

Modules and questions were developed and revised iteratively, and both patients' and physicians' needs were included in the design. The modules are configurable, which enables personalization according to the specific preferences of patients and physicians. Furthermore, How-R-you allows patients and physicians to gain an overview of historical data by converting them into graphs and tables.

Data Collection

We relied on data from a 2-year ethnographic field study of the impact of digital technology use in everyday life with JIA. The ethnographic approach helped us understand real-world problems empirically before seeking to explain them theoretically [48-50]. The fieldwork yielded both overall and individual accounts of 6 patients' everyday lives with JIA and their visits to the hospital. These accounts constituted thick descriptions [51] of patients' information needs and the extent to which How-R-you as an mHealth technology created value for patients [47]. The fieldwork comprised participant observations and interviews. Following Spradley [52], observations are always participatory, but to varying degrees. Observations were descriptive at the outset of the study to gain insights into the sociotechnical aspects of technology use. The researchers participated passively at the outset. Subsequently, observations became more focused, and participation became more involved in the sense of taking part in patients' daily activities. Thus, additional data were collected to gain a deeper understanding of selective aspects, that is, how How-R-you is used during consultations. The data were collected by the second author (KS), with support from the third author (SDM) who participated in the hospital. For this study, we carefully selected 6 specific observations of consultations as the empirical basis for our analysis. All observations were carefully planned and subsequently discussed to ensure reliable and valid interpretations.

The 6 cases comprised 1 consultation with each of the 6 patients included in the ethnographic study [47]. Patients were selected based on four criteria. First, all patients had the same disease (ie, JIA). Second, they were not diagnosed with other diseases (comorbidities). Third, both female and male patients were included. Finally, 1 female and 1 male patient were selected to represent each of the three predetermined maturity groups (7-10, 11-13, and 14-17 years old) that were a part of the study. The age groups were based on literature describing the medical assessments of JIA children and adolescents' cognitive and physiological development [53]. Children can assess their pain using a visual analogue scale, as in the case of How-R-you, from age 6 [54,55]. Furthermore, patients aged 18 years and above were treated as adults at Aarhus University Hospital. This means that our target group was 6-17 years old. In addition, the literature divides JIA children into 2 age groups; however, the cutoff age varies [53] between 12 [56] and 13 years [57] (Table 1).

Table 1. Overview of patients.

Patient	Sex	Age (years)
Nina	Female	7
Robert	Male	10
Rachel	Female	12
Oliver	Male	12
John	Male	14
Sophie	Female	16

We specifically selected these 6 consultations because they were held during the final stages of the fieldwork. During this stage of the fieldwork, both patients and the physician had become relatively familiar with How-R-you, and, therefore, technical questions and issues were less frequent. Moreover, at this selective stage of the fieldwork, we relied on extensive experience after 2 years of descriptive and focused interviews and observations of the patients' lives. During this time, the app underwent iterative development because of feedback from patients and physicians. Consequently, at this stage, we focused our observations specifically on the actual use of How-R-you during consultations [47]. Thus, these 6 consultations provide an ideal basis for our investigation into how How-R-you is used during consultations and how it affects empowerment.

All consultations were performed by the same physician to limit in- and cross-case variations. Although all the children's parents were present at the consultations, their involvement varied across the age groups. Parents of young children were highly involved, whereas parents of adolescents were not involved [47]. The duration of consultations varied between 20 and 30 minutes depending on the treatment needs and issues raised during conversation with the physician. The consultations were documented through participant observation [52], audio-recorded, and transcribed. Transcriptions were performed by the first (SK) and second (KS) authors. The consultations were discussed in detail to ensure that all aspects were included in the analysis. The observations were carefully planned with both the physician and patient. In accordance with the nature of passive participation, we interfered as little as possible in the consultations and only interacted with participants when encouraged by patients or the physician. To minimize the disruptive effects of our presence, we took field notes with pen and paper from the corner of the consultation room. Field notes were available to the participants.

Ethics

All patients, parents (due to the patients' ages), and the physician gave informed consent to all parts of the fieldwork. The physician collaborated with the research team throughout the fieldwork and participated in discussions about ethics. The patients and their parents were invited to a private informal meeting with one of the authors, who explained the details of the research projects. At least one week later, the author called patients and parents, who had expressed an interest in joining the study at the meeting. This gave patients and parents an opportunity to reconsider their interests and ask questions about the research project. Consent was given at the end of this conversation and more specific permissions, such as audio recording and taking pictures, were obtained throughout the entire study. The study complies with the ethical principles for medical research involving human subjects and with the American Anthropological Association's ethical principles for ethnographic fieldwork [58]. The study did not require approval from an ethical review committee according to the Danish National Committee on Biomedical Research Ethics.

Data Analysis

To address the research question, we draw on Foucault's concepts of power and power technology in an embedded case study of patient-physician consultations. This means that we seek to understand how How-R-you is used during consultations, what kind of practices it constitutes, and the rationale that drives the organization of these practices.

In our analysis, we are not concerned with the physician's intentions and motivations behind the use of the app, but only with how it is used and what it does to the consultation and the patient-physician relationship. Our interest lies not in the participants but in how the practices themselves lay the foundation for the exercise of power by organizing the consultation and inducing a certain behavior. Thus, How-R-you is not used by someone *in* power to assert power. Rather, power emerges as the way in which How-R-you organizes the relationship between the patient and the physician (Textbox 1).

Textbox 1. Data coding.

Identification of Deviation

- Pain
- Disturbed sleep
- Bad mood
- Physical inactivity

Structuring of Conversation

- Specifics about the deviation
- Patterns between disease indicators
- Ways of handling the deviation

Discipline

- Education
- Commending
- Questioning

Consultations were analyzed through an iterative process. By observing the consultations and listening to the recordings numerous times, we gained a preliminary understanding of the practices. Next, we transcribed and coded the data using the qualitative data analysis software NVivo 12 (QSR International). Top-level codes were identified based on our preliminary understanding of practices and our theoretical framework. This means that we sought to understand how the app is used organizes certain practices in specific ways and how it is invested with a specific rationale. Thus, we asked the following questions: How is the app used in specific practices? What registrations become visible to the physician and what are left unmentioned? How are the registrations used in conversation? Which topics become important during the conversation, and which are rendered irrelevant?

All authors were involved in data coding and analysis. The first (SK) and second (KS) authors provided deep insights and domain knowledge from participant observations and interviews. The third author (SDM) contributed to the in-depth text analysis of communication content, check coding, and challenging the interpretations of other authors. Through this process, we meticulously went through the transcriptions and coded the data according to the top-level codes. This led to the identification of sublevel codes for each top-level code. The process provided an in-depth understanding of the consultations and practices described in the following analysis.

Results

Overview

Our analysis reveals three interrelated practices around the use of How-R-you: ordering the patients' words; identifying deviations and structuring of patients' speech; and disciplining of patients. In the following, we argue that these practices collectively constitute How-R-you as a power technology. We devote each of the following three subsections to each specific practice. Finally, we conclude this chapter by summarizing the results.

Ordering the Patients' Words

How-R-you allows patients to register and monitor their health data. These data were examined by the physician and included in the health assessments of the patients during consultations. Therefore, How-R-you is believed to strengthen patients' voices by giving them the ability to provide personal insights. Before the introduction of How-R-you, patients arrived at consultations without a record of their health and well-being since their last consultations. In fact, patients and parents (who support their children) rarely take notes on their health from day to day. The result is recall bias when asked to account for their well-being since the last consultation. In How-R-you, patients make continuous health registrations by answering specific questions in the app. Thus, How-R-you constructs and builds a record of PRO data. During consultations, the data were presented to the physician as the patients' own words. However, in How-R-you, the registrations are ordered in certain ways, for example, in graphs that show how the patient felt each day since his or her last consultation:

> *Then we can use the registrations you have made (...) we just need to construct the graphs, because, you know, that's what's important—how your day has been.* [Physician]

The technology itself becomes an actor with a voice of its own. It simplifies patient experiences and confines registrations to specific questions. For instance, moods and feelings, which may be difficult to explain, are registered using smiley and slider scales (Figure 1). These registrations are presented in tables and graphs that allow physicians to examine the data. As a result of this ordering of the patients' words, physicians can quickly sum up otherwise complex experiences. For example, in the following quotation, a patient's mood and physical activity since the last consultation are summarized as follows:

> *Well, your mood seems to have been okay despite some tiresome nights. And your level of activity has been normal.* [Physician]

Thus, How-R-you is not a neutral instrument. It allows patients to continuously register health observations by answering specific questions, and it presents these registrations in a particular manner. The way How-R-you is used constitutes a practice that orders patients' words but presents them as their own voice. This allows for a seemingly empowering process through which patients' insights are incorporated during consultations. However, the ordering of the patients' words only enables very specific observations of the patients' lives with the disease. In the following section, we expand on this last point.

Identification of Deviations and Structuring of Patients' Speech

The ordering of patients' words exerts a structuring effect on conversations and patients' speech during consultations. During the physician's examination of data, it is evident that the physician scans the app modules for deviations, such as pain, disturbed sleep, mood swings, or physical inactivity. In other words, How-R-you renders deviations visible to physicians. How-R-you structures the conversation around the observed deviations. It does not reduce conversation as it expands it around very specific topics. With reference to their registrations in How-R-you, the patients were encouraged to speak and describe the deviations. Their speech is therefore structured by limiting the conversation to (1) specifics regarding the deviation, (2) patterns across disease indicators, and (3) how they *handle* the deviation:

> *What should I look at...your pain? Do you ever feel pain? Yes, you do actually—pain in the legs.* [Physician]

The above quote is from Nina's consultation, where the physician browsed the "My pain" module. The physician observed that Nina registered pain in her legs. The conversation then unfolds around this deviation. The physician probed the specifics of the pain, and Nina's mother described when the pain usually occurs and what they did to relieve it. In other words, it is about how they *handle* the deviation. This conversation helped the physician ascertain the cause of the pain.

In Robert's case, the physician's data analysis also revealed pain, and the conversation again focused on this topic. Neither Robert nor his father could remember the specific incidents where Robert experienced pain. However, Robert's father was uncertain whether the pain is attributable to arthritis or because Robert engaged in new and intense physical activities. This indicates that pain is not only related to arthritis:

> *...when it is something [pain] with the hand, well, that sounds like it's because you do something that you regularly don't, right?* [Physician]

During Rachel's consultation, the physician observed that Rachel had registered mood swings. However, Rachel attributed the cause to "...something at school," which seemed to indicate the physician that her mood was not relevant to the consultation. The physician continued by looking at other data in How-R-you and suggested that mood swings are connected to another disease indicator, namely physical inactivity. Similarly, Sophie attributed her mood swings to the lack of energy caused by a combination of pain and stress at work. In this case, the physician ascertained through How-R-you that there was no correlation with other disease indicators. The physician then told her that to cope with these mood swings, she will have to figure out what she can and cannot do:

> *That's part of what's going to be your challenge—to figure out the balancing act in what you are able to do and what you cannot do.* [Physician]

In the examples above, the structuring of conversations around deviations and the patients' own accounts led the physician to draw conclusions. The examples show that deviations are well-handled (Nina), do not relate directly to the arthritis (Robert and Sophie), or seem not relevant to the consultation (Rachel).

Notably, although the patients' perspectives have been included in the design of How-R-you to foster empowerment and strengthen the patients' voices, the app seems to structure the patient-physician consultations in a manner that seems to provoke somewhat opposite effects. One may argue that during the consultations, How-R-you renders certain relevant aspects of patients' lives irrelevant. These are aspects that the patients themselves bring up or have registered in the app (eg, what happens at school), indicating that they are relevant to their lives and, thus, to the self-management of their disease. However, the way How-R-you organizes registrations, for example, in graphs and tables, seems to leave these aspects in the blind spot of the physician's gaze, which is focused on deviations and patterns across disease indicators. Data are shared, but patients' voices are only selectively included as a basis for disease management and treatment during consultations. This is because How-R-you only enables very specific observations of patients' lives with the disease. As our analysis suggests, these observations leave relevant aspects unnoticed.

In other cases, patients' speech becomes a reference point for the exercise of power and identified deviations become targets for corrective, disciplinary power. We provide examples in the following section.

Disciplining of Patients

Our argument in the following is that by facilitating, ordering, and structuring patients' words and speech, How-R-you allows for the exercise of disciplinary power over patients with reference to their own spoken truths. The physician avoids referring to her superior medical knowledge and position. Instead, by referring to patients' own registrations, disciplining is conducted without the exercise of oppressive power. Specifically, disciplining takes the form of education, commending "right" (read in a medical sense) behavior and questioning patients.

During John's consultation, the physician browsed the How-R-you registrations and observed a deviation regarding his sleep patterns:

> *This is your sleep. So, disturbed [sleep], then a little steady and then very [disturbed].* [Physician]

John was asked to account for details around his sleep and he responded by describing his tiredness. This deviation, observed through the app, and the patient's description form the background for the physician's comment:

> *...it's still two days, where your sleep was very disturbed, so that's something, where you should keep in mind that the best thing that sleep knows is consistency. So, you go to bed at the same time, you wake up at the same time, you don't change it too much in the weekends...* [Physician]

With reference to the deviation, educating the patient about how to improve his sleep is legitimized. In other words, education is necessary because "it's still two days, where your sleep was very disturbed."

The physician continues by describing optimal bedroom temperatures and warnings against the effects of technology use before sleep:

> *This means that all kinds of tablet, tv, computer, and all that stuff should preferably not be switched on [...] So I've just asked you to use an app [How-R-you], and now I'm asking you to really not use it too much before bedtime, or at least that's something to think about.* [Physician]

Thus, education and suggested behavioral changes are used to *correct* the deviation. Both John and his mother engaged in conversations with the physician and showed signs of compliance. John mentioned that he switches his iPhone lighting to *night shift*, which changes the display to warmer colors. His mother emphasized that they imposed stricter bedtime rules regarding when to turn off video games. In response, the physician replied: "Right, it's those video games." Thus, John and his mother show compliance by explaining how they are going to *correct* the deviant behavior. A part of disciplining the patient is to make him or her recognize the need for behavioral change. This involves a conversation about the deviation during which compliant behavior is constructed as *right* and noncompliant behavior (eg, playing games before bedtime) is articulated as *wrong*.

During Rachel's consultation, the topic of physical inactivity emerged because she had registered periods of pain. The physician noted that the number of days of pain correlated with days where she was less active. This topic was revisited later during consultation. Although the physician did not reference the observed deviation in the subsequent disciplining, there was a correspondence between the observed deviation (physical inactivity) in How-R-you and the discipline. Thus, the registrations in How-R-you reveal that pain may be caused by physical inactivity (the deviation). In this sense, the registrations form the background for the following conversation:

> *Yesterday, I walked 30,000 [steps], because I rode [my horse] twice, then I had physical education and rode my bike and stuff.* [Rachel]
>
> *Well-done [...] I thought you'd be at around 8,000-10,000 [steps] most of the times, unless you're one of those, who play Fortnite, right.* [Physician]
>
> *Right.* [Rachel]
>
> *Then it's at a zero.* [Physician]

Rachel's response revealed compliant behavior (physical activity). This behavior was encouraged by the physician who commended her while at the same time alluded to noncompliant (ie, *wrong*) behavior, namely inactivity and too much gaming. Here, discipline takes the form of commending compliant behavior and constructing noncompliant behavior as *wrong*.

During Oliver's consultation, the physician observed that Oliver had registered periods of pain. When asked about the specifics, he revealed deviant behavior in the form of physical inactivity:

> *So, you nevertheless had one day in January, where you felt pain in your leg.* [Physician]
>
> *Yes, so I had a 7.5 (on the pain intensity scale) [...]* [Oliver]
>
> *Was it related to football, or was it just kind of sudden?* [Physician]
>
> *No, I don't really play football, just in the breaks...[Oliver]*

The physician returned to this issue later during the consultation:

> *Then what about getting in better shape. Besides playing a bit of football in the schoolyard, is there something specific you do?* [Physician]
>
> *Well, I actually think I'm in OK shape.* [Oliver]
>
> *Right OK, but I think we've talked about it a couple of times.* [Physician]

By referring to the patient's own statement, the physician can ask the question:

> *Then what about getting in better shape [...] is there something specific you do?*

Hence, the physician tries to *correct* the deviation, that is, encourage the patient to improve his physical condition. This type of questioning continues and included the nurse who asked whether the patient participates in physical education. Oliver's mother showed compliance and mentioned that they have talked about taking long walks during weekends and signing up for membership at a fitness center. The physician commented "Well, it sounds like you have a lot of good things up and running." Again, compliant behavior was encouraged.

How-R-you as a Power Technology

Our findings suggest that three interdependent practices constitute How-R-you as a power technology: first, it orders patients' words and presents them in a specific way. Second, it structures the patients' speech during conversations around deviations. In doing so, it may have a silencing effect on patients' voices. Third, it allows for the disciplining of patients by referring to their own words and speech, thereby enabling an exercise of power that does not appear oppressive. Thus, these practices are means by which disciplinary power is exercised, which entices, motivates, and commends the compliant behavior, and at the same time constructs noncompliant behavior as *wrong*. Naturally, we do not argue that specific suggestions in the discipline of patients are wrong or damaging. However, we argue that compliant and deviant behaviors are determined based on medical knowledge and expertise, and patients' voices are not included in this assessment. In Foucauldian terms, the exercise of power might produce more healthy subjects observed through a medical gaze focused on lifestyle choices, but in doing so, it might ignore relevant aspects of the patients' lives. This conflicts with the purpose of empowerment in chronic disease self-management, which emphasizes the strengthening of patients' voices and the importance of patients' everyday lives with the disease. As a power technology, How-R-you is an efficient management tool that spares physicians from lengthy conversations, which are often affected by patients' recall bias. Instead, it presents PRO data in a structured manner that allows physicians to quickly identify deviations. In a Foucauldian sense, the deviations become the object of a power that *corrects* behavior. It is therefore questionable whether How-R-you supports patient empowerment during consultations. Our analysis revealed practices in which patients' behaviors were governed toward specific ends, which might result in compliance. However, as a result, their voices may not be heard, and thus, relevant aspects of their lives may be ignored. In the following section, we discuss the implications of these results.

Discussion

Contribution and Implications

First, our results are surprising because they are in conflict with the perceived purpose of mHealth technology as described in the literature, which defines empowerment as giving patients greater control of their health and disease treatment [8,31,32]. Moreover, the findings are particularly interesting because they reveal a dimension to the study and use of mHealth technology, which has so far been largely neglected by the extant literature. Studies emphasize the importance of including patients in technology design [1,33,36] and studying the patient-physician relationship through data collected before, between, and after consultations [19]. Although How-R-you is developed through a user-centered design process, our study shows that the use of technology constitutes practices that promote compliance. This means that although user-centered design is a prerequisite for empowerment, it is not sufficient. The actual use of technologies during consultations also affects empowerment. In this particular case study, there is evidence to suggest that the technology could have a disciplinary rather than empowering effect during consultations, as it specifically structures the consultation around deviations and compliance. Our qualitative research design, with its focus on consultations from a process perspective, allows us to gain insights into how a particular technology orders and structures the consultation and patient-physician relationship and what the implications are for patient empowerment. Thus, we contribute to state-of-the-art knowledge by showing that technology use may have negative effects on empowerment, and we underscore the importance of future research to investigate the actual uses of different technologies.

From the perspective of the physician, our results show how technologies such as How-R-you construct records of patient registrations of PRO data, which are subsequently used to structure conversations with patients and discipline them by referring to their own words and thus foster compliance. This discipline occurs through education, commending compliant behavior, and questioning deviations. The disciplining of patients may also take the form of, for example, repeating patients' own words that indicate a desire to change behavior toward compliance [42]. Disciplining in this sense is about making use of patients' own words and statements to make them recognize a willingness to comply with treatment plans and medical recommendations. Physicians may use technologies during consultations to improve medical compliance, and our results show the manner in which this discipline occurs. Physicians may also use our study to increase their awareness of how technologies structure their observations. In doing so, they may come to appreciate that information other than that which the technology presents as *deviant* may also be relevant to the patients' lives and thus for their ability to self-manage their disease.

By contrast, to assert control, patients need to become aware of practices reducing them to mere deviations that must be *corrected*. Thereby, patients can take advantage of the empowering potential of technologies to steer conversations toward registrations that are important to them. For instance, patients could direct attention to registrations that might have gone unnoticed by the physician and expand on these registrations by dwelling on details that are important to them. Thus, as our findings underscore, this empowering potential does not reside innately in technologies. To nurture this potential, both physicians and patients must become aware of the way in which technologies organize and structure their relationships. Practical means of doing so include physicians spending time examining the registrations with the patients. In doing so, not only should deviations and noncompliance be attended to, but the physician should also initiate dialogue around what may at first glance seem like unremarkable registrations, asking questions such as, "How did you feel during this time, when you were seemingly physically active?" and "Did you do or notice something different?" Thereby, patients are encouraged to speak not only about reasons for deviations or noncompliance but also about other aspects that are relevant to their lives with the disease.

In conclusion, we argue that mHealth technology cannot simply be assumed to be empowering but must be studied in the specific contexts in which it is used. On one hand, it may effectively reduce the recall bias and provide physicians with more data. On the other hand, while studying empowerment from a patient perspective, it cannot be disentangled from its specific uses during consultations. Empowerment depends on patient-physician relationships, where data are shared and where patients' voices and experiences are heard. This has implications for the design of mHealth technologies. Given that empowerment depends on allowing patients' voices and their specific experiences to be heard, designers should prioritize the development of features that support dialogue around specific patient experiences. For instance, instead of turning quantitative PRO data into graphs, the technology may allow patients to register experiences for follow-up and elaboration during consultations. Overall, in addition to emphasizing the collection and sharing of data, mHealth technologies could incorporate design features that aim to invoke dialogue between patients and physicians where the patients' lived experiences with the disease are heard.

Call for Research

First, this study raises the question of whether other types of mHealth technology used in chronic disease management have similar effects. As mentioned, in extant literature, the question of how empowerment happens (or not) during consultations is understudied. Our study underscores the importance of studying how technology impacts patient-physician consultation to understand its potential to empower patients. We neither intend nor are we able to reveal a general pattern in the use of mHealth technologies during consultations. For generalization, additional cases need to be investigated, including different technologies, practices, and patient groups. Second, research is also needed to understand how the identified practices influence the work practices of physicians. Foucault emphasizes that power is not exercised by subject A over subject B. Power is relational and thus affects both subjects. Technologies that privilege patients' autonomy challenge physicians' reliance on medical knowledge. The question is, therefore, how physicians redefine themselves when they are expected to manage without managing? Third, our results raise questions regarding the relationship between empowerment and compliance, which calls for future investigations. Is the former always preferable to the latter, or is it possible to achieve both at the same time without compliance, preventing patients from assuming control and vice versa? Furthermore, it is possible that practices similar to those identified in this study lead to patients feeling empowered despite being disciplined. This raises questions about *real* versus perceived empowerment. To what extent does perceived empowerment improve clinical outcomes, and if it involves disciplining the patients, to what extent does it support patients in dealing with their diseases?

Limitations

A number of limitations of our study deserve mention. First, in our analysis, we did not differentiate between patient ages. For our analytical purposes, we focused on how How-R-you structures consultations. However, we recognize that physicians may approach consultations with patients from different age groups differently, and that different age groups react differently to mHealth technology and medical advice. Second, as the patients in our study were children and adolescents, the way How-R-you structures the consultations may vary from that of adults, and power relations will take different forms. Although we recognize that consultations with children and adults differ, we believe that the questions concerning mHealth and power relations raised by our study apply to both types of consultations. Thus, while our study does not make these differentiations, it points to the importance of studying the use of mHealth in different contexts and patient groups.

Conclusions

In this paper, we investigate the use of mHealth technology during patient-physician consultations with a focus on empowerment. We thereby shed light on an area that remains understudied, namely the use of mHealth during consultations. On the basis of our analytical findings, we argue that the use of the How-R-you app constitutes it as a power technology that promotes compliance with medical recommendations. Our findings contribute to the extant literature by showing how practices, emanating from the use of mHealth technologies, may have unintended consequences. This calls for future research into the use of various types of mHealth technology during consultations to investigate whether they in fact support patients in asserting control of their health and disease treatment.

Acknowledgments

The authors would like to thank the physicians, patients, and parents for their participation. Their contributions made this study possible.

Abstract

Background: Patient satisfaction with in-person medical visits includes patient-clinician engagement. However, communication, empathy, and other relationship-centered care measures in virtual visits have not been adequately investigated.

Objective: This study aims to comprehensively consider patient experience, including relationship-centered care measures, to assess patient satisfaction during virtual visits.

Methods: We conducted a large survey study with open-ended questions to comprehensively assess patients' experiences with virtual visits in a diverse patient population. Adults with a virtual visit between June 21, 2017, and July 12, 2017, were invited to complete a survey of 21 Likert-scale items and textboxes for comments following their visit. Factor analysis of the survey items revealed three factors: experience with technology, patient-clinician engagement, and overall satisfaction. Multivariable logistic regression was used to test the associations among the three factors and patient demographics, clinician type, and prior relationship with the clinician. Using qualitative framework analysis, we identified recurrent themes in survey comments, quantitatively coded comments, and computed descriptive statistics of the coded comments.

Results: A total of 65.7% (426/648) of the patients completed the survey; 64.1% (273/426) of the respondents were women, and the average age was 46 (range 18-86) years. The sample was geographically diverse: 70.2% (299/426) from Ohio, 6.8% (29/426) from Florida, 4.2% (18/426) from Pennsylvania, and 18.7% (80/426) from other states. With regard to insurance coverage, 57.5% (245/426) were undetermined, 23.7% (101/426) had the hospital's employee health insurance, and 18.7% (80/426) had other private insurance. Types of virtual visits and clinicians varied. Overall, 58.4% (249/426) of patients had an on-demand visit, whereas 41.5% (177/426) had a scheduled visit. A total of 41.8% (178/426) of patients had a virtual visit with a family physician, 20.9% (89/426) with an advanced practice provider, and the rest had a visit with a specialist. Most patients (393/423, 92.9%) agreed that their virtual visit clinician was interested in them as a person, and their virtual visit made it easy to get the care they needed (383/421, 90.9%). A total of 81.9% (344/420) of respondents agreed or strongly agreed that their virtual visit was *as good as* an in-person visit by a clinician. Having a prior relationship with their virtual visit clinician was associated with less comfort and ease with virtual technology among patients (odds ratio 0.58, 95% CI 0.35-0.98). In terms of technology, patients found the interface easy to use (392/423, 92.7%) and felt comfortable using it (401/423, 94.8%). Technical difficulties were associated with lower odds of overall satisfaction (odds ratio 0.46, 95% CI 0.28-0.76).

Conclusions: Patient-clinician engagement in virtual visits was comparable with in-person visits. This study supports the value and acceptance of virtual visits. Evaluations of virtual visits should include assessments of technology and patient-clinician engagement, as both are likely to influence patient satisfaction.

KEYWORDS

telehealth; virtual visit; patient experience; mobile phone

Introduction

Virtual visits have emerged at a time in health care when clinicians' decisions have become only one part of patients' experiences. Patients' and their families' needs, values, and inputs influence care decisions [1]. Patients are researching treatments on the internet and engaging as advocates and even as partners with physicians both on the internet and in person [1-5]. A crucial aspect of patient experience is the patient-clinician engagement or using a *relationship-centered care* approach. This approach prioritizes how the communication and emotions shared between patients and clinicians gradually affect patients' experiences as a whole person [5,6]. Furthermore, whether physicians empathize with their patients strongly shapes the patient-physician relationship and patient satisfaction [7]. Virtual visits must continue the best aspects of in-person care to be an acceptable substitute for in-person care. However, no studies have evaluated whether virtual visits are addressing patients' experiences comprehensively rather than simply whether or not they are satisfied.

Studies on virtual visits have examined patient satisfaction. For example, patients have reported positive experiences about communication, engagement, and building rapport with clinicians during their virtual visits [8-12]. Furthermore, patients have expressed that virtual visits are convenient in decreasing travel time, wait time, and stress and increasing comfort and convenience [13-15]. Virtual visits increased substantially during the initial phase of the COVID-19 pandemic, and physicians reported that patients respond positively to virtual visits [16], that telemedicine addresses both urgent and nonurgent care [17], and that telehealth has become a valuable way to evaluate patients before they enter a medical facility, thereby limiting potential clinician or patient exposure to COVID-19 [18]. Despite the increasing use of telehealth during the COVID-19 pandemic, these studies have not evaluated whether virtual visits actually serve the patient-clinician relationship [16-18]. In addition, studies that have examined patient satisfaction with virtual visits are mostly specialty- or disease-specific [19-21], have small sample sizes or low survey response rates [9,10,21,22], or include only one item to measure patient satisfaction [13].

To gain a more comprehensive understanding of the patient experience during virtual visits, especially patient-clinician engagement in a range of types of virtual visits, we conducted a survey study with patients who received virtual care from a variety of clinicians representing different practices.

Methods

We conducted a large survey study that included open-ended questions to comprehensively assess patients' experiences with virtual visits in the Cleveland Clinic Health System. This cross-sectional study was conducted with adults who had a synchronous virtual visit between June 21, 2017, and July 12, 2017. These visits took place on a synchronous video-visit platform developed by the American Well [23]. The study examined scheduled and on-demand virtual visits that used audio and video (telephonic only were not available). With this app, patients can locate and connect with clinicians in an *on-demand* fashion, and clinicians can also schedule visits in advance so that patients can simply click on a link at the designated time to connect directly with their clinician. Visits were termed an *Express Care Online* visit because patients could access a clinician quickly, though still comprehensively receive help. The user interface facilitates virtual visits over smartphones, tablets, and computers [23].

Eligible patients were identified by daily census reports from the previous day's virtual visits. When patients had more than one virtual visit during study accrual, only the first visit was included. In addition, visits used for clinician training, digital health testing, and those with a duration of 0 minutes were excluded from the study. All 648 eligible patients with visits during that period were sent an email invitation to complete a brief web-based survey regarding their experiences with their recent virtual visit. All nonresponders were sent reminder email invitations and were then called by a member of the research team. Patients were given a US $5 Amazon e-gift card upon completion of the survey. As part of their participation, they were informed about the gift card at the time of recruitment. Given the small amount of compensation, participation bias is likely to be minimal.

Survey items were designed to consider patients as whole persons, evaluate the patient-clinician relationship, and broadly assess patients' experiences with virtual visits; specifically, we sought to assess patient's overall satisfaction, overall ease, technical ease, convenience, relationship with the clinician, and perception of clinician empathy. The survey also aimed to evaluate how patients compared virtual visit quality and value with in-person visits. Survey questions were developed after an extensive review of the literature [14,15,24] and several iterations of expert stakeholder input from members of the digital health team, the office of patient experience, and patient volunteers. The survey consisted of 21 items evaluated on a 5-point Likert scale (1=strongly disagree, 2=disagree, 3=neutral, 4=agree, and 5=strongly agree) and text boxes for comments on what patients liked best about their virtual visit and what could be improved. The survey items are presented in Multimedia Appendix 1.

Survey data were collected and managed using the REDCap (Research Electronic Data Capture) electronic data capture system [25]. Survey data were merged with data from the hospital system that included virtual visit characteristics, such as visit type (scheduled or on-demand), device type (computer or mobile device), clinician type (physician or advanced practice provider), clinician specialty, insurance type, and patient demographic information.

First, we computed descriptive statistics. Factor analysis of the 21 survey items revealed three factors: overall satisfaction with the virtual visit (standardized Cronbach α=.93), comfort and ease using virtual visit technology (Cronbach α=.89), and patient-clinician engagement (Cronbach α=.92). Items associated with each factor were summed and dichotomized at the mean for analysis. We used multivariable logistic regression with backward variable selection to assess the associations among patient demographics; virtual visit clinician type and prior patient relationship with their virtual visit clinician; and overall satisfaction with their virtual visit, patient-reported experience using the virtual visit technology, and patient-clinician engagement. Quantitative data were analyzed using SAS 9.4 [26].

For the open-ended questions, a framework analysis of the content was used to identify themes in patients' narrative comments. Themes were used to create a coding checklist consisting of dichotomous (yes or no) variables. Themes that emerged from comments in response to what patients appreciated about their virtual visit included not having to travel outside home to receive care, enhanced access to care, and convenience. Themes related to recommendations for improvements included enhancements to the user interface and instructions to better prepare for virtual visits. A coding checklist was used to code the text data quantitatively and descriptive statistics were computed.

This study was approved by our medical center's institutional review board.

Results

Overview

Out of the 426 patients who responded to the survey (426/648, 65.7%), nearly two-thirds self-identified as female (273/426, 64.1%). The average age was 46 (range 18-86) years; 70.2% (299/426) of the patients were from Ohio, 6.8% (29/426) were from Florida, 4.2% (18/426) were from Pennsylvania, and 18.7% (80/426) resided in other states. Insurance coverage was undetermined for more than half of the patients (245/426, 57.5%), 23.7% (101/426) had the hospital's employee health insurance, and 18.7% (80/426) had other private insurance. The demographic characteristics of the respondents were similar to those of the nonrespondents.

A total of 58.4% (249/426) patients had an on-demand virtual visit for an acute concern, and 41.5% (177/426) had a scheduled virtual visit; 28.6% (121/423) of patients knew their virtual visit clinician from a previous in-person appointment with that same clinician, and those patients were older (*P*=.003) and more often male (*P*=.03) compared with patients who did not know their virtual visit clinician. Moreover, most patients who knew their virtual visit clinician had a scheduled rather than on-demand virtual visit (119/121, 98.3%). About 41.8% (178/426) of clinicians were family physicians, whereas the rest represented other physician specialties, and 20.9% (89/426) were advanced practice providers. Most patients used mobile devices such as phones or tablets for their visits (348/424, 82.1%), whereas the rest were connected using a computer. Patient and virtual visit characteristics are presented in Table 1.

Table 1. Patient and virtual visit characteristics (N=426).

Characteristics	Value
Age (years), mean (SD)	46 (15.5)
Female, n (%)	273 (64.1)
Ohio resident, n (%)	299 (70.2)
Hospital employee, n (%)	101 (23.7)
Insurance used, n (%)	
Employee Health Plan	101 (23.7)
Medical Mutual of Ohio	80 (18.8)
Undetermined	245 (57.5)
Physician virtual clinician, n (%)	336 (78.9)
Prior relationship with clinician (n=423), n (%)	121 (28.6)
Visit type, n (%)	
On-demand	249 (58.4)

Overall Satisfaction

The mean overall satisfaction score was 4.4 out of 5 with an SD of 0.78 (see Table 2 for detailed Likert scale survey results). Overall, 81.9% (344/420) of respondents agreed (107/420, 25.5%) or strongly agreed (237/420, 56.4%) that their virtual visit was *as good as* an in-person visit with a clinician. More than half of the respondents agreed (73/417, 17.5%) or strongly agreed (149/417, 35.7%) that their virtual visit was *better than* an in-person visit with a clinician. In multivariable logistic regression, employee patient status (vs nonemployee) was associated with higher odds of overall satisfaction with their virtual visit (odds ratio [OR] 1.9, 95% CI 1.14-3.47). The results from the multivariable logistic regression are presented in Table 3.

Table 2. Patient responses to Likert scale survey items (N=426).

Item	Total, n	Strongly disagree, n (%)	Disagree, n (%)	Neutral, n (%)	Agree, n (%)	Strongly agree, n (%)
Overall satisfaction						
My virtual visit made it easy to get the care I needed.	421	6 (1.4)	14 (3.3)	18 (4.3)	94 (22.3)	289 (68.6)
For my health concern, my virtual visit was *as good as* an in-person visit with a health care provider.	420	9 (2.1)	27 (6.4)	40 (9.5)	107 (25.5)	237 (56.4)
For my health concern, my virtual visit was *better than* an in-person visit with a health care provider.	417	19 (4.6)	49 (11.7)	127 (30.5)	73 (17.5)	149 (35.7)
My virtual visit saved me time.	422	9 (2.1)	6 (1.4)	19 (4.5)	62 (14.7)	326 (77.2)
My virtual visit was worth the money I spent on the visit.	420	21 (5)	8 (1.9)	46 (10.9)	81 (19.3)	264 (62.9)
I would use a virtual visit again.	422	8 (1.9)	7 (1.7)	15 (3.5)	90 (21.3)	302 (71.6)
I would recommend a virtual visit to others.	414	9 (2.2)	8 (1.9)	17 (4.1)	82 (19.8)	298 (72)
Comfort and ease using virtual visit technology						
My virtual visit platform was easy to use.	422	3 (0.7)	13 (3.1)	12 (2.8)	103 (24.4)	291 (68.9)
I was comfortable using my virtual visit platform.	423	0 (0)	2 (0.5)	20 (4.7)	105 (25.8)	296 (70)
The wait time to see my online health care provider was reasonable.	422	3 (0.7)	4 (0.9)	15 (3.6)	107 (25.4)	293 (69.4)
It was easy to see my health care provider during my online visit.	424	7 (1.6)	5 (1.2)	9 (2.1)	91 (21.5)	312 (73.6)
It was easy to hear my health care provider during my online visit.	423	9 (2.1)	9 (2.1)	11 (2.6)	92 (21.8)	302 (71.4)
It was easy to talk with my health care provider during my online visit.	423	7 (1.6)	6 (1.4)	10 (2.5)	87 (20.6)	313 (74)
The technology was easy to use.	423	5 (1.2)	8 (1.9)	18 (4.3)	105 (24.8)	287 (67.8)
Patient-clinician engagement						
My online health care provider was interested in me as a person.	423	2 (0.5)	2 (0.5)	26 (6.1)	98 (23.2)	295 (69.7)
My online health care provider fully understood my health concern.	417	0 (0)	4 (0.9)	14 (3.4)	86 (20.6)	313 (75.1)
My online health care provider and I made a plan of action to resolve my health concern.	421	2 (0.5)	6 (1.4)	15 (3.6)	95 (22.6)	303 (72)
I believe that the plan of action my health care provider recommended will resolve my health concern.	419	6 (1.4)	8 (1.9)	54 (12.9)	89 (21.2)	262 (62.5)
I understand what I need to do next to resolve my health concern.	422	1 (0.2)	3 (0.7)	18 (4.3)	106 (25.1)	294 (69.7)
I had enough time with my health care provider during my online visit.	418	1 (0.2)	4 (0.9)	14 (3.3)	102 (24.4)	297 (71)
My privacy was respected during my online visit.	415	0 (0)	0 (0)	10 (2.4)	102 (24.6)	303 (73)

Table 3. Predictors of overall satisfaction, patient-clinician engagement, and comfort and ease with virtual technology.

Factor	Odds ratio (95% CI)
Patient-clinician engagement	
Virtual clinician was nurse practitioner or physician assistant (vs family physician)	2.28 (1.25-4.16)
Employee patient status (vs nonemployee)	1.73 (1.01-2.95)
Overall satisfaction	
Employee patient status (vs nonemployee)	1.9 (1.14-3.17)
Technical difficulties (vs no technical difficulties)	0.46 (0.28-0.76)
Comfort and ease using virtual technology	
Prior relationship with virtual clinician (vs no prior relationship)	0.58 (0.35-0.98)

Most patients (383/421, 90.9%) reported that their virtual visit made it easy to receive the care they needed. A respondent noted, “It was quick and easy. Instead of finding babysitters for my 4-month-old twins, it was convenient to do right from my home.” Open-ended responses (Table 4) support this finding: patients valued receiving care from their home without traveling to their clinician’s office (145/363, 39.9%) and reported that virtual visits provided convenient access to health care (121/363, 33.3%) and saved them time (98/363, 26.9%). Most patients reported that they would use virtual care again (392/422, 92.9%) and would recommend it to other people (380/414, 91.8%).

Table 4. Patient feedback on their virtual visit in their own words.

Domain	Patients, n (%)	Illustrative quotes
What did you like best about your virtual visit? (n=363)		
No travel or stay at home	145 (39.9)	“It was so much better to be able to not have to leave the house when I felt so awful and in so much pain.” [P46]
Access or convenience	121 (33.3)	“I used it on a Holiday when my doctor’s office was closed, and it saved me the trip to Urgent Care while in pain.” [P487]
Saved time	98 (26.9)	“I saved time, money and my health by being able to have this visit online.” [P109]
Easy	94 (25.9)	“Having two kids, it was so easy to face time a provider to get the help I needed.” [P99]
Quick	60 (16.5)	“The process was quick.” [P418]
Clinician	50 (13.8)	“My online visit was with Dr. [name] and it was an honest pleasure interacting with her. She seemed legitimately interested and concerned regarding my health matter and at no time did I ever feel awkward or rushed.” [P530]
Cost	36 (9.9)	“It saved me a lot of time and money. My care and concerns were addressed as if I was visiting the doctor in person. I am very pleased.” [P444]
Continuity of care	20 (5.5)	“I loved the fact that I was able to see my provider, and not just anyone. I have seen this doctor for several years, and getting an in-person appointment with her is very hard to do. Therefore, getting an online appointment, I was able to see her faster.” [P82]
What can we improve? (n=100)		
User interface	30 (30)	“I would say the technology was faulty. I’m not an expert, but I followed the directions and it would not connect us.” [P459]
Virtual visit information	14 (14)	“Perhaps a pre-appointment preparation list might help set appropriate expectations for patients. For example, ‘for the following problems, you may need to get additional tests/go to the ER, etc.’ This is because some people may not know these things.” [P96]
Insurance coverage	10 (10)	“I would work to partner with more insurance providers to remove those barriers associated with utilizing health care coverage for this service, if I were the management team.” [P307]
Access to prescriptions	9 (9)	“I was not able to get my prescription for strep through the express care online.” [P70]
Link to the patient portal	5 (5)	“Cross-functionality with MyChart would be great.” [P223]
More clinicians	4 (4)	“I want more specialized care in the app. Please have therapists, psychologists and other specialized doctors.” [P51]

Comfort and Ease Using Virtual Visit Technology

The mean overall technology experience score was 4.6 out of 5 with an SD of 0.57, and 93.4% (394/422) of patients reported that the virtual visit interface was easy to use. Participants agreed and strongly agreed that they felt comfortable using it (401/423, 94.8%), and most agreed or strongly agreed that the wait times for using it were reasonable (400/422, 94.8%). Respondents could see (403/424, 95.1%), hear (394/423, 93.1%), and talk with (400/423, 94.6%) their clinician easily during their virtual visit. However, 19.9% (84/423) of patients reported that they had technical difficulties during their virtual visit (Table 5), and technical difficulties were associated with lower odds of overall satisfaction among patients (OR 0.46, 95% CI 0.28-0.76) in multivariable logistic regression. In addition, in multivariable logistic regression, having a prior relationship with their virtual visit clinician was associated with less comfort and ease with virtual technology among patients (OR 0.58, 95% CI 0.35-0.98). In open-ended comments, 23.5% (100/426) of patients commented on what could be improved, and 30% (30/100) of these comments recommended improvement of the user interface (see Table 4 for additional patient suggestions for improvement).

Table 5. Patient responses to dichotomous survey items (N=426).

Item	Yes; patient, n (%)	No; patient, n (%)
Have you had a previous in-person visit with the health care provider you saw using Express Care Online? (n=423)	121 (28.6)	302 (71.4)
Did you have any technical difficulties during your Express Care Online visit? (n=423)	84 (19.9)	339 (80.1)
Where would you have gone for medical care if you had not used Express Care Online? (n=426)		
Doctor’s Office	229 (53.8)	197 (46.2)
Urgent Care	112 (26.3)	314 (73.7)
Emergency Room	21 (4.9)	405 (95.1)
Retail Clinic	30 (7)	396 (92.9)
I would not have gone for medical care	50 (11.7)	376 (88.3)

Patient-Clinician Engagement

Most patients (393/423, 92.9%) agreed that their virtual visit clinician was interested in them as a person. A respondent commented, “The physician was very kind and really listened to my issue and what I had already tried to resolve it” (for additional patient responses, see Table 4). In addition, the patients felt that they were able to work together with their clinicians reciprocally—94.5% (398/421) of respondents reported that together with their virtual visit clinician, they made a plan of action to resolve their health concern. In multivariable logistic regression, a visit with an advanced practice provider (nurse practitioner or physician assistant) was associated with higher odds of patient-clinician engagement compared with visits with a family medicine physician (OR 2.28, 95% CI 1.25-4.16). In addition, employees of our medical center had higher odds of patient-clinician engagement than nonemployees (OR 1.73, 95% CI 1.01-2.95).

The mean patient-clinician engagement score was 4.6 out of 5, with an SD of 0.53. In open-ended comments, patients described the high quality of their virtual visit clinician (50/363, 13.8%), and 95.7% (399/417) of patients agreed that their virtual visit clinician fully understood their health concern. However, some results suggest a need to improve the patient-clinician relationship. Open-ended comments reflected a need for better orientation to virtual visits: 14% (14/100) of respondents recommended that patients be given more information before their virtual visits to know what to expect and how to prepare for their appointment.

Discussion

Principal Findings

The large and diverse sample size and high response rate (426/648, 65.7%) suggest robust findings about patient experience of virtual visits as compared with prior studies [27].

This large mixed methods study in a major health system found that patients reported high satisfaction with virtual visits, that the technology was easy to use, and that virtual visits were comparable or better than an in-person visit. However, technical difficulties were associated with lower odds of overall satisfaction among patients (OR 0.46, 95% CI 0.28-0.76) in the multivariable logistic regression. Our findings of high patient satisfaction with virtual visits align with those of other published studies [15,20,28,29]. For example, 95% of patients who participated in a MinuteClinic telehealth visit were very satisfied with the quality of the health care they received and rated telehealth as better than or just as good as a traditional in-person visit [15]. However, our findings are unique and go beyond these other studies because we measured satisfaction in terms of several indicators of patient-clinician engagement. We found that most patients in our study reported high engagement with their virtual visit clinician. There are concerns about the effect of telemedicine on trust-based relationships between patients and clinicians [30] and the ability to express empathy in digital settings [31,32]. Our study suggests that it is possible to measure the patient-clinician engagement and begin to evaluate empathy and collaborative relationships with patients during a virtual visit.

However, both clinician and patient identity influenced the likelihood of strong patient-clinician engagement during virtual visits. Having a pre-existing relationship with the clinician was associated with lower satisfaction. In terms of gender and age, older men who had previous relationships with their virtual visit clinicians were some of the patients that were least satisfied with their experiences. Patients who had a scheduled virtual visit were older than those who had an on-demand visit and were perhaps less comfortable with virtual technology than younger patients. In multivariable logistic regression, having a prior relationship with their virtual visit clinician was associated with less comfort and ease with virtual technology among patients (OR 0.58, 95% CI 0.35-0.98). However, patient age was not a significant predictor of overall satisfaction, patient-clinician engagement, or comfort and ease with virtual technology. Patients who received care from their clinician via a traditional in-person appointment may have experienced discomfort with, or simply did not like, this unfamiliar mode of care with a clinician they know. Gender, age, and the necessity of multiple or repeated virtual visits instead of in-person visits may contribute to less satisfaction and should be explored further in future studies.

In terms of employment and insurance status, employee status was associated with overall satisfaction with virtual visits. In multivariable logistic regression, employee patient status (vs nonemployee) was associated with higher odds of overall satisfaction with their virtual visit (OR 1.90, 95% CI 1.14-3.47). In addition, employees of our medical center had higher odds of patient-clinician engagement than nonemployees (OR 1.73, 95% CI 1.01-2.95). This may be because of benefit coverage for the virtual visit; medical center employees received the care they needed with little to no out-of-pocket costs. Employee patients were not charged for their virtual visit, whereas nonemployee patients were charged up to US $49, depending on insurance coverage. Employee patients may also be more familiar with clinicians, telehealth in general, and virtual visits specifically; thus, their expectations may have been better aligned with the virtual health care they received.

Our study has limitations that need to be considered. Although the sample was diverse in age, gender, and visit and clinician type, a large percentage of patients were from Ohio, insurance was unknown for more than half, and a quarter were employees, all of which may limit the generalizability of our findings. In addition, despite our relatively high response rate, we may have a response bias, but this is unlikely given the similarity of the responders to the nonresponders. Furthermore, we should be cautious not to generalize our findings to all virtual visits, given that this was a nonprobability sample in one health system.

In addition, we do not know the reason for patient visits. We collectively analyzed on-demand and scheduled visits together, although on-demand visits are typically low acuity infections (upper respiratory and urinary tract), whereas scheduled visits are usually more complex conditions where patients have more intense needs [13]. As nearly all patients who had a prior relationship with their virtual visit clinician had a scheduled virtual visit rather than an on-demand one, their expectations for the care they would receive were likely different from those of patients who did not know their clinicians. Furthermore, scheduled and on-demand visits may be fundamentally different. This study suggests that virtual visits may be most satisfactory when used for acute problems or when health care access is otherwise limited rather than nonacute or more complex issues when patients may prefer speaking with their provider in person at a medical facility. Although this study provides an analysis of many kinds of visits, future studies should disaggregate the types of visits and analyze them separately.

Future studies should consider both the quality of these visits and medical outcomes because both are likely to influence patient satisfaction.

In addition, future studies should further explore the range of clinician experience in virtual visits. In multivariable logistic regression, a visit with an advanced practice provider (nurse practitioner or physician assistant) was associated with higher odds of patient-clinician engagement than visits with a family medicine physician (OR 2.28, 95% CI 1.25-4.16). Our finding that patients were more likely to report high engagement with advanced practice providers rather than with family physicians aligns with findings on in-person visits [32] and highlights opportunities to leverage advanced practice providers in telehealth. Future studies should explore the basis of these differences.

Future research and efforts should also focus on the user interface, facilitating patient expectations of the technology, and associations with quality.

Conclusions

The impact of the virtual interface on patient-clinician relationships is largely unknown, but our findings are encouraging. Our study found that virtual visits facilitate health care access and relationship-building, contributing to satisfying relationship-centered care, a crucial aspect of contemporary patient experiences. Even during a single virtual visit, we found that patients and clinicians could meaningfully engage in relationship-building practices. Strategies to prepare established patients for virtual visits with their clinicians may ease the transition from in-person care to virtual care, resulting in better experiences for both. Patients should be aware of the capabilities and limitations of patient-clinician engagement in virtual visits [33]. Strategies to prepare clinicians for virtual visits would also support a seamless transition to delivering health care virtually (a tip sheet that outlines 10 best practices for communicating effectively with patients during a virtual visit has been provided in Multimedia Appendix 2) [34].

Conflicts of Interest

PR has a conflict of interest to disclose. He serves as the chief clinical officer of Cleveland Clinic American Well Joint Venture—a digital health company—and receives personal fees for his service on the Strategic Advisory Board of American Well. The other authors have no conflicts of interest.

Abstract

Background: Telemedicine has become a necessary component of clinical practice for the purpose of providing safer patient care during lockdowns due to the COVID-19 pandemic. It has been used to support the health care needs of patients with COVID-19 and routine primary care patients alike. However, this change has not been fully consolidated.

Objective: The objective of this study was to analyze the determinants of health care professionals' intention to use the eConsulta digital clinical consultation tool in the post–COVID-19 context.

Methods: A literature review of the Technology Acceptance Model allowed us to construct a theoretical model and establish a set of hypotheses on the influence of a variety of different factors relating to health care professionals, as well as the institutions where they work, on their intention to use eConsulta. In order to confirm the proposed model, a mixed qualitative and quantitative methodology was used, and a questionnaire was designed to serve as the data collection instrument. The data were analyzed using univariate and bivariate analysis techniques. To confirm the theoretical model, exploratory factor analysis and binary logistic regression were applied.

Results: The most important variables were related to perceived benefits (*B*=2.408) and the type of use that individuals habitually made of eConsulta (*B*=0.715). Environmental pressure (*B*=0.678), experience with technology (*B*=0.542), gender (*B*=0.639), and the degree to which eConsulta had been implemented (*B*=0.266) were other variables influencing the intention to use the tool in the post–COVID-19 context. When replicating the previous analysis according to professional group, experience with technology and gender in the physician group, and experience with tool use and the center where a professional worked in the nurse group, were found to be of considerable importance.

Conclusions: The implementation and use of eConsulta had increased significantly as a consequence of the COVID-19 pandemic, and the majority of health care professionals were satisfied with its use in practice and planned to incorporate it into their practices in the post–COVID-19 context. Perceived benefits and environmental pressure were determining factors in their attitude toward and intention to use eConsulta.

Introduction

Background

Lockdowns and social distancing in response to the high rate of COVID-19 transmission have become the main triggers of a challenging digital transformation in many sectors, especially in health care. In this scenario of extreme crisis, the rapid adoption of digital solutions and technological tools has played an important role in the response to the huge pressure on health care systems [1-3]. Telemedicine has become a necessary component of clinical practice for the purpose of providing safer patient care [4,5], and it has been used to support the health care needs of patients with COVID-19 and routine primary care patients alike [6-10].

While the digital transformation in health care has not been as disruptive as the transformations observed in other industries, the spread of COVID-19 seems to have provided a solid and inevitable reason to fully adopt the digital transformation [11]. However, despite the fact that health care services can largely be provided remotely via digital technologies [12], this change has not become fully consolidated [13,14]. This means that further research contributions are still required in relation to the definition and adoption of new digital care models.

To establish telemedicine in routine health care, acceptance by users—health care professionals—is of vital importance to the effective use of technological resources. A variety of factors may explain why a group adopts a specific technological tool to a lesser or greater extent [15]. Of these, social factors are perceived to be the most complex. Legal limitations, patient indifference, lack of remuneration, and uncoordinated implementation by those responsible for formulating policies are weighty arguments explaining stakeholders' refusal to engage [15,16]. Some studies have noted that these difficulties may be due to a lack of focus in the implementation of such interventions (ie, health care professionals do not see them as either necessary or effective [17]), or the paucity or inconclusive nature of the studies published thus far [18-20].

To understand whether and how the digital technologies adopted to cope with the COVID-19 crisis will continue to be useful in the postemergency phase—beyond research into outcomes thereof (efficiency, care service quality, etc)—it is necessary to understand the determinants of their use. This paper presents an ex-ante analysis and aims to provide evidence on the determinants of use of the Catalan public health care system's eConsulta tool.

eConsulta, which forms part of a personal health folder [21], is an asynchronous teleconsultation tool available to the 7.5 million inhabitants of Catalonia (located in northeastern Spain) and to its primary care professionals. It was launched in 2015 to complement face-to-face care. The tool's implementation has gradually been extended to the entire primary care network (more than 92% of primary care teams [PCTs] have used the tool at some point), and it has recently begun to be introduced into the public hospital setting. However, its rate of use up to March 2020 was low compared to face-to-face consultations (just 0.9% of the total) [22]. Previous studies of telemedicine acceptance by the Catalan public system's health care professionals have suggested that despite being rated positively, especially by nursing staff, the potential technical or organizational disadvantages of the tools were negative predictors of their use [23].

The objective of this study is, therefore, to analyze the determinants of Catalan public primary care professionals' intention to use the eConsulta digital clinical consultation tool in the post–COVID-19 context. These health care professionals (physicians and nurses) work for the Catalan Health Institute (Institut Català de la Salut [ICS]), the main provider of primary care services in Catalonia (providing a 74% coverage of the Catalan population).

Hypotheses and Model

Regarding the theoretical approach, the Technology Acceptance Model (TAM) was used [24,25]. Uptake and use of technological applications in the health care area can be formulated as an acceptance intention, and it is therefore possible to take the TAM approach. In TAMs, technology acceptance is considered a determinant of technology use. Hence, health care professionals' acceptance of a digital technology can be considered a determinant of its use [26-30]. Although TAMs have been widely used to explain the use of many different technologies, health care research has shown them to be highly suited to analyzing eHealth use. Following the TAM methodology, the proposed model contrasts health care professionals' intention to use a digital tool according to two main dimensions: (1) the perceived benefits of the tool's use and (2) its ease of use. Regarding health care professionals' perceived benefits of the tool, the study distinguishes between those connected with improved efficiency in their care activities (better care management or provision, and time savings or reductions [31,32]), and those connected with improved quality in relation to patients [33]. Regarding ease of use, it has been shown that when a health care professional feels that a technological tool is easy to use and does not require any additional training or specific competencies, the intention to use it clearly increases [34]. Within the specific context of the eConsulta digital tool, the first two research hypotheses are:

> *H1. The perceived benefits of eConsulta use have an influence on the intention to use it in the post–COVID-19 context.*
>
> *H2. eConsulta's ease of use has an influence on the intention to use it in the post–COVID-19 context.*

However, despite its generalized use for the purpose of corroborating health care professionals' use of digital tools, the TAM methodology has attracted some criticism, mainly stemming from the fact that it does not take into account the influence of other types of external variable that could increase its explanatory power [35,36]. In this respect, various methodological proposals such as the theory of reasoned action and the theory of planned behavior have noted the appropriateness of considering the external influence exerted by health care professionals' close contacts or environment [37,38]. In particular, it has been found that patients can exert pressure on a professional by asking him or her to use (or not to use) a tool [39]. Likewise, colleagues and other professional groups working in close collaboration may exert a social influence in relation to the tool's use, either because they are users within the same organizational area or because its use has been directly recommended by them [40,41]. Lastly, the organization in which a professional works can have a direct or indirect influence on the tool's use [29]. Thus, the organization itself can encourage its use by establishing policies and offering training, and by increasing the recognition of, or compensating, those professionals who decide to use it:

> *H3. Pressure from other groups (patients, health care professionals, the institution's management team) has an influence on the intention to use eConsulta in the post–COVID-19 context.*

A professional's intention to use the tool will also be affected by professional and demographic variables [42,43]. Thus, an individual's professional profile (physician or nurse) will determine his or her interest in, and use of, the tool. Specifically, an individual's professional profile determines whether the tool is used to care for patients or to carry out management activities. This indirectly means that the type of pressure exerted by the environment to ensure a tool is used, and even the perceived benefits and ease of use of the tool, may be different:

> *H4. The professional profile has an influence on the intention to use eConsulta in the post–COVID-19 context.*

Moreover, the amount of time a professional spends on doing his or her job has an influence on the intention to use the tool. Being older and more professionally experienced may have an influence on the ability or desire to learn about and use technology. Being in a certain occupational category with responsibilities may also have an influence:

> *H5. An individual's experience as a health care professional has an influence on the intention to use eConsulta in the post–COVID-19 context.*
>
> *H6. A health care professional's age has an influence on the intention to use eConsulta in the post–COVID-19 context.*

Similarly, gender has an influence on the intention to use the tool, mainly because there is a gender bias among professionals. In particular, there is a high percentage of women in the nurse group and, among general practitioners, the distribution of men and women varies as the population gets younger, due to the gradual feminization of the medical profession since the end of the 20th century. By the beginning of the 21st century, 70% of all new medical students were women. Since then the figure has risen to 85% [44,45]:

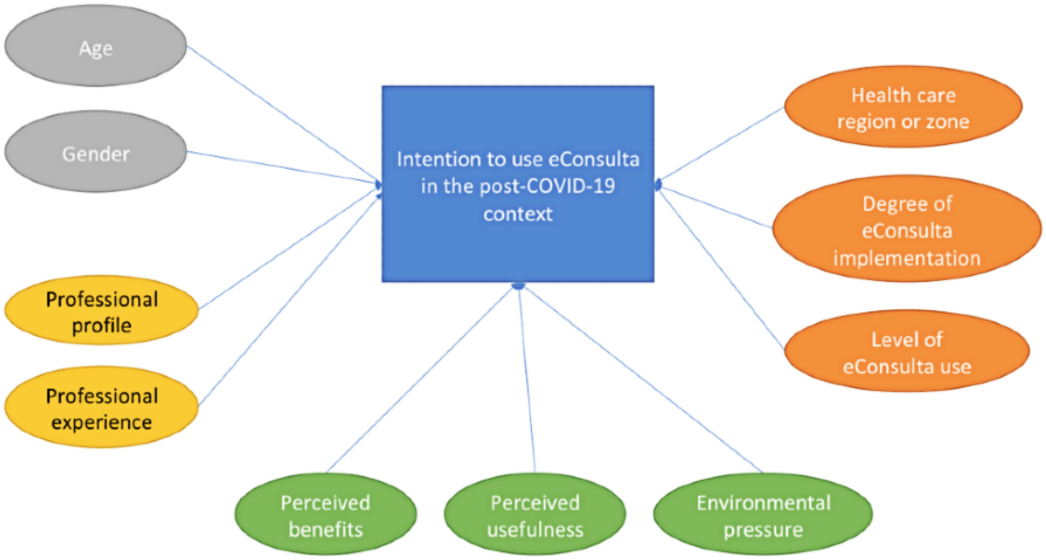
> *H7. A health care professional's gender has an influence on the intention to use eConsulta in the post–COVID-19 context.*

Lastly, the health care center where a professional works also determines the intention to use a tool, mainly for reasons of resource availability and management policies at the center:

> *H8. The health care region or zone in which the health care center where a professional works is located has an influence on the intention to use eConsulta in the post–COVID-19 context.*
>
> *H9. The degree of eConsulta implementation at the health care center where a professional works has an influence on the intention to use it in the post–COVID-19 context.*
>
> *H10. The ease of use of eConsulta (current version) has an influence on the intention to use it in the post–COVID-19 context.*

In summary, we consider that the health care professionals' intention to use the tool in the post–COVID-19 context depends on four main groups of variables: (1) their perception of the tool, (2) external pressure, (3) their profiles, and (4) an additional set of factors linked to the health care center where they work. The proposed model in this regard is shown in Figure 1.

Figure 1. Proposed model of health care professionals' intention to use the eConsulta tool in the post–COVID-19 context.



Methods

Study Design and Sample Selection

As an exploratory study focusing on the analysis of a single health care institution, a mixed qualitative and quantitative methodology was used, and a questionnaire was designed to serve as the data collection instrument (Multimedia Appendix 1). A review of the literature, together with the health care professionals' experience, served as the basis to create the study variables and the metrics used in the first version of the instrument. The measurement instrument was validated following a pretest.

The final questionnaire was organized into four blocks of questions: (1) sociodemographic and professional background, (2) tool use, (3) tool use motivations, and (4) perceived benefits of tool use.

A health care provider distributed the online questionnaire to physicians, nurses, reproductive and sexual health service staff, social workers, and client care staff working in the ICS's various PCTs across Catalonia. Sample selection was random. The questionnaire was sent to all professionals forming the study universe. Participation was voluntary, and no incentives were offered to fill in and return the questionnaire.

A literature review of TAMs allowed us to establish the theoretical model shown in Figure 1. From this, we derived a set of hypotheses about the influence that a variety of different factors relating to both health care professionals and the institutions where they work has on those professionals' intention to use eConsulta. All the variables shown in the hypotheses, which have an influence on the intention to use eConsulta, are described in Table 1.

The data obtained from the sample of health care professionals were analyzed using SPSS Statistics 20 software (IBM Corp). Univariate and bivariate analysis techniques were used. In order to validate the proposed hypotheses and, therefore, to confirm the theoretical model, several multivariate techniques were applied, such as explanatory factor analysis and binary logistic regression.

The study protocol was approved by the University Institute for Primary Care Research Jordi Gol Healthcare Ethics Committee (code 20/026-P).

Table 1. Model variables

Variable	Description
Intention to use eConsulta in the post–COVID-19 context	Dichotomous variable: 0=no, 1=yes
Perceived benefits	Metric variable indicating a professional's degree of perceived benefit from eConsulta use. This variable was created using exploratory factor analysis
Ease of use	Variable metric indicating the degree of eConsulta's ease of use. This variable was created using exploratory factor analysis
Environmental pressure	Variable metric indicating the degree to which a professional perceives that other agents within his or her environment (organization, patients, or colleagues) have an influence on his or her use of eConsulta. This variable was created using exploratory factor analysis
Professional profile	Categorical variable indicating an individual's professional profile, where 1=general practitioner, 2=pediatrician, 3=family nurse, and 4=reproductive and sexual health service nurse
Professional experience	Categorical variable indicating the amount of time a professional has worked in the health care sector, where 1=less than 1 year, 2=2-5 years, 3=6-10 years, 4=11-20 years, and 5=more than 20 years
Gender	Dichotomous variable indicating an individual's gender: 1=man, 2=woman
Age	Categorical variable indicating an individual's age range (in years), where 1=19-29, 2=30-39, 3=40-49, 4=50-59, and 5=60 or above
Health care region or zone in which a professional works	Categorical variable indicating the health care region or zone in which a professional works
Degree of eConsulta implementation	Categorical variable indicating the degree of eConsulta implementation, where 1=not yet fully implemented, 2=fully implemented, and 3=implemented due to COVID-19
Level of eConsulta use	Categorical variable indicating how eConsulta was used, where 1=no use, 2=management use, and 3=management and consultation use

Results

The target sample comprised 18,804 health care professionals working in 285 PCTs. The study included responses from 1189 professionals who had agreed to participate between July 6 and July 31, 2020, the period during which the questionnaire was distributed (margin of error=2.8%; 95%, p=q=0.05).

Sample Profile

Regarding age, we found that the majority of the respondents were over 40 years old. The mean age was 48 years. We found that 33.4% (n=397) were 40-49 years, and 29.2% (n=348) were 50-59 years. It is worth noting that 15.8% (n=188) were over 60 years old, and 16.8% (n=200) were under 30 years old.

The vast majority of the respondents (n=944, 79.2%) were women, meaning that just 20.8% (n=244) were men. In terms of professional profile, 62.2% (n=739) were physicians, with various profiles, and 35.2% (n=418) were other health care professionals—nurses, matrons, or social care workers. Lastly, just 2.2% (n=23) fell into the client care staff category.

In relation to the total, and focusing on the physician group, 43.4% (n=515) were primary care physicians, and 14.8% (n=175) were pediatricians. Regarding the nonphysician health care staff, 26.8% (n=318) of the total were nurses and 7.6% (n=90) were matrons. The majority of these professionals worked in one of three zones of the Barcelona health care region: Metropolitan North (n=250, 21%), Barcelona City (n=218, 18.3%), and Metropolitan South (n=133, 11.2%). Respondents also worked in the health care regions Girona (n=213, 17.9%) and Catalonia Central (n=174, 14.6%).

The majority of the respondents had considerable experience as health care professionals. Indeed, 47.4% (n=563) had over 20 years' experience, and 32.7% (n=390) had 11-20 years' experience. Having gained their experience at several centers, just 48% (n=563) stated that they had spent more than 11 years in the same post (more than 20 years: n=226, 19%; 11-20 years: n=354, 29.7%). Of the remaining respondents, 28% (n=333) had spent 2-5 years in the same post.

Focusing on the workplace, the degree of eConsulta implementation was quite high. Of the total respondents, 44.9% (n=531) indicated that the tool had been fully implemented, and 13.9% (n=164) reported that it had been largely implemented. It is worth noting that 38.6% acknowledged that the pace of the tool's implementation had quickened because of COVID-19.

Regarding the respondents' use of eConsulta, it was found that 60.3% (n=717) had just started using it, and that 26.4% (n=314) used it regularly and intensively. In fact, 40.5% (n=418) acknowledged that they used it at least once a week, and 45.8% (n=473) used it daily. Moreover, the majority of the respondents (n=828, 69.6%) used it to carry out consultations or to appraise test results and make diagnoses, and 16.9% (n=201) acknowledged that they used it for management processes only.

Lastly, it should be noted that the impact of COVID-19 on the tool's use was high. Of the total respondents, 38.6% (n=458) stated that the tool had been implemented in their workplace. On the other hand, 85.7% (n=1018) of respondents agreed or strongly agreed with continuing to use it in the post–COVID-19 context.

Intention to Use eConsulta

In order to identify the factors that have an influence on eConsulta adoption, a principal component exploratory factor analysis was performed. This statistical technique allows the underlying dimensions, constructs, or latent variables of the variables observed in the study to be explored with greater precision. It was on that basis that we endeavored to explain the process of eConsulta adoption.

The values obtained from the statistical tests carried out showed the suitability of the technique employed (Kaiser-Meyer-Olkin index of sampling adequacy=0.928; approximate χ^2=4122.650; Bartlett test of sphericity=171, $P<.001$) (Table 2). Three factors with an eigenvalue higher than 1 were obtained from the analysis, which in total explained 53% of the variance. Likewise, it should be noted that the rotation employed in this case was orthogonal (Varimax) because it was deemed that the different factors might not display any correlation.

Table 2. Rotated component matrix.[a]

Original variables	Perceived usefulness	Environmental pressure	Ease of use (experience with technology)
I feel that eConsulta is useful for managing the calendar with patients, making it easier to schedule visits at times that suit them	0.687	—[b]	—
I feel that it improves the outcomes of my care activities	0.791	—	—
It allows me to offer patients better treatment	0.752	—	—
I talk to other professional colleagues about the benefits of using eConsulta	0.718	—	—
eConsulta has been very useful to me during the COVID-19 pandemic because it has allowed me to care for patients remotely, thus reducing the risk of infection	0.586	—	—
I positively rate the potential benefits that eConsulta use can offer, both for the patients and the PCT[c]/service	0.815	—	—
I promote eConsulta use among my patients	0.744	—	—
As a result of eConsulta implementation in the PCT/service, ways of working have changed, or new ones have been introduced, at individual and group levels	0.632	—	—
The changes made to eConsulta in the COVID-19 pandemic context have made it easier to use	0.536	—	—
I feel that eConsulta is very useful for carrying out my professional activities	—	0.614	—
My colleagues use it often	—	0.662	—
The PCT/service that I work in encourages and facilitates eConsulta use	—	0.514	—
Some of my patients ask me to use it	—	0.541	—
Care professionals can access eConsulta very easily	—	0.629	—
Citizens can access eConsulta very easily	—	0.730	—
I am a habitual user of technology (both professionally and personally)	—	—	0.726
I am a habitual user of social media (both professionally and personally)	—	—	0.798
I have previous experience using telemedicine systems	—	—	0.660
Cronbach alpha	0.916	0.819	0.747
Eigenvalue	7.249	1.534	1.363
Variance explained (%)	28.4	15.3	9.6

[a] Rotation method: Varimax with Kaiser normalization.

[b] Not applicable.

[c] PCT: primary care team.

Three factors emerged from the analysis. The first explained 28.4% of the variance and included the various benefits of eConsulta use, as observed by the professionals. These benefits referred to improvements in the professionals' relationships with patients and in the efficiency of their work. The second factor explained 15.3% of the variance and showed the pressure that third parties—work colleagues, patients, or the institution itself—directly or indirectly exerted on the professionals. Lastly, the third factor was perceived ease of use. This factor explained 9.6% of the variance and showed that some of the professionals who decided to use eConsulta were those who had previous experience of using ICTs (information and communications technologies) (personally) and even telemedicine. A confirmatory factor analysis confirmed the results obtained from the exploratory factor analysis. The results show a goodness of fit (NFI [normed fit index]= 0.897, CFI [comparative fit index]=0.906, TLI [Tucker Lewis index]=0.870, RMSEA [root mean square error of approximation]=0.085).

In order to analyze the influence that these and other factors had on the health care professionals' intention to use eConsulta in the post–COVID-19 context, several logit analyses were performed.

Intention to Use eConsulta in the Post–COVID-19 Context

The various analyses performed showed the model's goodness of fit (Wald=467.731, *P*<.001; Hosmer-Lemeshow=8.525, *P*=.38). Likewise, the model displayed high explanatory power, with a Nagelkerke R^2 value of 0.615.

Regarding the variables in the model, it was found that most of them displayed a direct and significant relationship with the intention to use eConsulta in the post–COVID-19 context (Table 3). The most important variables were those referring to perceived benefits (*B*=2.408) and the type of use that individuals *B*=0.715). Environmental pressure also contributed to the intention to continue using the tool (*B*=0.678), as did experience of using technological tools, some of which were specific to the health care area (*B*=0.542). Lastly, gender had an influence on the intention to use eConsulta (*B*=0.639), as did the degree of its implementation at the health care center where a professional works (*B*=0.266).

Table 3. Logistic regression on eConsulta predictors.

Variable	*B*	SE	Wald	*df*	*P* value	Exp(B)
Age	0.076	0.159	0.227	1	.63	1.079
Gender	0.639	0.308	4.303	1	.04	1.895
Professional profile	–0.280	0.103	7.438	1	.006	0.755
Health care region or zone in which a professional works	0.062	0.048	1.683	1	.20	0.940
Professional experience in the health care area	–0.022	0.164	0.018	1	.89	0.978
Benefits	2.408	–0.199	146.029	1	<.001	11.113
Environmental pressure	0.678	0.129	27.649	1	<.001	1.971
Ease of use	0.542	0.129	17.559	1	<.001	1.720
Degree of eConsulta implementation	0.266	0.149	3.168	1	.08	1.304
Level of eConsulta use	0.715	0.176	16.469	1	<.001	2.045
Constant	0.989	0.894	1.223	1	.27	2.689

The negative value displayed by the profile of the health care professional stands out (*B*=–0.280). This would suggest that the types of activity that different groups carry out within an organizational area had an influence on the rating of, and the intention to use, eConsulta.

With that in mind, and with the aim of confirming or rejecting all the previously proposed hypotheses contained in the model, we replicated the previous analysis for two groups working in the family medicine area: general practitioners and family nurses (there was a total of 507 general practitioners, of whom 89.7% [n=455] used eConsulta and 10.3% [n=52] did not. There were 296 nurses, of whom 87.2% [n=258] used the tool and 12.8% [n=36] did not). Both groups care for adult patients, the majority of whom are advanced in years and are diagnosed with a chronic illness. They are patients whose knowledge and use of ICTs is low.

Considering the different models by group, we found that, among the general practitioner group, all the variables had a direct and positive effect on the intention to use eConsulta. This group was formed by 30.8% (n=156) men and 69.2% (n=351) women, with a mean age (in years) between 40 and 59 years (40-49 years: n=191, 37.7%; 50-59 years: n=151, 29.8%).

Analyzing Table 4, the variable with the greatest weight in the model was perceived benefits (*B*=2.472), followed by gender (*B*=1.011) and the type of use that individuals made of eConsulta (*B*=0.809). Regarding type of use, we found that 92.1% of the physicians made wide use of the tool. Environmental pressure was an important factor in the decision to use it (*B*=0.773). Lastly, an individual's experience of technology (*B*=0.724), together with the degree of eConsulta implementation in his or her workplace (*B*=0.671), also had an influence on the intention to use the tool.

Table 4. Logistic regression on eConsulta predictors (general practitioners).

Variable	*B*	SE	Wald	*df*	*P* value	Exp(B)
Age	0.257	0.310	0.690	1	.41	1.293
Gender	1.011	0.485	4.353	1	.04	2.749
Health care region or zone in which a professional works	0.066	0.096	0.482	1	.49	1.069
Professional experience in the health care area	0.118	0.290	0.166	1	.68	1.126
Benefits	2.472	0.330	56.054	1	<.001	11.850
Environmental pressure	0.773	0.221	12.190	1	<.001	2.166
Ease of use	0.724	0.220	10.864	1	.001	2.062
Degree of eConsulta implementation	0.671	0.332	4.085	1	.04	1.956
Level of eConsulta use	0.809	0.451	3.220	1	.07	2.246
Constant	–2.743	1.958	1.962	1	.16	0.064

The family nurse group (Table 5) was formed by 88.6% (n=285) women, with a mean age between 40 and 59 years (40-49 years: n=104, 33%; 50-59 years: n=95, 30%). Among the variables determining their intention to use eConsulta were, in first place, perceived benefits (*B*=2.100), followed by the use they make of it (*B*=1.362). Here, we found that 50.5% (n=160) stated that they made wide use of the tool, whereas 30% (n=96) only did so for management purposes (Multimedia Appendix 2). Lastly, environmental pressure was a fundamental factor (*B*=0.479). It is worth noting that the health care region or zone in which a health care professional works displayed a value of little importance, which was negative in the model (*B*=–1.91). Of the total cases, 32% (n=101) and 11.8% (n=37) of these professionals worked in the health care zones Metropolitan North and Barcelona City, respectively (Multimedia Appendix 3).

Finally, Table 6 shows the significant variables for the three calculated models.

A comparison of the different models shows that, in all of them, perceived benefits was the variable that had the highest explanatory power. After these, in descending order of importance, were experience of eConsulta use and, lastly, the influence that patients, colleagues, and the institution itself had on the professionals. Regarding these variables, it is worth noting the considerable importance that experience with eConsulta use had for the nurse group (*B*=1.362), compared to the values displayed by this variable in the physician group (*B*=0.809) or, indeed, in the overall model (*B*=0.715).

Meanwhile, some variables were significant for the overall model but were not for the partial models. This was the case for experience with technology, which had a value of *B*=0.724 in the physician group but was not significant in the nurse group. The situation regarding the gender variable was similar; in the physician group, the variable was found to be significant and had a high B value (*B*=1.011), whereas it was not significant in the nurse group.

Table 5. Logistic regression on eConsulta predictors (nurses).

Variable	*B*	SE	Wald	*df*	*P* value	Exp(B)
Age	–0.293	0.316	0.860	1	.35	0.746
Gender	–0.813	0.887	0.840	1	.36	0.444
Health care region or zone in which a professional works	–0.191	0.096	4.001	1	.045	0.826
Professional experience in the health care area	–0.113	0.350	0.105	1	.75	0.893
Benefits	2.100	0.390	29.048	1	<.001	8.169
Environmental pressure	0.479	0.287	2.783	1	.10	1.615
Ease of use	0.161	0.255	0.397	1	.53	1.174
Degree of eConsulta implementation	–0.053	0.309	0.029	1	.87	0.949
Level of eConsulta use	1.362	0.367	13.791	1	<.001	3.906
Constant	3.747	1.909	3.851	1	.05	42.380

Table 6. Significant variables for the three calculated models.

Variable	Overall model		General practitioners		Family nurses	
	B	*P* value	*B*	*P* value	*B*	*P* value
Age	0.076	.63	0.257	.41	–0.293	.35
Gender	0.639	.04	1.011	.04	–0.813	.36
Professional profile	–0.280	.006				
Health care region or zone in which a professional works	0.062	.20	0.066	.49	–0.191	.045
Professional experience in the health care area	–0.022	.89	0.118	.68	–0.113	.75
Benefits	2.408	<.001	2.472	<.001	2.100	<.001
Environmental pressure	0.678	<.001	0.773	<.001	0.479	.10
Ease of use	0.542	<.001	0.724	.001	0.161	.53
Degree of eConsulta implementation	0.266	.08	0.671	.04	–0.053	.87
Level of eConsulta use	0.715	<.001	0.809	.07	1.362	<.001
Constant	0.989	.27	–2.743	.16	3.747	.05

Finally, it should be mentioned that the health care region or zone in which a professional works was a variable that displayed a negative effect on the nurse group's intention to use eConsulta (Table 7).

Table 7. Distribution of the family nurse group by health care region or zone.

Health care region or zone	Nurses, n (%)	Cumulative %
Metropolitan North	45 (15.2)	15.2
Central Catalonia	39 (13.1)	28.3
Barcelona City	56 (18.9)	47.1
Lleida	12 (4.0)	51.2
Metropolitan South	38 (12.8)	64.0
Girona	58 (19.5)	83.5
Camp de Tarragona	24 (8.1)	91.6
Terres de l'Ebre	25 (8.4)	100.0
Total	297 (100.0)	—[a]

[a] Not applicable.

Table 8 shows the hypotheses that were confirmed or rejected for each of the three models.

Table 8. Hypotheses and results.

Hypotheses	Overall model	Physicians	Nurses
H1. The perceived benefits of eConsulta use have an influence on the intention to use it in the post–COVID-19 context.	Yes	Yes	Yes
H2. eConsulta’s ease of use has an influence on the intention to use it in the post–COVID-19 context.	Yes	Yes	No
H3. Pressure from other groups (patients, health care professionals, the institution’s management team) has an influence on the intention to use eConsulta in the post–COVID-19 context.	Yes	Yes	Yes
H4. The professional profile has an influence on the intention to use eConsulta in the post–COVID-19 context.	Yes	—[a]	—
H5. An individual’s experience as a health care professional has an influence on the intention to use eConsulta in the post–COVID-19 context.	No	No	No
H6. A health care professional’s age has an influence on the intention to use eConsulta in the post–COVID-19 context.	Yes	No	No
H7. A health care professional’s gender has an influence on the intention to use eConsulta in the post–COVID-19 context.	Yes	Yes	No
H8. The health care region or zone in which the health care center where a professional works is located has an influence on the intention to use eConsulta in the post–COVID-19 context.	No	No	Yes
H9. The degree of eConsulta implementation at the health care center where a professional works has an influence on the intention to use it in the post–COVID-19 context.	Yes	Yes	No
H10. The ease of use of eConsulta (current version) has an influence on the intention to use it in the post–COVID-19 context.	Yes	Yes	Yes

[a] Not applicable.

Discussion

Principal Findings

The objective of this study was to identify the factors that have an influence on eConsulta adoption, and the influence of these and other factors on the intention to use the tool in the post–COVID-19 context. To that end, a theoretical model based on a modified TAM was used as the analysis tool.

eConsulta has become a key tool for providing remote medical care owing to the challenges posed by the COVID-19 pandemic. The use of this tool has increased significantly since the start of the pandemic, and the majority of health care professionals are now able to consider using it in their routine medical practice, even after the relaxation of social distancing measures and a return to some degree of normality. We focused our research on forecasts for tool use in the post–COVID-19 context because, as soon as social distancing measures are removed, it is likely that professionals will have the option to choose how, that is, by which means, they connect with their patients. This possibility to choose, which is not feasible while social distancing measures are in place, is very significant, not only from the perspective of analyzing the explanatory factors of eConsulta use, but also from the perspective of health policies. With the experience of its mass use during lockdown, we analyzed explanatory factors for the future use of the tool within the context of a greater freedom of choice. The purpose of doing so was to find out whether the lockdowns had changed the factors driving the use of digital tools for the provision of medical care or, conversely, whether the health care professionals perceived such use to be exceptional, with their preferences being more aligned with a return to the prepandemic situation. These results are undoubtedly very useful for the design of public policies on health care delivery via digital technologies.

Our study confirms, as previous studies have done [5], that perceived usefulness was the explanatory factor with the biggest effect on the attitude toward and intention to use eConsulta in the post–COVID-19 context. As the TAM suggests, the significance of this determining factor refers back to the importance of perceived usefulness when the use of a technology needs to be explained [46,47]. Specifically, ICS health care professionals placed importance on improved patient relationships and the efficiency of their work in their intention to use the tool, and on perceived benefits in their intention to use the tool in the post–COVID-19 context. In this respect, several studies have shown that telecare reduces the number of low value-added face-to-face visits, thus providing evidence to support intervention efficiency from the health care provider’s viewpoint [48,49]. It is therefore crucial for the health care system’s best way of operating to be accepted by the professionals working within it.

The next most important variable was the type of use that individuals habitually made of eConsulta. Bearing in mind that the core work of physicians is patient care, whereas that of the nurse group involves either management or carrying out tasks related to communicating with, and sending information to, patients, an increase in perceived usefulness by the latter positively influenced their attitude toward, and increased their intention to use, the tool. This is consistent with many studies on the acceptance of telemedicine solutions by both primary care providers [50] and nursing staff [51].

Perceived ease of use also had a positive impact on the attitude toward using eConsulta, in particular on improving some professionals’ attitude toward and intention to use it because they felt that it would not involve any effort; this was especially so in the physician group [30,52]. As seen in previous studies, general practitioners with prior experience in digital health care technologies were more enthusiastic and optimistic than those who had yet to use it [19,49]. Despite the evidence showing that as knowledge of ICT use increases, the difficulties an individual encounters when using it decrease [53], it is worth noting the little weight that this factor had compared to benefits and environmental pressure. This might be due to either the generalized implementation of this tool by the administration or the rapid digital transformation that this sector has experienced as a consequence of COVID-19. However, experience using technological tools was a variable displaying a direct and significant relationship with the intention to use eConsulta in the post–COVID-19 context. This result highlights the importance of developing staff's competencies for the sustainable adoption of digital solutions in the health care field.

Second in order of importance in the explanation of the tool's use by ICS health care professionals was the pressure that third parties—work colleagues, patients, or the institution itself—directly or indirectly exerted on them. Environmental pressure also contributed to the intention to continue using eConsulta in the post–COVID-19 context. In this respect, we found that when patients had easy access to the tool, it made them ask health care professionals to use it. Access to the personal health folder, a tool that enables citizens to securely access their personal information and online services [54,55], was key. Similarly, the fact that some colleagues rated the tool positively, or actually used it, also had a direct influence on the intention to use it. This could also be attributed to network effects, which are crucial to the adoption of any technology [56]. Lastly, the fact that the health care institution itself had committed to eConsulta implementation was an important reason for adopting it.

Finally, it should be noted that the degree of eConsulta implementation at the health care center where a professional works had an influence on the intention to use it in the post–COVID-19 context, especially among the physician group. This might be due to the fact that the tool's implementation differed at each health care center. Regarding nursing staff, a plausible explanation as to why it did not affect them is that each health care region or zone is independent in terms of the types of activity (patient treatment or management) that the nurse group carries out, so the types of use made of the tool differs. In fact, the nurse group was the most reticent in terms of the continued use of the tool in the postlockdown phase. Research into the implications of eHealth and telemedicine on professional practice has repeatedly shown that implementation of digital practices for the provision of medical care leads to significant changes in the tasks that professionals carry out. For a sustainable eConsulta implementation, the tasks that the physician and nurse groups carry out will undoubtedly need to be reviewed to ensure that the provision of value-added health care is more efficient and of higher quality.

The COVID-19 pandemic has led to the implementation of digital solutions at record speed and with unprecedented impact. The experience that this has provided nurses and physicians with increases the likelihood of them continuing to use it in the post–COVID-19 context. It is worth taking advantage of the impetus that the current crisis has given us to implement at least some of the solutions proposed in the scientific literature. This study's data cannot be extrapolated to other health care systems; however, the results are critical for digital health care policy planners because the success of eConsulta will largely depend on whether health care professionals promote it. In any case, maintaining the drivers of a continued use of digital tools for the provision of medical care must go hand in hand with practices that promote their use by patients. Having professional groups that are active and ready for the digital transformation is of little use if, on the care services demand side, patients continue to opt for face-to-face care as a matter of preference. In this respect, it is important to make further advances in relation to the social dissemination of the strengths of social health care tools, while at the same time putting efforts into reducing their weaknesses, especially the care inequalities that their use may generate.

Limitations

This study has a number of potential limitations. First, it is a survey-based study, subject to the bias response rates that are inherent to all studies based on data of this type. Second, the survey we used was new and unvalidated, utilized to determine eConsulta use by health care professionals. It is our belief, however, that the survey questions posed were of a pragmatic nature, and that the answers faithfully reflected the sentiments of all the groups. Lastly, the survey was administered in less than 1 month in the midst of drastic changes to medical practice brought about by the pandemic, so opinions and preferences may continue to evolve. Notwithstanding the above, we believe that the sample size analyzed and the degree of statistical significance observed together make our results robust.

Conclusions

The implementation and use of eConsulta had increased significantly as a consequence of the COVID-19 pandemic, and the majority of the health care professionals were satisfied with its use in practice and planned to incorporate it into their practices in the post–COVID-19 context. Perceived benefits and environmental pressures were determining factors in the attitude toward and intention to use eConsulta. However, some reticence in terms of the continued use of the tool in the post–COVID-19 context was detected, especially among the nurse group. For this digital transformation in health care to continue beyond the pandemic, it is important to establish connections between health care professionals' use of the tool on one hand and modification of their tasks on the other, and thus improve the quality of their care. In addition, patients must be educated to use the tool more proficiently.

Abstract

Background: Telehealth is an increasingly important component of health care delivery in response to the COVID-19 pandemic. However, well-documented disparities persist in the use of digital technologies.

Objective: This study aims to describe smartphone and internet use within a diverse sample, to assess the association of smartphone and internet use with markers of health literacy and health access, and to identify the mediating factors in these relationships.

Methods: Surveys were distributed to a targeted sample designed to oversample historically underserved communities from April 2017 to December 2017. Multivariate logistic regression was used to estimate the association of internet and smartphone use with outcomes describing health care access and markers of health literacy for the total cohort and after stratifying by personal history of cancer. Health care access was captured using multiple variables, including the ability to obtain medical care when needed. Markers of health literacy included self-reported confidence in obtaining health information.

Results: Of the 2149 participants, 1319 (61.38%) were women, 655 (30.48%) were non-Hispanic White, and 666 (30.99%) were non-Hispanic Black. The median age was 51 years (IQR 38-65). Most respondents reported using the internet (1921/2149, 89.39%) and owning a smartphone (1800/2149, 83.76%). Compared with the respondents with smartphone or internet access, those without smartphone or internet access were more likely to report that a doctor was their most recent source of health information (344/1800, 19.11% vs 116/349, 33.2% for smartphone and 380/1921, 19.78% vs 80/228, 35.1% for internet, respectively; both *P*<.001). Internet use was associated with having looked for information on health topics from any source (odds ratio [OR] 3.81, 95% CI 2.53-5.75) and confidence in obtaining health information when needed (OR 1.83, 95% CI 1.00-3.34) compared with noninternet users. Smartphone owners had lower odds of being unable to obtain needed medical care (OR 0.62, 95% CI 0.40-0.95) than nonsmartphone owners. Among participants with a prior history of cancer, smartphone ownership was significantly associated with higher odds of confidence in ability to obtain needed health information (OR 5.63, 95% CI 1.05-30.23) and lower odds of inability to obtain needed medical care (OR 0.17, 95% CI 0.06-0.47), although these associations were not significant among participants without a prior history of cancer.

Conclusions: We describe widespread use of digital technologies in a community-based cohort, although disparities persist. In this cohort, smartphone ownership was significantly associated with ability to obtain needed medical care, suggesting that the use of smartphone technology may play a role in increasing health care access. Similarly, major illnesses such as cancer have the potential to amplify health engagement. Finally, special emphasis must be placed on reaching patient populations with limited digital access, so these patients are not further disadvantaged in the new age of telehealth.

KEYWORDS

telehealth; technology; health literacy; access to health care; mobile phone

Introduction

Background

The COVID-19 pandemic has highlighted the increasing dependence of the health system on telemedicine because providers have relied on telehealth to provide patient care while minimizing the risk of viral transmission [1-3]. Telehealth, or the use of technology—including the internet and mobile phones—to enable or improve health or health care [4,5], has expanded in scope and capabilities in recent decades. Patients can now access personal health information through patient portals [6], look up health information independently without professional medical guidance [7-11], and provide feedback to other consumers on their experiences with certain hospitals or providers through these media [12]. Studies have shown that the use of technology in the health sector can improve intervention efficacy, patient satisfaction, and, ultimately, clinical outcomes [13-17]. Technology has assumed a growing role within the health care landscape, with more than 60% of all US health care institutions using at least one form of telehealth [18], with some engaging in more telehealth visits than in-person visits [19].

Although telehealth has shown promise as a means to expand access to care [20,21], documented disparities persist among individuals who engage with health technology. The gap in access to technology based on social, physical, and societal factors is often referred to as the *digital divide* [22]. Previous work has characterized this divide extensively, with older, less-educated individuals having lower use of internet, mobile phone, and smartphone technologies [23-25] and preferring to receive health information through printed media compared with younger and more-educated individuals [26]. Furthermore, bridging the divide involves not only addressing gaps in physical access to technology, known as the *first digital divide*, but also the reliability of access and technological literacy, known as the *second digital divide* [27-30].

The second digital divide reflects the well-documented association between lower rates of phone and internet use with decreased health literacy [31-33]. This relationship seems to be multifaceted, with recent studies demonstrating an association not only between health literacy and the likelihood of technology adoption, but also between health literacy and the use of health information technology [34,35]. These findings allude to the evolving body of literature characterizing the relationship between digital technology and health outcomes. Preliminary studies have demonstrated that increased internet use can positively affect perceived health outcomes as well as the use of health care services. These differences in the outcomes, benefits, and impacts of technology use represent the *third digital divide* [30,36]. Work thus far describing the relationship between health literacy and health outcomes has led to mixed, inconclusive results [37].

A better understanding of the nature and ramifications of the digital divide is critical because patient populations who are already disadvantaged are at increased risk of being marginalized as the health system evolves to increasingly rely on telehealth to deliver care. Studies have already been published describing the widening inequity resulting from the health system's increased reliance on telehealth as a result of the COVID-19 pandemic and the negative repercussions that most frequently and meaningfully affect vulnerable communities [38]. Furthermore, given the United States' ongoing poor performance in health care access and affordability compared with peer developed nations [39], the US health care system is particularly vulnerable to widening disparities as a result of the stress of dealing with the COVID-19 pandemic.

Objective

This study seeks to provide valuable data from a racially diverse cohort of North Carolina residents to further characterize the current state of digital technology use and to explore the relationship among technological access, health literacy, and health care access. Furthermore, this study builds on preliminary research assessing how major illnesses such as cancer relate to internet- and smartphone-use behaviors and their associations with markers of health literacy and health care access [40,41].

Methods

Study Design and Participants

This cross-sectional study used survey data derived from a community health assessment initiative, Project PLACE (Population Level Approaches to Cancer Elimination). The survey was administered to a targeted convenience sample of diverse populations across a predefined patient catchment area in proximity to a National Cancer Institute–designated comprehensive cancer center in North Carolina, and it aimed to oversample historically underserved communities [42]. Data were collected from April 2017 to December 2017. The study protocol was approved by the Duke University Institutional Review Board (#00062661).

Most of the participants were recruited from community organizations located in Durham, Wake, Vance, Alamance, and Johnston counties in central North Carolina. Community navigators worked in conjunction with 24 community partners to collect survey data using a multimodal approach. The community partners—comprising community organizations, faith organizations, community outreach programs, and a health clinic—distributed the surveys to their constituents at 47 different community events. Community partners received stipends (US $10 per survey, up to US $2000) for their collaboration. Survey participants were offered items valued at US $5 or less (eg, water bottle and tote bag) for their participation [43].

Survey Design

The 91-item, self-administered survey was available in English, Spanish, and Chinese and could be completed on paper or on the web. The survey items included a combination of program-specific and pre-existing validated measures sourced from national surveys, including the Health Information National Trend Survey and the National Health Interview Study [44]. Data from select survey items that assessed sociodemographic factors, personal cancer history, patterns of mobile phone and internet use, and markers of health literacy and health care access were used in this study (Multimedia Appendix 1). The place of residence, metropolitan or nonmetropolitan, was captured with self-reported ZIP code that was coded using Rural-Urban Continuum Codes (RUCC) in which RUCC 1 to 3 were coded as metropolitan and RUCC 4 to 9 were coded as nonmetropolitan [45,46].

Independent Variables

The primary independent variables included internet use and smartphone ownership. Internet use was captured with this question: “Do you ever go on-line to access the Internet or World Wide Web, or to send and receive e-mail?” Smartphone ownership was captured with this question: “Do you currently have a Smart phone such as an iPhone, Android, Blackberry or Windows phone?”

Outcome Measures

The primary outcome measures were health care access and markers of health literacy. Health care access was captured with several items, including having a usual place of care when sick or in need of advice regarding health, the type of place attended for care, being unable to get care when needed, health insurance status, and participation in medical research. Markers of health literacy were captured with several additional items, including having looked for information on health topics, the source used for information on health topics, self-reported confidence in the ability to obtain health information, and self-reported understanding of numerical information (ie, numeracy). The variable “self-reported numeracy” was dichotomized by grouping survey responses 1-3 as “low self-reported numeracy” and survey responses 4-6 as “high self-reported numeracy.” The variable “confidence in ability to obtain health information if needed” was dichotomized with the survey responses “completely confident,” “very confident,” and “somewhat confident” grouped together compared with the grouping of “a little confident” and “not at all confident” (Multimedia Appendix 1).

Statistical Analysis

Descriptive statistics were used to summarize the study sample. Continuous and categorical variables were summarized as median (IQR), where IQR is reported as first quartile value–third quartile value, and n (%), respectively, by smartphone ownership and internet use. Differences were tested using the chi-square test or Fisher exact test for categorical variables, as appropriate, and the two-tailed *t* test for continuous variables.

Logistic regression was used to estimate the association of smartphone ownership and internet use, respectively, with health care use and literacy variables after adjustment for sociodemographic factors both in the total study cohort and after stratifying by personal history of cancer. Covariates were selected based on univariate analysis ($P<.10$). Only respondents with complete data were included in each analysis, and effective sample sizes are indicated for each table and figure. No adjustments were made for multiple comparisons. Two-tailed tests were used for all analyses, and the threshold for significance was set at $P<.05$. All statistical analyses were conducted using SAS version 9.4 (SAS Institute).

Results

Participant Sociodemographic and Digital Technology Use Characteristics

A total of 2315 surveys were completed. Of these 2315 surveys, 2149 (92.83%) respondents answered all 3 questions pertaining to mobile phone ownership, smartphone ownership, and internet use. Demographic, personal health history, and smartphone and internet use characteristics are shown in Table 1.

Table 1. Baseline characteristics of study cohort (N=2149)[a].

Characteristics	All respondents	Smartphone ownership				Internet use			
		No (n=349), n (%)	Yes (n=1800), n (%)	*P* value	Chi-square (*df*)	No (n=228), n (%)	Yes (n=1921), n (%)	*P* value	Chi-square (*df*)

Yes	340 (15.82)	92 (27.1)	248 (72.94)			45 (13.2)	295 (86.76)		

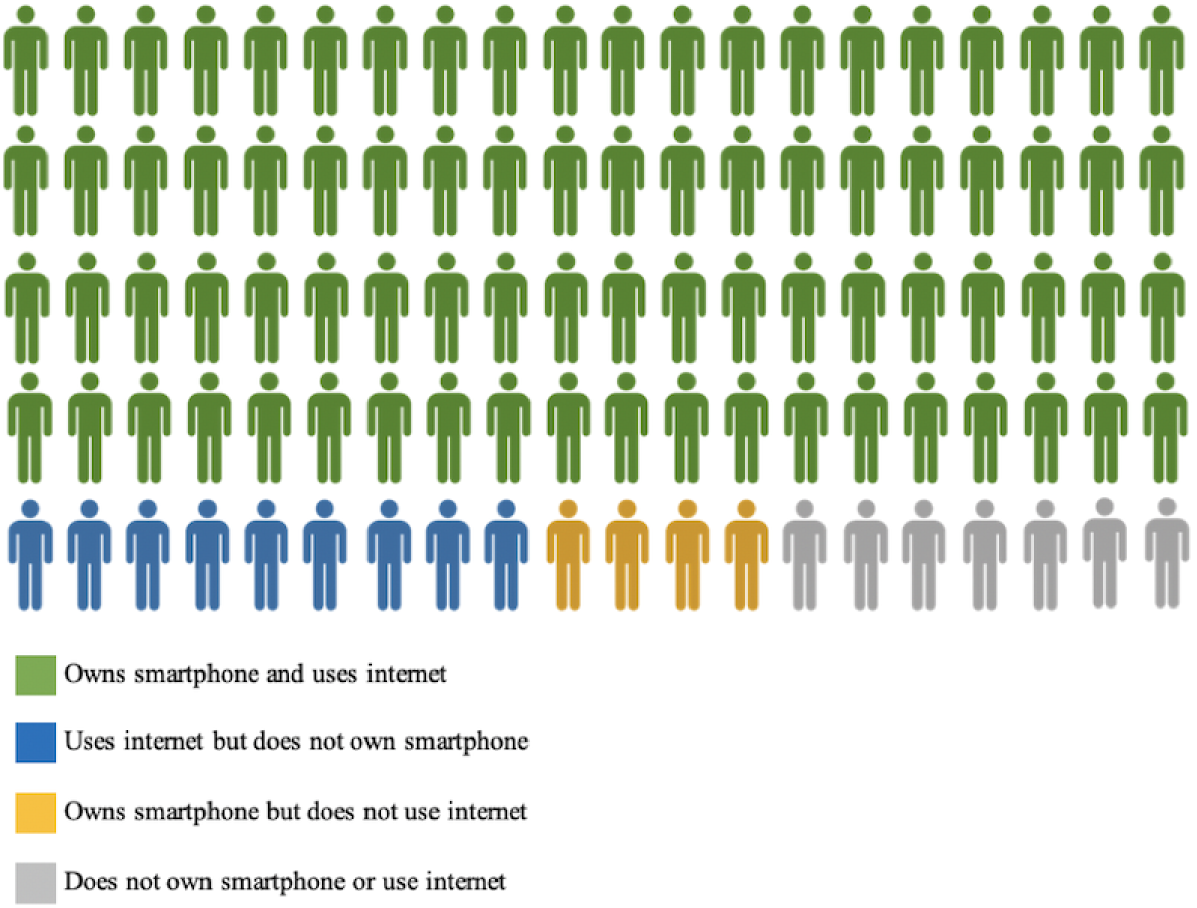
[a] Test statistics and *df* are presented for the chi-square and *t* test *P* values only.

[b] N/A: not applicable.

[c] Fisher exact test *P* value.

The median age was 51 years (IQR 38-65), and most of the participants were women (1319/2149, 61.38%). The racial and ethnic distribution was 13.96% (300/2149) Hispanic, 9.4% (202/2149) non-Hispanic Asian, 30.99% (666/2149) non-Hispanic Black, 30.48% (655/2149) non-Hispanic White, and 3.82% (82/2149) other, whereas 11.35% (244/2149) chose not to respond to this question. Overall, 75.8% (1629/2149) of the participants reported living comfortably or getting by on their present income, and 47.32% (1017/2149) reported an education level of college graduate or higher. Most of the participants lived in a metropolitan area (1696/2149, 78.92%), were employed (1192/2149, 55.47%), and did not have a history of cancer (1761/2149, 81.95%). In total, 89.39% (1921/2149) of the respondents reported using the internet, 96.32% (2070/2149) reported owning a mobile phone, and 83.76% (1800/2149) reported owning a smartphone (Figure 1).

Figure 1. Prevalence of smartphone ownership and internet use among study cohort.



Sociodemographic Factors Associated With Digital Access

Specific characteristics distinguished smartphone owners and internet users from nonsmartphone owners and noninternet users (Table 1). Compared with smartphone owners and internet users, the respondents who reported not owning a smartphone or not using the internet were more likely to be older (both *P*<.001), less-educated (both *P*<.001), disabled (both *P*<.001), retired (both *P*<.001), publicly insured (both *P*<.001), and living in a nonmetropolitan area (both *P*<.001). The respondents who reported not owning a smartphone were also more likely to find it difficult or very difficult to get by on current income compared with smartphone owners (*P*=.02).

Digital Technology Use and Markers of Health Literacy

Smartphone ownership and internet use demonstrated significant thematic associations with markers of health literacy (Table 2).

Table 2. Markers of health literacy and health access by smartphone ownership and internet use (N=2149).[a]

Survey response	All respondents, n (%)	Smartphone ownership				Internet use			
		No (n=349), n (%)	Yes (n=1800), n (%)	*P* value	Chi-square (*df*)	No (n=228), n (%)	Yes (n=1921), n (%)	*P* value	Chi-square (*df*)

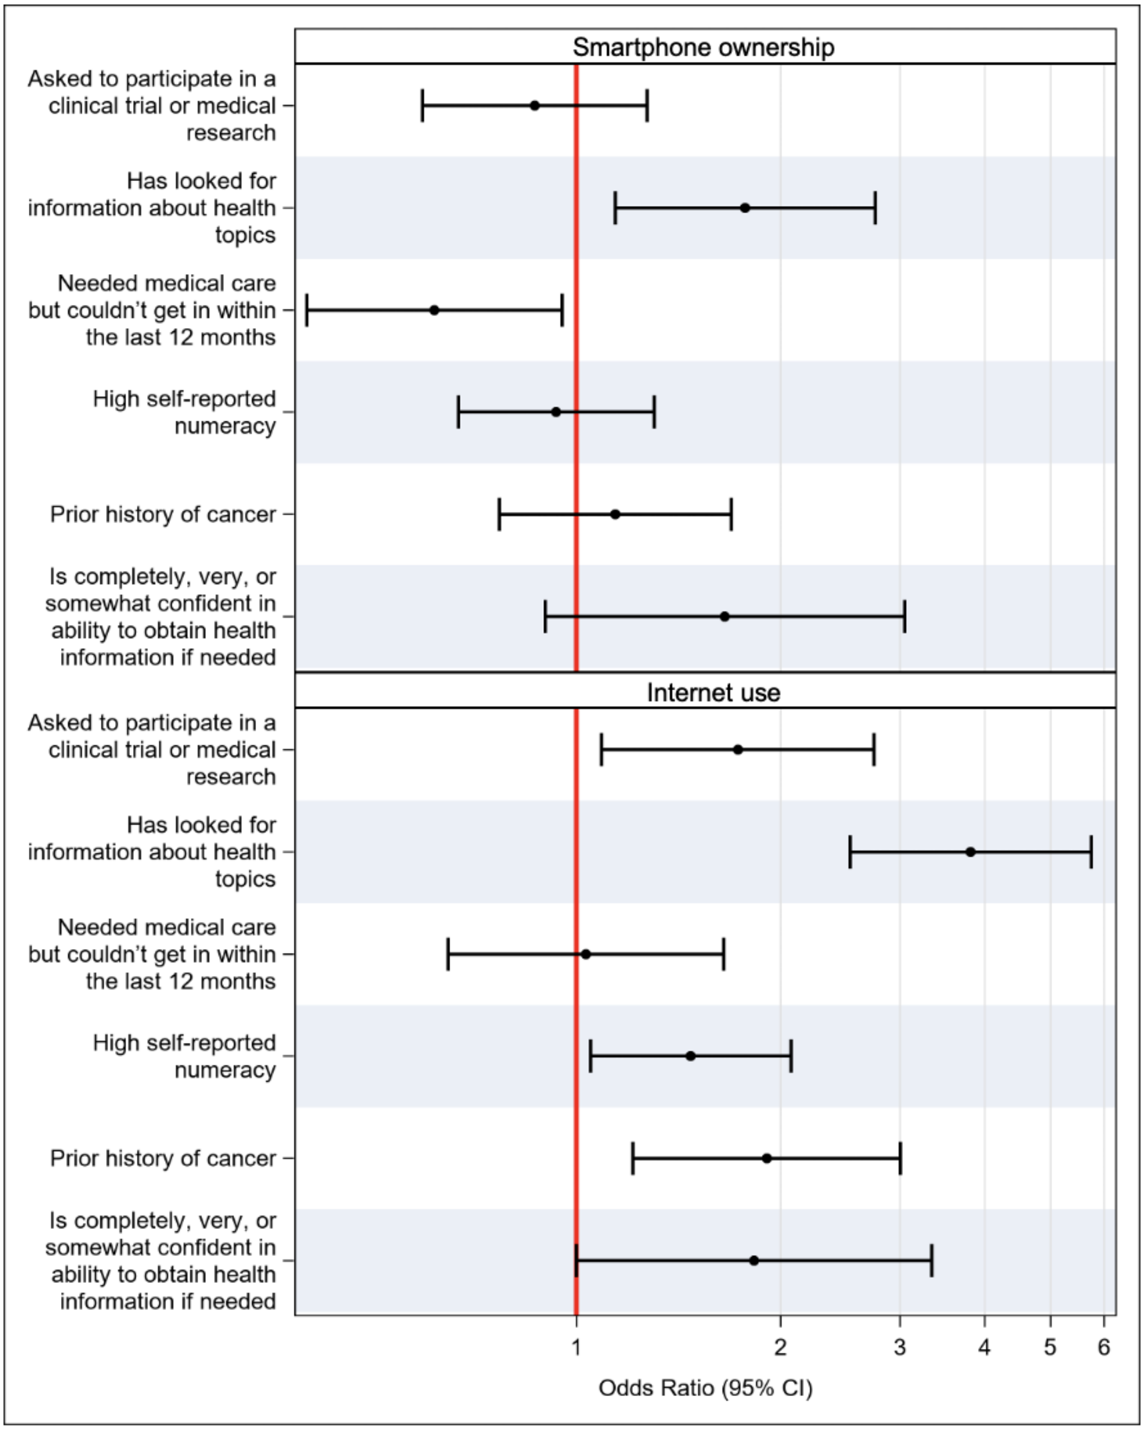
[a] Percentages may not add up to 100 owing to rounding or missing values.

[b] HMO: health maintenance organization.

On univariate analysis, both smartphone ownership and internet use were associated with higher self-reported numeracy (both *P*<.001), confidence in obtaining health information if needed (*P*=.001 and *P*=.003, respectively), and having looked for information on health topics from any source (*P*=.006 and *P*<.001, respectively).

In the adjusted analysis, smartphone ownership was associated with higher odds of having looked for health information (odds ratio [OR] 1.77, 95% CI 1.14-2.76), when controlling for age, race and ethnicity, nativity, language spoken at home, income adequacy, occupational status, education level, insurance status, and rurality (Figure 2). Similarly, internet use was associated with higher odds of having looked for information on health topics (OR 3.81, 95% CI 2.53-5.75), confidence in obtaining health information if needed (OR 1.83, 95% CI 1.00-3.34), and self-reported numeracy (OR 1.47, 95% CI 1.05-2.07) when controlling for age, occupational status, education level, insurance status, and rurality (Figure 2). Smartphone ownership models were adjusted for the following covariates: age, race and ethnicity, nativity, spoken language, income adequacy, occupational status, education level, insurance status, and rurality. Covariates were selected based on univariate analysis (*P*<.10 on univariate analysis). Internet use models were adjusted for the following covariates: age, occupational status, education level, insurance status, and rurality. Covariates were selected based on univariate analysis (*P*<.10 on univariate analysis).

Figure 2. Association of markers of health literacy and health access with smartphone ownership (top) and internet use (bottom). Separate models were used for each outcome listed on the left, with smartphone ownership or internet use included as a covariate.



These differences were reflected in the sources of information that the respondents reported using to obtain health information (Figures 3 and 4). Although most of the respondents did not use physicians as their most recent source of health information, the respondents without smartphones or internet access were more likely to have used a physician for this purpose (116/349, 33.2% of nonsmartphone owners vs 344/1800, 19.11% of smartphone owners; 80/228, 35.1% of noninternet users vs 380/1921, 19.78% of internet users; both *P*<.001). Similarly, nonsmartphone owners were less likely than smartphone owners to have used the internet (96/349, 27.5% vs 1098/1800, 61%, respectively; *P*<.001) or social media (9/349, 2.6% vs 93/1800, 5.17%, respectively; *P*=.04).

Figure 3. Source used most recently for health information by smartphone ownership.

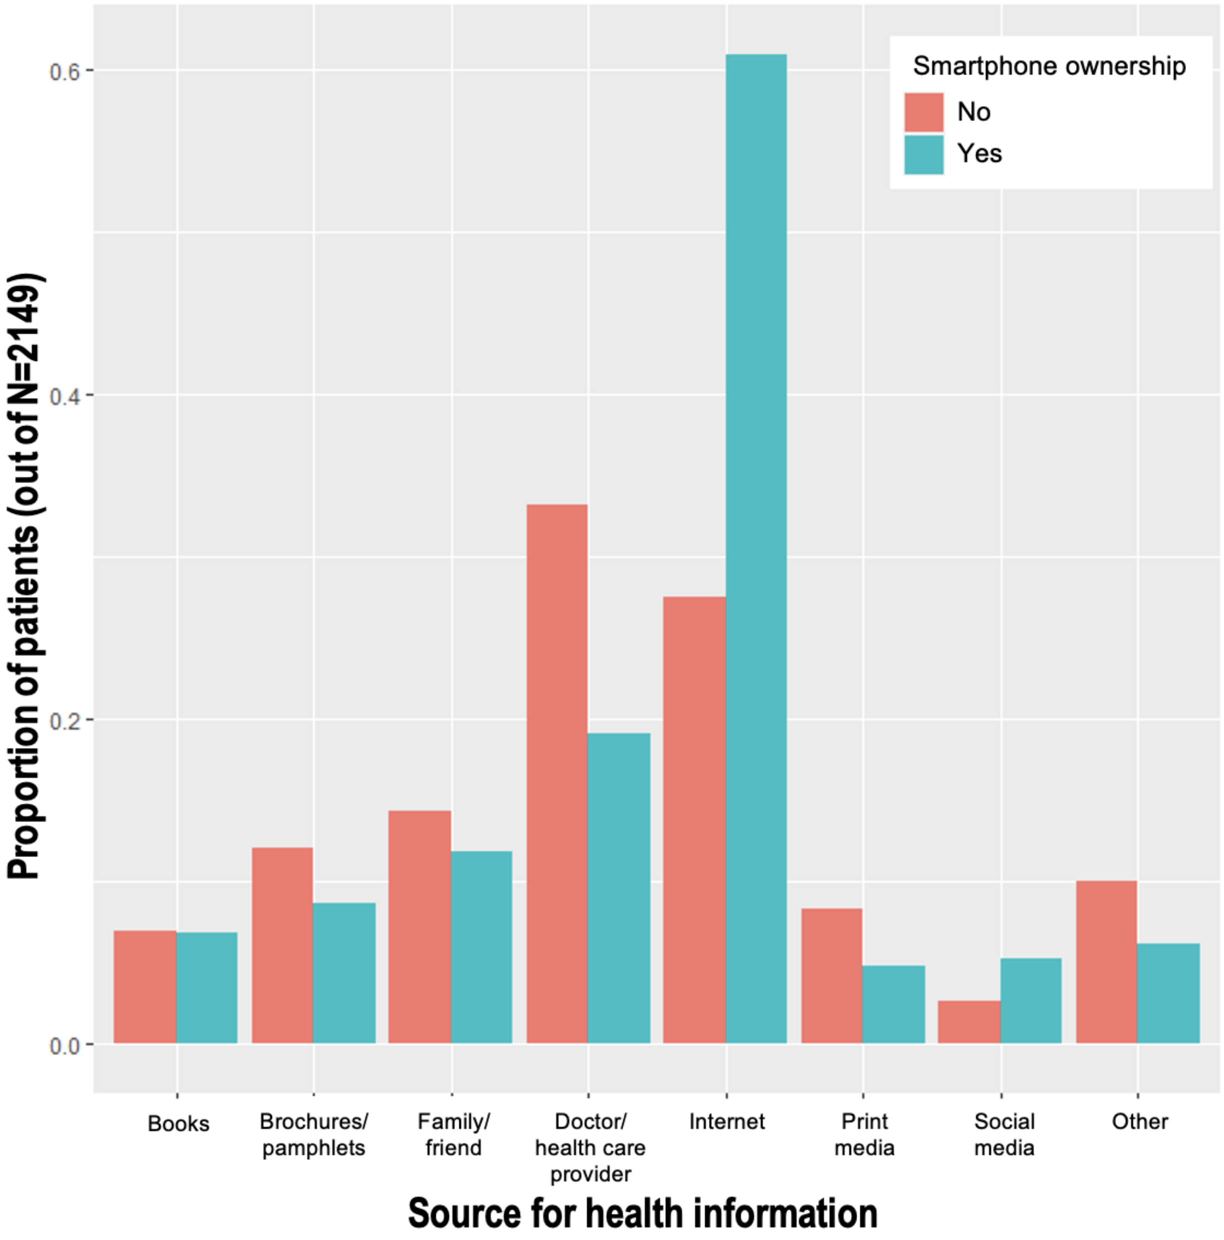


Figure 4. Source used most recently for health information by internet use.

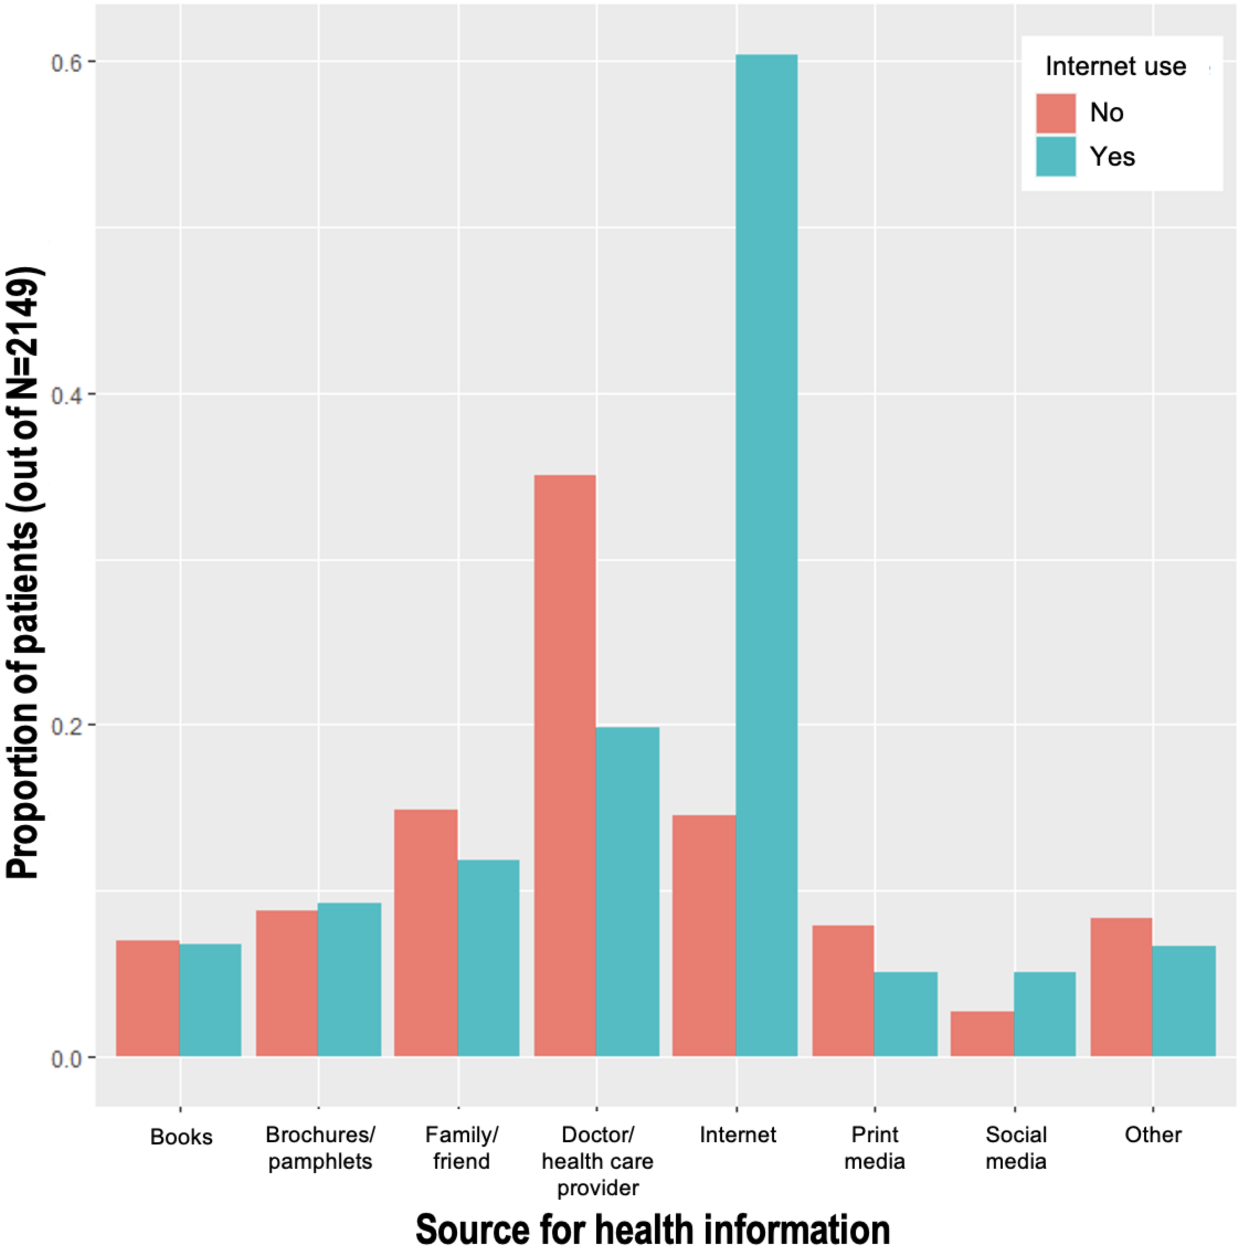


Digital Technology Use and Health Access

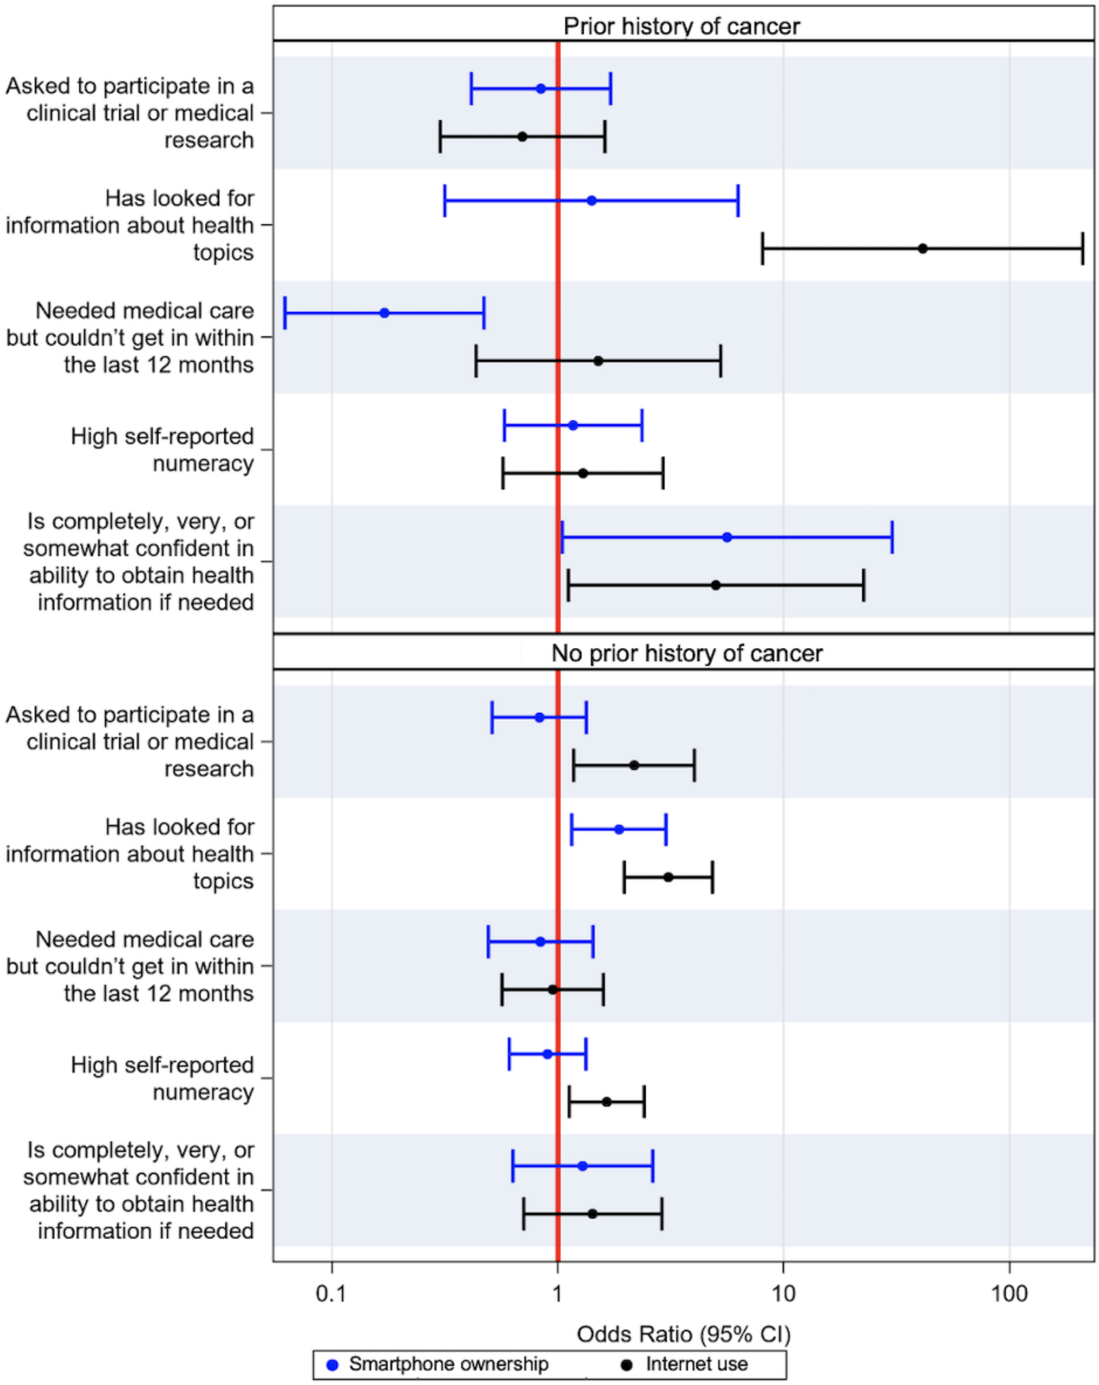
Smartphone ownership and internet use were also associated with markers of health care access (Table 2). Neither smartphone ownership nor internet use was significantly associated with having a usual place for health care or with using an outpatient office or clinic more frequently than the emergency room. However, smartphone owners were less likely than nonsmartphone owners to have been unable to obtain needed medical care within the last 12 months (234/1800, 13% vs 72/349, 20.6%, respectively; *P*<.001).

In adjusted analyses (Figure 2), controlled for age, race and ethnicity, nativity, language spoken at home, income adequacy, occupational status, education level, insurance status, and rurality, this relationship remained significant (OR 0.62, 95% CI, 0.40-0.95). On univariate analysis, internet use was associated with users having been asked to participate in medical research (73.7%, *P*=.002), and this relationship also remained significant in the adjusted analyses (OR 1.73, 95% CI 1.09-2.75) when controlling for age, occupational status, education level, insurance status, and rurality (Figure 2).

Digital Technology Use in Participants With a Personal History of Cancer

The respondents who used the internet had higher odds of a personal history of cancer (OR 1.91, 95% CI 1.21-3.01; Figure 2). In adjusted analyses, older age (OR 1.06, 95% CI 1.05-1.07), disability (OR 4.12, 95% CI 2.30-7.37), and retired status (OR 1.64, 95% CI 1.08-2.49) were associated with an increased likelihood of a personal history of cancer. After stratifying the cohort by personal history of cancer, distinct relationships among smartphone ownership, internet use, and markers of health literacy and health access were observed. For participants with a personal history of cancer, smartphone owners had higher odds of being confident in their ability to obtain health information if needed (OR 5.63, 95% CI 1.05-30.23) and lower odds of needing medical care but being unable to get it (OR 0.17, 95% CI 0.06-0.47) compared with nonsmartphone owners, whereas these associations were not maintained among participants without a personal history of cancer (Figure 5). Similarly, among the participants with a history of cancer, internet users had higher odds of being confident in their ability to obtain health information if needed (OR 5.02, 95% CI 1.12-22.55), whereas this association was not maintained among participants without a prior history of cancer. All models were adjusted for the following covariates: age, occupational status, education level, insurance status, and rurality. Covariates were selected based on univariate analysis (*P*<.10 on univariate analysis).

Figure 5. Association of smartphone ownership and internet use with markers of health literacy and health access in participants with (top) and without (bottom) a prior history of cancer. Separate models were used for each outcome listed on the left, with smartphone ownership or internet use included as a covariate.



Discussion

Principal Findings

Ensuring access to telehealth is an increasingly important priority for the medical community because the COVID-19 pandemic has shifted a large proportion of care into the digital realm, and the convenient and inexpensive nature of the medium suggests that its popularity will persist long after the pandemic eases [47]. As smartphone ownership and internet access are essential modes of digital connectivity in a world that increasingly relies upon such modalities to facilitate health care, smartphone and internet access could have significant implications for health outcomes. Prior studies describing patterns of connectivity are nearly a decade old, suggesting a gap in current evidence [48-50].

The rates of internet use, mobile phone ownership, and smartphone ownership in our cohort were high, with 89.39% (1921/2149) of the respondents reporting internet use, 96.32% (2070/2149) reporting mobile phone access, and 83.76% (1800/2149) reporting smartphone ownership. These rates are higher than prior estimates [51], highlighting the trend described in multiple studies of continued growth in digital usership [25,52,53]. Despite this increasing use, we found that a digital divide persists across socioeconomic dimensions [23,24]. Nonsmartphone and noninternet users were more likely to be older, disabled or retired, less well-educated, on public insurance, and residents of rural areas. Participants without smartphones were also more likely to report finding it difficult or very difficult to get by on their current income. These socioeconomic disparities in digital access have important implications. Both smartphone ownership and internet use were consistently associated with markers of health literacy. Importantly, our findings are the first to demonstrate an additional association between smartphone use and health care access. Finally, these data suggest that having a major medical condition, such as cancer, may serve to reverse previously described relationships between sociodemographic characteristics and technology use.

Smartphone and internet use were consistently and thematically associated with markers of health-specific and overall literacy [54]. Participants without smartphone or internet access had lower self-reported numeracy and lower confidence in their ability to obtain health information when needed. They also reported being less likely to look for information on health topics, even when controlling for potential sociodemographic confounders. These findings support an evolving body of literature that demonstrates an integral connection between digital access and health literacy. In a survey of 1077 patients at community health centers and outpatient clinics, Bailey et al [31] found that patients with adequate health literacy were more likely to own a mobile phone or smartphone and to have internet access. Similarly, a cross-sectional study of 131 low-income adults by Jensen et al [32] found that those with low health literacy skills were less likely to use the internet and related technologies. Low health literacy has been consistently associated with increased rates of hospitalization, greater use of the emergency department, increased medication nonadherence, decreased use of preventive services, and increased risk of mortality [55]. This body of data suggests that digital technology plays a key role in health outcomes.

Patient-provider communication may be an important mediator of the relationship between health literacy and health outcomes. In a survey of 823 patients presenting to an urban public hospital, Yin et al [56] found that patients with lower health literacy were more likely to rely on a doctor's knowledge to make medical decisions and less likely to rely on their own knowledge or beliefs. Similarly, the respondents in our study who did not own smartphones or use the internet were significantly more likely to use a health care provider as their most recent source of health information. Importantly, the survey study by Yin et al [56] found that patients with lower health literacy were less likely to feel like partners in shared decision-making with their providers. These findings point to the need for both provider-level and systemic changes to provide increased support for those who rely on face-to-face health communication to inform their care. In addition, these findings highlight the need for further research into provider reliance on patients' pre-existing medical knowledge or self-driven information seeking and how these behaviors may contribute to health disparities.

Our data are the first to demonstrate an association between smartphone ownership and disparities in access to care. Within our cohort, lack of smartphone ownership was significantly associated with being unable to obtain needed medical care, even when controlling for potential sociodemographic confounders, suggesting that characteristics associated with the use of digital technologies play a role in increasing health care access. Health literacy may be an important factor because prior studies have demonstrated an association between low health literacy and self-reported difficulty in accessing care [55,57]. However, health literacy is unlikely to be the only determinant because lack of internet use in our cohort was associated with lower markers of health literacy but was not significantly associated with being unable to obtain needed medical care. Taken together, these findings suggest that patients lacking smartphone access represent a unique subpopulation, distinct from those lacking internet access, and they may be the most vulnerable to the third digital divide [30] or the digital divide representing disparities in the impact of technology use on health outcomes. Indeed, even within our sample, nonsmartphone owners were distinct from noninternet users in key sociodemographic characteristics, including income adequacy. Future work should be directed toward identifying the unique barriers to care encountered by patients lacking smartphone access, including qualitative studies to assess patient experiences.

Finally, we found that a major health event such as a personal history of cancer may help overcome previously established sociodemographic patterns in digital technology use, with important implications for health outcomes. In our study, patients with a personal history of cancer were more likely to report internet use, despite being older than those without cancer, indicating that populations with historically low adoption of digital technologies, such as older patients [23], can be motivated to change their behavior when faced with a major illness. Importantly, our findings suggest that expanding digital access may also help to mitigate inequities in health care in this patient population. Among participants with a prior history of cancer, internet use and smartphone ownership were both significantly associated with confidence in being able to obtain needed health information. Smartphone use was also associated with lower odds of being unable to obtain needed medical care. In summary, the adoption of digital technologies in this patient population is associated with increased patient health activation, which in turn has been shown to have lasting benefits on health outcomes and health costs [58-60]. These findings demonstrate that engagement with the medical system in the form of a major illness can serve as a catalyst to overcome sociodemographic barriers to technology access, with the potential for improvement in long-term outcomes.

Study Limitations

Our study included limitations that should be acknowledged. First, this was a cross-sectional study, and as such no conclusions can be drawn regarding the causal relationships among the variables studied. Second, the goals of this study were mainly exploratory; therefore, no adjustments were made for multiple comparisons in the statistical analyses. Third, the study findings are derived from self-reported data, which are subject to recall bias and may not accurately reflect participant health literacy and health care use. Fourth, there was a relatively small sample size of participants with a prior history of cancer who did not engage in smartphone or internet use, limiting our goal of precisely estimating the relationship between technology use and markers of health literacy and access in this cohort. The impact of cancer history on the relationship among digital technology, health literacy, and health access may be best explored through an alternative study design, such as a case-control study. In addition, these survey data were collected in the second half of 2017, and although they capture more recent trends in digital connectivity than those available in currently published literature, patterns of digital technology use have continued to evolve since these data were collected. Finally, this study cohort represented a convenience sample in which study recruitment was purposefully targeted to allow the study of a diverse cohort that allows for in-depth analysis of previously understudied patient populations. Thus, there may have been unmeasured biases in the study population, and the extent to which our findings may be generalizable to the national or statewide population is unknown. Future work, including large-scale population-based studies and qualitative investigations, will help to elucidate the connections among digital technology use, health literacy, and health access that were explored here.

Conclusions

In conclusion, we found that access to digital technology has markedly increased across all social strata over the past decade in this diverse cohort of participants, leading to a more electronically connected society than ever before. This substantiates the claim that a broad digital infrastructure exists to support telemedicine as an increasingly important mode of patient engagement and health communication in the coming years. Nonetheless, a digital divide persists along sociodemographic and socioeconomic lines, with implications for both health literacy and access to care. Thus, dissemination of health technology must include measures to reach those with the most compromised health access. Importantly, our data support the idea that prolonged, meaningful contact with the health care system in the form of a major illness such as cancer has the potential to overcome sociodemographic trends in digital technology use and amplify the benefits these technologies confer. Future work should be directed toward the implementation of interventions to bridge the technology gap. In addition, more resources must be directed toward assisting vulnerable communities in engaging with applications of technology in the health sector because these applications hold promise in helping to mitigate health inequities and improve overall community health.

Abstract

Background: Previous studies have found that in general, poor health is associated with a lower likelihood of internet use in older adults, but it is not well known how different indicators of health are associated with different types of digital information technology (DIT) use. Moreover, little is known about the relationship between health and the types of DIT use in older ethnic minority and migrant populations.

Objective: The aim of this study is to examine the associations among depressive symptoms and self-rated health (SRH) with different dimensions of DIT use in older migrants.

Methods: We analyzed data from the Care, Health and Ageing of Russian-speaking Minority (CHARM) study, which is based on a nationally representative sample of community-dwelling, Russian-speaking adults aged 50 years or older residing permanently in Finland (men: 616/1082, 56.93%; age: mean 63.2 years, SD 8.4 years; response rate: 1082/3000, 36.07%). Data were collected in 2019 using a postal survey. Health was measured using depressive symptoms (measured using the Center for Epidemiologic Studies Depression Scale) and SRH. Binary logistic regression analyses were used to investigate the associations between the two health indicators and the following six outcomes: daily internet use, smartphone ownership, the use of the internet for messages and calls, social media use, the use of the internet for personal health data, and obtaining health information from the internet. A number of sociodemographic and socioeconomic factors were controlled for in the logistic regression regression analysis. Analyses were performed with weights accounting for the survey design and nonresponse.

Results: After adjusting for sociodemographic and socioeconomic factors, depressive symptoms (odds ratio [OR] 2.68, 95% CI 1.37-5.24; *P*=.004) and poor SRH (OR 7.90, 95% CI 1.88-33.11; *P*=.005) were associated with a higher likelihood of not using the internet daily. Depressive symptoms (OR 1.88, 95% CI 1.06-3.35; *P*=.03) and poor SRH (OR 5.05, 95% CI 1.58-16.19; *P*=.006) also increased the likelihood of smartphone nonuse. Depressive symptoms were additionally associated with a lower likelihood of social media use, and poor SRH was associated with a lower likelihood of using the internet for messaging and calling.

Conclusions: Poor SRH and depressive symptoms are associated with a lower likelihood of DIT use in older adults. Longitudinal studies are required to determine the directions of these relationships.

Introduction

Background

The use of digital information technology (DIT) has become an essential and pervasive part of daily living for all generations. However, the so-called digital divide continues to exist because certain segments of the population still cannot access the latest information technologies [1]. In general, there are still large differences between age and cohort groups: although virtually all young and middle-aged adults now use the internet, a considerable proportion of older adults, especially those aged above 75 years, do not have access to the web [2]. The other determinants of DIT use include socioeconomic factors such as education, income, and poverty [3-5], as well as ethnic background [4-8] and migrant status [8]. There is a strong link between traditional social exclusion and digital exclusion [9].

In addition, health is associated with DIT use. This becomes particularly relevant in older age, when health issues can increasingly hamper daily and social activities. A large survey of a representative sample of older adults in 17 European countries showed that better self-rated health (SRH) was associated with an increased likelihood of internet use [3]. This result has been confirmed in other studies [10-19]. Similarly, lower depression levels [5,20-22], better functional capacity [14], better well-being and quality of life [23-25], healthier lifestyles [23,26], fewer chronic medical conditions [5], and more favorable cardiovascular risk factors [27] have been associated with a higher likelihood of DIT use in older adults. In contrast, some studies have found no independent association between health status and internet use [4,13].

However, previous studies included several limitations. First, internet use has typically been assessed as a binary variable, although it comprises vastly different facets and dimensions. Health may affect different aspects of DIT use in different ways. Older adults use the internet in diverse ways, and smartphone use has increased dramatically over the last 5 years; both have implications for the patterns of internet use. Indeed, studies measuring the scope and heterogeneity of DIT use by older adults have been called for [3,17,25,28,29]. Second, many studies have measured health with only one indicator; this can be problematic because studies that have used a variety of physical and mental health and functioning indicators have shown differing associations with DIT use [11].

Third, *older adults* are becoming an increasingly diverse population group. In particular, the number and proportion of older migrants are increasing rapidly in many countries. Despite of this, older migrants have typically been overlooked in studies investigating health and DIT use. Moreover, there are only limited studies on DIT use in ethnic minority older populations other than African Americans and Hispanics in the United States [6,12].

Objective

To address these limitations, the aim of this study is to examine the associations among depressive symptoms and SRH with different dimensions of DIT use in a representative sample of older Russian-speaking migrants in Finland. Theoretically, this study is placed in the framework of multidimensional and intersectional forms of digital and social exclusion. Intersecting domains such as older age, ill-health, and a migrant background create a higher risk of social exclusion [30,31]. In a rapidly digitizing society, digital exclusion is becoming an increasingly important aspect of social exclusion; in this regard, older migrants with poor health may be a particularly vulnerable group. The so-called double jeopardy hypothesis states that older migrants are in danger of facing exclusion risks because of their age and migrant background [32]. If we add poor health to the mix, older migrants with poor health can be seen as being subject to triple jeopardy. However, there are differences in terms of the type and purpose of internet use. Because older adults engage in a diverse range of internet activities, the different types of uses are likely to be influenced by different (health and other) characteristics [5].

Methods

Data

The Care, Health and Ageing of Russian-speaking Minority in Finland (CHARM) study focuses on Russian-speaking community-dwelling older adults (aged 50 years or older) who reside permanently in Finland. People born in Russia or the former Soviet Union constitute the largest migrant group in Finland, accounting for approximately 20% of the total migrant population. The study examines issues related to health and well-being, public service experiences, digital inclusion, and access to different types of care. Data were collected in 2019. A random sample of 3000 people was drawn from the Population Registry, which covers all persons registered as living in Finland. The sample was stratified by gender. Of those invited, a total of 36.07% (1082/3000) of people (men: 616/1082, 56.93%; age: mean 63.2 years, SD 8.4 years) agreed to participate in the study. The participants were asked to answer the questionnaire in Russian or Finnish. A total of 82 participants responded on the web, and the rest responded through a postal survey. The survey responses were weighted to adjust for nonresponse bias. The Finnish Tax Administration register data from 2017 were used to model response propensity. The data included information on earnings and capital income, unemployment benefits, earnings-related and national pensions, and student benefits.

Participation was voluntary, and the participants were informed of their right to withdraw at any time without any consequences. The study protocol was approved by the University of Helsinki Ethical Review Board in the Humanities and Social and Behavioural Sciences (#6/2019). The study conformed to the principles embodied in the Declaration of Helsinki.

DIT Use

The frequency of internet use was measured on a 7-point scale with response options ranging from “never” to “several times a day.” For the analysis, this variable was dichotomized; the last 2 categories (“once a day” and “several times a day”) were merged to indicate daily internet use (vs others).

A dichotomized (yes or no) follow-up question captured the different types of internet use among the users. The following items were deemed potentially the most relevant for health and were therefore included in this study: messages and calls, social media, accessing personal health data, and obtaining health information. Messages, calls, and social media use relate to social relationships and social connectedness and interaction, which are well-established determinants of health, and accessing personal health data and obtaining health information relate to a person’s health matters. Smartphone use was assessed with a dichotomous question—“Do you own a smartphone?”

Health Indicators

The CHARM questionnaire included a number of health indicators, such as depressive symptoms; SRH; doctor-diagnosed diseases; limiting long-term illness; physical functioning measured as having difficulties in walking up 3 flights of stairs and difficulties in walking approximately half a kilometer without breaks with or without a walker or walking stick; and reporting hearing, vision or memory, concentration, and learning difficulties. Of these, for this study, we selected the 2 generic indicators that most widely and comprehensively cover physical and mental health—SRH and depressive symptoms.

The 8-item Center for Epidemiologic Studies Depression Scale [33] was used to measure depressive symptoms, with a score of 9 or more points indicating depressive symptoms. The scale and cut-off have been validated for use in community-dwelling older adults [34].

SRH (“In general, would you say your health now is...?”) was assessed on a 5-point scale (1=good; 2=fairly good; 3=average; 4=fairly poor; 5=poor). The groups reporting fairly poor (n=76) or poor (n=28) SRH were merged because of the low numbers of participants in these categories. The single-item SRH measure has been shown to be a valid and reliable instrument that strongly predicts mortality [35,36].

Covariates

Sex, age, marital status (married or cohabiting vs other), educational qualification in Finland (yes or no), educational level in the country of origin, proficiency in local languages, Finnish citizenship (yes or no), the receipt of income support (yes or no), and the type of survey participation (web-based or postal survey) were included as covariates. The highest educational level in the country of origin was categorized as having no education or basic education, vocational training, or higher education. This categorization is based on the structure of the educational system in the former Soviet Union (the participants were of school age during Soviet times and completed their education mainly in that country because most had moved to Finland as adults).

Acculturation was measured by the degree to which the participant had learned the local official language and whether they had obtained Finnish citizenship. The participants assessed their proficiency in local languages on a 4-point scale. The response options “I use Finnish or Swedish language in various ways in different situations” and “I can participate on everyday conversations in Finnish or Swedish” were categorized as having good proficiency. The response options “I can cope with simple everyday situations in Finnish or Swedish” and “I do not speak either language at all” were merged to indicate poor proficiency. Income support receipt was used to measure poverty. Income support is a means-tested, last-resort financial assistance benefit in Finland [37].

Statistical Analysis

Descriptive analyses of the sample included bivariate comparisons (frequencies) of sociodemographic characteristics and health indicators (depressive symptoms and SRH) between those who used DIT and those who did not and testing for any differences between these groups (using the chi-square test). Binary logistic regression analysis was used to examine the associations between the health indicators and DIT use. We estimated odds ratios (ORs) and their 95% CIs for different types of DIT use by the health indicators by first controlling for age and sex and then further controlling for marital status, educational attainment, proficiency in local languages, Finnish citizenship, income support, and the type of participation (web-based or postal survey). Sensitivity analyses were performed on the unweighted sample. The two health indicators were not entered simultaneously into the analyses. Health indicators may partly overlap, and entering them simultaneously into the models can cause overadjustment.

The analyses were conducted using Stata, version 15.1 (StataCorp LLC).

Results

Descriptive Statistics

Table 1 shows the characteristics of the sample and the distribution of the study variables by daily internet nonuse and smartphone nonuse. Most of the participants (796/1067, 74.6%) were married or cohabiting, 39.97% (400/1082) had obtained some educational qualifications in Finland, and 50% (541/1082) had acquired a higher education in their country of origin. Half of the participants had Finnish citizenship, and 37.78% (385/1019) rated their local language (Finnish or Swedish) skills as good. Deprivation levels were very high because 41.56% (421/1013) of the participants had received income support. Of the participants, 20.08% (194/966) reported depressive symptoms. Half of the participants had average SRH, 26.24% (281/1071) saw their health as fairly good, and 14.01% (150/1071) as good, whereas 9.71% (104/1071) reported that they had fairly poor or poor SRH.

[a] N varies by variable depending on the number of missing values.

[b] Differences in the prevalence of digital information technology nonuse between groups (from two-tailed chi-square test). *P* values are weighted.

Of the 1082 participants, only 137 (12.66%) did not use the internet daily. Daily internet nonuse and smartphone nonuse did not differ between men and women. Both internet nonuse and smartphone nonuse were much more prevalent among individuals aged 65 years or older (internet nonuse: 97/421, 23%; smartphone nonuse: 98/351, 27.9%) than in the younger age group (internet nonuse: 40/646, 6.2%; smartphone nonuse: 51/614, 8.3%). However, it is notable that for the smartphone use question, the number of missing values was very high, particularly in the older age group (78/429, 18.2%). This may be due to the formulation of the question, which required the participant to circle "Yes" if they owned a smartphone and "No" if they did not. The same question included 4 other items: a tablet, other computer, safety bracelet or safety phone, and web-based banking ID. Some of the participants had only ticked "Yes" to mark the items that they possessed but failed to tick "No" for those that they did not possess. We conducted a sensitivity analysis by recoding these cases as "No" for smartphone use, which increased the prevalence of nonuse to 13.8% (90/653) in working-age older adults and to 41% (176/429) in those aged 65 years or older. It is likely that the actual prevalence of smartphone nonuse is therefore somewhere between 7.8% (51/653) and 13.8% (90/653) in those aged 50-64 years and between 22.8% (98/429) and 41% (176/429) in those aged 65 years or older.

Participants who were married or cohabiting were more likely to use the internet daily, but there was no difference between these groups in terms of smartphone use. Similarly, those who had obtained qualifications in Finland, those who had obtained higher education in their country of origin, those with good local language skills, and those with Finnish citizenship were more likely to use the internet and own a smartphone. In addition, poverty, measured as income support receipt, increased the prevalence of DIT nonuse.

Both daily internet nonuse and smartphone nonuse were more common among the participants who reported depressive symptoms: out of the 189 participants, 36 (20.1%) with depressive symptoms did not use the internet daily compared with 8.8% (67/764) of the participants with no depressive symptoms. The corresponding figures for smartphone ownership were 23.1% (39/169) and 12.9% (93/717), respectively. A similar picture emerged for SRH: compared with those in good health, those with less than good health were more often nonusers of DIT, and the poorer the health, the more common the nonuse.

Of the different types of internet use, the most common was using the internet for calls and messages (n=855). In addition, using the internet to search for health information (n=650) and social media use (n=631) were common. Compared with these, using the internet to view personal health data was much less commonly reported (n=353).

Health and DIT Use

Table 2 shows the results of the logistic regression models examining the associations between health indicators and daily internet nonuse, and Table 3 presents the associations between health indicators and smartphone nonuse. As shown in Tables 2 and 3, after full adjustments, depressive symptoms were associated with both daily internet nonuse (OR 2.68, 95% CI 1.37-5.24; *P*=.004; Table 2) and smartphone nonuse (OR 1.88, 95% CI 1.06-3.35; *P*=.03; Table 3). Similarly, poor SRH was associated with daily internet nonuse (OR 7.90, 95% CI 1.88-33.11; *P*=.005; Table 2) and smartphone nonuse (OR 5.05, 95% CI 1.58-16.19; *P*=.006; Table 3). Compared with those with good SRH, those with fairly good or average SRH also reported more daily internet nonuse, but there were no associations between these categories and smartphone nonuse.

Table 4 and Table 5 display the associations between health indicators and types of internet use among those participants who reported using the internet. Depressive symptoms were associated with a higher likelihood of social media nonuse (OR 1.93, 95% CI 1.24-2.98; *P*=.003), and poor SRH was associated with a lower likelihood of using the internet for calls and messages (OR 5.27, 95% CI 1.50-18.55; *P*=.01). In terms of the other types of internet use, there were no differences by depressive symptoms or SRH.

The results for all covariates in the full models are shown in Multimedia Appendices 1 and 2. The results from the sensitivity analyses using the unweighted sample (Multimedia Appendix 3) were mainly in the same direction as the results obtained with the weighted sample. However, in the unweighted sample, depressive symptoms were associated with a lower likelihood of using the internet for messages and calls, and poor SRH was associated with a lower likelihood of social media use. In addition, average SRH was associated with a higher likelihood of using the internet for personal health data.

Discussion

Principal Findings

The aim of this study is to examine the associations between mental and physical health and different facets of DIT use among older Russian-origin migrants in Finland and to determine whether these associations are independent of sociodemographic and socioeconomic factors. Our study confirms that DIT use is now strongly embedded in the everyday lives of older adults: the prevalence of internet use was very high in our sample, with 93.8% (606/646) of adults aged below 65 years and 76.9% (324/421) of those aged 65 years or older using the internet daily. In 2019, Finland scored the highest among all European Union countries on the Digital Economy and Society Index, which is a composite index that summarizes relevant indicators of digital performance and includes the components of connectivity, human capital, use of internet services, integration of digital technology, and digital public services [38].

In our study, depressive symptoms were associated with a higher likelihood of daily internet and smartphone nonuse. These results are in line with earlier studies that have shown an association between internet use and depression in older adults [5,20-22]. A large prospective study among US older adults showed that one pathway explaining this association is that internet use influences depression by decreasing loneliness and social isolation [20]. It is well established that loneliness is associated with depression [39], and DIT use has been shown to protect older adults in poor health from social exclusion [40]. A previous study showed that the relationship between internet use and a higher quality of life was mediated by reduced loneliness [24].

In this study, depressive symptoms were additionally associated with a higher likelihood of social media nonuse. A previous study found that social media can become an increasingly important source of feelings of connectedness in older age when retirement and declining health decrease other forms of social engagement [16]. DIT use can considerably increase older migrants' ability to maintain and expand their dispersed support networks [41]. However, mental health problems such as depression may also result in decreased initiative to engage in new activities [42] such as social media use.

Similar to previous studies [3,10-19], we found an association between SRH and internet use. In addition, poor SRH was associated with smartphone nonuse. Physical changes such as reduced visual acuity, declining motor skills, and age-related changes in cognitive abilities are likely to affect the ability to use DIT [43], and these changes may be particularly critical in terms of hindering smartphone use.

DIT provides many specific health-related resources for those with health problems. It enables them to search for health information, communicate with their health care providers, access their laboratory results, renew their prescriptions, and seek peer support. Therefore, it could be expected that those with poorer health would be more likely to use the internet to seek health information and access personal health data. Indeed, an earlier study showed that having more chronic conditions increased the odds of internet use for health-related tasks [5]. However, in our study, depression and poor SRH did not have an effect on the search for health information among those who used the internet. This finding is consistent with that of a previous Australian study [15]. Moreover, we did not find an association between health status and the use of the internet to access personal health data.

Overall, our findings suggest that in older migrants, the digital divide still exists not only between adults aged 50-64 years and those aged 65 years or older but also between those with poor mental and physical health and those with good health. It is notable that this divide was evident even in our sample, which consisted of cognitively relatively well-functioning older adults who were able to respond to a lengthy questionnaire (20 pages). In fact, it has been noted that as more and more people access the web, the social gap between the majority (the digitally included) and the minority (those who are still digitally excluded) widens [14]. It seems that those who are digitally excluded therefore become even more socially excluded than before. Indeed, a study conducted in the United Kingdom and Sweden showed that now, when access to the internet is widespread and the proportion of those without internet access has become smaller, nonuse has become more concentrated in the most vulnerable groups. In other words, nonusers in both countries increasingly consist of the most vulnerable segments of the population, that is, older participants, those with the lowest amount of education, those with the poorest health, and those who are most socially isolated [9]. Helsper and Reidolf [9] therefore argue that we now see the emergence of a digital underclass. Older migrants may be particularly vulnerable in this regard because older age, poor health, low socioeconomic status, and a migrant background as intersecting domains increase the risk of social exclusion [30,31].

In our study, we were not able to investigate the mechanisms underlying the associations between health and DIT use. However, based on other studies, it can be assumed that functional limitations that can accompany health problems may pose barriers to DIT use [5,14]. It seems that decreased social isolation and loneliness may be one pathway to alleviating depression [20].

Strengths and Limitations

Our study included several strengths. First, we considered different dimensions of health. Second, we examined DIT use in a diverse way, including daily internet use, smartphone use, and different types of internet use as outcomes. Third, we were able to adjust for a number of relevant sociodemographic and socioeconomic factors that can affect both health status and DIT use.

However, this study also included some limitations. First, our data were cross-sectional; therefore, the associations found cannot be interpreted as causal relationships. It is likely that the relationship between health and DIT use is bidirectional, additive, and synergistic [14]: good health can increase DIT use, and DIT can improve health and well-being. In a large prospective study using a variety of methods, including matching, internet use was shown to reduce depression, and the effect was the largest for older people who lived alone [20].

Second, all our DIT use and health measures were self-reported, which can cause recall bias and misclassification. Third, our results cannot be generalized to the general population or to other migrant populations. In an earlier study on working-age migrants in Finland, Russian-origin migrants were more transnationally oriented than the other 2 migrant groups—Somalis and Kurds—which is likely to manifest as a higher level of DIT use [44]. Notwithstanding these limitations, this study is an important contribution to the growing literature on health and DIT use in older adults. This study provides results that will illuminate the design of future research to incorporate technology use for a better understanding of the mental and physical health situation of vulnerable populations.

Conclusions

In Finland, as in other Western countries, DIT use is nearing saturation among older age groups, but digital divides still exist. In this study on older migrants, we found that poor SRH and depressive symptoms were associated with a lower likelihood of DIT use. Older adults with poorer health and limited mobility are often the most socially isolated, and they would particularly benefit from the diverse use of DIT [5].

Medeiros et al [14] have proposed that because DIT use such as exchange of web-based messages demands adequate social and executive functioning, it could be used as a marker of older adults' functional capacity and depression. Therefore, the monitoring of functional capacity and depression could be done routinely by health professionals during health checkups by simply asking about the patients' DIT use. However, more importantly, there is an opportunity for the use of big data because this monitoring could be done with artificial intelligence using pattern recognition, and the results could be used in health policy planning [14]. The present results also open up possible health interventions that are now particularly relevant considering the COVID-19 pandemic circumstances.

Longitudinal studies are needed to elucidate the mechanisms underlying the associations between health and DIT use. These types of studies can better inform digital inclusion policies for migrants and older adults. Evidence-based digital inclusion strategies and policies are urgently needed to prevent increasing social exclusion of the digitally excluded populations who are also in other ways the most vulnerable, given that public services are rapidly becoming mainly or solely digitally accessible.

Abstract

Background: The COVID-19 pandemic has amplified the role of telehealth in health care delivery. Regional variation in internet access and telehealth use are well-documented, but the effect of neighborhood factors, including the pervasiveness of broadband internet, on older adults' telehealth usage in the context of internet access is not known.

Objective: This study aimed to investigate how individual and neighborhood characteristics, including the pervasiveness of neighborhood broadband internet subscription, are associated with engagement in telehealth among older adults with internet access.

Methods: In this cross-sectional study, we included 5117 community-living older adults aged ≥65 years, who participated in the 2017 National Health and Aging Trends Study with census tract–level data for participants' places of residence from the American Community Survey.

Results: Of an estimated 35.3 million community-living older adults, 21.1 million (59.7%) were internet users, and of this group, more than one-third (35.8%) engaged in telehealth. In a multivariable regression model adjusted for individual- and neighborhood-level factors, age, education, income, and the pervasiveness of neighborhood broadband internet subscription were associated with engagement in telehealth, while race, health, county metropolitan status, and neighborhood social deprivation were not. Among internet users, living in a neighborhood at the lowest (versus highest) tertile of broadband internet subscription was associated with being 40% less likely to engage in telehealth (adjusted odds ratio 0.61, 95% CI 0.42-0.87), all else equal.

Conclusions: Neighborhood broadband internet stands out as a mutable characteristic that is consequential to engagement in telehealth.

KEYWORDS

aging; broadband internet; neighborhood; telehealth

Introduction

The COVID-19 outbreak and the resultant reimbursement and policy changes of the Centers for Medicare and Medicaid Services have motivated a massive shift toward telehealth in routine clinical care [1]. Telehealth refers to the use of communication technologies to deliver health care remotely [2,3]. Older adults are major users of health services but may be unable or unwilling to engage in telehealth owing to the lack of internet-enabled devices, lack of internet access, or difficulties with using technology owing to sensory or functional disabilities or the lack of prior technology experience [2,4]. Older adults also face place-based challenges to telehealth as they are disproportionately likely to live in rural locations that have gaps in internet connectivity, including broadband internet [5,6].

Although the ability to engage in telehealth is affected by both individual and environmental characteristics, data constraints inhibit obtaining knowledge of how such factors jointly contribute to telehealth use. Prior studies have examined individual-level variability in predictors of telehealth use from national surveys, without regard to the neighborhood context [2,7,8]. More recent studies have examined geographic variability in telehealth use among all older adults, which have revealed, for example, smaller increases in primary care telehealth visits among rural providers early during the COVID-19 emergency compared to urban providers [1,4]. This study draws on a unique platform of linked national surveys that together afford comprehensive information on both older adults and neighborhood characteristics to assess the extent to which individual and neighborhood factors may affect engagement in telehealth among older adults with internet access.

Methods

We conducted a cross-sectional study using data of community-living older adults aged ≥65 years, who participated in the 2017 National Health and Aging Trends Study (NHATS) [9], which were linked to census tract–level data on the participants' place of residence from the American Community Survey [10]. In the 2017 NHATS, 6312 participants were interviewed: 736 participants lived in residential care facilities or nursing homes and 459 who died were excluded, yielding a final unweighted sample of 5117 participants. Measures of older adults' sociodemographic characteristics (age, gender, race, education, and income), health status (number of chronic conditions, receipt of help with daily self-care activities, and dementia status), technology use (internet use and engagement in telehealth activities), and county metropolitan status (whether participants lived in a metropolitan or nonmetropolitan county as designated by the US Office of Management and Budget) [11] were drawn from the NHATS. Census-tract measures of broadband internet subscription rates among people aged ≥65 years and a composite measure of neighborhood social deprivation [12] were derived from the American Community Survey and operationalized on the basis of the distribution within the analytic sample by tertile.

As the internet is an important technology for telehealth, we first assessed older adults' internet usage, defined by self-reports of having browsed the internet on a computer or mobile device in the last month for any reason other than emailing or texting, as previously described [7]. In this study, engagement in telehealth is defined as having browsed the internet in the last year to contact medical providers. Participants who reported browsing the internet in the past month were asked to respond with "Yes" or "No" to the following question: "in the last year have you gone on the internet or online to contact any of your medical providers…this includes making or changing medical appointments, getting test results, requesting referrals or prescriptions, or to get advice?" These activities have been referred to as "digital health technology use" [7] and "health-related internet use" [8] in other studies. We instead refer to these activities as "telehealth" because they have been an important part of the overall massive shift toward web-based health behavior during the COVID-19 emergency [13].

We then comparatively described the characteristics of older adults by internet usage across individual, census-tract, and county characteristics and assessed the adjusted odds of older adults' internet use in a multivariable logistic regression model that controls for individual, neighborhood, and county characteristics. Furthermore, among the subset of older adults who used the internet, we examined engagement in telehealth. We described the characteristics of older adults who did and those who did not engage in telehealth by individual, census-tract, and county characteristics and assessed the adjusted odds of older adults' engagement in telehealth in a multivariable logistic regression model that controls for individual, neighborhood, and county characteristics. Reported estimates are weighted with the 2017 survey weights to account for nonresponse, oversampling of subgroups (oldest-old and Black non-Hispanic persons), incomplete interviews, and replenishment of the original sample [14]. Analyses were conducted using Stata (version 13, Stata Corp), and $\alpha<.05$ indicated significance. NHATS participants provided written informed consent, and our study was approved by the institutional review board of Johns Hopkins Bloomberg School of Public Health (IRB00011232).

Results

Of an estimated 35.3 million community-living older adults, 21.1 million (59.7%) were characterized as internet users (Table 1). Relative to those who did not use the internet, those who did were younger and more likely to be male, White, more educated, higher income, in better health, and living in metropolitan counties and in census tracts at the top tertile of broadband internet subscription and the bottom tertile of social deprivation, based on unadjusted frequencies. With the exception of the number of chronic conditions and county metropolitan status, these factors were significantly associated with internet use in a fully adjusted multivariable regression model, and women had a significantly higher odds of reporting usage of the internet despite being less represented among internet users.

More than one-third (35.8%) community-living older adults who used the internet in 2017 had engaged in telehealth (Table 2). Internet users who engaged in telehealth were younger (73.5 vs 74.4 years; $P<.001$) and more likely to have a college education (54.0% vs 35.3%; $P<.001$) and be in the highest income tertile (64.4% vs 45.7%; $P<.001$) than those who did not. Internet users who engaged in telehealth were less likely to live in a nonmetropolitan county (11.5% vs 18.3%; $P=.01$) and in neighborhoods at the top 2 tertiles of social deprivation (50.4% vs 62.3%; $P<.001$), while being more likely to live in neighborhoods at the top tertile of broadband subscription (53.7% vs 38.3%).

[a] Weighted estimates of the 2017 National Health and Aging Trends Study (round 7): 13.5 million nonusers and 7.5 million users.

[b] Pearson chi-square test for frequencies and the adjusted Wald test for means.

[c] Adjusted odds ratios derived from a multivariable logistic regression model that is inclusive of all measures presented in the table.

[d] N/A: not applicable.

[e] Self-reported hearing difficulty, vision difficulty, heart attack, heart disease, hypertension, stroke, hip fracture, diabetes, cancer, lung disease, and arthritis.

[f] Daily activities include eating, bathing, toileting, and dressing.

[g] 2015 social deprivation index tertile: ranges from 0 to 100; higher values indicate greater social deprivation.

[h] Broadband subscription rates among older adults in accordance with the 2017 American Community Survey (Table S2802).

In a multivariable logistic regression model, age, education, income, and neighborhood broadband subscription remained highly associated with older adults' engagement in telehealth (Table 2): living in a neighborhood at the lowest (vs highest) tertile of broadband internet subscription was associated with a 40% lesser likelihood to engage in telehealth (adjusted odds ratio 0.61, 95% CI 0.42-0.87). No differences in telehealth use were observed by older adults' gender, race, health, neighborhood social deprivation, or county metropolitan status in the regression model.

Discussion

This nationwide study establishes that among community-living older adults who use the internet, the pervasiveness of neighborhood broadband internet is highly associated with engagement in telehealth. Prior studies have reported that more than 1 in 4 Medicare beneficiaries—more often those who are older, with lower incomes, and of Black or Hispanic racial or ethnic status—lack internet access at home [4,7] and that having more limited social and economic resources and living in a nonmetropolitan county are associated with "unreadiness" to engage in telehealth [2]. Our study extends this knowledge by drawing on a unique data source that affords the ability to differentiate older adults' internet use and engagement in telehealth alongside comprehensive information on both individual and neighborhood characteristics. Our findings indicate that, all else equal, living in a neighborhood at the lowest (vs highest) tertile of broadband internet subscription is associated with a 40% lesser likelihood to engage in telehealth. Importantly, of those characteristics that were most highly associated with engagement in telehealth (including age, education, and income), neighborhood broadband subscription stands out as uniquely amenable to policy intervention.

A recent study reported that nearly half of all fee-for-service primary care visits occurred through telehealth following the COVID-19 outbreak and that telehealth usage was disproportionately concentrated in urban and metropolitan counties [1]. Our study confirms that prior to the emergence of the COVID-19 outbreak, among internet users, living in a metropolitan county and low neighborhood social deprivation are associated with engagement in telehealth. However, there is promise in our finding that the strengths of these associations are attenuated and not significant in the context of individual and regional characteristics, including the prevalence of neighborhood broadband subscription. Although the lack of broadband internet may compound other barriers to health care access—for example, more limited availability of health care professionals and poor transportation infrastructure in rural areas [5]—prior studies of barriers to telehealth use among older adults have primarily focused on individual attitudes, capabilities, and resources [15]. While the expansion of broadband availability would remove a significant barrier to telehealth access, expansion of telehealth use will require attention to a broader set of cost and access factors such as affordability of broadband services and computer equipment, as well as education and assistance with technologies to overcome gaps in technology experience [2,6].

This cross-sectional study does not provide insight into the frequency, quality, modality, or setting of telehealth interactions. The survey information analyzed in this study was from 2017, prior to the more flexible telehealth environment promoted by Centers for Medicare & Medicaid Services since March 2020. Our study results are limited to telehealth use among the subset of older adults who reported using the internet in the previous 30 days. Audio-only telephone-based telehealth communication, which has become common during the COVID-19 emergency [16] was not measured in this study. Despite these limitations, our findings reinforce the relevance of broadband internet as a consequential factor in equitable access to telehealth and suggest possibilities from policies and programs to extend broadband internet availability and affordability [17,18]. The COVID-19 outbreak has disrupted a wide range of health-producing activities including education, health care, and commerce. In this context, study findings resonate with calls to recognize and invest in broadband internet as a social determinant of health, which is especially significant during this time of heavy reliance on remote technologies [18].

Acknowledgments

This study was supported by the National Institute on Aging (P30AG066587; T32AG000247; T32AG066576). The sponsor was not involved in the design and conduct of this analysis; the management, analysis, or interpretation of the data; the preparation, review, or approval of the manuscript; or the decision to submit the manuscript for publication. Abstract

Background: In many countries, sex work is criminalized, driving sex work underground and leaving sex workers vulnerable to a number of occupational health and safety risks, including violence, assault, and robbery. With the advent of widely accessible information and communication technologies (ICTs), sex workers have begun to use electronic occupational health and safety tools to mitigate these risks.

Objective: This study aims to explore the use of ICTs by sex workers for managing occupational health and safety risks and strategies for reducing these risks. This paper aims to answer the following question: what is known about sex workers' use of ICTs in the delivery of occupational health and safety strategies?

Methods: A literature review following the methodological framework for scoping reviews was conducted to analyze studies describing the use of ICTs by sex workers to mitigate occupational health and safety risks. Experimental, observational, and descriptive studies, as well as protocol papers, were included in this scoping review.

Results: Of the 2477 articles initially identified, 41 (1.66%) met the inclusion criteria. Of these studies, 71% (29/41) were published between 2015 and 2019. In these studies, the internet was the predominant ICT (24/41, 58%), followed by text messaging (10/41, 24%) and assorted communication technologies associated with mobile phones without internet access (7/41, 17%; eg, voice mail). In 56% (23/41) of the studies, sex workers located in high-income countries created occupational health and safety strategies (eg, bad date lists) and shared them through the internet. In 24% (10/41) of the studies, mostly in low- and middle-income countries, organizations external to sex work developed and sent (through text messages) occupational health and safety strategies focused on HIV. In 20% (8/41) of the studies, external organizations collaborated with the sex worker community in the development of occupational health and safety strategies communicated through ICTs; through this collaboration, concerns other than HIV (eg, mental health) emerged.

Conclusions: Although there has been an increase in the number of studies on the use of ICTs by sex workers for managing occupational health and safety over the past 5 years, knowledge of how to optimally leverage ICTs for this purpose remains scarce. Recommendations for expanding the use of ICTs by sex workers for occupational health and safety include external organizations collaborating with sex workers in the design of ICT interventions to mitigate occupational health and safety risks; to examine whether ICTs used in low- and middle-income countries would have applications in high-income countries as a substitute to the internet for sharing occupational health and safety strategies; and to explore the creation of innovative, secure, web-based communities that use existing or alternative digital technologies that could be used by sex workers to manage their occupational health and safety.

KEYWORDS

sex work; smartphone; mobile phone; occupational health and safety; online; internet; website

Introduction

Background

Sex workers encounter a number of occupational health and safety risks. In Germany [1], Thailand [2], Ireland [3], Israel [4], Cambodia [5], and Canada [6-8], studies have reported that sex workers are subjected to violence, assault, and harassment. These risks are experienced by transgender individuals who identify as women [6], cisgender women [7-9], cisgender men [10], and transgender sex workers who identify as men [10]. Although there are many categories of sex work, this paper will focus on sex work where a sex worker and their client have physical contact as commercial sex work [11].

To counteract these occupational health and safety risks, sex workers have begun to use information and communication technologies (ICTs)—most commonly, the internet and social media—to exchange tips and information [12]. In a study composed of a literature review and interviews with sex workers that was published in 2016, the Global Network of Sex Work Projects (NSWP) reported that ICTs are a new type of business tool for sex workers that has enabled a global change from outdoor sex work to indoor sex work [12]. In addition, their study reported that sex workers in high-income countries use the internet to advertise their services. In low- and middle-income countries (LMICs), sex workers provide regular clients with their phone numbers and receive calls from potential clients. In consultation with sex workers in 7 countries, ranging from low- to high-income countries, the NSWP reported that ICTs provide sex workers with the means to screen clients as well as set the terms of the encounter in advance of appointments with clients. This has led to a decrease in the rate of violence perpetrated against sex workers [12]. The predominant method for accessing ICTs was found to be through a smartphone [12]. The same study posited that the use of ICTs enhanced social cohesion among sex workers [12], which can lead to beneficial effects among sex workers in reducing occupational health and safety risks [13,14]. In addition, the NSWP highlighted in their review that the World Health Organization has published data on the value of ICTs in promoting condom use [12].

Objectives

This scoping review aims to answer the following research question: what is known about sex workers' usage of ICTs in the delivery of occupational health and safety strategies? Specifically, this study seeks to examine the types of ICTs used by sex workers, the types of occupational health and safety strategies delivered through ICTs, and the individuals and organizations engaged in the development of occupational health and safety strategies. A thorough search of the literature did not reveal any systematic reviews or scoping reviews on this topic.

Methods

Literature Review Strategy

A literature review consistent with the Preferred Reporting Items for Systematic Reviews and Meta-analyses Extension for Scoping Reviews guidelines and following the methodology pioneered by Arksey and O'Malley [15] and enhanced by Levac et al [16] was used to analyze studies on sex workers' use of ICTs in the delivery of occupational health and safety strategies.

Inclusion Criteria

Peer-reviewed studies were included if they met the following criteria: (1) published in English and (2) described an intervention in which sex workers used ICTs for occupational health and safety strategies (occupational health and safety strategies include, but are not limited to, violence prevention, having a buddy system, managing the effects of stigma on mental health, screening clients, condom use when providing sexual services, and clearly stating boundaries during the encounter), ICTs were developed for sex workers to apprise them of occupational health and safety strategies, and ICTs were developed with sex workers to exchange and communicate occupational health and safety strategies. Experimental, observational, and descriptive studies analyzing website contents, as well as protocol papers, were screened and included for review if the inclusion criteria were met. No limitations with regard to the year of publication were imposed.

Search Strategy

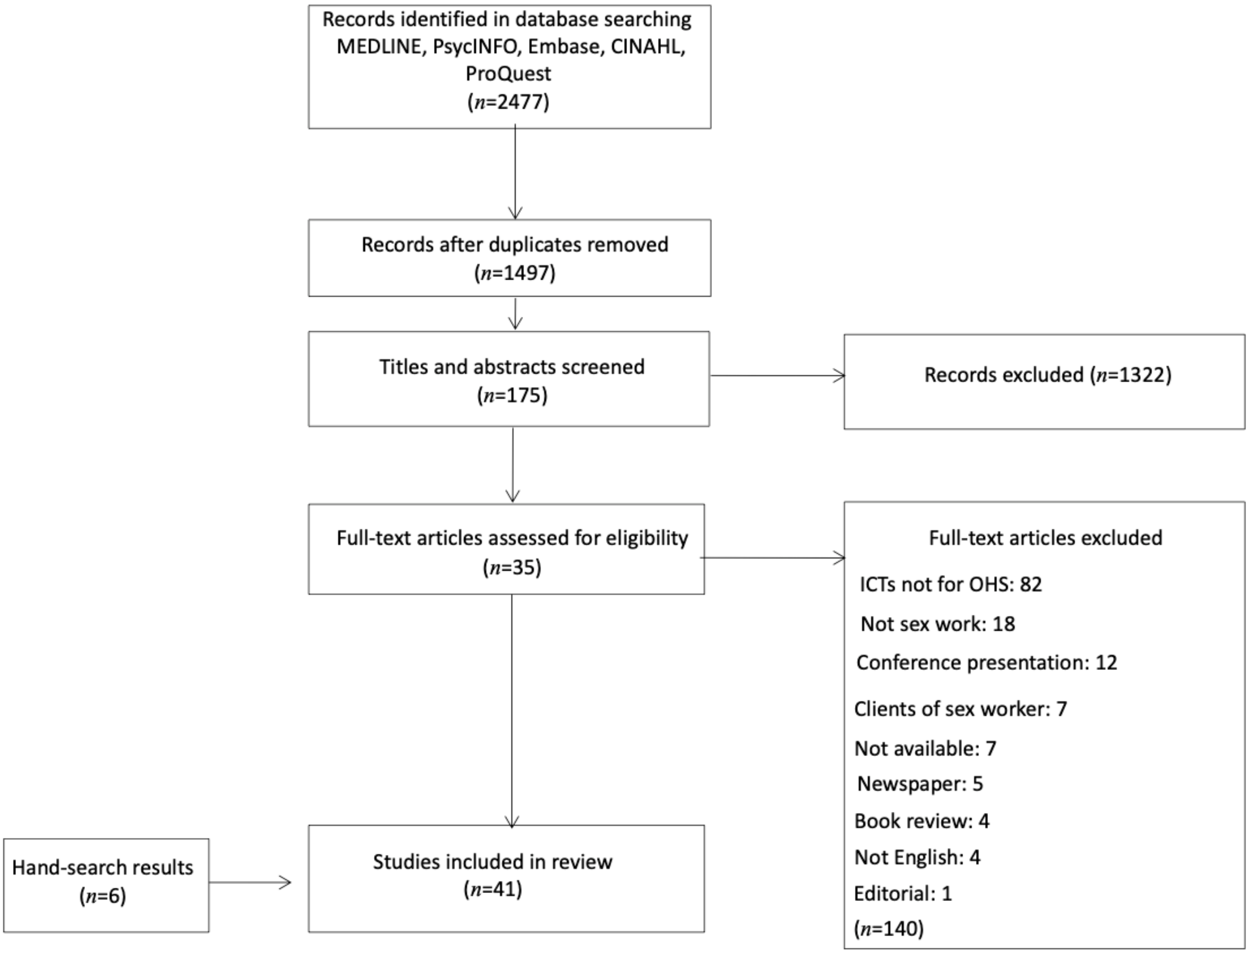
A comprehensive literature search was conducted in September 2019 using the following databases: MEDLINE, Embase, PsycINFO, CINAHL, and ProQuest Dissertations and Theses.

Search strategies were developed with the assistance of a professional librarian (Erica Lenton). Key concepts for the database search included sex worker and ICTs. The concept of occupational health and safety was screened manually because including it as a concept in the database search limited the results and excluded relevant papers. The final search strategy for MEDLINE can be found in Multimedia Appendix 1.

Selection Procedure

The selection criteria forms were developed by the primary author (TB). The initial database search resulted in 2477 articles returned (629 from MEDLINE, 713 from Embase, 420 from PsycINFO, 282 from CINAHL, and 433 from ProQuest Dissertations and Theses). The selection procedure is illustrated in the flow diagram in Figure 1. After removing 980 duplicates, 1497 articles remained. By applying the inclusion criteria, title and abstract screening was performed independently by TB and AS, resulting in 1322 excluded articles, leaving 175 articles for full-text review. The full-text review was performed independently by TB and AS. After the full-text review, 35 articles were selected for inclusion in the scoping review, and 140 were excluded. These 140 articles were excluded for the following reasons: (1) ICTs were not used for occupational health and safety strategies; (2) the article was not about sex work; (3) the article was a conference presentation (poster, oral, and plenary); (4) the article only addressed clients of sex workers and not sex workers; (5) the article was not available (eg, no longer in print); (6) the article was a newspaper article or book review; (7) the article was written in a language other than English; and (8) the article was an editorial. Disagreement between the reviewers TB and AS was resolved by discussion until a consensus was reached. A secondary search was performed by TB, consisting of screening the reference list of the included articles, which yielded 5 articles. A query to a sex work research network (Sex Work Research Hub) netted an additional single article. The search resulted in a total of 41 articles included for full data extraction and analysis. The final search strategy can be found in Multimedia Appendix 1.

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses flowchart. ICT: information and communication technology; OHS: occupational health and safety.



Data Extraction

A data charting table was developed by TB, discussed with AS, and consensus was reached on the table elements that included (1) research design and if sex workers were included in the design, (2) research ethics board approval, (3) aim and goals of study, (4) type of sex work and location, (5) legislative models, (6) specific study population, (7) characteristics of the study population, (8) type of ICT, (9) occupational health and safety addressed, (10) source of occupational health and safety strategy, (11) occupational health and safety strategy, and (12) main findings. These elements were chosen to reflect the types of sex work and the associated occupational health and safety risks. TB and AS each independently charted 5 articles and then discussed the results to ensure consistency in their understanding of each table element. TB and AS then proceeded to independently complete the data extraction for all 41 articles. Any disagreement between TB and AS was resolved through discussion until a consensus was reached. At the completion of data extraction, themes were identified by examining the exposure that sex workers face with regard to occupational health and safety risks, the provenance of occupational health and safety strategies, and the ICTs used to communicate these strategies.

Results

Study Characteristics

Of the 41 studies selected for review, 7 were experimental (5 were randomized controlled trials) [17-23], 19 were observational studies [10,24-41], 13 were descriptive studies analyzing website contents [42-54], and 2 were protocol papers

[55,56]. Each paper was a unique separate study, meaning that no two papers discussed the same data.

A total of 5 studies were conducted in high-income countries (Australia, Canada, China, the United Kingdom, and the United States), and 7 studies were conducted in LMICs (Cambodia, India, Kenya, Mexico, Mozambique, South Africa, and Zimbabwe).

Study publication dates ranged from 2004 to 2019, with 71% (29/41) of the studies published between 2015 and 2019. Since 2007, according to a study published by the NSWP in 2017, ICT use by sex workers, particularly the internet and smartphones, has risen, reflecting the pace of growth in the general population [12]. For example, 33% of the Canadian adults in 2012 were using smartphones. In 2013, this percentage increased to 56% [57]. By 2018, 90% of the Canadian adults were using smartphones [58].

Main Themes

The main themes identified in the literature were related to (1) sex work context, (2) ICTs, (3) sex workers' implementation of occupational health and safety strategies through ICTs, (4) implementation of occupational health and safety strategies through ICTs by organizations external to sex workers, and (5) researchers collaborating with sex workers in the study of ICTs used for occupational health and safety strategies. Representative studies (exemplars) are presented and discussed for themes 3, 4, and 5.

Sex Work Context

Within the sex work context, four concepts were identified: occupational health and safety concerns, gender, sex work venue, and legislative models.

The 41 papers reported on one or more of the following categories of occupational health and safety concerns: (1) sexually transmitted infection and HIV prevention, testing, and risk behaviors (13 studies); (2) risk management practices (13 studies); (3) sexual and reproductive health (3 studies); (4) hepatitis B virus prevention (1 study); (5) drug use (1 study); and (6) stigma (1 study). The occupational health and safety concerns and associated studies are presented in Table 1.

Of the included studies, 41% (17/41) pertained to cisgender women [18,19,21,26-30,34,36,37,39,46,50,55,56,59]. Approximately 27% (11/41) were on cisgender men [20,31,32,40,42,43,48,51-54], and 7% (3/41) addressed the following genders: cisgender women, cisgender men, and transgender women [33,44,49]. Of the studies, 4% (2/41) addressed cisgender women, cisgender men, and transgender individuals whose gender identity was not specified [41,45], and 12% (5/41) of the studies did not specify a gender [17,22,23,25,35]. Approximately 5% (2/41) of the studies pertained to cisgender women and cisgender men [24,47], and 1 study addressed cisgender men and transgender sex workers who identified as men [10]. No studies were found that focused solely on transgender sex workers.

The sex work venue is generally regarded as indoor, outdoor, or both. Of the 13 studies that did not specify the venue, extrapolation was performed to determine the venue. Extrapolation was based on studies taking place in the same country or used information contained in the study or used other reliable sources (such as government websites). A total of 14 studies specifically mentioned indoor sex work as the type of venue in which sex workers conducted their business [25,26,31,33,34,37,43,47-52,56]. A total of 6 additional studies were extrapolated to be indoor [22-24,42,53,54]. Venues that were specified as "internet-based" [45] or "web-based" [44] were considered to be indoor sex work. Sex tourism was categorized as indoor based on the content of the study [46]. A total of 3 studies mentioned outdoor (street-based) sex work [9,17,40]; 2 were extrapolated to be outdoors [18,55]; and 8 studies addressed occupational health and safety for both indoor and outdoor (street-based) sex workers [10,27-30,35,36,59], with 5 studies extrapolated to be as such [20,21,32,39,41]. Of the 41 studies, 23 (56%) addressed indoor sex work, 5 (12%) addressed outdoor sex work, and 13 (32%) addressed sex workers in both indoor and outdoor settings.

Legislative models pertaining to sex work for each country in the study are shown in Table 2. Legislative models are categorized as (1) full criminalization, (2) partial criminalization, (3) criminalization of purchase of sex, (4) regulatory models, and (5) full decriminalization (definitions included in the notes for Table 2) [60]. Sex work is deemed to be a criminal activity in 83% (10/12) of the countries in the papers selected for this study and is regulated in 17% (2/12) of the countries in the study.

Table 1. Occupational health and safety concerns for indoor, outdoor, and indoor and outdoor sex workers.

[a] The definition of each legislative model was obtained from Platt et al [60]. *Full criminalization:* all aspects of selling and buying sex or organization of sex work are prohibited. *Partial criminalization:* organization of sex work is prohibited, including working with others, running a brothel, involvement of a third party, or soliciting. *Criminalization of purchase of sex:* often referred to as the sex-buyer model—laws penalize sex workers working together (under third-party laws), any aspect of participating in the sex trade as a third party, and buying sex. *Regulatory models:* the sale of sex is legal in licensed models or managed zones and is often accompanied by mandatory condom use, HIV and sexually transmitted infection testing, or registration. *Full decriminalization:* all aspects of adult sex work are decriminalized, but condom use is legally required in some locations (eg, New Zealand).

[b] Unless otherwise indicated, data on legislative models were obtained from Platt et al [60].

[c] A total of 12 countries in study.

[d] Percentages have been rounded.

[e] South Africa, Zimbabwe, and Mozambique were documented in the same study.

[f] N/A: not applicable.

Use of ICTs

The internet, including websites and web-based activities (defined as performing activities such as participating in a discussion forum, researching a potential client's credentials, using email, or being active on social media), accounted for 58% (24/41) of the studies. The remainder of the studies investigated the use of mobile phones without internet access; of these, 24% (10/41) examined text messaging, and the other 17% (7/41) looked at assorted communication technologies associated with mobile phones without internet access, such as phone calls, interactive voice response (IVR), audio broadcast messaging, and voice mail.

Sex Workers' Implementation of Occupational Health and Safety Strategies Through ICTs

In 56% (23/41) of the studies, occupational health and safety strategies were initiated by the sex workers themselves, using the internet (through computers or smartphones), text messaging, or mobile phones without internet access.

Using the internet, indoor sex workers were found to use an array of electronic strategies to implement risk management practices for screening clients. In the United Kingdom and Montréal (Canada), screening tools such as electronic bad-date lists (a bad-date list is a list consisting of descriptions of clients that have been abusive (eg, violence) toward sex workers) were made available to sex workers through sex worker–run organizations [33,35]. Indoor sex workers also searched for information on potential clients by consulting closed sex worker Facebook groups and web-based sex worker forums and by using Google (Alphabet Inc). Prebooking clients and negotiating services and fees through email or web chats were all part of the occupational health and safety strategies used by sex workers to screen potential clients. Through these strategies, sex workers can assess a potential client for violence, nonpayment, and other abusive behavior. These strategies were used by indoor sex workers in Vancouver (Canada) [10], the United Kingdom [33,34], and the United States [44]. Sex workers may also report abusive content to their website administrator because anonymous web-based communication can sometimes result in threats [34] or harassment [33]. In addition, by using the internet, indoor sex workers communicated safe work practices on their website advertisements. In Vancouver (Canada), sex workers advertised the use of condoms and emphasized no drugs and no alcohol during the encounter; cisgender women specified in their advertisements the services that would be provided during client encounters [45]. Sex workers in Detroit (United States) using a web-based service to advertise their services specified the services they would provide during client encounters [44]. Similar practices were used by sex workers in the United Kingdom, Florida (United States), and Sydney (Australia) through communications through web-based advertisements [47,49,52]. With the two-way electronic communication capabilities offered by the internet and with access to the internet through mobile phones, sex workers managed the risks inherent in their profession by engaging in a dialog with clients regarding their acceptable business practices, also known as safe work practices, which mitigated their occupational health and safety risks.

As another example of sex worker–initiated occupational health and safety strategies, sex workers in the United Kingdom used the text messaging app WhatsApp (Facebook, Inc) to form private chat groups to exchange information on clients [33]. In addition, in the United Kingdom, sex workers have implemented an occupational health and safety strategy known as the “buddy system”; this strategy consists of a sex worker using a mobile phone to text a colleague to apprise them about scheduled client encounters, the location of the encounters, and start and end times of the encounters [34].

Verbally communicating with clients using mobile phones is yet another sex worker–initiated occupational health and safety strategy. In India, mobile phones without internet access are the most frequently used ICT. The main occupational health and safety strategy of cisgender women was negotiating condom use with regular clients and potential clients through phone calls [28,30]. The possibility of successfully convincing the client to use a condom was dependent on the cisgender woman’s income streams. If she had no other income apart from sex work, the odds of providing services without a condom were higher [28,30].

Implementation of Occupational Health and Safety Strategies Through ICTs by Organizations External to Sex Workers

In 44% (18/41) of the studies, occupational health and safety strategies were found to be created by organizations external to sex work. These organizations were composed of researchers, public health agencies (PHAs), community-based organizations, and social enterprises working either separately or together. In the studies, the predominant occupational health and safety concern of these organizations was the transmission and prevention of sexually transmitted infection and HIV. The strategies created by these external organizations were disseminated by using the internet, text messaging, and audio broadcast messages through mobile phones. In 24% (10/41) of the studies, occupational health and safety strategies were developed without an explicit indication of sex workers’ input. The next 4 exemplar studies highlight the internet and text messaging as the ICTs used.

Using the internet, and without describing whether collaboration with sex workers occurred on occupational health and safety strategy content, external organizations have reached out to sex workers to apprise them of sexually transmitted infection and HIV prevention strategies. In the first exemplar, in the 2000s (early 21st century) in the United States, PHAs and community-based organizations initiated a health information dissemination campaign by engaging with cisgender male sex workers and their clients in web-based forums and chat rooms in 8 US cities to discuss the risks and prevention of syphilis and HIV [51]. In this study, the forum participants in New York City engaged the PHAs in discussions regarding the risks of condomless sex [51]. The next two exemplars are from China; collaboration with sex workers was not specified in either study. Two quantitative studies examined the feasibility of using the internet to communicate HIV prevention information to indoor cisgender female sex workers [26,27]. In the first study, web-based public service announcements were used to attempt to reduce inconsistent condom use among indoor cisgender female sex workers, with a small percentage of sex workers (6.7%) reporting that they were using condoms consistently after seeing the announcements [26]. In the second study, most of the sex workers surveyed (64%) indicated that they would join a web-based HIV and sexually transmitted infection prevention program [27].

The fourth exemplar features text messaging. In this study, HIV testing was the focus for outdoor cisgender female sex workers in sub-Saharan African countries. The North Star Alliance, a social enterprise, operates roadside wellness clinics in Africa. It designed and implemented a text messaging intervention for HIV prevention by formulating the content of text messages without sex worker input. A cluster randomized controlled trial with two arms was conducted, with one arm receiving the text messaging intervention (the other arm received verbal HIV prevention information at the clinic). A total of 167 sex workers were part of the intervention arm; they were located in South Africa, Zimbabwe, and Mozambique. The text messages encouraged the study participants to use condoms during sex and obtain regular HIV testing. A total of 35 messages were sent over a 29-week period. The study found that condomless sex did not diminish in the cohort using text messaging, but there was an increase in self-reported HIV testing [17].

In 20% (8/41) of the studies, organizations external to sex workers collaborated with the sex worker community in the development of occupational health and safety strategies, as demonstrated in the following four exemplars that highlight these ICTs: IVR, audio broadcast messaging, text messaging, and voice mail messaging.

In the first exemplar, a pilot study in Kolkata, India, was conducted to examine the potential of daily messaging using IVR to improve antiretroviral therapy adherence in people living with HIV. The IVR messages were developed with a community advisory board composed in part of sex workers who were part of a peer support network for sex workers. Brief messages (less than 1 min in duration) focused on strategies for self-management of three domains: medical, mental health, and nutrition and hygiene. In addition, 3 antiretroviral therapy appointment reminders were sent each month. A total of 46 participants were enrolled in the study, and 65% (30) were cisgender female sex workers. After the 1-month pilot, focus groups were convened with the participants to provide feedback on the IVR messages. The results of the focus group discussions demonstrated appreciation for the health and wellness messages. The results after 1 month indicated that medication adherence improved [39].

In the second exemplar, in an ethnographic study in Bangalore, India, audio broadcast messages were formulated by outreach workers with lived urban sex worker experience. The goal of these broadcast messages was to remind urban sex workers (cisgender women) to get tested for HIV and syphilis. In the study, the messages were sent to 230 phone numbers; 121 recipients listened to the entire message [36].

The third exemplar is a study that was conducted in Mexico at 2 locations: Tijuana, with 141 cisgender women, and Ciudad Juarez, with 129 cisgender women. Focus groups with 25 cisgender women in Tijuana provided feedback on the content and relevance of the text messages. There were two types of text messages. One type was short-term oriented, for example, encouraging cisgender women to have condoms handy before they went out for the evening. The second type was more long-term (future) oriented; for example, although condoms are expensive, the gains achieved in maintaining one's health are worth the investment. The text messages were randomly assigned to participants in both cities in the study. The goal of the study was to evaluate the impact of the short- and long-term text messages that were designed to maintain improvements in safer sex practices among drug-using and nondrug-using cisgender female sex workers. The outcome measure was the HIV and sexually transmitted infection incidence rate over the 6-month follow-up period. Cisgender women in Tijuana, where there was a lower percentage of hard drug use, benefited from future-oriented text messages that focused on the advantages of long-term safer sex maintenance practices to achieve future-oriented goals. In contrast, cisgender women in Ciudad Juarez, where there was a higher percentage of methamphetamine, cocaine, heroin (ie, hard drugs), and injectable drug use, did not benefit from either the short-term or future-oriented text messages [21].

The fourth exemplar is a pilot study conducted in Chennai, India. The initial goal of the pilot was to assess whether HIV prevention messages sent by either voice mail or text messages would be acceptable to cisgender male sex workers. Message construction was based on the results of the interviews and focus groups that were conducted using semistructured questions. In addition to acceptable message content for the HIV prevention intervention, the researchers asked the study participants if there were future additional services that they would like to receive. The cisgender men voiced their concerns regarding sexual health, negotiating condom use with clients, stigma, mental health, tuberculosis prevention, and assistance in exiting sex work [40].

The results found in the fourth exemplar were also observed in a number of studies included in this scoping review, meaning that when organizations external to sex work applied participatory methods to the research design, other issues, in addition to the prevention and transmission of sexually transmitted infection and HIV [20,21,36,39,40,56], surfaced. Specifically, sex workers voiced their concerns regarding sexual and reproductive health [40,55], stigma [40], mental health [39], tuberculosis prevention [40], and assistance in exiting sex work [40].

Researchers Surveying Sex Workers' Use of ICTs for Occupational Health and Safety Strategies

Although external organizations worked collaboratively with sex workers to develop occupational health and safety strategies, as illustrated in the aforementioned four exemplars, the use of collaborative methods such as participatory action research (PAR) and community-based participatory research (CBPR; PAR and CBPR come under the umbrella of participatory methods. Participatory methods in research emphasize research with, not on, communities and are a collaborative form of research involving the community in all aspects of the research [65,66]) were applied to studies that involved a collaboration between the sex worker community and researchers endeavoring to investigate the use of ICTs by sex workers for managing occupational health and safety. In the included studies for this scoping review, three collaborations took place in 2 high-income countries, the United Kingdom [33] and Canada [10,35], and one in India, an LMIC [59].

The next two exemplars demonstrate these collaborations. In Vancouver (Canada), a collaboration between researchers and members of the sex work community analyzed the content of qualitative interviews conducted with indoor and outdoor cisgender men and transgender individuals who identify as men to explore the safety aspects involved in transitioning from outdoor to internet-based indoor sex work, such as using webchats to assess a potential client's propensity for violence [10]. In moving to indoor sex work facilitated through the internet, the men in Vancouver (Canada) experienced less stigma perceived to be because of reduced visibility on the street [10]. However, the study found that not all sex workers in the community shifted to an indoor work environment. With more clients having followed the shift to having services provided indoors, fewer clients were available to the street-based sex workers, with an associated loss of income for these sex workers. The study found that the sex workers made up the loss of income by offering services such as anal sex that could be detrimental to their health [10].

The other exemplar was conducted in India [59]. A collaborative effort with sex workers, nongovernmental organizations, and academics resulted in the development of interview guides to study the challenges of using mobile phone communication for indoor and outdoor cisgender female sex workers. Using a mobile phone without internet access to solicit clients assisted the sex workers in moving their work indoors and avoiding the harassment associated with outdoor work [59].

In both studies, the sex workers expressed that the move to indoor work resulted in a decrease in violence, stigma, and harassment. However, the sex workers in both countries experienced a sense of loss of community because they no longer saw each other on the strolls (ie, on the streets) [10,59].

Discussion

Principal Findings

This scoping review examined the occupational health and safety risks experienced by sex workers and the use of ICTs as an occupational health and safety tool to mitigate these risks. Of the 41 studies included, 29 were published between 2015 and 2019, indicating that sex workers have begun to use a number of electronic tools to mitigate the occupational health and safety risks present in their profession. The included studies revealed that sex workers used one or more of the following ICTs: (1) the internet, (2) mobile phones, (3) messaging technology through mobile phones (IVR, voice mail, text, and audio broadcast messaging), and (4) social media apps. The findings suggest that the type of ICT used by sex workers is shaped by the country of employment. In high-income countries, the internet has become a commonly accepted commercial sex venue [67]. Moreover, internet use in high-income countries is greater than that in LMICs [68] and social media apps are commonly used. In LMICs, the predominant ICT is text messaging through mobile phones.

In 83% (10/12) of the countries included in this review, sex work is criminalized, and in 17% (2/12), it is regulated. No studies were found that addressed sex work in a country where it was decriminalized (in New Zealand, where decriminalization has occurred, sex workers are protected by labor laws that enhance their occupational health and safety, and mobile phones are considered an essential safety tool [69]). Legislative models that criminalize sex work in the country of employment were just one of the structural determinants that influenced a sex worker's occupational health and safety risks [70]. Other structural determinants such as working conditions, location, and income outside of sex work [28,30,71] all affected whether a condom was used during the provision of services and the type of services provided [10,50]. In public health studies, condom use is the recommended method for preventing the acquisition and transmission of sexually transmitted infections and HIV, and regular and frequent testing is also recommended to detect possible acquisition. In LMICs, the occupational health and safety strategies delivered through ICTs found in the included studies reflected this public health approach. However, these studies did not address possible financial and societal barriers that could impede sex workers—particularly women—from accessing HIV testing [72].

The criminalization of sex work and the accompanying stigma, as well as the technology available in high-income countries and LMICs, directed the choice of ICTs used by sex workers. In collaborative research projects in LMICs, discretion in receiving occupational health and safety risk mitigation strategies was the overriding concern; therefore, IVR, voice mail, and audio broadcast messaging were the preferred communication methods, as opposed to a text message that could inadvertently be seen by a family member on a sex worker's mobile phone [36,39,40]. In high-income countries, the internet is the prevalent ICT. However, the use of the internet has been impeded by the passage of the 2018 Allow States and Victims to Fight Online Sex Trafficking Act (FOSTA) and Stop Enabling Sex Traffickers Act (SESTA) in the United States, which prohibit sex work content on websites, including harm reduction techniques and advertising [73-75]. Backpage [76] was a popular site for sex worker advertisements [44], but after the passage of the acts, its management no longer allowed sex workers to advertise on the site. The FOSTA-SESTA have also affected Canadian sex workers because 60% of the sex workers used to advertise on Backpage [76] before it was banned [77]. Craigslist, a popular web-based classified advertisements site in Toronto (Canada) and environs, has also banned all sex work–related advertisements [78]. Sex worker organizations are concerned that the safety precautions that internet-based sex workers were able to take are now disappearing because sex workers are being pushed back to outdoor work [73,77]. A recommended area of research would be to examine whether the use of text messaging, IVR, voice mail, and audio broadcast messaging could serve as safe alternative electronic spaces in high-income countries to replace those that have disappeared, not only for advertising purposes but also for sex workers to be able to once more create secure online communities to manage the structural determinants that constrain their health and safety. However, the protection of information communicated through these ICTs would depend on the laws governing electronic communication in these countries (in Canada, the Supreme Court has ruled that electronic conversations are protected by that country's privacy laws [79]). A further recommendation is to examine the creation of new secure online communities using existing or alternative digital technologies, for example, Red Cloud [80] in Australia, a web hosting enterprise that does not come under the FOSTA-SESTA.

This review found that the predominant occupational health and safety concern of organizations external to sex work was the transmission and prevention of sexually transmitted infection and HIV, and the ICT interventions developed by these organizations consisted of pushing sexually transmitted infection and HIV prevention and testing messaging out to either the internet or to sex workers' mobile phones. Only a small number of studies included in this scoping review used collaborative research methods such as PAR and CBPR to either design or study an ICT intervention. In these collaborative studies, sexual and reproductive health, stigma and its associated mental health effects, and violence emerged as the occupational health and safety risks that sex workers were most concerned about [10,33,40,56,59]. PAR and CBPR fall under the umbrella of participatory methods. When sex workers are involved in the research project as members of the research team, the research is no longer a passive exercise [81]. The sex workers' agency is leveraged, and their experiences, both personal and professional, are discussed. Through participatory research methodology used in previous studies with sex workers, structural determinants that affect sex workers' occupational health and safety, such as violence [82], stigma, social norms, lack of support from family and friends [82,83], and social support from community resources and sex worker colleagues emerged, as well as their resilience skills in managing their circumstances [83]. On the basis of these findings, it is recommended that future research involve sex workers in the formulation of the research question and scope of the study to accurately identify the issues that sex workers face in their personal and professional lives. A further area of research would be to compare the longevity and continued effectiveness of interventions designed with sex workers with those designed without sex worker input.

Limitations and Strengths

A limitation of this review is that, for feasibility reasons, only studies published in English were included. By limiting the studies to English, relevant findings may have been missed. In addition, the gray literature was not consulted, which may have resulted in novel ways of using ICTs by sex workers not being represented. Another limitation is that no studies were found that focused solely on transgender sex workers, and studies that did include transgender individuals combined them with cisgender women and cisgender men.

The strengths of this review include the rigor of the methods, including the use of duplication at each phase of the review (article screening and selection, data extraction, and full-text analysis), the absence of limitations with respect to year of publication, and the inclusion of a wide range of study designs. In addition, this study provides a broad overview of the different aspects of ICT use among sex workers across the globe because studies published during the last 15 years were included to account for recent developments in electronic communications technology.

Conclusions

This study provides important insights into how the use of ICTs during the first two decades of the 21st century has shaped the methods that sex workers use to keep themselves safe on the job in environments where sex work is criminalized. This review found that a considerable amount of research on ICT use demonstrated that internet-based sex workers, that is, sex workers using the internet to conduct business, were active creators and sharers of the occupational health and safety strategies used in their work. This review also found that researchers, PHAs, and social enterprises use text messaging as their ICT of choice for pushing sexually transmitted infection and HIV prevention and testing messages out to sex workers' mobile phones, although this is not the main occupational health and safety concern for sex workers. Only a small number of studies in this review engaged sex workers in collaborative research; yet, these collaborations yielded insights into the lives of sex workers and provided direction for future research efforts. Applying participatory methods that engage sex workers of all genders as active participants in the research process will produce applications of digital technology geared toward their occupational health and safety needs.

Abstract

Background: Dysphonia influences the quality of life by interfering with communication. However, a laryngoscopic examination is expensive and not readily accessible in primary care units. Experienced laryngologists are required to achieve an accurate diagnosis.

Objective: This study sought to detect various vocal fold diseases through pathological voice recognition using artificial intelligence.

Methods: We collected 189 normal voice samples and 552 samples of individuals with voice disorders, including vocal atrophy (n=224), unilateral vocal paralysis (n=50), organic vocal fold lesions (n=248), and adductor spasmodic dysphonia (n=30). The 741 samples were divided into 2 sets: 593 samples as the training set and 148 samples as the testing set. A convolutional neural network approach was applied to train the model, and findings were compared with those of human specialists.

Results: The convolutional neural network model achieved a sensitivity of 0.66, a specificity of 0.91, and an overall accuracy of 66.9% for distinguishing normal voice, vocal atrophy, unilateral vocal paralysis, organic vocal fold lesions, and adductor spasmodic dysphonia. Compared with the accuracy of human specialists, the overall accuracy rates were 60.1% and 56.1% for the 2 laryngologists and 51.4% and 43.2% for the 2 general ear, nose, and throat doctors.

Conclusions: Voice alone could be used for common vocal fold disease recognition through a deep learning approach after training with our Mandarin pathological voice database. This approach involving artificial intelligence could be clinically useful for screening general vocal fold disease using the voice. The approach includes a quick survey and a general health examination. It can be applied during telemedicine in areas with primary care units lacking laryngoscopic abilities. It could support physicians when prescreening cases by allowing for invasive examinations to be performed only for cases involving problems with automatic recognition or listening and for professional analyses of other clinical examination results that reveal doubts about the presence of pathologies.

Introduction

The impact of a voice disorder has been increasingly recognized as a public health concern. Dysphonia influences the quality of physical, social, and occupational aspects of life by interfering with communication [1]. A nationwide insurance claims data analysis of treatment seeking for dysphonia showed a prevalence rate of 0.98% among 55 million individuals [2], and this rate reached 2.5% among those older than 70 years [2]. However, the overall dysphonia incidence for the aging population is estimated to be much higher (12%-35%) [3], which may imply that dysphonia is commonly overlooked by patients, resulting in underdiagnosis.

According to the state-of-the-art clinical practice guidelines for dysphonia of the American Academy of Otolaryngology-Head and Neck Surgery Foundation, a laryngoscopic examination is recommended if dysphonia fails to resolve or improve within 4 weeks [4]. A comparison of diagnoses made by primary care physicians and those made by laryngologists and speech-language pathologists with experience in interpreting stroboscopy at multidisciplinary voice clinics indicated that the primary care physicians' diagnoses of dysphonia were different in 45%-70% of cases [4]. However, the laryngoscopic examination is an invasive procedure. To achieve an accurate diagnosis, it must be performed by an experienced laryngologist. The examination equipment is expensive and not generally available in primary care units. In places without sufficient medical resources, delayed diagnoses and treatments are common [5]. Therefore, a noninvasive diagnostic tool is needed to resolve this problem. Although this tool cannot replace the laryngoscopic examination by an experienced physician, it is worthwhile to develop because a noninvasive tool to screen significant clinical conditions could encourage patients to visit a voice clinic for further evaluation.

Several recent studies have attempted to distinguish normal and abnormal voices by using various machine learning–based classifiers that have the potential for detecting pathological voices [5-9]. To date, the highest accuracy of pathological voice detection achieved by using a deep neural network has been 99.32% [5]. However, the differential diagnosis of various types of pathological voices has not been widely reported. The vibration patterns of vocal fold observed by high-speed video for common vocal fold diseases, including vocal atrophy, unilateral vocal paralysis, and organic vocal fold lesions, are completely different [10]. We hypothesized that different vibration patterns could result in different voice features. This study sought to detect various vocal fold diseases through pathological voice recognition using a deep learning approach.

Methods

Sample Collection

This study was performed following the principles expressed in the Declaration of Helsinki, and approved by the Institutional Ethics and Research Committee of Cheng Hsin General Hospital and Fu Jen Catholic University. Voice samples were obtained from the Voice Center of Chen Hsin General Hospital and the Department of Otorhinolaryngology-Head and Neck Surgery of Fu Jen Catholic University Hospital. These samples included 189 normal voice samples and 552 samples of voice disorders, including vocal atrophy (n=224), unilateral vocal paralysis (n=50), organic vocal fold lesions (n=248), and adductor spasmodic dysphonia (n=30). Voice samples of a sustained vowel sound /a:/ followed by continuous speech of a Mandarin passage [11] (Multimedia Appendix 1) were recorded at a comfortable loudness level with a microphone-to-mouth distance of approximately 15-20 cm using a high-quality microphone with a digital amplifier and a 40- to 45-dB background noise level. The sampling rate was 44,100 Hz with 16-bit resolution, and data were saved in an uncompressed .wav format.

Comparison and Evaluation

We first divided the 741 samples into 2 sets: 593 samples for the training set and 148 samples for the testing set. Using computer-based randomization, we selected 152 of the 189 normal voice samples, 40 of the 50 unilateral vocal paralysis samples, 24 of the 30 adductor spasmodic dysphonia samples, 179 of the 224 vocal atrophy samples, and 198 of the 248 organic vocal fold lesion samples for the training set (Table 1).

Table 1. Details of the voice samples used for experiments (N=741).

Sample	Training set (n=593)	Test set (n=148)
Normal	152	37
Unilateral vocal paralysis	40	10
Adductor spasmodic dysphonia	24	6
Vocal atrophy	179	45
Organic vocal fold lesions	198	50

To manage the limited size of the training set, we used a mix-up approach for data augmentation [12]. The mix-up approach has been applied for audio scene classification using convoluted neural networks (CNNs) to reduce overfitting and obtain higher prediction accuracy [13]. We randomly selected 2 voice files and mixed them into 1 voice file with randomly selected weights to construct the virtual training examples. Next, we randomly cropped each of these voice files to achieve 10 voice files with a length of 11.88 seconds (plateau point of the training length within the graphics processing unit memory limitations of our hardware, according to our preliminary tests). Additionally, we used oversampling to adjust the class distribution of the data [14].

A 2D graph is ideal for extracting features when using CNNs. Therefore, we performed Mel frequency cepstral coefficients (MFCCs) for the processed voice file to obtain a spectrogram. Feature extraction from MFCCs was performed using pre-emphasis, windowing, fast Fourier transform, Mel filtering, nonlinear transformation, and discrete cosine transform [15]. The first feature consisted of 40-dimension MFCCs [16,17]. Next, for the second and third features, we calculated the MFCC trajectories over time (delta MFCCs) and the second-order delta of MFCCs. Therefore, there were 3 channels of input features that could be considered a color image (ie, red–green–blue in the computer vision field).

CNNs have distinct feature representation–related characteristics, among which the lower layers provide general feature-extraction capabilities and the higher layers include information that is increasingly more specific to the original classification task [18]. This allows verbatim reuse of the generalized feature-extraction and representation of the lower CNN layers; the higher layers are fine-tuned toward secondary problem domains with characteristics related to the original. Therefore, instead of designing a new CNN with random parameter initialization, it is more suitable to adopt a pretrained CNN and fine-tune its parameterization toward specific classification domains. Spectrograms were quite different from normal images at first glance. However, the low-level features, including edges, corners, and shapes, were common in the normal images and spectrograms [19]. In a previous study, a spectrogram-based crowd sounds analysis using pretrained CNN models from the ImageNet data set showed great accuracy when distinguishing crowd emotions [19]. Another study also proved that pretrained CNN models yielded better performance than nontrained CNN models for classifying normal or pathological cases [18]. We used different CNN architectures, such as EfficientNet-B0 to B6 [20], SENet154 [21], Se_resnext101_32x4d [21], and se_resnet152 [21] models, from the ImageNet data set that have been pretrained for transfer learning. We classified pathological conditions into 2 (normal voice; adductor spasmodic dysphonia plus organic vocal fold lesions plus unilateral vocal paralysis plus vocal atrophy), 3 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions plus unilateral vocal paralysis plus vocal atrophy), 4 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions; unilateral vocal paralysis plus vocal atrophy), or 5 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions; unilateral vocal paralysis; vocal atrophy) different conditions and trained the CNN. For the final prediction of an input instance, we used the maximum probability to obtain the label.

In terms of hyperparameter settings for fine-tuning among the training set, 474 of 593 samples (79.9%) were used for initial training and 119 of 593 samples (20.1%) were used for validation. We added the dropout function and different data augmentation methods to prevent the model from overfitting in our data set [22,23]. The dropout rate was set at 0.25-0.5 for regularization. Then, we trained the model using minibatches of 32 that were selected based on memory consumption [24]. The learning rate was tuned based on cosine annealing and a 1–cycle policy strategy [25,26]. By using the cosine annealing schedule, the model repeatedly fitted the gradient to the local minimum. The network was trained end-to-end using the Adam optimization algorithm, and it optimized the cross-entropy as a loss function [27]. For different classification problems in the model head, we applied a SoftMax layer as an output layer for multiclass classification or a sigmoid layer for binary classification. Finally, we assembled the model by average output probability to receive more robust results to minimize the bias of prediction error to improve the prediction accuracy of the CNN models [25]. The machine learning process was performed using Python 3.8 (Python Software Foundation) and PyTorch 1.7.1 for Ubuntu 18.04 (Facebook's AI Research lab [FAIR]). Furthermore, we invited 2 laryngologists and 2 general ear, nose, and throat (ENT) physicians who could speak Mandarin to categorize the voice samples of the testing sets into 5 classifications. We compared their classifications with those of our model.

Statistical Analysis

The effectiveness of our model was evaluated by several metrics, including accuracy, sensitivity, specificity, F1 score, receiver-operating characteristic (ROC) curve, and area under the curve (AUC). All metrics were calculated using Python.

Results

Voice samples in this study were composed of a sustained vowel sound and a continuous essay speech. We first compared the results by training different parts: the vowel sound alone, the essay alone, and the whole voice sample (ie, the vowel sound and essay). Because the vowel sound and essay group (F1 score=0.65) achieved better F1 scores than the vowel sound group (F1 score=0.54) and the essay group (F1 score =0.57), we applied whole voice samples during subsequent machine learning. Figure 1 shows the changes in the loss function value over the training and validation sets, which demonstrated that our model could converge after running the optimization for a number of epochs.

Figure 1. Illustration of the changes of the loss function value over the training and validation sets.

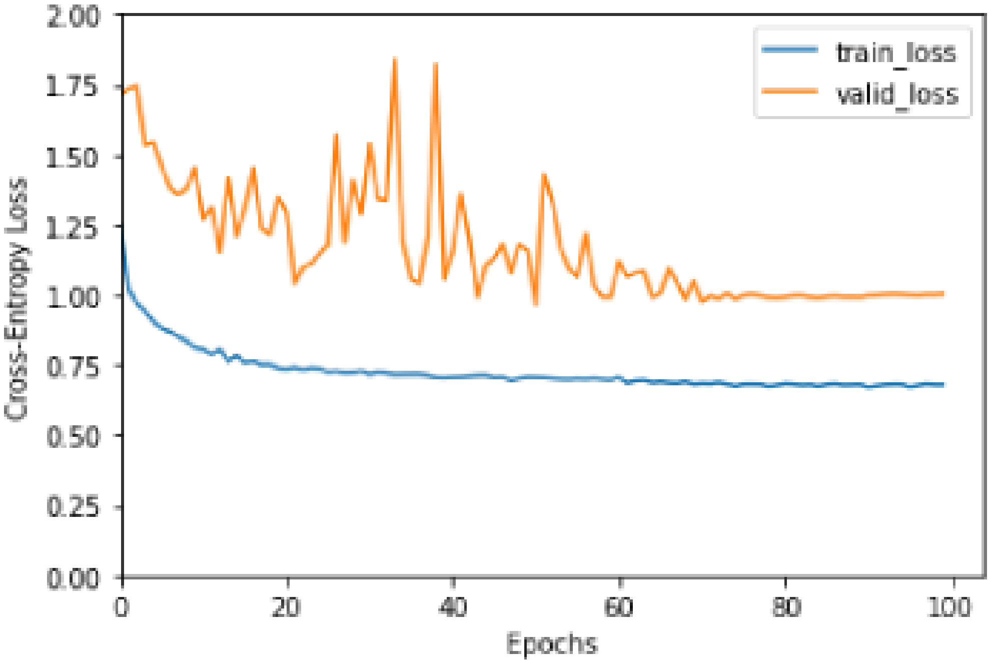

Table 2 presents the training results for the different classification methods, including 2 (normal voice; adductor spasmodic dysphonia plus organic vocal fold lesions plus unilateral vocal paralysis plus vocal atrophy), 3 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions plus unilateral vocal paralysis plus vocal atrophy), 4 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions; unilateral vocal paralysis; vocal atrophy), or 5 (normal voice; adductor spasmodic dysphonia; organic vocal fold lesions; unilateral vocal paralysis; vocal atrophy) different conditions trained by the CNN. The 2-classification condition could equally distinguish pathological voices from normal voices. In our model, the accuracy of pathological voice detection reached 95.3%; the sensitivity was 99%, specificity was 84%, and AUC was 0.98. Using the 3-classification condition, we aimed to identify adductor spasmodic dysphonia patients from those with other vocal fold pathologies. The accuracy was 91.2%, sensitivity was 82%, specificity was 93%, and AUC was 0.91. Using the 4-classification condition, vocal atrophy and unilateral vocal paralysis could be clinically grouped as "glottic insufficiency." For this condition, the accuracy was 71.0%, sensitivity was 75%, specificity was 89%, and AUC was 0.88. Using the 5-classification condition, the accuracy was 66.9%, sensitivity was 66%, specificity was 91%, and AUC was 0.85. Figure 2 shows the confusion matrix of these results. Figure 3 shows the ROC curves of these results.

Table 2. Performance of the artificial intelligence model for classifying voice disorders under different classification conditions.

Class	Sensitivity	Specificity	Accuracy, %	F1 score	Average area under the curve values
2	0.99	0.84	95.3	0.97	0.98
3	0.82	0.93	91.2	0.80	0.96
4	0.75	0.89	71.0	0.75	0.88
5	0.66	0.91	66.9	0.66	0.85

Figure 2. Confusion matrix of 2, 3, 4, and 5 classifications. AN = pathological voice; NC = normal voice; SD = adductor spasmodic dysphonia; PAATOL = unilateral vocal paralysis/vocal atrophy/organic vocal fold lesions; OL = organic vocal fold lesions; PAAT = unilateral vocal paralysis/vocal atrophy; PA = unilateral vocal paralysis; AT = vocal atrophy.

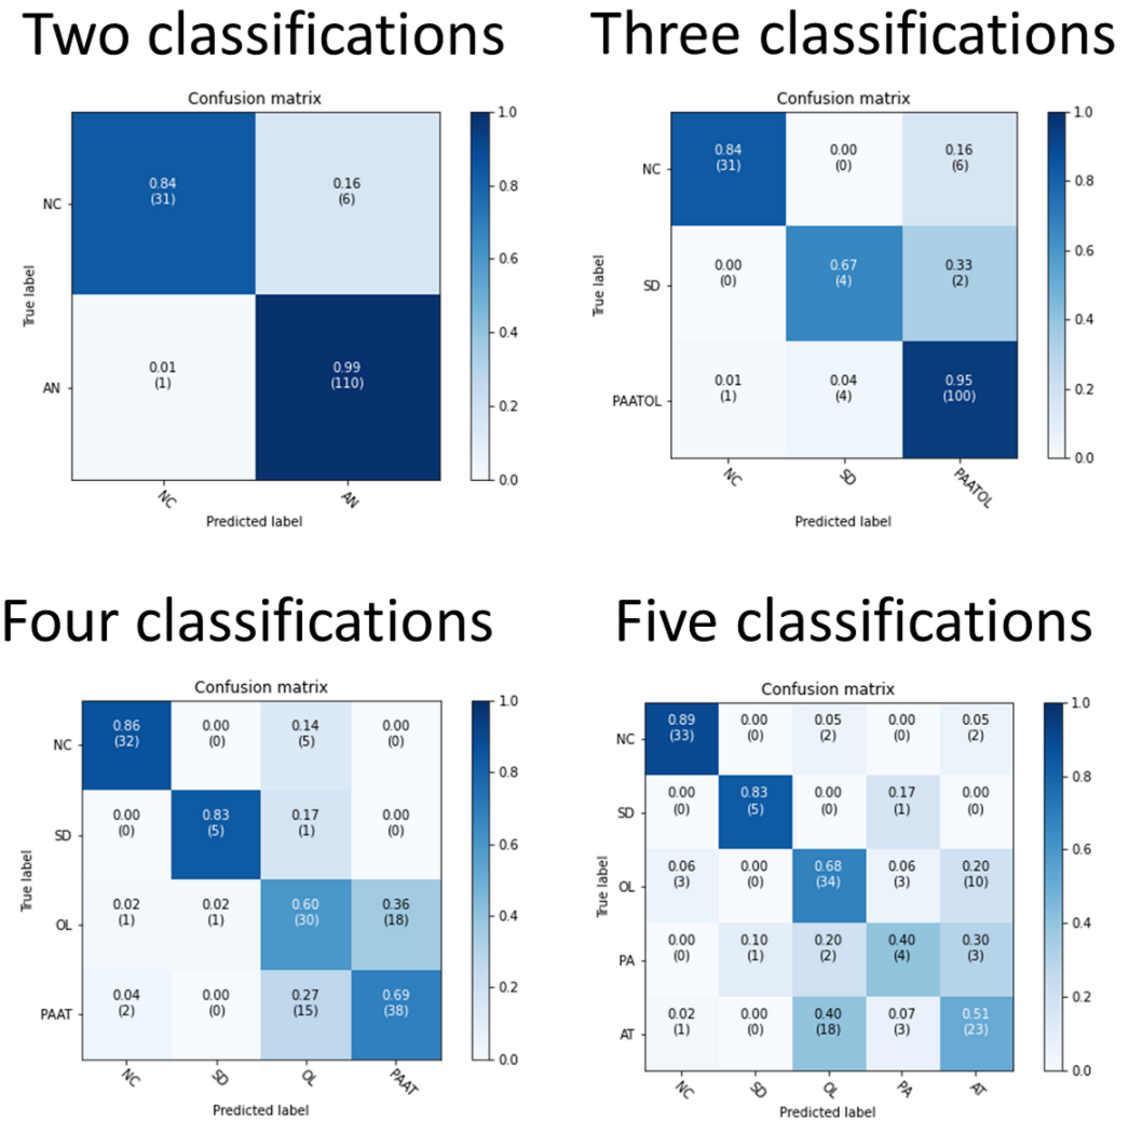

Figure 3. Receiver operating characteristic curves of 2, 3, 4, and 5 classifications. NC = normal voice; SD = adductor spasmodic dysphonia; PAATOL = unilateral vocal paralysis/vocal atrophy/organic vocal fold lesions; OL = organic vocal fold lesions; PAAT = unilateral vocal paralysis/vocal atrophy; PA = unilateral vocal paralysis; AT = vocal atrophy.

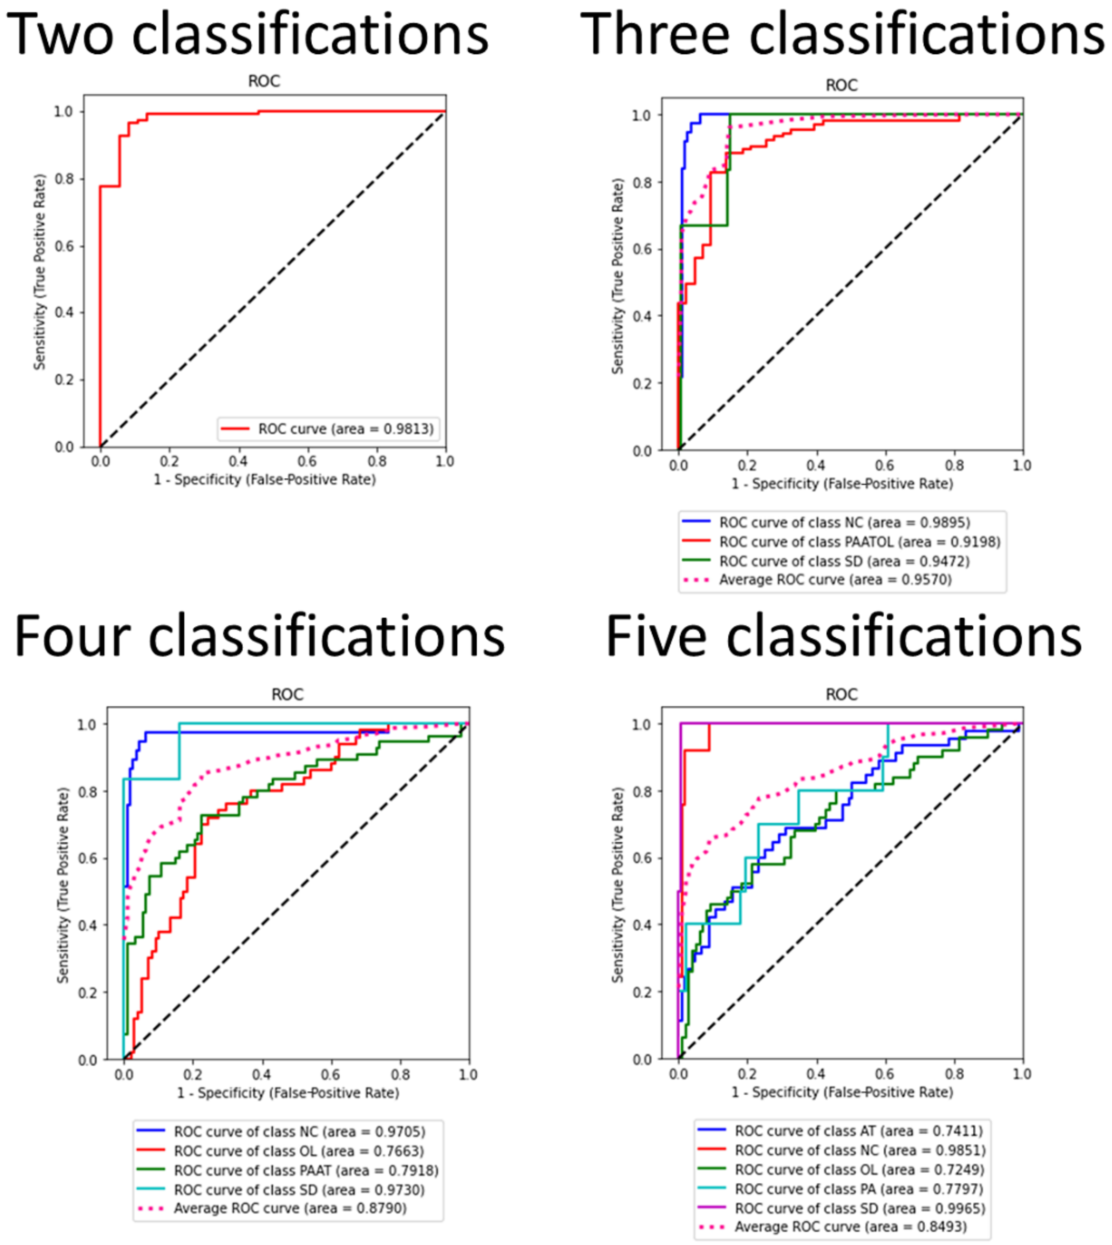


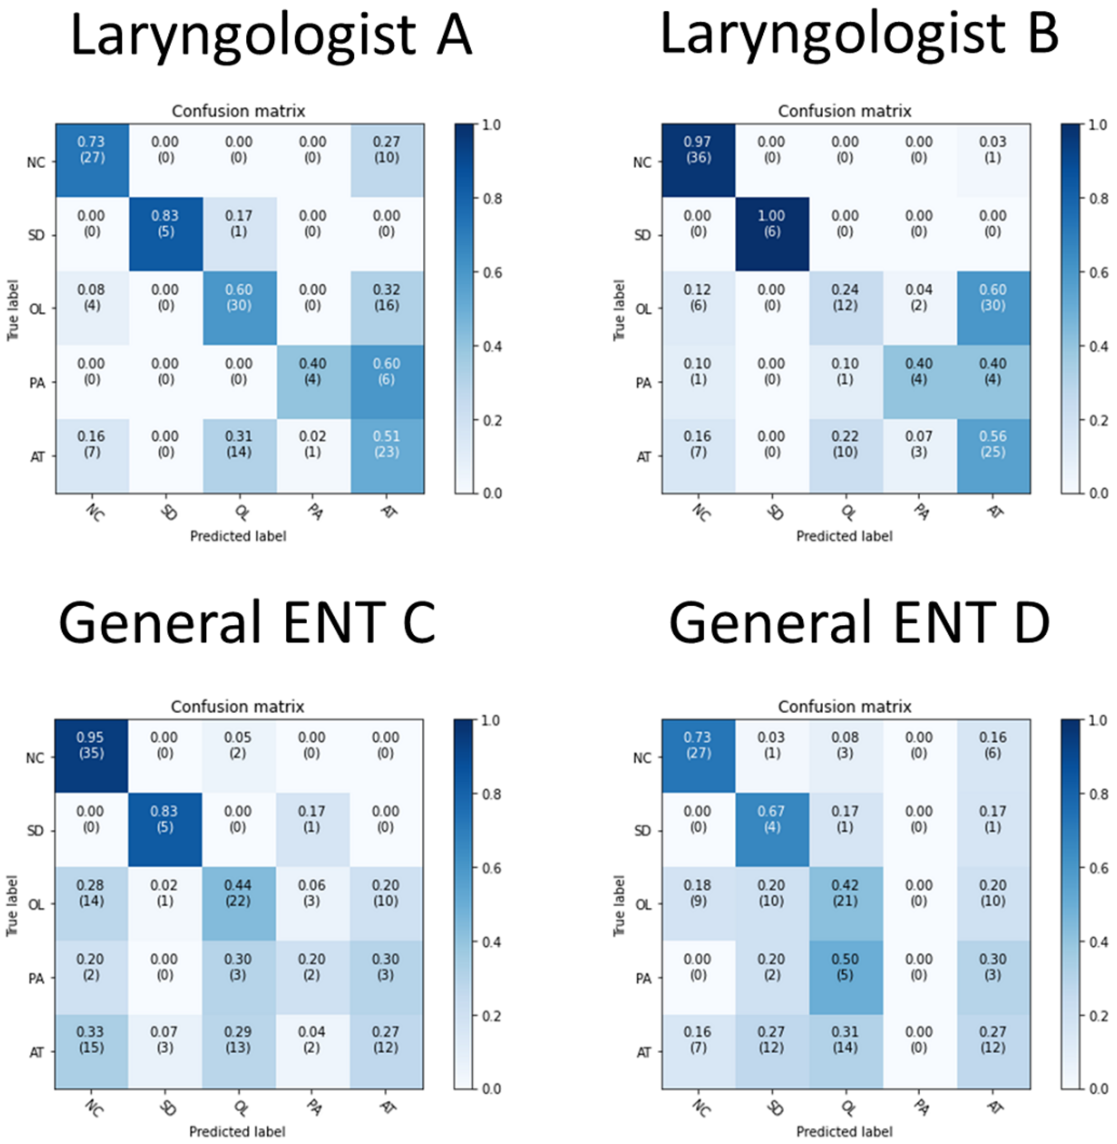
Furthermore, we invited four ENT specialists to identify vocal fold pathology by voice using these 5 classifications. The results are shown in Table 3 and Figure 4. The accuracy rates were 60.1% and 56.1% for the 2 laryngologists and 51.4% and 43.2% for the 2 general ENT specialists.

Table 3. Comparison of the performance for a 5-classification condition by our artificial intelligence model and 4 human experts.

Test participants	Sensitivity	Specificity	Accuracy, %
Deep learning model	0.66	0.91	66.9
Laryngologist A (11 years of experience)	0.61	0.89	60.1
Laryngologist B (10 years of experience)	0.63	0.88	56.1
General ENT[a] C (8 years of experience)	0.54	0.88	51.4
General ENT D (14 years of experience)	0.42	0.85	43.2

[a] ENT: ear, nose, and throat.

Figure 4. Confusion matrix of 5 classifications in human specialists. NC = normal voice; SD = adductor spasmodic dysphonia; OL = organic vocal fold lesions; PA = unilateral vocal paralysis; AT = vocal atrophy.



Discussion

Principal Findings

During this study, we built a CNN model that could distinguish, with high specificity (91%), different pathological voices attributable to common vocal diseases based on voice alone. To the best of our knowledge, no previous study has used artificial intelligence to distinguish different types of pathological voices speaking Mandarin. Using our model, we obtained better results by training the CNN with a whole voice sample than by training it with the vowel sound only or with the essay speech only.

Our model could distinguish normal voice and adductor spasmodic dysphonia with great performance for the 5-classification condition (AUC values: 0.985 and 0.997, respectively). The overall accuracy of our model was also better than that of all ENT specialists participating in the study. This was compatible with our clinical observation that the first impression of the pathological voice is usually over-ruled by the laryngoscopic examination. Additionally, laryngologists demonstrated higher accuracy when diagnosing voice disorders than general ENT specialists. This may imply that it would be possible to improve the accuracy of human physicians in terms of their impressions of pathological voices by increasing clinical experience. After comparing the accuracy of each classification, we found that artificial intelligence was markedly better than laryngologists when identifying organic vocal fold lesions (artificial intelligence, 68%; laryngologist A, 60%; laryngologist B, 24%). However, laryngologists were slightly better at vocal atrophy identification (artificial intelligence, 51%; laryngologist A, 51%; laryngologist B, 56%).

Organic vocal fold lesions, unilateral vocal paralysis, and vocal atrophy could result in a closure gap during phonation, inducing a weak and breathy sound [28-30], and vocal fold tension imbalance, inducing diplophonia (when a voice is perceived as being produced with 2 concurrent pitches) [31]. Specifically, in the case of organic vocal fold lesions during vibration, the lesion divided the fold into 2 oscillators. However, in the case of unilateral vocal paralysis, vibrating frequencies were different between the normal vocal fold and paralysis vocal fold. Vocal atrophy will show a breakdown of vibration with a visible repetition in the loss of normal vibration every few glottal cycles [10]. However, the difference in the vibration pattern could only be observed by high-speed video and multislice digital videokymography [10], and the resulting pathological voice is difficult for humans to identify. We speculated that our model may identify related features through deep learning to achieve better outcomes.

Laryngologists could distinguish aged and young patients, and they could validate their judgment during the test based on their knowledge. Vocal atrophy is the most common vocal fold pathology in older patients [3]. Therefore, laryngologists may classify the pathological voice as vocal atrophy if they judged that the voice was that of an aged person.

Regarding misclassification, we have found that our model could successfully identify normal voice and spasmodic dysphonia. However, it was relatively difficult to differentiate organic vocal lesions, unilateral vocal paralysis, and vocal atrophy from each other. Although the vibration patterns were different for these 3 diseases, the different severity levels of disease could result in different degrees of hoarseness. For example, with tiny vocal nodules compared with huge vocal polyps, unilateral vocal paralysis with fair compensation compared with unilateral vocal paralysis with a huge closure gap, and vocal atrophy with a mild anterior closure gap compared with vocal atrophy with a huge closure gap, there could be different degrees of hoarseness in the same group. We assumed that the less severe cases in each group may not show the typical pathological vibration pattern. Further studies are needed to validate our hypothesis.

Four human specialists required 40-80 minutes to identify 148 voice samples of the test set; however, our model only required 30 seconds to perform the same task. The processing time of our model is quite promising in terms of the development of future screening tools.

Comparison With Prior Work

Most previous studies have used sustained vowel sounds for pathological voice detection [5,7,8]. However, other studies have used continuous speech samples for analyses [6]. CNNs extract features automatically from the spectrogram of voice recordings for dysphonia diagnosis, and a larger amount of training data yields better results [32]. Therefore, the CNN used here may have extracted more features from these entire voice samples, thereby achieving better training results with our model.

In this study, we used our voice database for the deep learning approach. The most widely used voice disorder database is the Massachusetts Eye & Ear Infirmary (MEEI) Voice Disorders Database (commercially available from KayPENTAX Inc.). The MEEI voice samples (53 normal and 662 pathological voices) are composed of the vowel /ah/ (53 normal and 657 pathological voices) and the utterance of a sentence ("When the sunlight strikes raindrops in the air, they act as a prism and form a rainbow") [33]. However, the voice recordings in the MEEI database were recorded at various sampling rates (10, 25, and 50 kHz), and normal and pathological voice recordings were recorded in 2 different environments [32]. Therefore, it was not clear whether artificial intelligence was classifying voice features or environments when trained using the MEEI samples.

The other widely used voice disorder database is the Saarbruecken Voice Database, which contains voice recordings from more than 2000 individuals. Each participant file contains recordings of sustained vowel sounds of /a/, /i/, and /u/ in low, neutral, high, and low–high–low pitches, as well as a continuous speech sentence ("Guten Morgen, wie geht as Ihnen?"). All these samples were recorded at 50-kHz sampling rates and 16-bit resolution [32]. The Saarbruecken Voice Database is considered to be superior to the MEEI database because it uses the same recording environment and the same sampling rates. However, it contains 71 different dysphonia pathologies and many patients recorded in this database had multiple disorders. Therefore, it is difficult to achieve denotation before machine learning.

Our database has several advantages. First, all voice data were from patients visiting our clinics who had detailed chart documents that were carefully reviewed by 2 experienced laryngologists (H-CH and S-YC). Therefore, the quality of the primary data was better than that of the primary data of other studies during which voice data were retrieved from a public database. Second, all voice data were recorded using 44.1-kHz sampling rates and 16-bit resolution, which comprise the standard audio CD format. This widely used format could increase the usability of this data set. Third, we focused on 4 vocal fold diseases that were chosen by experienced laryngologists based on the cause of hoarseness, clinical significance, and prevalence of the disease.

In terms of the cause of hoarseness, adductor spasmodic dysphonia is a focal laryngeal dystonia characterized by irregular and uncontrolled voice breaks that interrupt normal speech [34]. However, organic vocal fold lesions, unilateral vocal paralysis, and vocal atrophy could induce a breathy sound with a different diplophonia pattern [10]. The voice pattern of adductor spasmodic dysphonia is quite different from that of the other pathologies included in this study, and classic cases of adductor spasmodic dysphonia could be diagnosed based on voice alone by experienced laryngologists. The accuracy rates of adductor spasmodic dysphonia among laryngologists using the 5-classification condition were 100% and 83% during this study. Therefore, we anticipated that the sensitivity and specificity for diagnosing adductor spasmodic dysphonia could be higher than those of other categories. However, during the first attempt at CNN training, the accuracy of adductor spasmodic dysphonia identification was poor (data not shown). When we attempted to splice the original voice file into 1-second clips while training the model, we found that the voice break in adductor spasmodic dysphonia did not always emerge within every 1-second period.

After prolonging the duration of the voice clips in the training model, the results improved substantially. This also emphasized that the domain knowledge could significantly influence the training results by tuning the training model according to real clinical conditions.

According to a meta-analysis, in terms of clinical significance, patients with neurologic voice disorders have more challenges than patients with inflammatory or traumatic laryngeal diseases [1]. Specifically, adductor spasmodic dysphonia showed the worst Voice Handicap Index (VHI) score, followed by unilateral vocal paralysis [1]. This result was compatible with our clinical observation that adductor spasmodic dysphonia could markedly interfere with communication and socialization during the daily lives of patients. Although adductor spasmodic dysphonia is a rare disease with a prevalence of 14 out of 100,000 [35], it is worthwhile to offer a model for rapid screening because the symptoms can be treated easily and effectively by regular intralaryngeal botulinum toxin type A injections or surgery [35].

According to VHI scores, unilateral vocal paralysis could also induce a severe voice handicap [1]. The most common cause of unilateral vocal paralysis is an idiopathic or postviral infection, which accounts for 67% of cases [36]. However, 6% of patients have underlying malignancies that invade the recurrent laryngeal nerve or vagus nerve [36]. Computed tomography of the skull base, neck, and chest is often recommended during the search for a potential cause of the voice disorder [37]. Thyroid disease, including benign nodules, thyroid malignancy, thyroiditis, hyperthyroidism, and hypothyroidism, may also result in vocal fold paresis [38]. Heman-Ackah et al [38] reported that 47.4% of patients with unilateral vocal paralysis are diagnosed with concurrent thyroid disease. Therefore, it is important to determine an early diagnosis of unilateral vocal paralysis to investigate the existence of underlying disease.

Organic vocal fold lesions comprise benign lesions, such as nodules, polyps, cysts, polypoid vocal folds, precancerous leukoplakia, and malignant lesions [39,40]. The cause of hoarseness with benign and malignant vocal fold lesions involves changes in the laryngeal mucosa and mass effects [10,40]. To date, it has been difficult to differentiate organic vocal fold lesions further by voice alone because they involve various pathologies. However, it is worthwhile to inform patients about the possibility of organic vocal fold lesions and to advise them to undergo further investigations. Early stage malignant lesions and benign lesions could be treated with office-based surgery, which is safer and relatively inexpensive compared with surgery in the operating room [29,41,42]

The most common cause of vocal atrophy is aging. Aging may result in atrophic musculature and a thinner lamina propria of the vocal fold [43]. However, vocal atrophy can also occur in a relatively young population [28]. It may result from a congenital anomaly or prolonged laryngopharyngeal reflux [44]. The symptoms associated with vocal atrophy are relatively subtle compared with those of other vocal fold diseases [45]. The concern about significant underlying diseases is also reduced with vocal atrophy. However, vocal atrophy is the most common vocal fold pathology among patients older than 65 years [3]. With the aging of the population, vocal atrophy may become a significant geriatric issue in the future.

Limitations

Our study had some drawbacks. First, all the voice files were recorded in the studio with a silent environment, with sensitive audio-recording technology, and using a certain format. Further studies are needed to validate this approach in different recording environments. Second, all the voice data in this study are from Mandarin speakers. Further studies are needed to compare the results of speakers of different languages. Third, the voice sample numbers of each class were unequal because of the different disease prevalence. We have applied several data augmentation methods to ameliorate the influence of these unequal data. Fraile et al [46] showed that laryngeal pathology detection using voice records based on MFCC and prior differentiation by sex can significantly improve the performance. Fang et al [47] also showed that a deep neural network combining supervectors with medical records could improve pathological voice classifications. Therefore, in the future, we will combine demographic data with voice records to improve our model.

Conclusions

We demonstrated that voice alone could be used for common vocal fold disease recognition using a deep learning application after training with our Mandarin pathological voice database. Specifically, adductor spasmodic dysphonia, organic vocal fold lesions, unilateral vocal paralysis, and vocal atrophy could be recognized, which could increase the potential of this approach to be more beneficial than simply distinguishing a pathological voice from a normal voice. This approach shows clinical potential for use during general screening of different vocal fold diseases based on voice and could be included in quick evaluations during general health examinations. It could also be used for telemedicine in remote regions that lack laryngoscopy services in primary care units. Overall, it could support physicians during prescreening of cases by allowing for invasive examinations to be performed only for cases involving problems with automatic recognition or listening and for professional analyses of other clinical examination results that reveal doubts about the presence of pathologies.

Abstract

Background: As a daily point measurement, basal body temperature (BBT) might not be able to capture the temperature shift in the menstrual cycle because a single temperature measurement is present on the sliding scale of the circadian rhythm. Wrist skin temperature measured continuously during sleep has the potential to overcome this limitation.

Objective: This study compares the diagnostic accuracy of these two temperatures for detecting ovulation and to investigate the correlation and agreement between these two temperatures in describing thermal changes in menstrual cycles.

Methods: This prospective study included 193 cycles (170 ovulatory and 23 anovulatory) collected from 57 healthy women. Participants wore a wearable device (Ava Fertility Tracker bracelet 2.0) that continuously measured the wrist skin temperature during sleep. Daily BBT was measured orally and immediately upon waking up using a computerized fertility tracker with a digital thermometer (Lady-Comp). An at-home luteinizing hormone test was used as the reference standard for ovulation. The diagnostic accuracy of using at least one temperature shift detected by the two temperatures in detecting ovulation was evaluated. For ovulatory cycles, repeated measures correlation was used to examine the correlation between the two temperatures, and mixed effect models were used to determine the agreement between the two temperature curves at different menstrual phases.

Results: Wrist skin temperature was more sensitive than BBT (sensitivity 0.62 vs 0.23; *P*<.001) and had a higher true-positive rate (54.9% vs 20.2%) for detecting ovulation; however, it also had a higher false-positive rate (8.8% vs 3.6%), resulting in lower specificity (0.26 vs 0.70; *P*=.002). The probability that ovulation occurred when at least one temperature shift was detected was 86.2% for wrist skin temperature and 84.8% for BBT. Both temperatures had low negative predictive values (8.8% for wrist skin temperature and 10.9% for BBT). Significant positive correlation between the two temperatures was only found in the follicular phase (*rmcorr* correlation coefficient=0.294; *P*=.001). Both temperatures increased during the postovulatory phase with a greater increase in the wrist skin temperature (range of increase: 0.50 °C vs 0.20 °C). During the menstrual phase, the wrist skin temperature exhibited a greater and more rapid decrease (from 36.13 °C to 35.80 °C) than BBT (from 36.31 °C to 36.27 °C). During the preovulatory phase, there were minimal changes in both temperatures and small variations in the estimated daily difference between the two temperatures, indicating an agreement between the two curves.

Conclusions: For women interested in maximizing the chances of pregnancy, wrist skin temperature continuously measured during sleep is more sensitive than BBT for detecting ovulation. The difference in the diagnostic accuracy of these methods was likely attributed to the greater temperature increase in the postovulatory phase and greater temperature decrease during the menstrual phase for the wrist skin temperatures.

Introduction

Background

Basal body temperature (BBT) is the lowest body temperature in the circadian rhythm. Monitoring BBT is one of the simplest and least invasive methods for determining the occurrence of ovulation and estimating its timing during the menstrual cycle [1]. In most women, BBT reaches its lowest point in each cycle just before ovulation and increases in the luteal phase because of the thermogenic properties of progesterone [2]. This physiological change is known as a temperature shift that presents as a biphasic pattern on the BBT curve [3].

Oral temperature taken immediately upon waking is widely used for measuring BBT by women who are interested in tracking their menstrual cycles or women who are trying to conceive because it is easy to use and noninvasive [4]. As a daily point measurement, BBT curves are sensitive to missing values and the time of measurement; a temperature shift may go undetected because a rise in body temperature may not have occurred yet at the time of the measurement [5]. In addition, lifestyle factors may strongly influence the reliability of this method [6]. A number of devices offering continuous temperature measurements at different body sites have been developed over the past decade [7-13]. In our previous studies, we have shown that continuously measured wrist skin temperature during sleep also presented a biphasic pattern in menstrual cycles, with 82% of the observed cycles having a sustained 3-day temperature shift [9,12].

Objectives

The primary objective of this study is to determine whether continuously measured wrist skin temperature during sleep was more accurate in detecting ovulation than BBT measured by oral temperature, using luteinizing hormone (LH) tests as the standard reference. The secondary objective is to investigate the correlation and agreement between these two temperatures in describing thermal changes in menstrual cycles.

Methods

Study Design and Participants

This prospective comparative diagnostic accuracy study was conducted from February to August 2019. The study was conducted in accordance with the Declaration of Helsinki and was approved by the Cantonal Ethics Committee of Zurich, Switzerland (BASEC-Nr 2016-02241). All participants provided written informed consent before any study procedures were performed.

A convenience sample of participants was recruited through social media advertisements and networks from January to February 2019. At the time of enrollment, the research staff assessed the eligibility of potential participants using a screening questionnaire. This assessment was conducted at the Department of Reproductive Endocrinology, University Hospital of Zurich. Healthy women who met the following criteria were considered eligible: aged 18-45 years, not currently on hormonal therapy, willing to comply with the study protocol for up to six cycles, not planning pregnancy within the following 6 months, and currently living in Switzerland. Women were excluded if they had problems wearing the bracelet, had difficulty understanding the study procedures, had any health-related issues potentially affecting their menstrual cycles, were taking any medication or other substances that could affect the menstrual cycles or any physiological parameters being studied, were working night shifts or frequently traveling between different time zones, had a sleeping disorder or slept less than 4 hours per night, or were actively breastfeeding. Eligibility criteria had no restrictions on the regularity or length of menstrual cycle.

Information on age, body weight, body height, race, and time since stopping hormonal contraception was collected after receiving informed consent. BMI was calculated as kg/m^2. During the study period, participants measured continuous wrist skin temperature using the Ava Fertility Tracker, BBT using the Lady-Comp, and a home-based urine LH test using the ClearBlue Digital Ovulation Test (Swiss Precision Diagnostics GmbH). Participants received all the study materials, including detailed guidelines and study devices. The research staff provided participants with instructions on using the study devices and steps to be completed during the study. Contact details of the research staff and technical support staff for the Ava Fertility Tracker are provided. Participants were instructed to start all study measurements from the first day of enrollment, independent of their menstrual cycle day. This was done to enhance compliance and ensure that any issues were promptly resolved before the commencement of the next cycle.

Continuous Wrist Skin Temperature and BBT Measurement

Participants wore the Ava Fertility Tracker bracelet (version 2.0, Ava AG) on the dorsal side of their wrist (always of the same arm) each night while sleeping. The bracelet measures four physiological parameters simultaneously: wrist skin temperature, heart rate, heart rate variability, and breathing rate. The latter three parameters were not of interest to this study and thus were not included. At least 4 hours of relatively uninterrupted sleep each night is required for the physiological parameters to stabilize according to the manufacturer's packaging. The bracelet automatically saves physiological information every 10 seconds throughout the night. For this study, the first 90 minutes and the last 30 minutes of each night's data were excluded to avoid disturbances of the falling asleep and waking up phases. Temperature data were smoothed using locally weighted scatterplot smoothing. The 99th percentile (stable maxima) was chosen out of several percentiles (10th, 50th, and 90th percentiles) as the daily wrist skin temperature in the final analyses [12]. During the initial interview, participants were shown how to synchronize the device with the complementary Ava app on their smartphones and were instructed to synchronize their data each morning after waking up. During synchronization, the anonymized device data were transferred to the server. After completion of the study, the research staff retrieved the wrist skin temperature data obtained during the study period from the server for the final analysis.

BBT was measured by Lady-Comp (Valley Electronics AG), which is a computerized fertility tracking device with a digital thermometer. The device includes a display panel that provides immediate temperature readings to its user. The participants measured their oral temperature using the device each morning immediately after waking up, before getting out of bed, and before starting any activity such as drinking water. BBT data were retrieved by connecting the device to a computer. For each participant, a file containing the BBT data obtained during the study period was downloaded from the manufacturer's website. After completing the study, participants either retrieved the data and sent them to the research staff or they sent the device to the research staff, who retrieved the data. The device was returned to the participants after the data retrieval.

Participants recorded the first day of menstrual bleeding on both the Ava app and Lady-Comp. The first day of bleeding was defined as the first day of the cycle. In case of discrepancies, the date on the Ava app was used.

LH Test

Participants performed a home-based urine LH test using the ClearBlue Digital Ovulation Test [14] for each cycle according to the manufacturer's instructions. Home-based LH tests are widely used to detect ovulation and determine the fertile window [1,15]. For this study, the test was performed on prespecified days of the participant's menstrual cycle. The starting day was calculated by identifying a participant's average number of cycle days and then subtracting it by 17 days. After the initial test, the participant continued doing the LH test daily until a positive result, which was shown as *a stable smiling face* symbol on the device, or until the next menstruation. A positive result indicates an LH surge, which typically occurs 1 day before ovulation [13]. Participants reported the LH test results in the dedicated field of their Ava app. The day following the LH surge was defined as the day of ovulation. A cycle with a positive LH test was considered as an ovulatory cycle, and one with only negative LH tests was considered an anovulatory cycle. The LH test served as the reference standard for evaluating the diagnostic accuracy of the two temperatures.

Statistical Analyses

This study was a subanalysis of a prospective diagnostic accuracy study that compared the 2 fertility tracking devices with the LH test. The hypothesis of the main study was that the Ava Fertility Tracker bracelet was equivalent to the Lady-Comp and LH tests in determining the ovulation day. The final analyses in the main study were restricted to ovulatory cycles. Assuming a clinically meaningful margin of ±2 days, SD of 3 days, a mean difference of 0, an intraclass correlation coefficient of 0.147, and three cycles per woman, 39 cycles from 13 women were required with 90% power and a one-sided α of .025. Assuming a 20% loss to follow-up and up to 50% of the cycles were excluded because of being anovulatory or missing data, a total of 58 women were planned for this study. This subanalysis study only used the temperatures collected by the 2 devices as index tests. All ovulatory and anovulatory cycles, except those affected by missing data, were included in this subanalysis study.

A simplified diagram presented the numbers of screened, eligible, consented, compliant, withdrawing, and lost to follow-up participants. Cycles with missing LH test results or ≥30% missing temperature measurements of either device were excluded from the final analysis. The baseline characteristics of the participants and their cycles were summarized using descriptive statistics. Continuous parameters were summarized as mean (SD), and categorical parameters were summarized as frequency (%). A temperature shift occurred if three temperature measurements were 0.2 °C above the highest value of the previous six measurements or of the previous five out of six measurements in case of missing values [1]. On the basis of this definition, multiple temperature shifts could be detected within a cycle. To avoid including variations in temperatures because of reasons other than the menstrual rhythm, such as sickness, we analyzed only those temperature shifts occurring during the last 14 days of a cycle. The total number of temperature shifts per cycle, the percentage of cycles showing at least one temperature shift, and the first day of the temperature shift relative to the day of ovulation were recorded. The diagnostic accuracy of using at least one temperature shift on the two temperature curves for detecting ovulation was evaluated using the LH test as the reference standard. Diagnostic accuracy measures included sensitivity, specificity, and predictive values, considering the nested design of the study.

The analyses of correlation and agreement between the two temperatures were performed only for ovulatory cycles because the ovulation day was required to separate the menstrual phases. Correlations between mean wrist skin temperature and mean BBT at the follicular and luteal phases were examined using repeated measures correlation (R package *rmcorr*). The *rmcorr* correlation coefficient (r_{rm}) determines the common intraindividual association for paired measurements assessed on two or more occasions for multiple individuals [16]. Linear mixed effects models with random intercepts and random slopes were used to examine the agreement between the curves of the wrist skin temperatures and BBT. In these analyses, daily temperature measurements were nested within cycles, and the cycles were nested within the participants. Linear mixed effects models allow the modeling of repeated measurements, further accounting for correlated intraindividual and intracycle observations [12]. Daily temperature measurements were estimated from the models. The temperature curves at the cycle level were smoothed using locally weighted scatterplot smoothing. As curve patterns changed within a cycle, the agreement between curves was examined in three separate phases: (1) the menstrual phase referred to the period from day 1 to day 5 of a menstrual cycle; (2) the preovulatory phase referred to the period starting 10 days before ovulation and lasting through the day of ovulation; and (3) the postovulatory phase referred to the period starting 1 day after ovulation to 10 days after ovulation. A temperature curve was considered biphasic if at least one temperature shift was present. A curve was monophasic if a temperature shift was absent.

All statistical analyses were performed using the R software (version 3.6.0). All hypotheses were two-tailed. Statistical significance was set at *P*<.05.

Results

Participants and Cycles

In total, 266 cycles were collected from 63 women (Figure 1). The final analysis included 193 cycles of 57 women. A total of 88.1% (170/193) of cycles from 55 women were ovulatory (cycles with positive LH test), and 11.9% (23/193) from 18 women were anovulatory (cycles with only negative LH test). Table 1 presents the characteristics of the participants and their cycles. In total, 9% (2/23) anovulatory cycles were less than 24 days, and 13% (3/23) were more than 35 days. No ovulatory cycles were less than 24 days, but 4.1% (7/170) were more than 35 days. Most of the ovulatory cycles (146/170, 85.9%) had a luteal phase length between 11 days and 17 days and only 13.5% (23/170) were ≤10 days.

Cycle length (days), min-max	24-60
Luteal length (days), mean (SD)	12.2 (1.9)
Luteal length, min-max	3-20

Temperature Shifts and Diagnostic Accuracy

For ovulatory cycles, the percentage of cycles with at least one temperature shift was significantly higher on the wrist skin temperature curves than that on the BBT curves (106/170, 62.4% vs 39/170, 22.9%; *P*<.001); however, the temperature shift occurred almost 2 days earlier on the BBT curves than on the wrist skin temperature curves (*P*<.001; Table 2). For anovulatory cycles, the percentage of cycles with at least one temperature shift was also significantly higher on the wrist skin temperature than on the BBT curves (17/23, 74% vs 7/23, 30%; *P*=.004).

Using the LH test as the reference standard for ovulation, the wrist skin temperature was more sensitive than the BBT (sensitivity 0.62 vs 0.23; *P*<.001) with a higher true-positive rate (106/193, 54.9% vs 39/193, 20.2%); however, it also had a higher false-positive rate (17/193, 8.8% vs 7/193, 3.6%), which resulted in a lower specificity (0.26 vs 0.70; *P*=.002; Table 2).

The positive predictive value was slightly higher for the wrist skin temperature. For a temperature shift detected on a wrist skin temperature curve, there was an 86.2% probability of ovulation. On the BBT curve, this probability was 84.8%. The negative predictive value was low for both temperatures (*P*=.39). If no temperature shift was shown on a wrist skin temperature curve, there was only an 8.6% probability that this had been an anovulatory cycle. This probability on a BBT curve was slightly higher (10.9%), but the difference was not statistically significant (*P*=.74).

Table 2. Temperature shifts and diagnostic accuracy for wrist skin temperature and basal body temperature.

Variables	Wrist skin temperature	Basal body temperature
Ovulatory cycles		
Total number of temperature shifts detected, n	240	47
Cycles with ≥1 temperature shift, n (%)	106 (62.4)[a]	39 (22.9)[a]
With 1 temperature shift	40 (37.7)[b]	31 (79)[c]
With 2 temperature shifts	31 (29.2)[b]	8 (21)[c]
With 3 temperature shifts	15 (14.2)[b]	0 (0)
With >3 temperature shifts	20 (18.9)[b]	0 (0)
The first day of temperature shift relative to ovulation day, mean (SD)	4.4 (2.75)	2.69 (1.89)
Anovulatory cycles

Correlation of the Two Temperatures

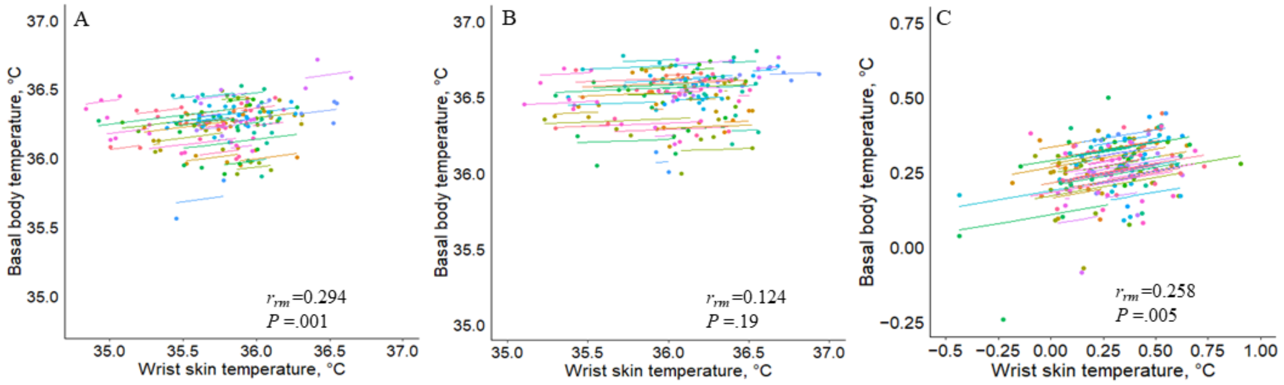
Both temperatures differed between the follicular and luteal phases, with the latter having higher temperatures (Table 3). Throughout the menstrual cycle, the wrist skin temperature was generally lower than BBT. The mean between-phase temperature change was 11% higher for the wrist skin temperature than for the BBT.

Table 3. Mean follicular and luteal phase temperatures for wrist skin temperature and basal body temperature.

Phases	Wrist skin temperature (°C), mean (SD)	Basal body temperature (°C), mean (SD)
Follicular phase	35.78 (0.34)	36.25 (0.16)
Luteal phase	36.07 (0.35)	36.51 (0.16)
Between-phase temperature change	0.29 (0.21)	0.26 (0.1)

Figure 2 shows the repeated measures correlation plot for the means of the two temperatures. Each dot represents the mean of the two temperatures in one menstrual cycle of a woman. Observations from the same woman are given the same color, with corresponding lines showing the repeated measures correlation fit for each woman. Positive correlations were found only in the follicular phase (r_{rm}=0.294; 95% CI 0.117-0.454; *P*=.001). This correlation showed a minimal interindividual variation, which was reflected by the mostly parallel lines. In the luteal phase, no correlation was found between the two temperatures (r_{rm}=0.124; 95% CI −0.061 to 0.301; *P*=.19). We found positive correlations for between-phase temperature changes measured at the two temperatures (r_{rm}=0.258; 95% CI 0.078-0.422; *P*=.005).

Figure 2. Repeated measures correlation (rmcorr) plots of mean wrist skin temperature and basal body temperature. A: correlation in the follicular phase; B: correlation in the luteal phase; C: correlation of between-phase temperature changes between the two temperatures.



Agreement of Temperature Curves

The agreement of temperature curves was analyzed for ovulatory cycles. Figure 3 shows the smoothed curves of wrist skin temperatures and BBT during the postovulatory, menstrual, and preovulatory phases. There was no overlap between the two curves, and the agreement differed by phase. Changes in the two temperatures were not observed during the postovulatory and menstrual phases. Both temperature values increased during the postovulatory phase with a greater and more continuous increase in the wrist skin temperature (range of increase 0.50 °C vs 0.20 °C). The estimated daily difference between the two temperatures was the greatest on day 2 (0.64 °C) and the smallest on day 10 after ovulation (0.32 °C), with a mean of 0.49 °C (*P*<.001). During the menstrual phase, the wrist skin temperature exhibited a more substantial decrease (from 36.13 °C to 35.80 °C, range of decrease: 0.33 °C) than BBT (from 36.31 °C to 36.27 °C; range of decrease: 0.04 °C). The estimated daily difference between the two temperatures ranged from 0.18 °C on day 1 to 0.46 °C on day 5, with a mean difference of 0.32 °C (*P*<.001). During the preovulatory phase, there were minimal changes in both the wrist skin temperature (range: 0.09 °C) and BBT (range: 0.07 °C) and a small variation in the estimated daily difference between the two temperature values, indicating an agreement between the two curves. The mean daily difference between the two temperatures was 0.53 °C (*P*<.001).

Figure 3. Smoothed temperature curves according to phases. A: postovulatory phase; B: menstrual phase; C: preovulatory phase. Solid and dotted lines represent wrist skin temperature and 95% CIs, respectively; dashed and dotted lines represent basal body temperature and 95% CIs, respectively.

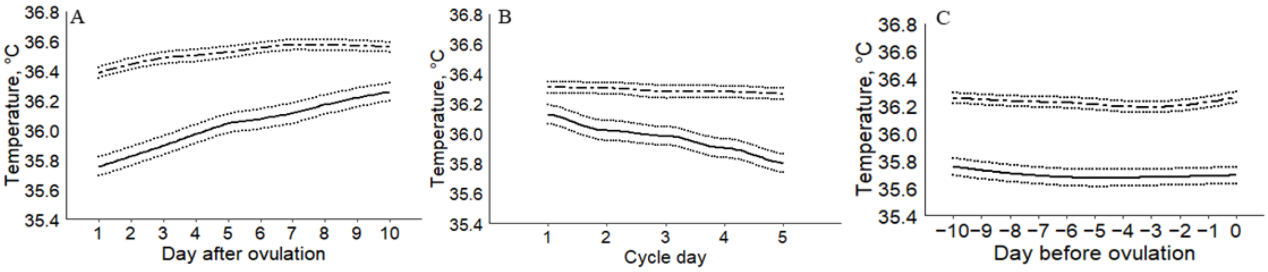


Figure 4 shows the agreement based on the curve patterns. A significant overlap of the two curves was found when the BBT curve was biphasic and the wrist skin temperature curve was monophasic. However, the wide CIs could be the result of the small number of cycles in this category (n=12). The agreement between the two curves, particularly during the postovulatory phase, was highest when both curves were monophasic (n=52), with estimated daily differences between the two temperatures ranging from 0.34 °C to 0.57 °C. The most prominent disagreement during the postovulatory phase was observed when the wrist skin temperature curve was biphasic and the BBT curve monophasic (n=79), with daily differences between the two temperatures ranging from 0.32 °C to 0.74 °C. Even when both curves were biphasic (n=27), the disagreement could still be observed during the early postovulatory phase, with the largest difference between the two temperatures on day 2 after ovulation (0.67 °C). The two curves overlapped during the late postovulatory phase.

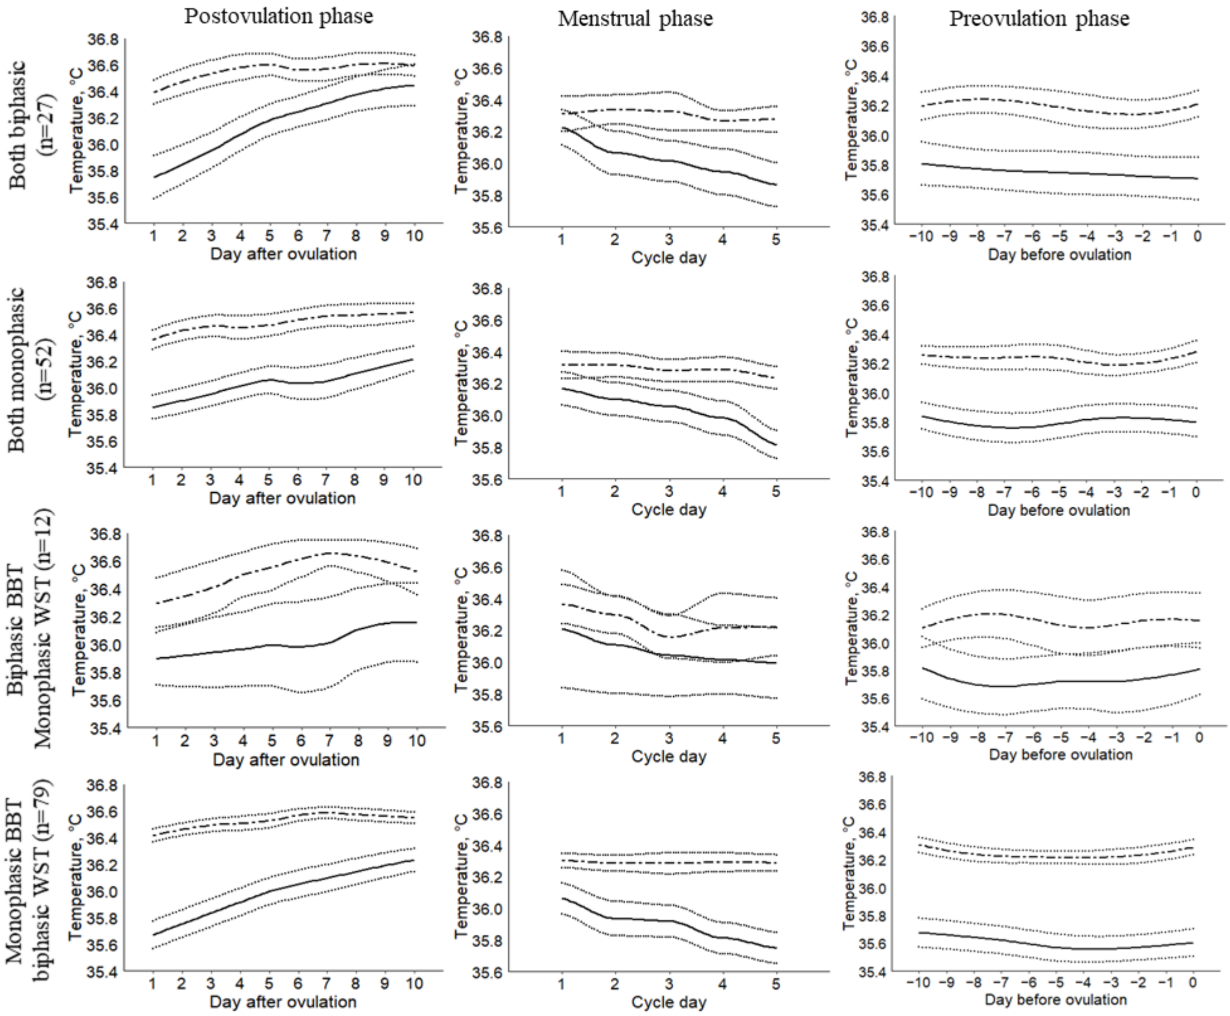
Figure 4. Smoothed temperature curves according to phases and patterns. Solid and dotted lines represent wrist skin temperature and 95% CIs, respectively; dashed and dotted lines represent basal body temperature and 95% CIs, respectively. BBT: basal body temperature; WST: wrist skin temperature.



Discussion

Principal Findings

Continuously measured wrist skin temperature had a higher sensitivity and lower specificity for detecting ovulation than BBT measured orally. The two temperatures were significantly correlated in the follicular phase but not in the luteal phase, indicating that changes in the 2 temperatures were not coupled in the luteal phase. The wrist skin temperature curve showed a greater increase during the postovulatory phase and a greater decrease in the menstrual phase than the BBT curve. The disagreement between the temperature curves was most prominent when the BBT curve was monophasic and the wrist skin temperature curve was biphasic. Our results suggest that the continuously measured wrist skin temperature is more sensitive than BBT to detect ovulation and determine the fertile window.

This study is the first to compare the wrist skin temperature and BBT in detecting ovulation. As skin tissues are not close to major blood vessels but exposed to the environment and heat transfer from the core to surface tissue is not instantaneous, the skin temperature is generally lower than BBT but not by a fixed amount [17]. Previous studies have explored how continuously measured temperatures at various body sites change across different menstrual phases. The study by Maijala et al [10] showed that both finger skin temperature measured nocturnally and oral temperature measured upon waking up differed between the luteal and follicular phases. The average between-phase temperature change was 0.07°C higher for the finger skin temperature, and this difference was statistically significant [10]. The intestinal core temperature showed changes in the circadian rhythm over the menstrual cycle, with a higher daily mean temperature during the luteal phase than during the follicular phase, and the daily minimum temperature was at its lowest value before the LH peak [14]. Regidor et al [11] reported an accuracy of 88.8% in predicting a window of 3 days before ovulation, the day of ovulation, and 3 days after ovulation with a device that continuously measured the vaginal temperature throughout the menstrual cycle. Details about the device or the methods used to evaluate the temperature curves were not provided in their paper. Findings from our previous research confirmed that wrist skin temperature could detect menstrual phase–related temperature changes, and these changes were robust to common confounding factors known to affect BBT such as sexual activity, food intake, and alcohol consumption [9,12].

One particularly encouraging finding of this study is the higher sensitivity of the continuous wrist skin temperature than oral BBT, which indicates that continuous rather than point measurement may be more useful for pregnancy planning. Moreover, the nightly data of wrist skin temperature were handled in a more sophisticated mathematical way, allowing it to be more sensitive in detecting temperature shift in a menstrual cycle. Its lower specificity may reflect a similar trade-off between the sensitivity and specificity of any diagnostic test. One compelling argument is that specificity is more relevant for avoiding an unplanned pregnancy, as the test should have both a high true negative rate and a high negative predictive value. Although we can conclude that wrist skin temperature is more sensitive than BBT for maximizing the chances of pregnancy, neither temperature should be used as a standalone method to avoid an unplanned pregnancy given their low negative predictive values.

The difference in diagnostic accuracy between the two temperatures can be explained by the different thermal changes revealed by the two temperature curves. In particular, compared with BBT, the wrist skin temperature exhibited a greater magnitude of increase during the postovulatory phase. This allows the wrist skin temperature to be more sensitive in detecting the temperature shift. In addition, the wrist skin temperature increased in a steeper and more continuous manner. This explains why it detected more temperature shifts than BBT. Few studies have compared the two temperature curves [4,13]. Krauchi et al [4] reported a similar pattern of temperature changes in a menstrual cycle between BBT and skin temperature. In contrast, Wark et al [13] reported poor agreement between BBT and the mean upper arm skin temperature measured at 10-, 30-, 60-, 90-, and 120-minute intervals before waking.

The different modes of measurement and the different circadian rhythms of wrist skin and oral temperature, which are more pronounced during sleep [18-20], might explain the disagreement between the two temperatures. The oral temperature decreases continuously during sleep, with the lowest value occurring at approximately 5 AM, and then rises sharply after waking up [21]. Point measurements such as BBT are susceptible to variations in waking times and compliance because a single measurement is located on the sliding scale of the circadian rhythm. During the preovulatory period, the amplitude of the circadian rhythm reaches the highest value [14], which might further limit the ability of BBT to identify a temperature shift. In contrast, the circadian rhythm of wrist skin temperature features a sharp increase before lights off, a plateau at a higher temperature during sleep, and then a sharp drop immediately after rising [18,20]. Sleep propensity is accompanied by an increased skin blood flow and less cold-induced vasoconstriction, particularly in the distal skin areas that are most strongly involved in the regulation of heat loss because of their richness in arteriovenous anastomoses, thus increasing the skin temperature [22,23]. Once awake, cold-induced vasoconstriction is restored, thereby decreasing the skin temperature. In this study, participants wore a wearable device that continuously measured the wrist skin temperature during sleep. As the first 90 and the last 30 minutes of recorded data were excluded, the nocturnal steady state when the temperature was maintained at a high level was captured. As a result, the effect of the circadian rhythm was, to a certain extent, removed and the temperature changes reflected mostly the menstrual rhythm. Consequently, this measurement is more sensitive for detecting temperature shifts during menstrual cycles.

Limitations

Our study has several limitations. First, factors that could potentially influence temperature were not evaluated. These factors include sexual activity, exercise, food intake, alcohol consumption, sleep duration and quality, and wake-up time [6]. An examination of the potential influence of these factors on the curve patterns and their agreement would have been particularly interesting. Second, because of the relatively small number of participants, we were unable to conduct subgroup analyses on the influence of BMI or cycle length on the difference in diagnostic accuracy between the two temperatures. Third, 27.4% (73/266) of the collected cycles were excluded from the final analysis because of missing measurements. The percentage of cycles with ≥30% missing wrist skin temperature was comparable with that reported in a previous study [12]. It remains unclear whether compliance would improve under real-world conditions where users are actively track their menstrual cycles. Furthermore, the participants in our study were recruited by nonrandom sampling and consisted of mostly young White women. Novel digital technology might be particularly appealing to these participants. Whether our results are generalizable to other races and real-world conditions requires further study.

Conclusions

For women interested in maximizing the chances of pregnancy, the wrist skin temperature continuously measured during sleep is more sensitive than BBT to detect ovulation. The difference in the diagnostic accuracy of these two methods was likely attributed to the greater temperature increase in the postovulatory phase and a greater decrease during the menstrual phase for the wrist skin temperature. However, when used as a standalone method, neither of the temperatures could reliably avoid unplanned pregnancy, given the low negative predictive values. Our results underpin the importance of validation studies, especially against a standard reference test, while developing wearable devices that measure physiological parameters for women or clinicians to track menstrual cycles.

Acknowledgments

The authors gratefully acknowledge Innosuisse (17324.1 PFLS-LS, 28715.1 IP-LS, 40347.1 IP-LS) for funding the development of the wearable device. The authors thank all participating women for supporting our study.

Authors' Contributions

MR, GH, MS, and BL designed the study. GH and AH acquired the data. MR conducted the data analyses. TYZ and MR interpreted the data. TYZ drafted the manuscript. The draft was critically revised by TYZ, MR, JW, MK, NK, MS, and BL. All authors approved the final version of the manuscript for publication.

Conflicts of Interest

MR is an employee of Ava AG (Zurich, Switzerland). MS is a former employee of Ava AG. BL is a member of the advisory board of Ava AG.

Abstract

Background: The Clock Drawing Test (CDT) has been widely used in clinic for cognitive assessment. Recently, a digital Clock Drawing Text (dCDT) that is able to capture the entire sequence of clock drawing behaviors was introduced. While a variety of domain-specific features can be derived from the dCDT, it has not yet been evaluated in a large community-based population whether the features derived from the dCDT correlate with cognitive function.

Objective: We aimed to investigate the association between dCDT features and cognitive performance across multiple domains.

Methods: Participants from the Framingham Heart Study, a large community-based cohort with longitudinal cognitive surveillance, who did not have dementia were included. Participants were administered both the dCDT and a standard protocol of neuropsychological tests that measured a wide range of cognitive functions. A total of 105 features were derived from the dCDT, and their associations with 18 neuropsychological tests were assessed with linear regression models adjusted for age and sex. Associations between a composite score from dCDT features were also assessed for associations with each neuropsychological test and cognitive status (clinically diagnosed mild cognitive impairment compared to normal cognition).

Results: The study included 2062 participants (age: mean 62, SD 13 years, 51.6% women), among whom 36 were diagnosed with mild cognitive impairment. Each neuropsychological test was associated with an average of 50 dCDT features. The composite scores derived from dCDT features were significantly associated with both neuropsychological tests and mild cognitive impairment.

Conclusions: The dCDT can potentially be used as a tool for cognitive assessment in large community-based populations.

Introduction

The Clock Drawing Test (CDT) is a widely used neuropsychological test to screen cognitive impairment and dementia because of its ease of administration and clinical assessment capability [1,2]. The test is typically administered by specifying a time, for example, ten past eleven, and asking patients or participants to draw a clock showing that time (the command condition), followed by asking patients or participants to copy a predrawn clock image (the copy condition). Both test conditions require multiple cognitive domains. The command test condition requires intact attention, auditory comprehension, semantic memory, executive function, and visuoconstructional abilities, whereas the copy test condition relies primarily upon visuospatial, attention, and executive function skills [3-6]. Keen observation of the process by which drawings are produced is key to the evaluation of the type and severity of cognitive impairment [7,8]. Multiple manual scoring systems have been created to objectively quantify test performance. However, none of these scoring systems can capture the full breadth of cognitive skills used in completing the test [3].

Recently, a digital version of the CDT (dCDT) that uses a digital ballpoint pen and smart paper was developed as an alternative to the standard clock drawing scoring systems [9,10]. The digital pen can record its position with a timestamp and has excellent precision in capturing all graphomotor, spatial, and temporal information [11-13]; however, the characterization of these features and their correlations with standard neuropsychological tests has yet to be examined in a large community-based setting.

The objective of this investigation was to examine the association between dCDT features and cognitive functions in the Framingham Heart Study (FHS) cohort. We also investigated the association between dCDT features and cognitive status (clinically diagnosed mild cognitive impairment compared to those with normal cognition).

Methods

Study Sample

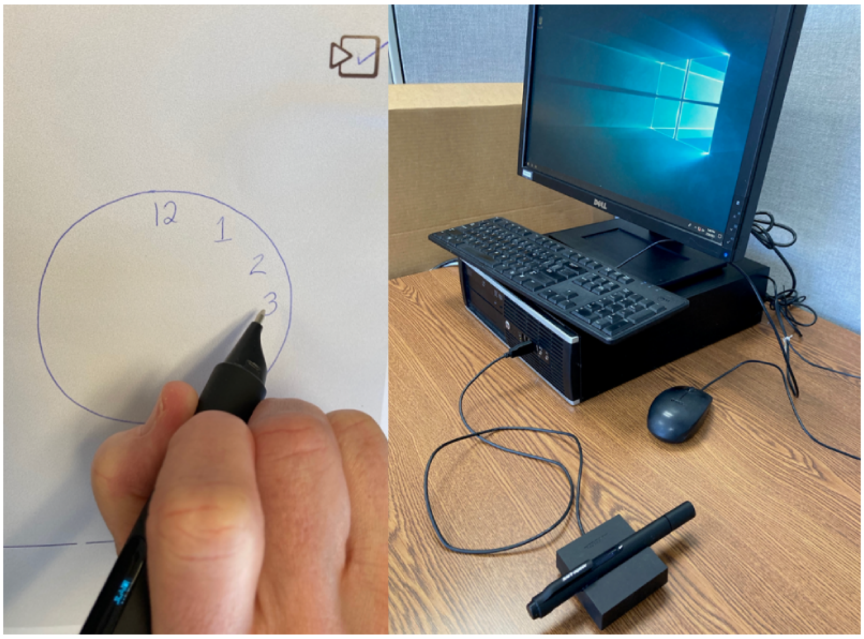
The FHS is a community-based prospective cohort study that was established in 1948. Three generations of participants have been enrolled. Details about the FHS cohort have been previously published [14-16]. This study included participants who completed at least one dCDT and neuropsychological assessment. Participants with prevalent dementia (n=23) or who had not been reviewed by the expert panel (n=138) were excluded. The Boston University Medical Campus Institutional Review Board approved the study procedures and protocols. Written informed consent was obtained from all participants.

The dCDT

Since October 2011, FHS participants who have come for their regular neuropsychological test visit were simultaneously administered the dCDT using a digital pen. The test was jointly developed by the Massachusetts Institute of Technology and the Lahey Hospital and Medical Center with the collaboration of the Clock Sketch Consortium [9-11,17]. Participants used the digital pen (Anoto Inc), to draw a clock on smart paper with a faint dot pattern (Figure 1). The digital pen functions as a regular ballpoint pen does but also measures the pen's position 80 times per second at a spatial resolution of 0.002 inches with a built-in camera [10,11]. Drawings are automatically classified into different categories, such as numbers, hands, and lines. For quality control, an external rater can replay and deconstruct each drawing to ensure appropriate classification. It typically takes 1 to 2 minutes to classify clocks drawn by healthy or mildly impaired individuals. Any classification errors can be corrected by the rater using a user-friendly drag-and-drop interface. Additional time may be required for classification of more complex clock images, however, most tasks are completed within 5 minutes.

More than 100 dCDT features have been derived to measure the entire drawing process, including capturing all strokes and their corresponding latencies. These features reflect a range of cognitive functions related to drawing efficiency, simple motor operations, information processing speed, and spatial reasoning (Multimedia Appendix 1, Table S1). The rank-based inverse normal transformation was later applied to all dCDT features to reduce the distribution skewness.

Figure 1. Digital Clock Drawing Test digital pen, smart paper, and docking setup.



Neuropsychological Assessment

A neuropsychological test protocol, measuring multiple cognitive domains of verbal memory, visual memory, attention and concentration, executive function, abstract reasoning, language, and visuoperceptual organization, was administered to all FHS participants [18]: Wechsler Memory Scale [19] Logical Memory—Immediate Recall, Delayed Recall, and Recognition; Visual Reproduction—Immediate Recall, Delayed Recall, and Recognition; Paired Associate Learning—Immediate Recall, Delayed Recall, and Recognition; the Wechsler Adult Intelligence Scale [20] Digit Span—Forward, Backward, and Similarities; Boston Naming Test—30-item version [21]; Trail Making Test A and B [22]; Hooper Visual Organization Test [23]; Verbal Fluency and Verbal Fluency—Animal [24,25]. All tests were administered by trained raters.

Ascertainment of Mild Cognitive Impairment

In addition to regular research center visits, FHS participants underwent neuropsychological assessments every 4 to 5 years [26,27]. For participants with possible cognitive impairment, regular neuropsychological tests were conducted every 1 to 2 years and neurological exams were performed on a subset of participants. When potential cognitive impairment decline was present, a clinical review was conducted by a panel with at least one neurologist and one neuropsychologist. Mild cognitive impairment diagnosis was determined by the review panel, which required that the patient exhibit evidence of a decline in cognitive performance in one or more cognitive domains, have no records indicating functional decline, and did not meet criteria for dementia. Although the Clinical Dementia Rating scale [28] was not formally applied, the panel used the Clinical Dementia Rating scoring scale (0-3) to quantify the severity of impairment; for mild cognitive impairment, a rating of 0.5 was given.

Statistical Analyses

Linear regression models were used to assess the association between each dCDT feature and neuropsychological tests. The models were adjusted for age and sex. Bonferroni correction was used to adjust for multiple testing, and significant associations were claimed if $P<.05/n_t$, where n_t was the number of tests performed; therefore, tests were significant if $P<4.8\text{x}10^{-4}$, with $\alpha=.05$ and 105 tests. A composite score was also created for each neuropsychological test based on dCDT features that were significantly associated with the test. The score for sample i is defined as

where m is the number of dCDT features significantly associated with the neuropsychological test, β_j is the estimate of effect size for feature j, and V_{ij} is the normalized dCDT feature j for sample i. The score represented a weighted combination of all dCDT features for the neuropsychological test. The associations between the composite score and each neuropsychological test were also tested with linear regression models adjusted for age and sex.

The association between neuropsychological tests and dCDT composite scores with mild cognitive impairment was assessed by logistic regression models adjusted for age, sex, and education. Age was treated as a continuous variable, whereas sex was treated as a dichotomous variable. Education was treated as a categorical variable (eg, no high school degree, high school degree, some college, and college graduate). The difference between groups was assessed with the Wilcoxon rank-sum test for continuous variables or the chi-square test for dichotomous and categorical variables. Bonferroni correction was used to adjust for multiple tests, and associations were significant if $P<2.8\times10^{-3}$, given that 18 neuropsychological tests were used. All statistical analyses were performed using R software (version 4.0.3, The R Project).

Results

As shown in Table 1, our study sample included 2,062 participants (age: mean 62, SD 13 years; 51.6% women; and 43.4% received college-level education or higher). Among them, 36 participants had been diagnosed with mild cognitive impairment. As expected, participants with mild cognitive impairment were generally older and had worse cognitive performance than those in the normal cognition group.

Table 1. Clinical characterization.

A total of 105 distinct dCDT features were derived from each dCDT drawing. Associations between each individual dCDT feature and 18 neuropsychological tests assessing different cognitive functions are shown in Table S1 (Multimedia Appendix 1). In addition, dCDT features that were significantly associated different cognitive domains were summarized in Table S2 (Multimedia Appendix 1). On average, each neuropsychological test was associated with 50 dCDT features after adjusting for multiple testing.

The weighted composite scores built from significant dCDT features for each neuropsychological test were all significantly associated with their corresponding neuropsychological tests (Table 2).

Table 2. Association between digital Clock Drawing Test (dCDT) composite scores and neuropsychological tests.

Discussion

Neuropsychological tests have been widely used in the assessment of cognitive performance. All 18 neuropsychological tests, for the assessment of multiple cognitive domains, were significantly associated with an average of 50 dCDT features (range 13 to 86 features), and dCDT composite scores were significantly associated with mild cognitive impairment compared to normal cognition.

The CDT examines a wide range of cognitive abilities [5]. The command condition requires that an individual first understand the verbal command, recall all clock related attributes from semantic memory, understand the visuospatial relationships between clock features, and execute the command using necessary mental planning and visuoconstructional abilities. For the copy condition, successful performance requires that an individual recognize the visuospatial attributes in the model to be copied and then marshal the necessary executive abilities to execute output in an organized fashion. However, the standard pencil-and-paper CDT for dementia assessment is usually subjective and time intensive. Given only a limited number of features can be scored, the standard CDT has relatively inferior sensitivity and variable specificity for mild or questionable dementia [2]. On the other hand, the dCDT provides comprehensive and objective assessment of multiple cognitive domains with far greater time efficiency [29,30]. It was reported that the total completion time of dCDT was positively correlated with cognitive functions, whereas the post–clock face latency and pre–first-hand latency were negatively associated with the working memory and processing speed [31]. Our study extended this work by including more than 100 dCDT features and assessing their association with 18 different neuropsychological tests. The composite scores built from dCDT features were significantly associated (all *P*<.001) with multiple neuropsychological tests, such as Trail Making Test A, Trail Making Test B, Hooper Visual Organization Test, and Visual Reproduction subtests. Our results suggested that dCDT composite scores represent better surrogates for their corresponding neuropsychological tests than individual dCDT features. The results also underscore the psychometric characteristics of the dCDT for measuring multiple cognitive domains, such as attention, executive function, visuoperceptual organization, and visual memory, findings which are consistent with those of prior studies [1,5].

A complete neuropsychological test protocol must be administered by a trained rater and interpreted by a neuropsychological expert, which takes at least 45 minutes; therefore, financial and medical resource requirements limit the application of a complete neuropsychological test protocol in general clinics. In contrast, the dCDT is much more convenient, and the test generally takes less than 2 minutes. It is also worth noting that some patients with mild cognitive impairment may show normal performance in some of cognitive domains of neuropsychological test, demonstrating reduced sensitivity of these neuropsychological tests in detecting mild cognitive impairment for some patient groups [32]. As dCDT composite scores were derived from a combination of multiple features associated with neuropsychological tests, they have the potential to identify more subtle cognitive impairment than individual neuropsychological tests. In an earlier study, Dion et al [31] analyzed 202 older adults without dementia and found that participants with mild cognitive impairment tended to take more time to complete the entire test—more “Think than Ink” (ie, percentage of time thinking vs percentage of time drawing)—and drew smaller clock face areas than those drawn by participants with normal cognition. In another study consisting of 138 patients with mild cognitive impairment and amnesia, 106 patients with mild Alzheimer disease, and 137 normal cognition participants; a tablet-based dCDT provided a slightly higher diagnostic accuracy for patients with mild cognitive impairment and amnesia than the CERAD (Consortium to Establish a Registry for Alzheimer's Disease) total score (81.5% vs 77.5%) [33]. The dCDT features have also been used to differentiate between other neurological diseases, such as memory impairment disorders, vascular cognitive disorders, and Parkinson disease [17].

Several study limitations merit consideration. First, this was a cross-sectional study, which cannot reveal temporal relationship between dCDT performance and mild cognitive impairment. It would be interesting to perform longitudinal analysis to investigate early cognitive markers of dCDT features that predict future cognitive decline. Second, only a moderate number of patients with mild cognitive impairment were included. The number of patients with dementia was even smaller, and therefore, patients with dementia were excluded. Third, neuropsychological tests were used to diagnose mild cognitive impairment, which possibly caused some circularity and overestimated diagnostic performance of neuropsychological tests. On the other hand, neither dCDT features nor derived composite scores were used for the mild cognitive impairment diagnosis, which reduced the bias of potential overestimation. Fourth, due to the increasing exposure to digitalized clock displays, a recent study found that some participants drew digital clocks instead of analog clocks required by the test [34]. It is thus important to continue to explore novel cognitive assessment strategies to better capture new features from different neuropsychological tests to avoid potential bias caused by this new technology trend. Finally, yet importantly, FHS participants were mostly of European ancestry and English speakers, therefore, the applicability of these findings to populations of other race and ethnicity is unknown. Notwithstanding these limitations, our study had several strengths. We studied the association between dCDT and a standard epidemiologic neuropsychological test protocol with community-based FHS study data. FHS data have been collected consistently with rigorous quality control and clinical diagnosis by consensus review. Notably, unlike tablet-based apps, the digital pen used in our study offers an almost identical user experience as that of a traditional ballpoint pen; no extra training is needed, which is particularly important for older adult participants who might be unfamiliar with new digital technologies. The performance was thus less likely distorted [10,11].

Associations between dCDT features and standard neuropsychological test data, as well as composite scores from dCDT features as an alternative to neuropsychological tests for the classification of mild cognitive impairment, from more than 2000 participants from a large community-based cohort suggest the potential of dCDT as a cost-effective and easy-to-administer tool for general practitioners, with potential for use in low-resource countries or regions where clinical dementia expertise is limited.

Abstract

Background: Patients with multidrug-resistant tuberculosis (MDR-TB) face challenges adhering to medications, given that treatment is prolonged and has a high rate of adverse effects. The Medication Event Reminder Monitor (MERM) is a digital pillbox that provides pill-taking reminders and facilitates the remote monitoring of medication adherence.

Objective: This study aims to assess the MERM's acceptability to patients and health care providers (HCPs) during pilot implementation in India's public sector MDR-TB program.

Methods: From October 2017 to September 2018, we conducted qualitative interviews with patients who were undergoing MDR-TB therapy and were being monitored with the MERM and HCPs in the government program in Chennai and Mumbai. Interview transcripts were independently coded by 2 researchers and analyzed to identify the emergent themes. We organized findings by using the Unified Theory of Acceptance and Use of Technology (UTAUT), which outlines 4 constructs that predict technology acceptance—performance expectancy, effort expectancy, social influence, and facilitating conditions.

Results: We interviewed 65 patients with MDR-TB and 10 HCPs. In patient interviews, greater acceptance of the MERM was related to perceptions that the audible and visual reminders improved medication adherence and that remote monitoring reduced the frequency of clinic visits (performance expectancy), that the device's organization and labeling of medications made it easier to take them correctly (effort expectancy), that the device facilitated positive family involvement in the patient's care (social influences), and that remote monitoring made patients feel more *cared for* by the health system (facilitating conditions). Lower patient acceptance was related to problems with the durability of the MERM's cardboard construction and difficulties with portability and storage because of its large size (effort expectancy), concerns regarding stigma and the disclosure of patients' MDR-TB diagnoses (social influences), and the incorrect understanding of the MERM because of suboptimal counseling (facilitating conditions). In their interviews, HCPs reported that MERM implementation resulted in fewer in-person interactions with patients and thus allowed HCPs to dedicate more time to other tasks, which improved job satisfaction.

Conclusions: Several features of the MERM support its acceptability among patients with MDR-TB and HCPs, and some barriers to patient use could be addressed by improving the design of the device. However, some barriers, such as disease-related stigma, are more difficult to modify and may limit use of the MERM among some patients with MDR-TB. Further research is needed to assess the accuracy of MERM for measuring adherence, its effectiveness for improving treatment outcomes, and patients' sustained use of the device in larger scale implementation.

Introduction

Background

Multidrug-resistant tuberculosis (MDR-TB) is a major global challenge to tuberculosis (TB) control. In 2018, approximately 484,000 people worldwide were estimated to have developed MDR-TB, including approximately 130,000 people in India [1]. Despite considerable advances in therapy in the last decade, treatment outcomes remain poor for individuals with MDR-TB, with treatment success rates of 56% worldwide and 48% in India for the 2017 patient cohort [1]. Although some of the variability in treatment outcomes may be attributable to the composition of the patient's drug regimen [2], suboptimal adherence to medications may be another critical problem contributing to poor MDR-TB treatment outcomes.

Successful adherence for diseases with a prolonged treatment course, such as MDR-TB, requires a high level of dosing implementation (ie, taking a medication dose on a given day) and persistence (ie, taking medications for the entire duration of therapy [3]). Factors contributing to nonadherence are complex and include therapy-related (eg, toxicities [4]), psychosocial (eg, alcohol use [5], depression [6], and stigma [7]), structural (eg, distance from clinics and medication costs [8,9]), and health system–related challenges (eg, poor user experience with the health system). Patients with MDR-TB face particularly high levels of drug toxicity [4] and psychosocial barriers, including depression, substance use disorders, stigma, and discrimination [10]. These challenges may lead to poor outcomes and increased transmission of drug-resistant strains.

As such, there is an urgent need for new strategies to improve medication adherence in patients with MDR-TB. Many TB programs have historically used directly observed therapy (DOT) to monitor adherence; however, recent studies have questioned the efficacy of this strategy for improving clinical outcomes [11-13] and raised concerns that DOT adversely affects patient autonomy [14,15]. Limited autonomy with DOT may be greater for patients receiving MDR-TB treatment, given the prolonged course of therapy required. In addition, recent recommendations favoring the use of regimens containing only oral medications may decrease the required frequency of clinic visits for patients with MDR-TB if they are allowed to take therapy without in-person observation [16].

In recent years, driven by the global expansion of cellular networks, there has been a growing use of digital adherence technologies (DATs) as alternative approaches for monitoring adherence to TB medications [3]. These technologies, which include cellphones, digital pillboxes, and ingestion sensors, have the potential to improve clinical outcomes via multiple pathways [3]. Although there are numerous DATs aimed at addressing nonadherence in patients with drug-susceptible TB [3], few have attempted to address the more complex medication regimens taken by patients with MDR-TB [17].

The Medication Event Reminder Monitor (MERM) is a digital pillbox that has been designed to monitor MDR-TB treatment in resource-constrained settings by using relatively affordable evriMED technology produced by Wisepill Technologies. This system is designed to be used with multiple blister-packaged medications in MDR-TB regimens, incorporates visual and audible reminders for daily dosing and refills, compiles dosing histories by capturing data on pillbox opening as a proxy for dose ingestion, and transmits these data to a server so that health care providers (HCPs) can remotely visualize patients' dosing histories. By providing near real-time adherence data, the MERM may facilitate the identification of high-risk patients and prompt early intervention by HCPs to reduce nonadherence. When compared with facility-based DOT, in which patients travel to clinics to be observed taking medications, monitoring by using the MERM may reduce the required frequency of patient visits to TB clinics.

Pilot studies of digital pillboxes conducted in Uganda and China with patients with drug-susceptible TB and in South Africa with patients with MDR-TB have shown these devices to have relatively high acceptability [17-19]. A cluster randomized trial conducted in China with patients with drug-susceptible TB found digital pillboxes to be effective in reducing the percentage of patient months with high nonadherence [20]. However, subsequent studies on the large-scale implementation of these digital pillboxes in China have revealed challenges in their uptake. For example, after accounting for patients who were not eligible to use these pillboxes, refused to use them, withdrew from using them early in treatment, or were shifted to monitoring with DOT, only approximately 49% and 39% of patients with TB used digital pillboxes in a sustained manner in a single province [21] and 30 counties [22], respectively, in China. In addition, a study of the MERM conducted in Vietnam with patients with drug-susceptible TB found that only approximately half of the patients used the device as intended, with many separating the time when the pillbox was opened from the time that doses were ingested, because of concerns about the device's portability [23]. These existing studies evaluating the use of digital pillboxes reveal variability in patient acceptance in different contexts and highlight a relative paucity of data on the use of these devices for patients with MDR-TB.

Objectives

In this study, based on qualitative interviews with patients and HCPs, we evaluated the MERM's ability to monitor adherence to MDR-TB therapy during pilot rollout in the government's National TB Elimination Program (NTEP) in 2 Indian cities. Although this novel strategy has potential advantages, previous research has not been conducted in India to evaluate whether patients will accept and use the MERM, to identify potential modifiable and nonmodifiable barriers to its acceptability, and to understand how its implementation might impact HCP work efficiency and quality of care. Understanding the acceptability of MERM during pilot implementation is also important because recent studies of other DATs in India suggest that suboptimal acceptability and use by patients could reduce the accuracy of these technologies for measuring adherence [24], which might in turn greatly reduce the value of real-time adherence data for guiding interventions. We analyze our findings using the Unified Theory of Acceptance and Use of Technology (UTAUT), a framework that synthesizes constructs that predict engagement with novel technologies [25,26].

Methods

Ethical Approvals

This protocol received approval from the Indian Council of Medical Research-National Institute for Research in TB Institutional Ethics Committee (FWA00005104) on March 7, 2017. The study was approved by the Brigham and Women's Hospital Institutional Review Board (FWA00000484) on January 31, 2017, and the Tufts Health Sciences Institutional Review Board (FWA00004517) on June 6, 2018. Written informed consent was obtained from all the participants.

Study Setting

This study was conducted in 2 Indian cities with a high TB burden in the general population [27,28]: Chennai (estimated population of 7.1 million in metropolitan area), in the southern Indian state of Tamil Nadu, and Mumbai (estimated population of 18.4 million in the metropolitan area), in the western Indian state of Maharashtra. Mumbai in particular has one of the world's most severe urban epidemics of drug-resistant TB [29-31]. All patients in Chennai spoke Tamil, and all patients in Mumbai spoke Hindi or Marathi. Consistent with the broader population of patients with TB who seek government care in India, more than half of whom earn less than US $2 a day of income [32], patients with MDR-TB in these 2 cities come from socioeconomically disadvantaged backgrounds.

MERM Implementation

Medications are dispensed in blister packs, and each drug is placed in a different partitioned compartment within the MERM, which facilitates storage and organization of the multiple medications that comprise MDR-TB regimens (Figure 1). In India's pilot implementation, the container and internal partitions were made of cardboard. The device was provided to patients at different time points in the continuation phase of therapy when injectable agents had generally been discontinued and patients were only taking oral medications. At the time of our study, most patients with MDR-TB in India's NTEP were placed on a standardized drug regimen for a treatment course lasting 24 to 27 months, with the continuation phase consisting of levofloxacin, ethionamide, cycloserine, and ethambutol taken once daily [33]. Patients who were provided the MERM subsequently used it for the remaining duration of treatment.

The MERM was programmed to provide audible and visual reminders to take medications at a specific time each day, per patient and HCP preference. The visual reminder consisted of a blinking green light corresponding to a label encouraging the patient to take a dose; separate yellow and red lights blink to alert patients about the need to refill medications and replace the MERM's battery, respectively. The audio reminder consisted of a ringing sound that occurred at the same time as the visual dose-taking reminder.

The device contained a removable battery-powered module. Triggered by a magnetic sensor, this module captures and stores data each time the container is opened as a proxy for medication ingestion. These data on patient engagement with the MERM were transmitted every 72 hours using cellular networks and recorded on a computer server. HCPs could log into an app on a mobile device or a website, where each patient's adherence history was presented as a color-coded calendar in which green suggested that the MERM was opened on a given day (suggesting dose ingestion), whereas red suggested that the device was not opened (suggesting that the dose was not ingested).

These dosing histories were meant to help HCPs have individualized discussions with patients regarding their adherence. In addition, a series of probable missed doses would result in automated SMS text messaging notifications prompting HCPs to intervene with these patients, who might be at a higher risk for unfavorable outcomes.

Figure 1. The Medication Event and Reminder Monitor in a cardboard version used for the initial rollout among patients with multidrug-resistant tuberculosis in India. The device includes partitions for organizing medications, medication labels inside the box lid, and a digital module that provides reminders and captures adherence data. This cardboard version was provided by Wisepill Technologies.

Recruitment of Study Participants and Collection of Qualitative Data

Interviews were conducted by 3 field researchers in Mumbai (1 man and 2 women) and 3 field researchers in Chennai (2 men and 1 woman), all of whom had a master's degree in social work or another social science field who underwent a 2-day training in qualitative interviews at the National Institute for Research in TB in Chennai. Study participants included patients with MDR-TB and HCPs. We use the term *MDR-TB* to describe patients with confirmed resistance to isoniazid and rifampin as well as individuals who were diagnosed as having rifampin-resistant TB using Xpert MTB/RIF (Cepheid, Inc) because patients with rifampin-resistant TB in India are treated as having likely MDR-TB. Data collection was conducted a few months after the MERM was introduced in Mumbai and Chennai for monitoring patients with MDR-TB from October 2017 to September 2018. Before the rollout of the MERM, HCPs were extensively trained on the appropriate use of the MERM. HCPs dispensed medication refills in the MERM for patients with MDR-TB in the continuation phase of therapy after any injectable agents (eg, kanamycin) were discontinued.

Field researchers met patients at MDR-TB clinics, where patients were screened for inclusion in the study. At these clinics, HCPs were recruited for the study, including health visitors (individuals with at least a high school level of education who monitor therapy), senior treatment supervisors (individuals with at least a high school level of education who supervise health visitors), medical officers (doctors with an MBBS or higher degree), and district TB officers (doctors who supervise TB care across a district).

For patients, an unannounced home visit was made at least 3 weeks after enrollment into the study to conduct the qualitative in-depth interviews regarding the MERM, which lasted about 45 minutes. A pill count was also conducted to better understand the patients' adherence to medications. We ensured a minimum of 3 weeks lapsed between when a patient was consented to the study and when the unannounced home visit was conducted. This time gap minimized the impact of temporary changes in medication adherence that may result from the patient knowing that he or she will be visited as part of the study (ie, the Hawthorne effect). For HCPs, interviews lasted about 30-45 minutes and were conducted in a private space in the TB clinic.

To ensure uniformity in data collection, separate patient and HCP interview guides, each consisting of open-ended and semistructured questions with follow-up probes, were used to conduct the interviews. Examples of questions from the patient interview guide are provided in Multimedia Appendix 1. The interview questions had the goal of assessing key constructs in the UTAUT framework. Interviews were conducted in Tamil, Hindi, or Marathi and audio recorded. They were later transcribed and translated to produce deidentified English language transcripts. To ensure translation accuracy, one-fourth of the English transcripts were evaluated against the original audio recordings for correctness and completeness.

Analytical Framework: UTAUT

The UTAUT integrates constructs from previous literature on technology acceptance into a single framework [25,26]. Of these constructs, 3—performance expectancy, effort expectancy, and social influences—help to predict the intention of individuals to use a technology, which is necessary, but not sufficient, to result in actual use. Performance expectancy refers to the perceived usefulness of technology for users. For example, for patients with MDR-TB, this may refer to the extent to which the MERM is perceived to improve their medical care, whereas for HCPs, it may refer to the extent to which it is perceived to improve the quality or efficiency of their work. Effort expectancy refers to the ease of using the technology. For patients, this may refer to the effort required to correctly understand the different functions of the digital pillbox (eg, storage function and reminders), whereas for HCPs, this may refer to the effort required to use and understand the web-based adherence dashboard and SMS text messaging reminders that notify HCPs about nonadherent patients. Social influences refer to how other individuals may influence a person's acceptance and use of technology. For patients, this may include family members or community residents, whereas for HCPs, this may include coworkers. Of these 3 constructs, performance expectancy has the strongest influence on the intention to use a technology [25].

Facilitating conditions, the fourth construct in the UTAUT, is thought to directly affect the actual use of a new technology. Facilitating conditions comprise the underlying infrastructure to enable the use of a technology. For patients with MDR-TB, we interpreted this broadly to include factors in the TB program, such as the quality of counseling regarding the MERM provided to patients and any outreach to patients by HCPs that might have been prompted by adherence data from the MERM. For HCPs, we interpret this to include the quality of training they received before the rollout of the MERM and any higher-level support they received during the rollout process.

Analysis of Qualitative Data

Transcribed interviews were coded using a thematic approach and analyzed using Dedoose software (version 8.0.35; SocioCultural Research Consultants, LLC). The study team first identified possible codes (ie, themes) related to the central research question from the data collected by using the qualitative interview guides as a foundation and the UTAUT as an organizing framework. The transcripts were then independently coded by 2 researchers for relevant themes using descriptive content analysis. In parallel, the researchers tracked new codes that were added to the coding scheme to describe unexpected themes that emerged. The two researchers frequently met to reconcile inconsistencies in the application of codes and to ensure that emergent codes were added to the coding scheme. Because all coding differences were reconciled by consensus, we did not assess the interrater reliability between the coders.

We analyzed the data to identify emergent themes that could influence the acceptability and use of MERM. Emergent themes were organized within the 4 UTAUT constructs, and illustrative quotations were selected for each theme. In reporting our findings, we follow the principles of qualitative research by avoiding the quantification of codes (or themes) from our data [34]. In our findings, we report not only common themes (ie, those that emerged most frequently) but also salient themes (ie, themes reported by a minority that are still important).

We also specifically did not classify each patient based on whether they reported a high or low acceptance or use of the MERM. In contrast, we focus on reporting specific features of the MERM that were associated with higher or lower acceptance of the device because individual patients might find some components to be acceptable while simultaneously finding other components to be unacceptable. For example, a patient might appreciate the MERM's organization of medications but, at the same time, have concerns about the audible reminder because of fear that it could lead to the disclosure of her or his MDR-TB diagnosis. In addition, there is often individual variation in whether patients accept a particular technology [35]. As such, we avoid making a blanket declaration that the device is either *acceptable* or *unacceptable* to the larger patient population with MDR-TB in India.

Results

Characteristics of Study Participants

We interviewed 65 patients with MDR-TB, for whom the median age was 33 years (range 18-75 years).

Home visits were conducted for a median of 5 weeks (range 3-8 weeks) after the patients started using the MERM. Most patients were men, had some primary or secondary school education, and lived in the Chennai metropolitan area (Table 1).

We interviewed 10 HCPs, with a median age of 35 years (range 29-54 years). They had a median of 5.5 years of work experience in the NTEP (range 2-15 years). Most HCPs were men, had an undergraduate education, and had jobs as health visitors (Table 2).

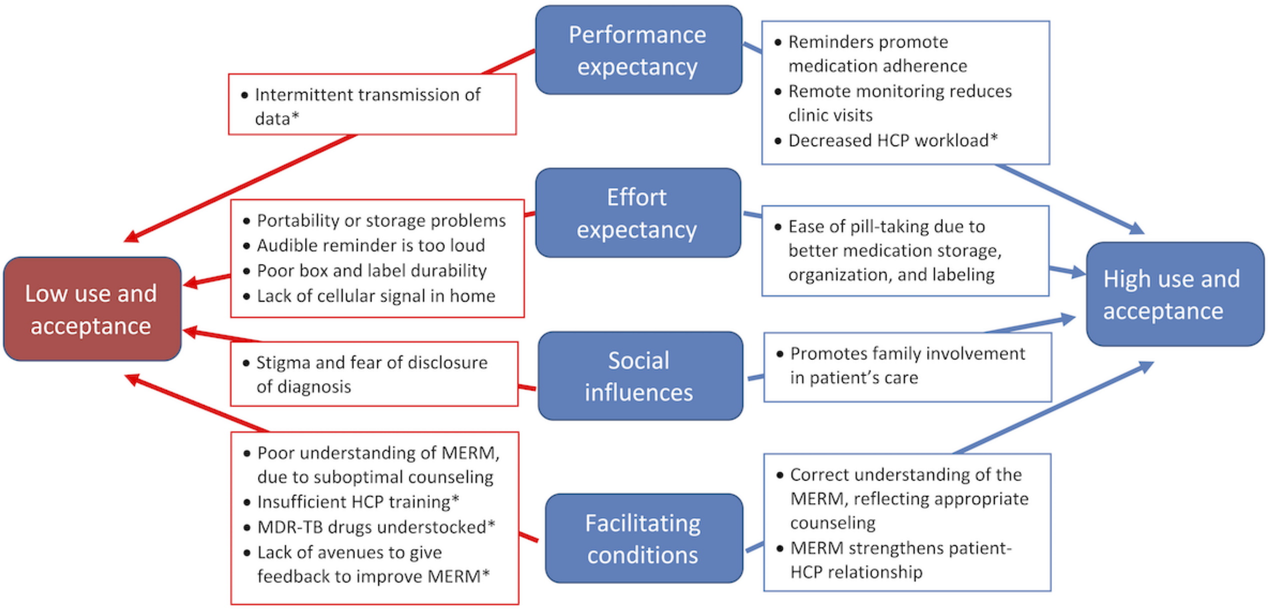
Findings From Patients With MDR-TB

Interview findings revealed facilitators of and barriers to patient acceptance of MERM (Figure 2).

Figure 2. Key findings regarding determinants of high and low acceptance and use of the Medication Event Reminder Monitor by patients with MDR-TB and health care providers based on the Unified Theory of Acceptance and Use of Technology (UTAUT) framework. *Findings are from health care provider interviews; all other findings are from patient interviews. HCP: health care provider; MERM: Medication Event Reminder Monitor; MDR-TB: multidrug-resistant tuberculosis.



Facilitators of Patient Acceptance and Use of the MERM

Several factors were associated with a higher acceptance of MERM (Textbox 1).

With regard to performance expectancy (perceived usefulness), many patients felt that the reminders prevented them from forgetting to take their medications and helped them take it at the same time every day, with most preferring audible (Textbox 1; quote 1) and a few preferring visual (quote 2) reminders. One patient described the following benefits of audible reminders:

> *I finish my breakfast before 10 O' clock and wait for the alarm to ring. The alarm is useful because even when I forget it reminds me to take the tablets.* [Patient, male, 49 years]

Some patients also appreciated the yellow light, which served as a reminder to return to the clinic for medication refills.

Before being given their medications in the MERM, patients with MDR-TB usually visited clinics more frequently (eg, daily or weekly) for closer monitoring by HCPs. Some patients appreciated that remote monitoring of adherence resulted in reduced time and money spent on clinic visits (quote 3), as described by the following patient:

> *I previously had to visit the hospital three or four times in a month, but now I am going there once a month, so it is very good that you have provided this box. It is like a blessing for me.* [Patient, male, 39 years]

Several patients also appreciated the manner in which the MERM stores, organizes, and provides helpful internal labeling of medications. Patients previously stored medication blisters in plastic bags or a cardboard box provided by the TB program that did not have internal partitions to organize medications (quotes 4 and 5). These findings speak both to favorable perceived usefulness (ie, performance expectancy) of the MERM for organizing medications and favorable ease of use (ie, effort expectancy) because most patients found it easy to follow and understand the MERM's internal labels that guide pill taking, as noted by the following patient:

> *There are different compartments for each tablet, so they don't get mixed with each other....It is helpful. I like the arrows with the dots that explain how many of each medication I need to take.* [Patient, male, 38 years]

With regard to social influences, several patients reported that the audible reminder function promoted increased involvement of family members in their TB care (quotes 6-8), although occasionally such involvement was because of annoyance from the audible reminder (quote 7) or perceptions that the MERM facilitated government surveillance (quote 8). In some cases, however, this family involvement was prompted by the positive perception that the MERM represents an extension of the care provided by HCPs:

> *As soon as the alarm rings, my son immediately runs to me and says "Your doctor is calling you. Go and take your medicine and then do your work."* [Patient, male, 49 years]

Counseling of patients by HCPs in the appropriate use of the MERM is an important facilitating condition. The quality of counseling was assessed indirectly based on whether patients had appropriate or inappropriate knowledge of the functions of the MERM. There was variability in patient understanding of the MERM; however, most patients expressed a correct understanding of its medication labeling (quote 9) and other basic functions. For example, the following patient correctly interpreted the different lights on the MERM, reflecting appropriate counseling:

> *If red color [light] blinks there is no charge; if the green color blinks, it signals that the tablets have to be taken at 10 O'clock; and if the yellow color blinks, it means that the tablets are going to run out.* [Patient, male, 22 years]

Some patients reported that HCPs deployed the MERM in a manner that strengthened the patient-HCP relationship (quote 10). These findings highlight aspects of the MERM's perceived usefulness (performance expectancy), as well as favorable facilitating conditions in the health system's implementation of this technology. For example, patients appreciated that HCPs seemed to use the adherence data generated by the MERM in a positive manner, which resulted in patients feeling *caredfor* remotely:

> *If I don't open the [pill]box, somebody from the health center calls me to find out whether I have taken the tablets or not. They care for me.* [Patient, male, 61 years]

Textbox 1. Representative quotations on factors facilitating the acceptance of the Medication Event Reminder Monitor by patients based on constructs in the Unified Theory of Acceptance and Use of Technology (UTAUT).

Performance expectancy

- Reminders promote medication adherence
    - Quote 1: "The sound of the alarm forces me to take the medicine on time." (Patient, female, aged 42 years)
    - Quote 2: "Even when the alarm is not audible, the light is useful, especially when I am not near the box." (Patient, male, aged 25 years old)
- Remote monitoring reduces clinic visits
    - Quote 3: "I can do work at home properly now and do not have to worry about going to the health center." (Patient, female, aged 27 years)

Effort expectancy

- Ease of pill taking because of better medication storage, organization, and labeling
    - Quote 4: "Previously, I kept the tablets in a plastic cover, but now they are safer in the box. I used to be so confused, as there were so many medicines to take. Now it is easier." (Patient, female, aged 21 years)
    - Quote 5: "The pills were previously given in an ordinary cardboard tablet box, which does not have an alarm, but this box has an alarm to remind me." (Patient, male, aged 61 years old)

Social influences

- Promotes family involvement in patient's care
    - Quote 6: "When the alarm rings and I am outside my house, they send a person to inform me to take my pills." [Patient, male, aged 49 years]
    - Quote 7: "My mother complains when I delay taking the medicines. She would say, 'The box has been making noise constantly' and makes sure I take the medicines so the noise will stop." (Patient, male, aged 44 years)
    - Quote 8: "There is a camera in the box, so if you don't take the pills, people in Delhi will come to know. So take your pills." (Mother of a 25-year-old male patient)

Facilitating conditions

- Correct understanding of the Medication Event Reminder Monitor, reflecting appropriate counseling
    - Quote 9: "I take the tablets according to the dots shaded in each column above the compartment." (Patient, female, aged 28 years)
- Medication Event Reminder Monitor strengthens patient-health care provider relationship
    - Quote 10: "At the time of discharge...[a] health worker explained the MERM box and told me about the need to take my medicines regularly and that the box would help remind me. Those words motivated and encouraged me. My anxiety was reduced, and I was filled with happiness." (Patient, male, aged 53 years)

Barriers to Patient Acceptance and Use of the MERM

Patients also experienced barriers to the acceptance and use of MERM (Textbox 2).

A few patients admitted a lack of understanding regarding the purpose of the MERM, which suggests limitations in performance expectancy (perceived usefulness) for this minority of individuals:

> *I did not know that when I don't take pills, it will be shown [to HCPs] by a computer.* [Patient, female, aged 45 years]

More commonly, patients described limitations in effort expectancy (ease of use). For example, one patient described how the MERM's lack of portability led him to remove medication blisters from the device, which would result in the MERM recording adherence inaccurately:

> *I take my pills out of the box when I leave for work and put them in my pocket. I cannot carry such a big box to work that makes so much noise when I open it. I take the medicines [at work] when I am free. I do not benefit from the alarm or the light [audible and visual reminders] because I leave the box at home.* [Patient, male, aged 21 years]

Other patients similarly described how the device's large size served as a barrier to taking it to work (Textbox 2; quote 11) or storing it inside the house (quote 12). In addition, some of these concerns were related to stigma and privacy. Patients were concerned that the device's size and the loud sound of the audible reminder would draw attention and potentially raise questions about the patient's underlying medication condition (quote 13). Some patients found the audible reminder to be a major annoyance (quote 14). For example, one patient propped the box open to prevent the alarm from going off:

> *The alarm is too loud. So to avoid it [from going off], I put a paper in between the box and the lid and take the medicine.* [Patient, female, aged 18 years]

This action breaks the magnetic seal on the lid of the MERM and interferes with the recording of daily dose taking, thereby resulting in an inaccurate adherence record.

Patients also found that the body of the MERM, which is made of commercial-grade cardboard, poorly withstood the humidity and monsoon weather conditions in India. Medication labels peeled from the box (quote 15), and the box's shape became distorted:

> *My box bulged after it had rained continuously, and the inside of the house became damp, so it would be better if the box was made out of plastic.* [Patient male, aged 48 years]

A few patients found the MERM medication labels to be challenging; however, some of these difficulties may have reflected poor organization of medications in the box by HCPs, such that medications were not in the partitions corresponding to the appropriate labels:

> *This box is useful as there are instructions about its use, but sometimes the arrows [labeling each medication] don't match with the [correct] medicines. I get confused.* [Patient, male, aged 40 years]

Patients reported various other technical problems that limited the ease of using the MERM, including weak cellular signal in the patient's home resulting in the nonreporting of doses taken (quote 16), failure of the device's battery (quote 17), and malfunction of the reminder lights (quote 18).

With regard to social influences, several patients reported concerns regarding violations of the privacy and confidentiality of their MDR-TB diagnoses, which reflects the stigma surrounding this disease. As described earlier, patients were particularly concerned about stigma when traveling with the MERM (quote 13), but many patients were equally concerned about stigma when taking the device with them to clinic visits (quote 19), when friends or relatives visited the home (quote 20), or when family members heard the audible reminder, even if the device was hidden (quote 21). One patient was even concerned that the audible reminder was loud enough to draw the attention of her neighbors:

> *When the alarm rings, my neighbors can hear it. I am scared that they will come to know about my disease.* [Patient, female, aged 21 years]

With regard to facilitating conditions, some patients conveyed an incorrect understanding of the functions of the MERM (quote 22). For example, when asked about the visual reminders, the following patient conveyed an incorrect understanding:

> *I have to close the box when the yellow light blinks and I understand that if the red light blinks the tablets are going to be over.* [Patient, female, aged 75 years]

Textbox 2. Representative quotations on barriers to acceptance and use of the Medication Event Reminder Monitor by patients based on constructs in the Unified Theory of Acceptance and Use of Technology (UTAUT).

Effort expectancy

- Size, portability, and storage problems
  - Quote 11: “Sometimes I have to go for work for 2 or 3 days, and during that time I can’t carry this big box to the workplace. A smaller box with an alarm would be useful when I go for work.” (Patient, male, aged 41)
  - Quote 12: “I keep my box in a hen cage [outside of the house], because my children used to play with it. I don’t have a place in my home to keep the box where my children won’t reach it.” (Patient, male, aged 33 years)
  - Quote 13: “How can I carry this big box when I have to attend a marriage function in my village? I am sure my relatives will ask me questions when I take the medicines out of the box and when they hear the alarm sound. I usually take the medicines out of the box when I travel and leave the box at home.” (Patient, female, aged 45 years old)
- Audible reminder is too loud
  - Quote 14: “The sound is so loud, even the neighbors can hear it....Maybe it [the audible reminder] is useful for elders but not for youngsters like me because I feel irritated when it alerts me.” (Patient, female, aged 18 years)
- Limited durability of the box and labels
  - Quote 15: “The label in the box is not properly fixed and it has started peeling off.” (Patient, female, aged 18 years)
- Other technical problems with the Medication Event Reminder Monitor
  - Quote 16: “Sometimes due to [cellular] signal problems, although I was opening the box, these doses were not reported. I received calls from the health center [in which HCPs told me] to keep the box [at locations in the house] where the network might be better.” (Patient, male, aged 38 years)
  - Quote 17: “The alarm did not ring once and when I took it to the centre, they told that the box has run out of charge and needs to be replaced or recharged.” (Patient, male, aged 44 years)
  - Quote 18: “I am confused because all the three lights were glowing every day.” (Patient, female, aged 37 years)

Social influences

- Problems related to privacy and stigma
  - Quote 19: “When I carry the box when leaving the health center, people know that I have TB. This is embarrassing, so I try to hide it, but it is too big.” (Patient, male, aged 39 years)
  - Quote 20: “Suppose that my relatives visit my home. The box’s alarm could ring in front of everybody....They may come to know that I have this disease. I would be so embarrassed in front of them. So, I don’t like this box.” (Patient, female, aged 18 years)
  - Quote 21: “I keep the MERM inside the cupboard in my bedroom. I go inside my bedroom and take the medicine [privately]. If the alarm goes off and there is somebody at home, they sometimes ask me where that sound came from.” (Patient, male, aged 49 years)

Facilitating conditions

- Incorrect understanding of the Medication Event Reminder Monitor, reflecting suboptimal counseling
  - Quote 22: “The green color light helps me as a reminder but the red color means danger, which indicates that I have to go for the refill.” (Patient, female, aged 18 years old; description reflects incorrect understanding of the meaning of each light)

Findings From HCPs

The interview findings revealed both facilitators of and barriers to HCP acceptance of the MERM (Figure 2).

Facilitators of HCP Acceptance and Use of the MERM

For HCPs, perceptions of positive performance expectancy (ie, perceived usefulness) were the strongest facilitators of their acceptance and use of the MERM. In particular, most HCPs felt that remote monitoring of adherence was beneficial for both patients and HCPs. During the pilot implementation of the MERM, patients with MDR-TB were generally dispensed 1 month of medications. Clinic visits to pick up medications, which were previously required on a weekly or biweekly basis, were reduced substantially under the assumption that remote monitoring minimized the need for more frequent in-person monitoring. Most HCPs felt that patients benefited from this reduction in required clinic visits, as described in the following quotation:

> *Patients now do not have to travel long distances, spending their money to collect their drugs every week, or sometimes twice a week. Most of our MDR TB patients come from distant villages, and transportation is very difficult. We feel comfortable giving them a month’s supply in the box [MERM] as*

> *it is easier for them to take and the light and alarm [reminders] help them to take their drugs on time.* [Senior treatment supervisor]

Reduced frequency of patient visits decreased the workload for many HCPs, resulting in decreased stress:

> *Previously, we had to supervise therapy on a daily basis [ie, DOT]. But now the patients come [to the clinic] only once a month, so our work pressure has reduced.* [Senior treatment supervisor]

Some HCPs reported that the decreased workload allowed them to focus more on each patient interaction, as well as other tasks, which increased job satisfaction:

> *I have more time now to check whether patients have taken their tablets or not. I am also able to concentrate on other tasks as well, which gives me more satisfaction in my work.* [Health visitors]

With regard to social influences, some HCPs perceived that providing medications in the MERM, compared with the cardboard box previously used to dispense medications, was potentially less stigmatizing for patients because some cardboard boxes contained messages regarding TB:

> *The good thing about the MERM is that it does not carry any messages on TB [on the outside of the box], so there is no stigma attached to it. Patients can carry it freely.* [Medical officer]

Barriers to HCP Acceptance and Use of the MERM

HCPs also reported barriers to the acceptance of the MERM for both patients and HCPs. With regard to performance expectancy, HCPs found intermittent (every 72 h) updating of patients' adherence records to be the most significant limitation to the MERM's perceived usefulness, as described by the following HCP:

> *It takes 72 hours for the [MERM] dashboard to show that the patient has taken medications. This makes it difficult for us to monitor the patient's drug intake on a daily basis. We cannot take action as promptly and lose time.* [Pharmacist]

With regard to effort expectancy (ease of use), many HCPs felt that the size of the MERM made transporting the device to clinic visits prohibitive:

> *It is good [for patients] to have a device like the MERM, but...it is difficult to carry, as they need to go by bus and train. We need to provide them with a big bag for [the device].* [Health visitors]

The MERM's size also resulted in challenges for HCPs themselves:

> *Even for us [HCPs] at the health centers, it is difficult to find space to store these MERM boxes.* [Senior treatment supervisor]

Consistent with findings from the patient interviews, HCPs described a lack of cellular signal in patients' homes as a barrier to MERM use for rural patients in particular. This barrier contributed to limitations in HCPs' ability to obtain adherence data from and communicate with patients:

> *Some of the patients are not willing to use the box [MERM], as people living in the villages are not always getting [adequate cellular] signal, so the device is not working.* [Senior treatment supervisor]

During the pilot implementation of the MERM, HCPs found that some facilitating conditions on the part of the health system were suboptimal. For example, some HCPs felt that the single-day training provided would be insufficient for new personnel:

> *One day of training will be difficult if we have newly recruited staff, because they have to understand the [MDR TB] program, and then undergo training [in use of the MERM].* [Senior treatment supervisor]

Some barriers to implementation arose from more fundamental challenges in the MDR-TB program. For example, MDR-TB medications were supposed to be dispensed in the MERM on a monthly basis; however, some medications were sometimes understocked. This problem was easier to manage when patients were refilling medications on a weekly or more frequent basis because fewer medications had to be dispensed at any given visit. MERM implementation therefore worsened challenges related to the understocking of drugs:

> *Sometimes MDR-TB drugs are not available, and so we are not able to give all the medicines required....How do we leave that compartment [in the MERM for a specific medication] empty, and what can we tell the patient?* [Pharmacist]

Finally, some personnel felt that when problems were identified with the implementation of the MERM, they did not have channels to communicate these challenges:

> *When we started using the MERM, we were excited about the device. When patients came back for their medication refills, they raised concerns with regard to technical problems—the alarm, light, texture and size of the box, for example. I was not sure who to notify. Maybe we could have had those who made the device discuss our feedback so it could be improved?* [Senior treatment officer]

Discussion

Principal Findings

This study describes the evaluation of a low-cost digital pillbox aimed at promoting medication adherence among patients with MDR-TB during pilot implementation in India's NTEP. We find that acceptability of the MERM is variable; some features of the technology facilitate acceptability, whereas other features and contextual factors serve as barriers to engagement by some patients. Although previous studies have evaluated the use of similar digital pillboxes as part of TB care [3,18-20,22,23], to our knowledge, only one previous study conducted in South Africa [17] has evaluated the use of these technologies for patients with MDR-TB, who face unique challenges, including the complexity of their medication regimens, prolonged duration of therapy, increased risk of drug toxicities, and greater disease-related stigma. In addition, our study is unique in that it assessed the perspectives of both patients and HCPs.

Implications of Findings From Patients With MDR-TB

Multiple factors increase patient acceptance and the use of MERM. For most patients, audible and visual signals served as helpful reminders to take medications. Forgetfulness is a common barrier to adherence [36]. Although often thought of as a cognitive problem, forgetfulness may also reflect other life challenges faced by patients, such as depression or spending long hours at work. In a qualitative study in India assessing the acceptance of 99DOTS, a cellphone-based DAT used to monitor patients with drug-susceptible TB, most patients reported that SMS text messages were not useful reminders to take medications because these messages were lost amid a high volume of *spam* SMS text messages [35]. In contrast, an advantage of the MERM was that the reminders drew patients to the site where medications were stored. This increased the likelihood that patients with MDR-TB immediately took their doses, which may promote habit formation in pill taking behavior [37,38]. In addition, the MERM's reminders sometimes transformed household social dynamics by drawing family members into patients' TB care, a finding also reported in studies of other DATs [35].

Patients appreciated aspects of the MERM's design—in particular, the secure storage provided by the box, the labels to help patients take an appropriate number of tablets of each medication, and the organization of different medications facilitated by internal partitions. These features were valued in light of the complexity of MDR-TB treatment regimens, which include at least 4 or 5 different medications, as well as the fact that MDR-TB medications had previously been dispensed in a cardboard box without internal partitions to separate medications or labels to guide pill taking.

In some patients, MERM enhanced their relationship with the health system. Most patients appreciated saving time and money by not having to visit the clinic as often because the frequency of routine clinic visits for patients with MDR-TB was reduced during the MERM pilot implementation. Although this resulted in decreased face-to-face interactions with HCPs, some patients actually described feeling more *cared for*. This feeling was derived from the perception that HCPs were remotely watching over their clinical progress, as well as from positive responses to actual phone or in-person outreach by HCPs, guided by patients' adherence data. Previous studies evaluating the use of DATs to support HIV and TB treatment adherence in Uganda, India, and South Africa similarly found that remote monitoring enhanced some patients' perceptions of the care provided by the health system [17,35]. This may be one of the behavioral pathways by which DATs may motivate patients to adhere to treatment.

Patients also reported barriers to the acceptance and use of MERM. Some of these barriers may be modified by altering the MERM's design or implementation (Textbox 3). For example, the loud volume of the audible reminder—a common complaint from patients also reported in a previous study of the MERM from China [18]—could potentially be modified or the audible reminder disabled completely, ideally based on patients' personal preferences. As another example, during pilot implementation, the MERM was made of commercial-grade cardboard, which did not wear well in India's humid weather conditions. Redesigning the MERM using plastic would be feasible and minimize weather-related damage, although it would likely increase the cost of the device. Other technical problems, such as battery failure or inappropriate blinking of the reminder lights, could likely be addressed with product improvements in future iterations of the MERM.

Textbox 3. Recommendations for improving the Medication Event Reminder Monitor device and its implementation, based on findings from patients with multidrug-resistant tuberculosis and health care provider interviews.

Design of the device

- Data transmission from the device on a daily basis may facilitate better near real-time monitoring
- Redesign using plastic (rather than cardboard) may reduce wear because of weather conditions
- Strengthening internal partitions may help avoid accidental mixing of different medications
- Device reuse should be limited, given considerable wear and tear even after single patient use

Reminder functions

- Allowing patients to reduce the volume of the audible reminder or to deactivate audible or visual reminders may address concerns about privacy and stigma
- Malfunction of visual reminders (eg, all lights blinking at once) should be fixed

Counseling and monitoring of patients

- Health care providers should be trained to provide standardized counseling to ensure patient understanding of key Medication Event Reminder Monitor functions
- Health care providers should use pill counts and ask adherence questions to patients at clinic and home visits to cross-check the Medication Event Reminder Monitor's adherence data

Screening out patients for whom the Medication Event Reminder Monitor may not be appropriate

- Systematic screening should be performed upfront to identify patients for whom the Medication Event Reminder Monitor may not be appropriate, including those with concerns about stigma, a fear of disclosure of diagnosis, difficulties with portability, and lack of cellular signal in the home

Training of health care providers

- Mechanisms should be created for the training of newly hired National Tuberculosis Elimination Program personnel and provision of periodic refresher training in the Medication Event Reminder Monitor for existing personnel
- Mechanisms should be created for National Tuberculosis Elimination Program personnel to provide ongoing feedback to facilitate device improvements

Although some barriers may be addressable, others may present more fundamental challenges that could limit the use of the MERM among some patients. For example, the MERM's large size was a barrier for patients who were traveling or who preferred to take their medications at work. However, the MERM's size is necessary to hold a 1-month supply of MDR-TB medications, and patients benefit from having their medications dispensed in an organized manner with appropriate labeling. Furthermore, because of its prohibitive size, patients who need to take doses when traveling or at work tend to remove doses from the device rather than carry it with them. The lack of cellular signals in the home is another nonmodifiable barrier that limits the benefits of remote monitoring because adherence data cannot be transmitted from the device on a regular basis.

Disease-related stigma, from family and community members, is a common challenge faced by patients with MDR-TB [10]. Owing to stigma, patients often do not disclose their diagnosis to family members, friends, and coworkers; as a result, patients fear situations that could result in disclosure of their diagnosis to others. The MERM's large size, as well as its audible and visual reminders, raised patient concerns regarding the risk of disclosure of diagnosis. Indeed, as ascertained from their interviews, patients who faced barriers related to their social context, including stigma, a fear of disclosure, or frequent work-related travel, seemed to be the most likely to not use the MERM.

All of these problems—removal of doses from the device because of its lack of portability, the nonreporting of box openings because of lack of cellular signal, and the nonuse of the device because of disease-related stigma—could result in underreporting of medication doses, resulting in inaccuracies in patients' adherence records. Recent studies found that these same barriers contribute to relatively high rates of patient nonengagement with 99DOTS in India [35], especially in the continuation phase of therapy, which contributed to the technology's suboptimal accuracy for measuring adherence to TB medications [24]. A qualitative study of drug-susceptible TB patients monitored with the MERM in Vietnam found that only approximately half of the patients used the device as intended largely because of the difficulties with the device's portability, with the result that the MERM data often did not reflect actual adherence [23]. A high rate of device nonuse was also found in a study that used the Wisepill device (a similar digital pillbox) to monitor adherence to HIV preexposure prophylaxis in young men who have sex with men in the United States [39].

These barriers to use suggest that if implementation of the MERM is expanded among patients with MDR-TB in India, there could be limits to the device's reach, or overall coverage, in this patient population. Wide-scale implementation of a similar digital pillbox among patients with drug-susceptible TB in China has revealed meaningful limitations in the reach of the device [21,22]. For example, in one study of the implementation of a digital pillbox in 30 counties in China, even after excluding 41% of the patient cohort who were either not eligible to use the device or who did not receive the device for unclear reasons, only approximately two-thirds of the remaining 1314 patients who received the pillbox had sustained use for the remainder of the treatment [22]. The other one-third of patients who received the digital pillbox either stopped using the device or met the criteria to be shifted back to monitoring with DOT because of a high proportion of missed doses. These missed doses could have represented either true nonadherence to medications or inappropriate use of the device.

In light of such findings from other contexts, it would be reasonable to assume that some proportion of patients with MDR-TB in India might not use the MERM in wide-scale implementation. On the basis of our findings, the NTEP could consider screening patients with MDR-TB upfront to identify individuals who might be unlikely to use the device, for example, because of patient concerns about stigma and portability or lack of cellular signal in the home (Textbox 3). In addition, HCPs should use other strategies to verify medication adherence, including pill counts and asking adherence-related questions to patients at every in-person clinic and home visit, which will help HCPs to cross-check the adherence data being received from the MERM.

Implications of Findings From HCPs

In the HCP interviews, NTEP personnel affirmed some of the patient-oriented benefits of the MERM, in particular, the time and money saved by patients from the reduced frequency of clinic visits; however, HCPs' perceptions that the MERM was associated with fewer patient concerns about stigma were not shared by some patients. HCPs also reported that implementation of the MERM reduced their workload because of the reduced frequency of clinic visits by patients and the ability to monitor adherence from the clinic rather than by home visits. As a result, HCPs dedicated greater time to other tasks and reported improved job satisfaction, similar to the findings of a previous study of the MERM conducted in China [18]. HCPs did find some aspects of the pilot implementation to be suboptimal; however, most of these concerns were potentially addressable. In particular, they reported a need for more training in the use of the MERM, especially in light of the high turnover of staff, and the need for a platform to communicate any implementation challenges they faced (Textbox 3).

Directions for Future Research

This initial evaluation has identified several features that may facilitate high acceptability of the MERM for many patients with MDR-TB, especially if modifications are made to improve the device. Future research should focus on understanding how often patients face critical barriers to acceptability (eg, disease-related stigma), the extent to which these barriers lead to device nonuse and whether screening for these barriers can be used to better target the MERM to patients most likely to use it. In addition, further research is needed to understand the accuracy of the MERM for measuring adherence to MDR-TB medications, its effectiveness for improving treatment outcomes, and its reach, that is, coverage or uptake by patients, in large-scale implementation [3].

Even for patients who agree to use the MERM, the adherence record could be inaccurate because of underreporting (eg, if patients take medications out of the device, resulting in device nonuse) or overreporting (eg, if patients open and close the device without actually taking medications). Indeed, a recent study of 99DOTS, in which its adherence record was compared with urine isoniazid test results from patients with TB collected during unannounced home visits, found that both under- and overreporting of adherence contributed to the technology's suboptimal accuracy [24]. A similar research approach, involving unannounced home visits with measurement of urine biomarkers for MDR-TB medications, could be used to evaluate the accuracy of MERM, although pill counts should also be conducted to provide insights into whether patients have differential adherence to different medications in the MDR-TB regimen.

Existing studies of the use of DATs to promote adherence to TB medications have found both positive [20,40] and negative or equivocal [41-43] impacts on adherence and TB treatment outcomes. As such, studies of effectiveness, especially high-quality randomized trials, are needed to assess whether MERM use translates into improvements in treatment outcomes and recurrence-free survival for patients with MDR-TB. Even when DATs have been shown to be effective, as with digital pillboxes in China [20], subsequent large-scale implementation studies have shown suboptimal reach or coverage of patients [21,22]. As such, studies of the MERM's coverage of patients with MDR-TB in large-scale implementation will be critical to ensure that it achieves population-level impact. Finally, in light of the diverse psychosocial barriers to adherence faced by patients with MDR-TB [10], the benefits of monitoring with the MERM in this population will depend on the development of interventions to address problems, such as medication toxicities, depression, stigma, and substance use disorder, which are often the underlying causes of nonadherence [44].

Study Limitations

Our study was limited to assessing patient and HCP perceptions, rather than more objective findings, such as the accuracy of the MERM or impact on clinical outcomes. As such, we may have overestimated the acceptability and benefits of this technology because of socially desirable responses, which is a common bias in qualitative research. In addition, patients attributed the reduced frequency of their clinic visits to the MERM, as a longer supply of medications was dispensed in the device. The reduced frequency of clinic visits may have therefore biased patients in favor of higher acceptance of the device; however, provision of a longer supply of medications could have just as easily been implemented without the MERM.

Our deductive approach to analysis allowed us to organize and report our findings using the UTAUT, which is a robust and evidence-based framework for understanding technology acceptance; however, a limitation of this approach is that we could have overlooked findings that did not fit into this predetermined framework.

Another limitation of our study is that we assessed patients' perceptions of the MERM within a few weeks of their use of the device. In light of the prolonged duration of MDR-TB treatment, it is possible that patients' acceptance and use of the device could change over time. In addition, our study was limited to 2 cities and may not be representative of barriers to the use of the MERM in rural parts of India. Future studies could consider including diverse geographic settings and conducting multiple interviews to understand the acceptability of the MERM throughout the treatment course.

Conclusions

In this study of the pilot implementation of a low-cost digital pillbox to promote adherence to MDR-TB medications, we identified several features that facilitate high acceptability of the device among patients. These included helpful organization and labeling of medications, feeling more *cared for* by the health system because of remote monitoring, and appreciation of the audible and visual reminders, which often drew family members into patients' care.

At the same time, we identified barriers that could limit the acceptance and use of the MERM by some patients. Although some of these barriers could be addressed relatively easily with modification of the device, other barriers—such as difficulties with the device's portability, lack of cellular signal in the home, and a fear of disclosure of diagnosis because of disease-related stigma—are more difficult to modify and may limit the reach or population coverage of this technology. Future research is needed to assess the accuracy of the MERM for measuring adherence, its effectiveness for improving treatment outcomes, and patients' sustained use of the device in larger scale implementation in India's MDR-TB treatment program.

Abstract

Background: Medical crowdfunding utilizes the internet to raise medical funds. Medical crowdfunding has developed rapidly worldwide; however, most medical crowdfunding projects fail to raise the targeted funds. Therefore, a very important research problem that has not received sufficient attention from the existing literature is identifying which factors affect the success of medical crowdfunding projects.

Objective: The aim of this study was to examine the effect of textual features of medical crowdfunding projects on their success rate using 4903 real projects from the Tencent Charity platform, a well-known medical crowdfunding platform in China. In particular, according to Aristotle's theory of persuasion, we divided the project text of medical crowdfunding into the project title and project details, which were analyzed from two perspectives (existence and extent) to explore their respective impacts.

Methods: We established a research framework to meet our research goals. The process was divided into five main parts. We first collected data from Tencent Charity using Python programs and cleaned the datasets. Second, we selected variables and built the research model based on previous studies and the theory of persuasion. Next, the selected variables were extracted from the project text. We then performed econometric analysis using multiple regression analysis. Finally, we evaluated the results of econometric analysis to extract knowledge.

Results: In the project title, the presence of the patient's disease (*P*=.04) and occupation (*P*=.01) had a positive impact on the success rate of fundraising, whereas the presence of age (*P*<.001), gender (*P*=.001), and negative emotions (*P*=.04) had a negative impact. In the project details, the presence of the patient's occupation (*P*=.01), monetary evidence (*P*=.02), and negative emotions (*P*=.04) played a positive role in the fundraising success rate, whereas the presence of age (*P*<.001) and positive emotions (*P*<.001) played a negative role. Moreover, in the project details, high-frequency monetary evidence (*P*=.02) and negative words (*P*=.02), as well as a short narrative length (*P*=.01) were conducive to succeeding in medical crowdfunding. Younger patients were more likely to obtain a higher success rate in medical crowdfunding. For patients whose occupations were national civil servant, professional skill worker, clerk, business and service worker, solider, child, student, and public-spirited person, the success rate of fundraising decreased sequentially.

Conclusions: This study collected 4903 valid data from Tencent Charity, and identified which factors in the project text play an important role in the success rate of medical crowdfunding from the perspective of existence and extent. We found that in addition to the project details, the features of the project title also have an important impact on the success rate of fundraising. These findings provide important theoretical and managerial implications for medical crowdfunding.

medical crowdfunding; textual features; project title; project details; fundraising success; theory of persuasion

Introduction

Background

With an aging population, the widespread prevalence of chronic diseases, a growing number of serious illnesses, and advances in medical technology, global health spending is rising rapidly. From 2018 to 2022, global health spending is expected to increase at an annual rate of 5.4%, representing a significant increase from 2.9% in 2013-2017 [1]. However, access to good health care such as through medical insurance and government subsidies is not available to all. Currently, half of the world's population still lacks access to essential health services [2]. Additionally, even with partial health care, many medical conditions still incur high out-of-pocket medical costs, leading to significant financial stress on individuals and their families. In 2018, approximately 100 million people worldwide fell into extreme poverty because of out-of-pocket medical expenses [2].

In recent years, medical expenses in China have also increased rapidly. According to statistics from the National Health Commission, China's medical expenses exceeded US $97.4 billion in 2019 [3]. Although China has established a relatively complete medical security system, many patients still have to pay large medical expenses themselves. China has established a multilevel medical security system with a basic medical insurance system as the main body, commercial insurance as a supplement, and social charity relief as a base. China has a basic medical insurance system, which receives subsidies for poor patients so they can be covered by insurance. As of January 2020, China's basic medical insurance system covers more than 1.35 billion people, a coverage rate of approximately 97%, according to the National Healthcare Security Administration [4]. There are few people who currently purchase commercial insurance. As of October 2019, the number of people with major illness insurance policies in China did not exceed 100 million [5]. However, the current medical insurance system still has the following three problems. First, medical insurance reimbursement is restrictive, with reimbursements only provided for the hospital's medical expenses, excluding nutrition and other expenses. Moreover, the expenses above this standard can be reimbursed only when the medical expenses reach the reimbursement standard. The reimbursement ratio ranges from 30% to 90%, and the maximum reimbursement limit is approximately US $40,000 [6]. Second, some drugs are not covered by reimbursement. For example, Neulasta/Peglasta is an imported drug that is effective in the treatment of cancer, but it is not on the reimbursement list. Finally, there are still more than 40 million Chinese people without medical insurance. Consequently, the existence of the above-mentioned problems has caused out-of-pocket medical expenses to remain high for many patients. There are still many families who suffer from poverty due to illness. As an example, Sohu News revealed that an 8-year-old girl in Tianjin, China was diagnosed with malignant neuroblastoma. Because of this illness, the family has spent more than US $60,000 and has accrued approximately US $30,000 of debt as a result. To cure this disease, follow-up treatment costs will reach nearly US $60,000 [7].

A unique and increasingly popular type of crowdfunding application, namely medical crowdfunding, is being used by many patients and their families to pay for medical bills. Medical crowdfunding has developed rapidly worldwide. GoFundMe, a US crowdfunding platform, raises US $650 million from approximately 250,000 medical crowdfunding campaigns each year [8]. A medical crowdfunding platform in China, Shuidichou, successfully provided fundraising services for more than 800,000 patients in economic distress as of the end of September 2018, raised more than US $1.4 billion, and aided over 340 million patients [9]. Other medical crowdfunding platforms have also grown rapidly in China. It is expected that medical crowdfunding worldwide will experience an annual growth rate of 25% [10]. However, the success rate is low for medical crowdfunding projects, as most of these campaigns fail to raise the target funds [11,12]. Berliner and Kenworthy [13] found that only 10% of the 200 raisers of medical funds randomly selected on the GoFundMe platform achieved their fundraising goals. Howard [14] pointed out that only a small proportion of medical fundraising campaigns are fully funded. The statistical data of 143,917 medical crowdfunding projects on Qschou.com show that only 7% of the projects successfully raised the target amount [15]. Therefore, a very important research goal is to identify the factors that affect the success rate of medical crowdfunding projects.

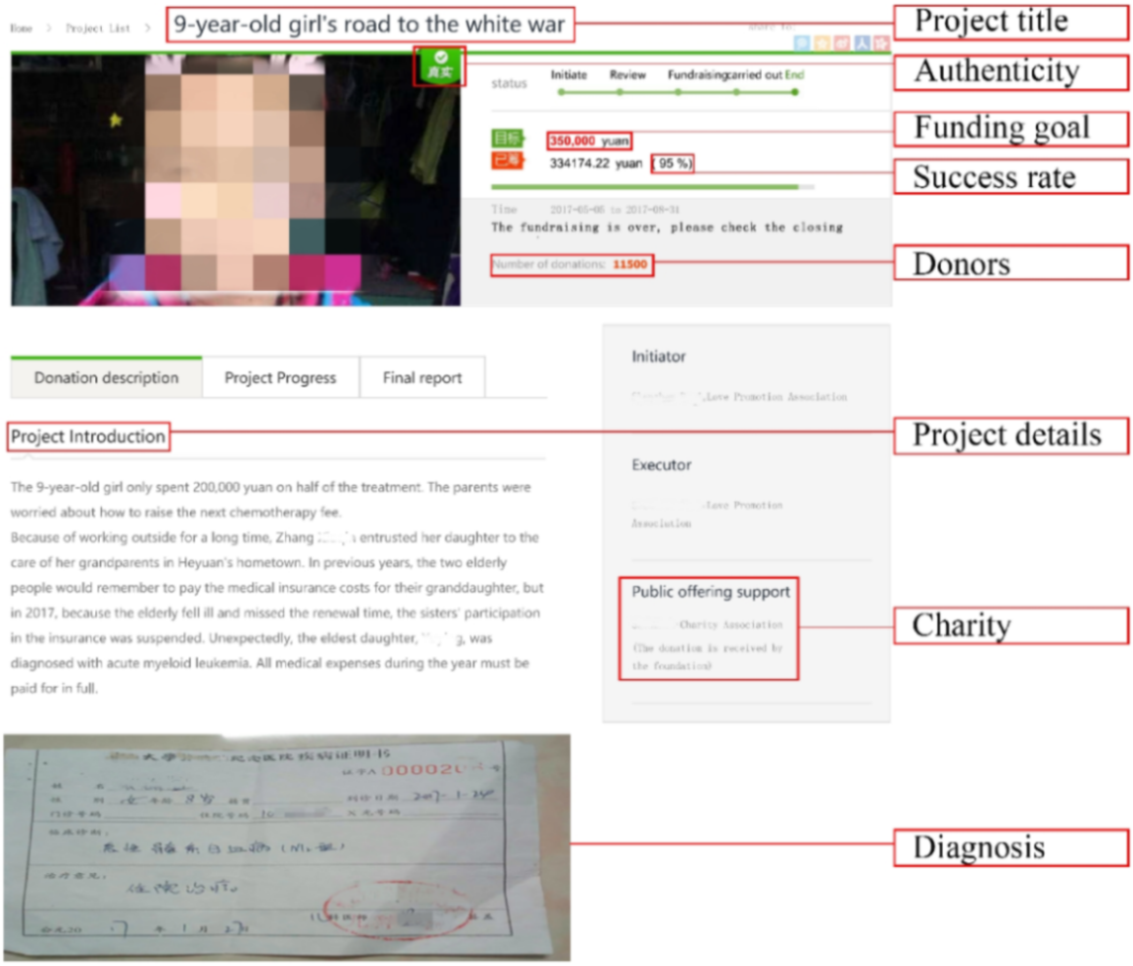
With the rapid development of medical crowdfunding, many studies have begun to examine this topic. Most researchers in this field have focused on the development of medical crowdfunding; the relationship with personal bankruptcy; and the fraud, privacy, and ethics issues that may be caused by medical crowdfunding [10,16-19]. However, little research has focused on the factors that impact the success of a medical crowdfunding project.

Medical crowdfunding is a new form of online crowdfunding. The role of the text on a fundraising page is important because project creators try to convince potential supporters with a compelling story [20]. Numerous studies have analyzed the effect of textual features on the success of online crowdfunding; however, determining whether these features also affect the success rate of medical crowdfunding projects is an extremely important and unsolved problem. Additionally, Aristotle's theory of persuasion has been widely used in the online crowdfunding literature [20-22]. For example, Majumdar and Bose [20] studied the impact of narrative text on the possibility of pizza donation according to this theory. However, there is no literature related to the influence of textual features on the success of medical crowdfunding based on this theory at present. Therefore, we proposed research question 1: According to previous research and Aristotle's theory of persuasion, do textual features have an important impact on the success of medical crowdfunding?

In medical crowdfunding, the project information generally consists of two parts: the project title and the project details, as shown in Figure 1. The project title is used to provide a brief overview of the crowdfunding project information using concise phrasing, and the project details are used to provide more complete information about the patient. Some studies have already investigated the impact of textual features on medical crowdfunding success; however, they focused on the impact of the text features of the project details and ignored the text features of the project title [23,24]. Medical crowdfunding projects are usually spread via social media in the form of links; therefore, potential donors often see the project title first. Accordingly, the textual features of the project title may affect the behavior of potential donors. If potential donors want to know more after reading the project title, they will further read the content of the project details. At this time, the text features of the project details may affect readers' donation behavior. Therefore, it is possible that the text features of both the project title and project details will affect donors' decision-making behavior, which in turn will affect the success of medical crowdfunding projects. Therefore, we proposed the following two research questions to explore the characteristics of the project title and project details that affect the success rate of medical crowdfunding projects:

- Research question 2: In the project title, what features can influence the success of medical crowdfunding?
- Research question 3: In the project details, what features can influence the success of medical crowdfunding?

Figure 1. Screenshot of a medical crowdfunding project.



The 9-year-old girl only spent 200,000 yuan on half of the treatment. The parents were worried about how to raise the next chemotherapy fee.

Because of working outside for a long time, Zhang [redacted] entrusted her daughter to the care of her grandparents in Heyuan's hometown. In previous years, the two elderly people would remember to pay the medical insurance costs for their granddaughter, but in 2017, because the elderly fell ill and missed the renewal time, the sisters' participation in the insurance was suspended. Unexpectedly, the eldest daughter, [redacted], was diagnosed with acute myeloid leukemia. All medical expenses during the year must be paid for in full.

Literature Review

Medical Crowdfunding

Medical crowdfunding is a form of donation-based online crowdfunding. Online crowdfunding involves enterprises or individuals obtaining, through the internet, financial support from a large group of participants who provide small amounts of money [25]. There are many types of crowdfunding such as reward-based crowdfunding, equity-based crowdfunding, debt-based crowdfunding, and donation-based crowdfunding [26]. Reward-based crowdfunding involves individuals contributing comparatively small amounts of money to projects in return for some kind of reward. Rewards can range from a simple token such as a thank-you postcard to a production version of the crowdfunded product [27]. Equity-based crowdfunding is a mechanism that enables broad groups of investors to fund startup companies and small businesses in return for equity [28]. Debt-based crowdfunding is based on the relationship between a debtor and lender, and possesses a certain yield rate [29]. Donation-based crowdfunding, also called charitable crowdfunding, requires donors to devote themselves to the public good with no expectation of obtaining material rewards [30].

Medical crowdfunding aims to help those who are unable to pay their medical bills by enabling them to receive donations from others, and its text narrative usually involves many personal characteristics of the requester. In recent years, medical crowdfunding has attracted extensive attention within the academic community. Specifically, Snyder et al [18] analyzed 80 medical crowdfunding activities as examples of how Canadians prove to others that they should finance the medical expenses of requesters, and these reasons were evaluated according to relevant theories of ethics. Renwick and Mossialos [31] examined possible economic risks and benefits in the development of medical crowdfunding. Gonzales et al [16] demonstrated that medical crowdfunders often balance two aspects of a fundraising campaign: assistance from others and perceived privacy risks. Zenone and Snyder [19] summarized four possible types of fraud in medical crowdfunding: faking/exaggerating illnesses, impersonation, and misapplication of funds. Moore [17] studied an ethical issue involving the role of donors in medical crowdfunding. The research of Burtch and Chan [10] indicated that the number of individual bankruptcy filings in the United States is experiencing a trend of gradual decrease as a result of the rapid advancement of medical crowdfunding. Bassani et al [32] discussed the formation process and development direction of medical crowdfunding platforms, explored the relationship between medical crowdfunding and the national health system, and found that substitution effects function when the coverage rate of public health is low. After analyzing news reports on medical crowdfunding in the United States and Canada, Murdoch et al [33] discovered that there is little reportage of the negative descriptions of crowdfunding campaigns (4.76%), and found that the patients' conditions were mostly cancer (49.11%) and rare diseases (36.01%).

In summary, previous studies have not directly elucidated the influencing factors of medical crowdfunding results but have rather probed the development of medical crowdfunding, and its impact on social and economic activities.

Influence of Textual Features on the Success of Online Crowdfunding

Crowdfunding projects are usually associated with a description of how the funds will be used [20]. In recent years, many studies have analyzed the impact of textual features on the success of online crowdfunding. Greenberg et al [34] found that some project information characteristics such as the project goal, project category, magnitude of the reward, project duration, whether the project is connected to social networks, and the number of words in the narrative can predict the success or failure of a reward-based crowdfunding campaign. Lukkarinen et al [28] discovered that the investment decisions of participants in equity-based crowdfunding are associated with the comprehensibility of the campaign and other easily grasped informational features to a great extent, with the traditional investment decision criteria used by venture capitalists or business angels having less importance. Lin [35] suggested that the language characteristics of the campaign requirements description, including readability, positivity, and deception cues, can predict the performance of the loan project.

Unlike other types of online crowdfunding, donation-based crowdfunding does not require financial returns, and the narrative usually contains little information about the economic benefits. Some scholars have explored the influence of textual features on the success of donation-based crowdfunding. Kshetri [36] pointed out that the identity of the fundraiser displayed in a donation-based crowdfunding campaign has a significant influence on donors' behavior. Xu [37] examined the impact of three manifestations (video, pictures, and text) on the success rate of donation-based crowdfunding. Majumdar and Bose [20] analyzed 5671 real data items and found that donors' behavior is influenced by many variables, including money-related words, the extent of use of negative emotions, and evidence relating to women and the authenticity of the information they provided. Additionally, Zubrickas [38] and Cason and Zubrickas [39] discussed how the inclusion of a refunding mechanism in the information can affect donors' decision-making behavior. Sasaki [40] explained the effect of the amount of other people's donations on subsequent behavior, and the empirical results showed that subsequent donors are more likely to increase their donations when the amount of the previous five donations increases. Cheng et al [41] proposed an optimal threshold in the number of donations provided by donation-based crowdfunding campaigns that promotes more donation activities.

Medical crowdfunding is a new form of donation-based crowdfunding. However, it is unknown whether the text characteristics of these projects affect their success rate. Only a few researchers have aimed to study this problem to date. Durand et al [23] indicated that medical crowdfunding for transplant surgery was more successful when the campaigns had longer descriptions, higher goal amounts, more positive emotions, and third-person narratives. Majumdar and Bose [20] discovered that reasonable and credible requests during a campaign can improve the chance of receiving donations. Xu and Wang [24] considered that certain messaging aspects such as constructing an image of being vulnerable and worthy of help, utilizing a tragic narrative with elements of Chinese traditional culture, and contrasting patients' experiences before and after the illness can arouse the sympathy of potential donors and prompt them to donate to patients. However, these studies analyzed the impact of only a small number of textual features on medical crowdfunding from a specific theoretical perspective. Whether the large number of textual features found in the online crowdfunding literature has an impact on the success rate of medical crowdfunding remains an unresolved research question. Moreover, these previous studies focused only on the influence of the textual features of the project details and ignored the role of the textual features of the project title. However, the project title also embodies a wealth of information that may play a prominent role in the success rate of medical crowdfunding projects.

Theory of Persuasion and Online Crowdfunding

As an important channel for people to understand the needs of a medical crowdfunding project, the main expectation of text narration is to persuade readers to donate to the requester. The type of persuasive strategy that can be used to improve the persuasiveness of the text is particularly significant. Aristotle supposed that rhetoric signifies "the faculty of observing in any given case the available means of persuasion" and proposed the theory of persuasion. This theory mainly includes three important methods of persuasion: Ethos, Logos, and Pathos [42]. Ethos means that speakers should show some authentic and reliable content to gain psychological recognition and the trust of the audience. Logos means that speakers should use logical statements to convince others. Pathos means that speakers should display their emotional factors and arouse the emotions of the audience [42,43].

Aristotle's theory of persuasion has also been applied to the field of online crowdfunding. Tirdatov [21] examined the 13 most-funded crowdfunding texts from Kickstarter, and found that all of them contained the three types of rhetorical styles mentioned in the theory of persuasion (ie, Ethos, Pathos, and Logos). Majumdar and Bose [20] studied the content factors of rationality, emotion, and credibility in text narratives, and found that the presence of rational and credible content in charity messages is positively related to the probability of receiving pizza donations, but this was not the case for the emotional content. Wang and Wu [22] explored the impact of photographic narratives on online medical crowdfunding campaigns. They found that Pathos (emotional-related) and Ethos (credible-related) photos have positive persuasion effects on medical crowdfunding performance, whereas Logos (rational-related) photos have a negative persuasion effect. However, the existing literature has not yet used the theory of persuasion to study the influence of persuasive strategies of textual features on the results of medical crowdfunding.

Complementing this line of existing research, this study empirically examined the effect of the textual features of medical crowdfunding projects on their success rate, taking 4903 real projects collected from the Tencent Charity platform in China as the research sample. Based on the theory of persuasion, we divided the appeals in the text into three categories (rational, emotional, and credibility appeals), explored them from the two dimensions of project title and project details, and analyzed them from two perspectives of existence and extent.

Methods

Study Design

To meet the research objectives, a research framework was developed. The process was divided into five main sections: (1) collecting and cleaning the dataset, (2) selecting the variables and building the research model, (3) extracting the variables, (4) performing econometric analysis, and (5) evaluating the results of the econometric analysis to extract knowledge.

Collecting and Cleaning the Dataset

There are two types of medical crowdfunding in China: public fundraisers and individual appeals. The "Charity Law" promulgated in 2016 stipulates that for public fundraisers, patients or their families must post fundraising information on the crowdfunding platform prescribed by the Civil Affairs Department of the State Council with the help of philanthropic organizations. These projects are publicly available on the crowdfunding platform where information is easily obtained. Individual appeals are published and disseminated exclusively on social media such as microblogs and cannot be publicly displayed on crowdfunding platforms. Compared to individual appeals, the information on crowdfunding platforms is more complete and has higher credibility, and the platforms have certain specifications for fundraisers so that the process is more normalized. Hence, the datasets in this study were obtained mainly from public fundraisers.

Our data sample was obtained from the Tencent Charity platform, which is one of the largest donation-based crowdfunding platforms in China and provides easy access to information. Tencent Charity was initiated by the Tencent Company in 2007. As of January 2019, its cumulative fundraising amount had exceeded US $700 million. We collected data using a crawler program, which we developed based on the Python language. The program first uses a Python third-party library ("requests") to obtain webpage data containing crowdfunding projects. It then uses regular expressions to parse and extract the required information, and finally saves the data in an Excel table. The pseudocode of the crawler program is provided in Multimedia Appendix 1.

We collected all disease crowdfunding projects displayed on Tencent Charity in January 2019. An initial total of 5400 projects were obtained. We deleted projects that were raising funds for certain groups through manual filtering, because the focus of this study was personal medical crowdfunding. The main process was as follows. First, two graduate students marked projects for which the donation objects were not individuals by reading crowdfunding text from the dataset. Second, a third student compared the results of the previous two students. If there was substantial divergence, the three students discussed it until they reached agreement. In the end, a final dataset containing information on 4903 medical crowdfunding projects containing both nontextual features (funding goal, fundraising amount, and donors) and textual features (project title and project details) was obtained. In the dataset, the average values of funding goal, fundraising amount, and number of donors were 149,673, 34,569, and 1467, respectively. We used the fundraising amount divided by the funding goal to calculate the project's fundraising success rate. Overall, the success rate of medical crowdfunding projects was found to be relatively low, with an average success rate of 0.31.

Selecting Variables and Building the Research Model

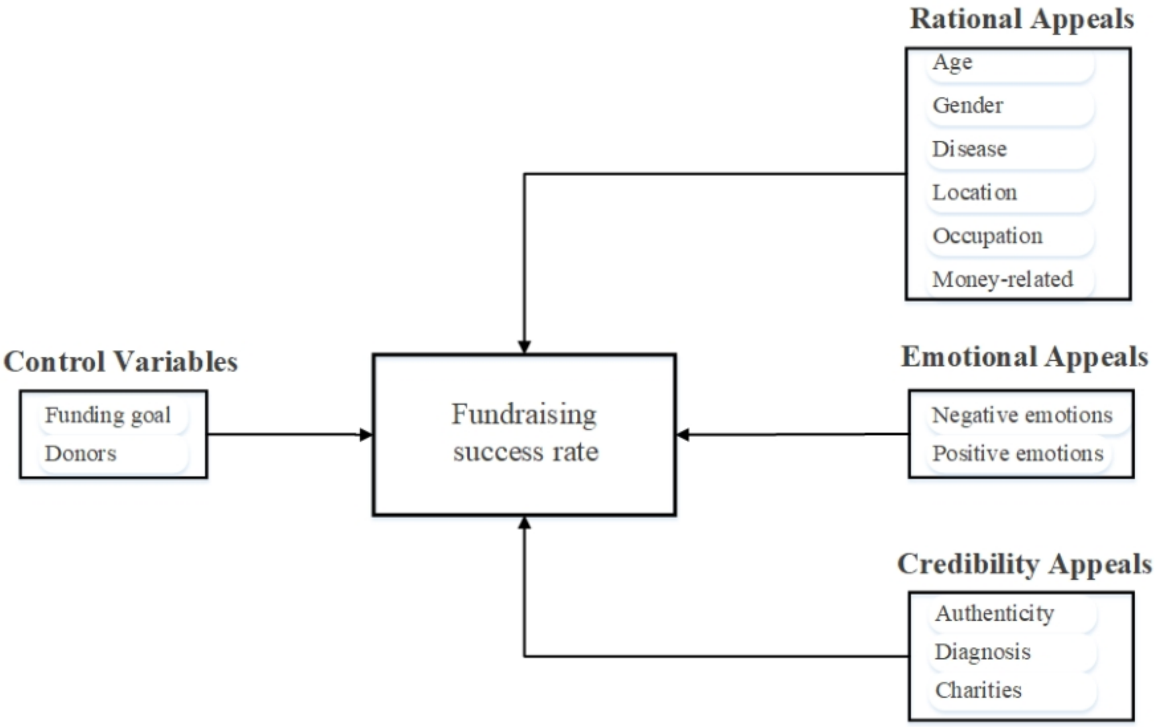
We first selected variables according to the previous literature on online crowdfunding, which showed that certain textual features play an important role in the success rate of online crowdfunding projects, as shown in Table 1. The main textual features that have been found to have a significant impact include disease description, patient age, patient gender, regional economic development level, patient occupation, emotional and economic descriptions, vivid language, inclusive language, money-related language, title length, project information quality, description elaborateness, video, images, number of updates, prior experience, and duration. These features constituted the candidate feature set of the crowdfunding texts. We then determined the variables related to medical crowdfunding based on this feature set, including textual and nontextual features (Table 1).

Table 1. Textual features affecting the success rate of online crowdfunding projects.

Reference	Online crowdfunding type	Research variables
Xu and Wang [24]	Donation-based crowdfunding	Illness narrative and the patients' identity such as disease severity and financial plight, tragic narrative strategies, etc
Aleksina et al [44]	Donation-based crowdfunding	Disease characteristics, medical research characteristics, organizational characteristics, comments, length, platform, etc
Kusumarani and Zo [45]	Donation-based crowdfunding	Perceived financial resources, perceived information resources, political interest, negative perception toward political situation, online community engagement, etc
Liang et al [46]	Reward-based crowdfunding	Funders' trust, project information quality, fundraiser's ability, project type and funding level, gender, age, education, income, prior experiences, website familiarity, etc
Petitjean [47]	Reward-based crowdfunding	Goal, geography, photo, video, website, updates, comments, Facebook friends, shares, etc
Durand et al [23]	Donation-based crowdfunding	Disease category, narrative perspective, gender, patient age group, location, goal amount, cumulative sentiment, sentiment range, description length
Majumdar et al [20]	Donation-based crowdfunding	Title length, reciprocity phrases, gratitude, popularity, comments received, account age, past participation, authentic, text length, presence of image, presence of monetary evidence, presence of negative emotions, presence of female references, extent of monetary evidence, extent of negative emotions, extent of female references
Kim et al [48]	Reward-based crowdfunding	Identity disclosure, prior experience, number of comments, number of updates, description elaborateness, campaign duration, funding goal, country, category
Allison et al [49]	Reward-based crowdfunding	Log funding, requested funding, adopted group, identity, positive narrative tone, etc
Bi et al [50]	Reward-based crowdfunding	Goal, duration, introduction word count, video count, "like" count, number of reviews
Lukkarinen et al [28]	Equity-based crowdfunding	Number of investors, amount raised, team rating, markets rating, concept rating, etc
Gorbatai et al [51]	Reward-based crowdfunding	Money-related language, vivid language, positive emotion, inclusive language, campaign duration, video, images, length of the campaign text, campaign goal, etc
This study	Donation-based crowdfunding	Age, gender, disease, location, occupation, money-related words, negative emotions, positive emotions, authenticity, diagnosis, charities, length of the project title and project details, funding goal, donors

We further built the research model based on Aristotle's theory of persuasion, which includes three important methods of persuasion: Ethos, Logos, and Pathos [42]. Some previous studies have applied the theory of persuasion to the study of human behavior [20,22,43]. Majumdar and Bose [20] categorized content factors of online crowding into rational, emotional, and credibility based on this theory. Similarly, in this study, we divided the persuasion strategy of medical crowdfunding text into three categories: rational, emotional, and credibility appeals, corresponding to Logos, Pathos, and Ethos, respectively. Age, gender, disease, location, occupation, and money-related words all describe actual information about the patient, highlighting the characteristics of the donation objects, and therefore constitute rational appeals. Negative emotions and positive emotions express the feelings of the seeker and focus on appealing to the sympathy of potential donors, and therefore belong to emotional appeals. Authenticity, diagnosis, and charities are used to prove that the crowdfunding project is true and reliable, and are therefore classified as credibility appeals. Moreover, consistent with previous research [50], the nontextual features of funding goal and donors are regarded as control variables. The research model is schematically depicted in Figure 2.

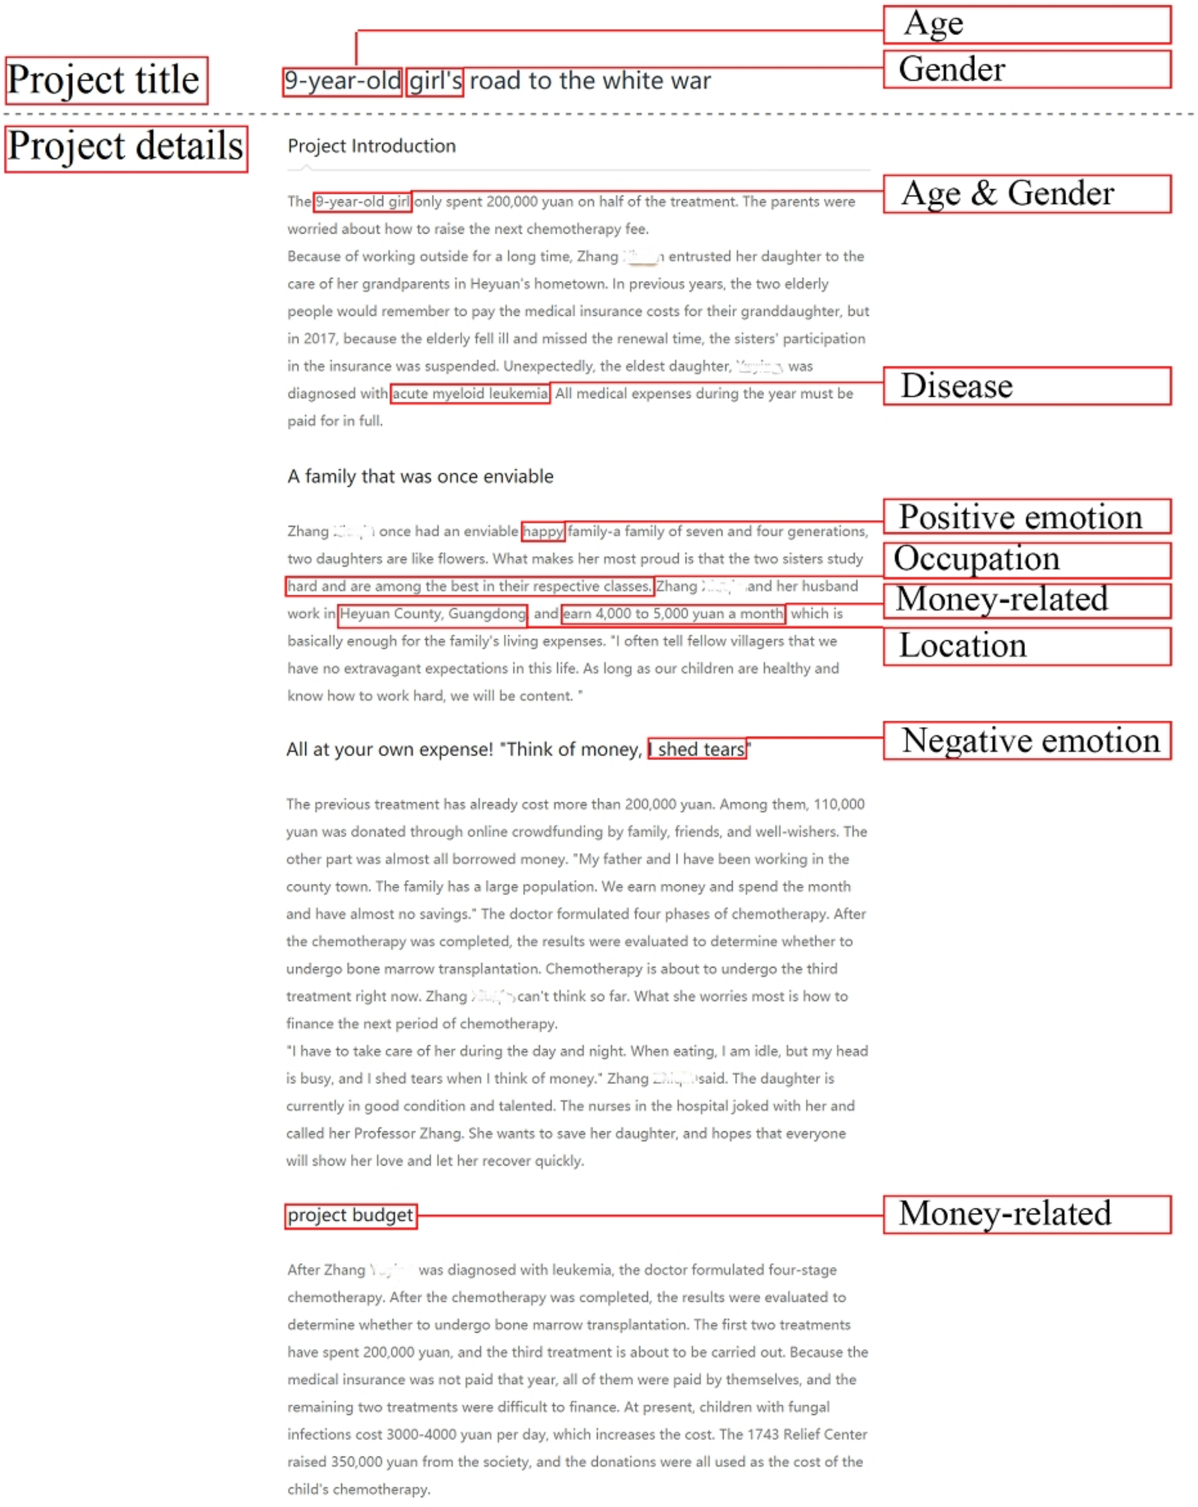
Figure 2. Research model.



Extracting Variables

In medical crowdfunding, some textual features appear in the project title, while others appear in the project details, and some may be reflected in both. Figure 3 shows a medical crowdfunding project from Tencent Charity with the textual features marked. We classified these variables into project title and project details. Moreover, a textual feature has two dimensions: whether the feature exists and the extent of the feature if it does exist. Majumdar and Bose [20] found that the presence of textual features (money-related terms and female references) and the extent of textual features (money-related terms, negative emotions, and female references) impact the success of donation-based crowdfunding. Therefore, we adopted a similar method to quantify all textual features in the dataset as existence variables or extent variables. Table 2 lists all of the variables considered with their descriptions.

Figure 3. Textual features of a medical crowdfunding project.



9-year-old girl's road to the white war

Project Introduction

The 9-year-old girl only spent 200,000 yuan on half of the treatment. The parents were worried about how to raise the next chemotherapy fee.

Because of working outside for a long time, Zhang [redacted] entrusted her daughter to the care of her grandparents in Heyuan's hometown. In previous years, the two elderly people would remember to pay the medical insurance costs for their granddaughter, but in 2017, because the elderly fell ill and missed the renewal time, the sisters' participation in the insurance was suspended. Unexpectedly, the eldest daughter, [redacted] was diagnosed with acute myeloid leukemia. All medical expenses during the year must be paid for in full.

A family that was once enviable

Zhang [redacted] once had an enviable happy family-a family of seven and four generations, two daughters are like flowers. What makes her most proud is that the two sisters study hard and are among the best in their respective classes. Zhang [redacted] and her husband work in Heyuan County, Guangdong and earn 4,000 to 5,000 yuan a month, which is basically enough for the family's living expenses. "I often tell fellow villagers that we have no extravagant expectations in this life. As long as our children are healthy and know how to work hard, we will be content. "

All at your own expense! "Think of money, I shed tears"

The previous treatment has already cost more than 200,000 yuan. Among them, 110,000 yuan was donated through online crowdfunding by family, friends, and well-wishers. The other part was almost all borrowed money. "My father and I have been working in the county town. The family has a large population. We earn money and spend the month and have almost no savings." The doctor formulated four phases of chemotherapy. After the chemotherapy was completed, the results were evaluated to determine whether to undergo bone marrow transplantation. Chemotherapy is about to undergo the third treatment right now. Zhang [redacted] can't think so far. What she worries most is how to finance the next period of chemotherapy.

"I have to take care of her during the day and night. When eating, I am idle, but my head is busy, and I shed tears when I think of money." Zhang [redacted] said. The daughter is currently in good condition and talented. The nurses in the hospital joked with her and called her Professor Zhang. She wants to save her daughter, and hopes that everyone will show her love and let her recover quickly.

project budget

After Zhang [redacted] was diagnosed with leukemia, the doctor formulated four-stage chemotherapy. After the chemotherapy was completed, the results were evaluated to determine whether to undergo bone marrow transplantation. The first two treatments have spent 200,000 yuan, and the third treatment is about to be carried out. Because the medical insurance was not paid that year, all of them were paid by themselves, and the remaining two treatments were difficult to finance. At present, children with fungal infections cost 3000-4000 yuan per day, which increases the cost. The 1743 Relief Center raised 350,000 yuan from the society, and the donations were all used as the cost of the child's chemotherapy.

Table 2. Description of the variables.

Variables	Description and measure
Success rate	Ratio of raised amount to target amount
Funding goal	The total amount to be raised by a fundraiser in a project (10,000)
Donors	Number of people contributing to a project
TPAge	Dummy variable; 1 if there is an age in the title, otherwise 0
TPGender	Dummy variable; 1 if there is a gender in the title, otherwise 0
TPDisease	Dummy variable; 1 if there is a disease description in the title, otherwise 0
TPOccupation	Dummy variable; 1 if there is an occupation in the title, otherwise 0
TPLocation	Dummy variable; 1 if there is a location in the title, otherwise 0
TPMoney	Dummy variable; 1 if there is a funding target in the title, otherwise 0
TPNWords	Dummy variable; 1 if there are negative words in the title, otherwise 0
TPPWords	Dummy variable; 1 if there are positive words in the title, otherwise 0
DPAge	Dummy variable; 1 if there is an age in the details, otherwise 0
DPGender	Dummy variable; 1 if there is a gender in the details, otherwise 0
DPDisease	Dummy variable; 1 if there is a disease description in the details, otherwise 0
DPOccupation	Dummy variable; 1 if there is an occupation in the details, otherwise 0
DPLocation	Dummy variable; 1 if there is a location in the details, otherwise 0
DPMoney	Dummy variable; 1 if there is a financial description in the details, otherwise 0
DPNWords	Dummy variable; 1 if there are negative words in the details, otherwise 0
DPPWords	Dummy variable; 1 if there are positive words in the details, otherwise 0
TLength	Number of words in the project title
TAge	Patient’s age in the project title
TGender	Patient’s gender in the project title
TDisease	Patient’s disease in the project title; 1 for mild disease and 0 for severe disease
TLocation	Patient’s location in the project title; sorted according to per capita GDP in 2018 of each city in descending order, and assign 1, 2, 3..., as shown in Multimedia Appendix 2
TOccupation	Patient’s occupation in the project title; classify patient’s occupation into nine categories and assign them values from 1 to 9, as shown in Multimedia Appendix 3
TNMWords	Number of mentions of money-related words in the project title
TNNWords	Number of negative emotion words in the project title
TNPWords	Number of positive emotion words in the project title
DLength	Number of words in the project details
DAge	Patient’s age in the project details
DGender	Patient’s gender in the project details
DDisease	Patient’s disease in the project details; 1 for mild disease and 0 for severe disease
DLocation	Patient’s location in the project details; sorted according to per capita GDP in 2018 of each city in descending order, and assign 1, 2, 3..., as shown in Multimedia Appendix 2
DOccupation	Patient’s occupation in the project details; classify patient’s occupation into nine categories and assign them values from 1 to 9, as shown in Multimedia Appendix 3
DNMWords	Number of mentions of money-related words in the project details
DNNWords	Number of negative emotion words in the project details
DNPWords	Number of positive emotion words in the project details
Authenticity	1 indicates that the project has been verified by the platform; otherwise, 0
Diagnosis	1 indicates that the project includes a hospital diagnosis certificate; otherwise, 0

Variables	Description and measure
Charities	1 indicates that charities are involved in the project; otherwise, 0

Automatic extraction and manual filtering were used to extract the textual features and corresponding variables. The patient's age, gender, disease, occupation, and location, as well as money-related items were manually extracted because it was difficult to automatically process these variables, as the writing style of the text was personal and had no fixed or standardized format. For each feature, we determined the value of its existence variable and extent variable in the project title and project details. For example, for patient gender, we determined the values of four variables: *TPGender*, *DPGender*, *TGender*, and *DGender*. The manual extraction process took approximately 2 months to complete and was divided into two main stages. First, two graduate students independently extracted each feature by reading each individual text from the dataset. Second, a third student compared the results of the previous two students. If there was substantial divergence, the three students discussed it until they reached agreement. However, owing to the requirements of the Tencent Charity platform, all projects meet the credibility appeals. All of the crowdfunding projects we collected were certified by the platform, with hospital diagnostic reports and charities participation. Therefore, authenticity, diagnosis, and charities were set to a value of 1.

Other variables, including *TLength*, *DLength*, *TPNWords*, *TPPWords*, *TNNWords*, *TNPWords*, *DPNWords*, *DPPWords*, *DNNWords*, and *DNPWords*, were automatically extracted using Python and the HowNet lexicon, which is the Chinese version of WordNet and has been widely used for text mining and sentiment analysis [52-54]. First, we calculated the number of words in the project title and project details to obtain the values of the variables *TLength* and *DLength*. Next, we used a Chinese word segmentation component called Jieba in Python to segment the project title and project details, and then compared the words in the project title with the positive emotional vocabulary in the HowNet dictionary. If the match was successful, the value of the variable *TPPWords* was recorded as 1 and the value of the variable *TNPWords* was increased by 1. The values of other variables were calculated in the same manner.

Building the Econometric Model

To better appreciate the effects of the textual features of the project title and project details, we used multiple regression analysis to construct five econometric models. Model 1 was the control-only model. Model 2 considered the presence variables of the project title and the control variables. Model 3 added the presence variables of the project details on the basis of Model 2. Model 4 considered the extent variables of the project title and the control variables. Model 5 added the extent variables of the project details on the basis of Model 4. Since the values of authenticity, diagnosis, and charities were all constant, indicating that there was no difference in the credibility appeals among the crowdfunding projects, these three variables were removed when building the econometric models.

- Model 1:

  $\text{Success rate} = \alpha_0 + \alpha_1\text{Funding goal} + \alpha_2\text{Donors} + \varepsilon$
- Model 2:

  $\text{Success rate} = \alpha_0 + \alpha_1\text{Funding goal} + \alpha_2\text{Donors} + \alpha_3\text{TPAge} + \alpha_4\text{TPGender} + \alpha_5\text{TPDisease} + \alpha_6\text{TPOccuption} + \alpha_7\text{TPLocation} + \alpha_8\text{TPMoney} + \alpha_9\text{TPWords} + \alpha_{10}\text{TPPWords} + \varepsilon$
- Model 3:

  $\text{Success rate} = \alpha_0 + \alpha_1\text{Funding goal} + \alpha_2\text{Donors} + \alpha_3\text{TPAge} + \alpha_4\text{TPGender} + \alpha_5\text{TPDisease} + \alpha_6\text{TPOccuption} + \alpha_7\text{TPLocation} + \alpha_8\text{TPMoney} + \alpha_9\text{TPWords} + \alpha_{10}\text{TPPWords} + \alpha_{11}\text{DPAge} + \alpha_{12}\text{DPGender} + \alpha_{13}\text{DPDisease} + \alpha_{14}\text{DPOccupation} + \alpha_{15}\text{DPLocation} + \alpha_{16}\text{DPMoney} + \alpha_{17}\text{DPNWords} + \alpha_{18}\text{DPPWords} + \varepsilon$
- Model 4:

  $\text{Success rate} = \alpha_0 + \alpha_1\text{Funding goal} + \alpha_2\text{Donors} + \alpha_3\text{TLength} + \alpha_4\text{TAge} + \alpha_5\text{TGender} + \alpha_6\text{TDisease} + \alpha_7\text{TOccupation} + \alpha_8\text{TLocation} + \alpha_9\text{TNMWords} + \alpha_{10}\text{TNNWords} + \alpha_{11}\text{TNPWords} + \varepsilon$
- Model 5:

  $\text{Success rate} = \alpha_0 + \alpha_1\text{Funding goal} + \alpha_2\text{Donors} + \alpha_3\text{TLength} + \alpha_4\text{TAge} + \alpha_5\text{TGender} + \alpha_6\text{TDisease} + \alpha_7\text{TOccupation} + \alpha_8\text{TLocation} + \alpha_9\text{TNMWords} + \alpha_{10}\text{TNNWords} + \alpha_{11}\text{TNPWords} + \alpha_{12}\text{DLength} + \alpha_{13}\text{DAge} + \alpha_{14}\text{DGender} + \alpha_{15}\text{DDisease} + \alpha_{16}\text{DOccupation} + \alpha_{17}\text{DLocation} + \alpha_{18}\text{DNMWords} + \alpha_{19}\text{DNNWords} + \alpha_{20}\text{DNPWords} + \varepsilon$

Results

Descriptive Statistics

Table 3 provides the descriptive statistics of the variables. *DPGender*, *DPDisease*, *Authenticity*, *Diagnosis*, and *Charities* were constant, and were therefore removed from subsequent analyses. The correlations between the variables are provided in Multimedia Appendix 4 and Multimedia Appendix 5. Given the overall lack of a strong correlation between the variables, we proceeded to the regression analysis.

Table 3. Descriptive statistics of variables.

Variables	Maximum	Minimum	Median	Mean	Variance
Success rate	1.47	0.00	0.12	0.31	0.14

Regression Results

We first estimated the effect of control variables on the success rate of project fundraising with Model 1. As shown in Table 4, the funding goal and number of donors were significantly related to the success rate. Specifically, the funding goal had a negative impact on the success rate of fundraising, and the coefficient of donors (19.00, *P*<.001) significantly and positively affected the success rate.

Based on these control variables, we then increased the number of existence variables in the project title with Model 2. As shown in Table 4, the effects of the funding goal and number of donors were significant in this model, coinciding with the findings for Model 1. Moreover, in rational appeals, the presence of a patient's disease and occupation had a positive impact on the success rate of crowdfunding, whereas the presence of a patient's age and gender had a negative impact. The presence of location and monetary evidence exhibited no significant effect. In emotional appeals, the coefficient of *TPNWords* (–3.83, *P*=.04) indicated that the presence of negative emotions in the project title played a negative role in the fundraising success rate. The presence of positive emotions was insignificant, which shows that the persuasive strategy of positive emotions had no effect.

Additionally, we added the factors of project details to Model 2 to build Model 3, so as to estimate the role of project details. As indicated in Table 4, the control variables still exhibited significant effects, consistent with Models 1 and 2. The significant variables in the project title were also the same as those found for Model 2. In rational appeals of the project details, the coefficients of *DPOccupation* and *DPMoney* were 3.07 (*P*=.01) and 5.01 (*P*=.02), respectively, reflecting that the presence of the patient's occupation and money-related words had a positive relationship on the fundraising success rate. The presence of the patient's age had a negative relationship and the presence of the patient's location had no significant effect, which indicates that this information cannot persuade a donor. In emotional appeals, the presence of negative emotions was found to play a positive role in the success rate of fundraising, while the presence of positive emotions played a negative role, implying that the presence of negative emotions, rather than positive emotions, is more persuasive to donors.

Table 4. Regression results of existence variables.

Variables	Model 1 (adjusted R^2=0.637)			Model 2 (adjusted R^2=0.639)			Model 3 (adjusted R^2=0.643)		
	β	*P* value	VIF[a]	β	*P* value	VIF	β	*P* value	VIF

[a] VIF: variance inflation factor.

[b] —: not included in model.

Furthermore, we estimated the extent variables of the project title and project details to explore how the extent of a feature, if it exists, affects the fundraising results. Table 5 demonstrates the regression results for the extent variables of the project title and the control variables in Model 4. The funding goal exhibited a significant negative impact and the number of donors exhibited a significant positive effect, consistent with the results of the other models. None of the extent variables in the project title was statistically significant, indicating that the extent of the features in the project title causes no discernible effect on fundraising success rate.

Moreover, we examined the impact of the extent variables in the project details in Model 5. As shown in Table 5, the control variables also significantly affected the fundraising results. In addition, the length of the description in the project details exhibited a significant negative effect on fundraising success. *DNMWords* and *DNNWords* emerged as positive predictors of project success, which demonstrates that the more money-related and negative emotion words there are in the project details, the higher the success rate. The coefficient of *DAge* (–2.11, *P*<.001) suggests that younger patients are more likely to fundraise successfully in medical crowdfunding. The coefficient of *DOccupation* was also negative, showing that for patients whose occupations are national civil servant, professional skill worker, clerk, business and service worker, solider, child, student, and public-spirited person, the success rate of fundraising will decrease sequentially.

[b] TNMWords was missing the correlation coefficient, and was therefore removed.

[c] —: not included in model.

Robustness Test

We used two methods to test the robustness of these empirical results: increasing sample data from other platforms and eliminating specific samples.

First, we increased the sample data to verify whether the results will be affected by platform differences. We collected 382 crowdfunding projects from the “Fun in Funding” platform [55], which is also a well-known medical crowdfunding platform in China. We use the new sample dataset to reexamine Model 3, and the results are presented in Table 6; the regression results using the original sample data (Table 4) are also shown for comparison. In the project title, except for the presence of the patient’s disease that became insignificant, the conclusions of the remaining variables were consistent. In the project details, the presence of the location changed from insignificant in the original model to significant with the added data, and there was no difference in the results for the other variables.

Second, specific samples were eliminated to test whether they had a major driving effect on the results. There was a relatively large number of samples with a small success rate in the original dataset. Therefore, we removed the sample data below the average success rate (0.31) and used the remaining sample data to perform multiple regression analysis on Model 3. Table 6 shows that in the project title, the presence of the patient's age and gender exhibited significant effects, coinciding with the previous conclusions. The presence of disease and location was significant at a 90% CI, which can also be statistically explained. The presence of occupation and negative emotions changed from significant to insignificant, whereas the presence of positive emotions transformed from insignificant to significant. By contrast, in the project details, the presence of money-related words became insignificant, and there was no change in the results for the other variables.

In summary, after using the two methods to complete the robustness test, we found that the results were mainly consistent with those obtained previously, indicating that our findings are relatively robust.

Discussion

Principal Findings

According to 4903 medical crowdfunding projects obtained from the Tencent Charity platform in China and using the theory of persuasion as the theoretical basis, this study applied multiple regression analysis to examine the impact of the existence variables and extent variables in the project title and project details on the success rate of medical crowdfunding. Owing to the requirements of the platform, all projects met the three aspects (authenticity, diagnosis, and charities) of credibility appeals; hence, we discuss the research results from two categories of appeals: rational and emotional appeals.

First, in rational appeals of the project title, the regression results of the existence variables showed that the presence of the patient's disease and occupation had a positive impact on the success rate of the medical crowdfunding project. Providing a narrative of the patient's disease and occupation allows potential donors to quickly understand who is raising money for what disease in a specific crowdfunding project. The presence of the patient's age and gender had a negative impact on the success rate, indicating that the seeker may not need to describe these attributes of the fundraiser. In emotional appeals of the project title, the presence of negative words had a negative impact on the success rate, which shows that people do not wish to see the requesters' negative emotions in the title description.

With respect to rational appeals of the project details, analysis of the existence variables suggested that the presence of a patient's occupation and money-related words is positively correlated with the fundraising success rate. The patient's occupation can arouse readers' pity, and money-related words can accurately describe the economic plight of the requesters. Majumdar and Bose [20] also suggested that the presence of monetary evidence can promote the success of crowdfunding. The presence of the patient's age was negatively correlated with the success rate, which indicates that the patient's age does not need to be described in the project details. In emotional appeals of the project details, the presence of negative emotions exhibited a positive impact on the fundraising success rate. However, Majumdar and Bose [20] suggested that the presence of negative emotions had no significant effect because almost all requests describe the suffering of the seeker. We consider this difference to be related to differences in the primary concerns of people in different countries. Chinese donors intend to understand the distress that patients are suffering, which can only be expressed accurately with negative phrases. We found that the presence of positive emotions exhibited a negative effect on success rate, whereas Durand et al [23] proposed that positive emotions contributed to the success of organ transplantation crowdfunding projects. The reason for this difference may be that the physically disabled but optimistic image in crowdfunding for organ transplantation is more persuasive, which is not the case with crowdfunding for medical diseases.

Furthermore, we estimated the extent variables of the project's textual features. The results reflect that in the project details, the patient's age, occupation, and text length had a negative impact on the fundraising success rate, whereas the numbers of money-related words and negative emotions words had a positive impact. We further analyzed the causes of these results in detail. First, we suggest that the number of money-related words has a significant positive impact on the success rate of fundraising, which coincides with the findings of Majumdar and Bose [20] and Xu and Wang [24]. Second, we found that the number of negative phrases has a positive impact on the success rate, whereas Majumdar and Bose [20] came to the opposite conclusion. They believed that the excessive use of negative appeals may seem manipulative to the potential donor. The reason for this difference may be related to the different cultures of multiple countries, as Chinese donors may be more likely to be moved by descriptions of patients' suffering that use more negative phrases. Xu and Wang [24] suggested that using a tragic narrative strategy can arouse the sympathy of Chinese potential donors. Third, we found that the length of the detailed narrative negatively affects the success rate, which is also inconsistent with the results of Majumdar and Bose [20]. The reason for this conflict may be that a long description can make people impatient and cause them to lose interest in donating. Iyengar and McGuire [56] suggested that humans are "cognitive misers," meaning that they will predigest limited information and make a rapid decision according to the principle of least possible effort. Fourth, Liang et al [46] proposed that age has no significant impact on reward-based crowdfunding, whereas our results show that young patients are more likely to succeed in medical crowdfunding because they more easily arouse people's sympathy. Similar to this conclusion, Ren et al [57] found that people are generally more generous with fundraising projects targeting children than adults. Finally, our study suggests that in the project details narrative of medical crowdfunding, for patients whose occupations are national civil servant, professional skill worker, clerk, business and service worker, solider, child, student, and public-spirited person, the success rate of fundraising will decrease sequentially.

Our results have clear implications with respect to the impact of the funding goal and donors as control variables. These two variables had evident significant effects on the fundraising success rate. Specifically, the funding goal was negatively correlated with the success rate, which is in accordance with the conclusions of Gorbatai and Nelson [51] and Kim et al [48], whereas the number of donors had a positive impact on the success rate, coinciding with the results of Aleksina et al [44], which revealed that sharing or forwarding information about crowdfunding activities on social networks can result in more financial support and an increased fundraising success rate.

Theoretical Implications

This study makes the following four theoretical contributions. First, this paper enriches and expands research in the realm of medical crowdfunding. The success rate of medical crowdfunding worldwide is generally low at present, yet few previous studies have directly explored the impact of textual features on the success rate of medical crowdfunding projects. This study used real projects to study the roles of textual features of the project title and project details, and the findings can provide a reference for researchers in medical crowdfunding.

Second, this study supplements and improves the online crowdfunding literature. Existing studies have mainly discussed the effect of the project details features but ignored the project title. By examining the project title features, we found that the presence of a patient's disease and occupation has a significant positive impact on the success rate of fundraising, whereas the presence of age, gender, and negative words has a negative impact. Thus, the role of the project title cannot be overlooked.

Third, the results of this study also contribute to the literature on persuasion theory. Although there have been many studies on human behavior based on the theory of persuasion, this study is the first to use this theory to explore the effects of textual persuasion strategies in the field of medical crowdfunding. Specifically, there is very little research on the persuasive strategy of the project title in online crowdfunding, although we discovered that this also has a contribution to fundraising results. For rational appeals, the presence of the patient's age, gender, disease, and occupation in the project title exhibited significant effects on the success rate of fundraising, whereas the presence of monetary evidence exhibited no important effect. For emotional appeals, the presence of negative emotions in the project title played a negative role on the success rate, whereas the presence of positive emotions had an insignificant effect. Moreover, the persuasion strategy of the project details in medical crowdfunding also differs from that in other types of crowdfunding. Liang et al [46] proposed that age has no significant impact on reward-based crowdfunding, whereas our results showed that young patients are more likely to successfully raise funds. There is no literature proposing that occupation has an important impact, although our results indicated that the presence of the patient's occupation makes the project more persuasive. Consistent with the findings of Majumdar and Bose [20], we suggest that the presence of monetary evidence can better persuade people to donate, and this persuasion effect increases with a greater frequency of that presence. For emotional appeals, the persuasion strategy of medical crowdfunding also diverges from that of other crowdfunding types. Majumdar and Bose [20] indicated that the presence of negative emotions had no significant effect on obtaining pizza donations. Durand et al [23] discovered that positive emotions contribute to the success of organ transplantation crowdfunding projects. However, our results indicate that the presence of negative emotions and positive emotions significantly affect the success rate of crowdfunding, but that the former affects the rate positively while the latter affects it negatively.

Fourth, this paper is beneficial for the online donation literature. In recent years, many studies have explained the donation behaviors of online users through external factors such as the celebrity effect and individual factors [30,58,59]. Behl and Dutta [60] also found that gamification has a positive impact on donor behavior on crowdfunding platforms for disaster relief operations. This study delineates how textual features in medical crowdfunding affect users' online donation behaviors, showing that the presence of a patient's disease and occupation in the project title has a positive relationship with the fundraising success rate, whereas the presence of age, gender, and negative words has a negative relationship. Moreover, the presence of the patient's occupation, monetary evidence, and negative emotions in the project details plays a positive role in the success rate, whereas the presence of the patient's age and positive emotions plays a negative role. Therefore, these features of the crowdfunding text may also affect the donation behaviors of online users. The conclusions can therefore provide assistance for research in the field of online donations.

Practical Implications

On the basis of our findings and previous research, we propose three implications for fundraisers from two categories (rational and emotional appeals) of the theory of persuasion and the three perspectives of the project title, project details, and nontextual features. First, for rational appeals of the project title, the results show that the presence of the patient's disease and occupation is positively related to the success rate of the medical crowdfunding project; thus, fundraisers should be advised to clearly describe the patient's illness and occupation in the project title. We also found that the presence of patient's age and gender is negatively related to the success rate, implying that age and gender are unnecessary in the narrative of the project title. For emotional appeals of the project title, the presence of negative words has a negative impact on the success rate, which suggests that the requester does not need to include negative emotions in the description of the project title.

Second, for rational appeals of the project details, the results indicate that the presence of a patient's occupation and money-related words has a positive impact on the fundraising success rate, which suggests that the description can include information about the patient's occupation and finances. Projects that use more money-related words are more likely to succeed, and the success rate will gradually decrease when the patient's occupation is national civil servant, professional skill worker, clerk, business and service worker, solider, child, student, and public-spirited person. In addition, the presence of the patient's age has a negative impact on the success rate, implying that the patient's age can be omitted from the description of the project details. However, if the patient is young, this information should be stated in the project details. For emotional appeals of the project details, the presence of negative words has a positive impact on the fundraising success rate, while the presence of positive words has the opposite effect, indicating that using as many negative phrases as possible is conducive to promoting fundraising success. The last suggestion is that the description in the details should be concise and powerful, and should not be too long.

Third, our investigation of the control variables showed that the fundraising success rate increases with increases in the number of donors but decreases with increases in the funding goal. This finding implies that requesters need to set appropriate goals when raising funds, and should widely disseminate and share their projects on social networks to seek more donations instead of forwarding the projects only to relatives and friends.

Finally, our study also has important implications for crowdfunding platform managers. Specifically, they can use a method similar to that presented herein to explore factors that are of concern to users in other types of crowdfunding text narratives. The managers of medical crowdfunding platforms may take our conclusions as a reference and provide proposals for fundraisers who have no idea how to create the crowdfunding text. Additionally, we recommend that some tags be intercalated in crowdfunding projects to highlight critical information that will be beneficial to the user experience of both fundraisers and donors.

Limitations and Future Research

Although this study makes several contributions, there are still some limitations that need to be recognized. First, our work considered the effects of textual features on the success of medical crowdfunding and did not examine noncontent features other than the funding goal and donors, such as the number of updates. Second, the process of feature extraction was somewhat cumbersome and time-consuming, and should be improved in the future. For example, future research can consider using machine learning and artificial intelligence to improve the efficiency of feature extraction. Third, this study collected only data related to the crowdfunding projects and excluded donor information. Future research can include donor information data and further analyze the impact of textual features on different donors. Fourth, this study only used fundraising projects from a Chinese crowdfunding platform, and therefore it is unclear whether the conclusions will be applicable to crowdfunding platforms from other countries. Thus, future research should be extended to collect data from multiple crowdfunding platforms in different countries for exploring the differences between crowdfunding in China and other countries from a cultural perspective. Finally, this study did not compare the effect of credibility appeals because of the limitation of the dataset.

Conclusion

This study focused on the effect of the textual features of medical crowdfunding projects on their success rate, taking 4903 real projects collected from the Tencent Charity platform in China as the research sample. We developed our research model according to previous studies and Aristotle's theory of persuasion. We further divided the textual features of the project title and project details into three categories of rational, emotional, and credibility appeals, which were analyzed from two perspectives of existence and extent. We show how some of the persuasive appeals and nontextual cues have a significant impact on fundraising success rates. The results show that in addition to the project details, the features of the project title also have an important impact on the success rate of fundraising. These findings provide important theoretical and managerial implications for medical crowdfunding. Additionally, our research will be beneficial to all donation-based charity platforms and requesters with medical fundraising needs.

Abstract

Background: Perioperative quantitative monitoring of neuromuscular function in patients receiving neuromuscular blockers has become internationally recognized as an absolute and core necessity in modern anesthesia care. Because of their kinetic nature, artifactual recordings of acceleromyography-based neuromuscular monitoring devices are not unusual. These generate a great deal of cynicism among anesthesiologists, constituting an obstacle toward their widespread adoption. Through outlier analysis techniques, monitoring devices can learn to detect and flag signal abnormalities. Outlier analysis (or anomaly detection) refers to the problem of finding patterns in data that do not conform to expected behavior.

Objective: This study was motivated by the development of a smartphone app intended for neuromuscular monitoring based on combined accelerometric and angular hand movement data. During the paired comparison stage of this app against existing acceleromyography monitoring devices, it was noted that the results from both devices did not always concur. This study aims to engineer a set of features that enable the detection of outliers in the form of erroneous train-of-four (TOF) measurements from an acceleromyographic-based device. These features are tested for their potential in the detection of erroneous TOF measurements by developing an outlier detection algorithm.

Methods: A data set encompassing 533 high-sensitivity TOF measurements from 35 patients was created based on a multicentric open label trial of a purpose-built accelero- and gyroscopic-based neuromuscular monitoring app. A basic set of features was extracted based on raw data while a second set of features was purpose engineered based on TOF pattern characteristics. Two cost-sensitive logistic regression (CSLR) models were deployed to evaluate the performance of these features. The final output of the developed models was a binary classification, indicating if a TOF measurement was an outlier or not.

Results: A total of 7 basic features were extracted based on raw data, while another 8 features were engineered based on TOF pattern characteristics. The model training and testing were based on separate data sets: one with 319 measurements (18 outliers) and a second with 214 measurements (12 outliers). The F1 score (95% CI) was 0.86 (0.48-0.97) for the CSLR model with engineered features, significantly larger than the CSLR model with the basic features (0.29 [0.17-0.53]; *P*<.001).

Conclusions: The set of engineered features and their corresponding incorporation in an outlier detection algorithm have the potential to increase overall neuromuscular monitoring data consistency. Integrating outlier flagging algorithms within neuromuscular monitors could potentially reduce overall acceleromyography-based reliability issues.

KEYWORDS

neuromuscular monitoring; outlier analysis; acceleromyography; postoperative residual curarization; train-of-four; monitoring devices; neuromuscular; machine learning; monitors; anesthesiology

Introduction

Postoperative residual curarization remains a frequent and often concealed event within modern anesthesia care [1]. It translates clinically into complications such as aspiration of gastric contents [2,3] and an impaired ventilatory response to hypoxia [4]. This is ultimately linked to an increase of morbidity and mortality due to postoperative pulmonary complications [5]. As such, perioperative quantitative monitoring of neuromuscular function in patients receiving neuromuscular blockers has become internationally recognized as an absolute and core necessity in modern anesthesia care [6,7]. Besides a reduction of the incidence of severe respiratory complications [8-10], quantitative monitoring also potentially leads to considerable financial health care savings, with complications stemming from suboptimal neuromuscular monitoring being estimated to be as high as US $25.000 per patient per event [7].

Although a seemingly straightforward procedure, neuromuscular monitoring presents users with nuances that are frequently overlooked or that are prone to misinterpretation [11]. This has been exemplified by research [12,13] showing that baseline (control) train-of-four ratios (TOFRs; T4/T1) at the adductor pollicis frequently assume supra-physiological values (TOFR > 1) when measured using acceleromyography (AMG). Similarly, Kopman et al [13] have scrutinized some algorithmic simplifications used by common AMG monitors (T4/T2 ratio as a substitute for T4/T1) and how their validity is dependent on the degree of recovery from nondepolarizing neuromuscular block. Such interpretative considerations, associated frequent artifactual confounders, and known overestimation tendencies when compared with electromyography (EMG) or mechanomyography [14] contribute to the perpetuation of anesthesiologist's cynicism toward objective neuromuscular monitoring methods, further hindering their widespread adoption [15].

The herein presented research has been motivated by the development of a smartphone app intended for neuromuscular monitoring based on combined accelerometric and angular hand movement data [16]. During the paired comparison stage of this app against existing AMG monitoring devices, it was noted that the results from both devices did not always concur. For instance, it was observed that the collected raw movement data regularly displayed nonstandard TOF patterns, whereas the AMG neuromuscular monitoring device did not appear to detect these outliers and displayed a seemingly (oversimplified) TOFR plotting. As with any instrument that aims to measure a certain signal [17], the measurement of TOFR is similarly prone to the appearance of outliers, which can be erroneously interpreted as correct measurements.

From a data analysis standpoint, outlier analysis techniques can be adopted to increase data reliability. Outlier analysis (or anomaly detection) refers to the problem of finding patterns in data that do not conform to expected behavior [18]. This study aims to conduct an offline exploratory analysis on raw AMG neuromuscular monitoring data and to engineer features (or variables) to be able to flag erroneous TOF measurements. These features will be subsequently evaluated for their usability in outlier analysis.

Methods

Overview

This manuscript follows the "Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research: A Multidisciplinary View" [19]. The key steps of the feature engineering and the development of the outlier analysis algorithm are summarized below.

Data Recruitment and Preprocessing

All data for this study have been collected during a prospective open-label bicentric clinical trial (Clinical Trial Identifier NCT03605225) that took place in Ziekenhuisnetwerk Antwerpen Middelheim (Antwerp, Belgium) and Universitair Ziekenhuis Brussel (Brussels, Belgium). Registration occurred prior to the start of the trial. Data collection started in February 2018 and terminated in April 2019. The trial was conducted in accordance with the established protocol after approval by the Medical Ethical Committees of both hospitals (ZNA Middelheim reference number 5055; UZBrussel reference 2018/031, BUN 009201835039). It followed current good clinical practice guidelines and applicable law(s), as well as adhered to the applicable CONSORT guidelines.

The data used for the algorithm development were collected using a purpose-built smartphone app specifically aimed to monitor hand movements evoked by extraneural supramaximal stimulation of the ipsilateral nervus ulnaris by means of a peripheral nerve stimulator. Collected data included triaxial (3D) raw acceleration values (m/s^2) as well as raw 3D angular velocity values (rad s^{-1}).

Earlier trials involving beta versions of this app have been published and they reported bidirectional 95% limits of agreement of 0.12 (TOFR, absolute units) when compared with a standard AMG neuromuscular CE/FDA-labeled monitor [16]. This study included 35 patients, with a total of 533 TOF measurements. The offline evaluation of the observations was performed by 2 authors of this paper (MV and HC), who performed the evaluation independently from one another. The classification of outliers was afterward compared and corresponded to a 98% agreement on the labeling of TOF patterns. In total, 30 of the 533 observations were identified as outliers. These anomalies were detected in the TOF measurements of 18 patients.

Feature Engineering

The acceleration and angulation signals were collected through the open-source Cordova Plugin Device-motion library [20], and measure the movement of the muscle contractions in the 3 orthogonal directions of movement (X, Y, and Z). Similar to studies in mechanomyography [21], root-mean square analysis was performed on these signals to indicate the range of muscle displacement represented by its acceleration (expressed with units of m/s^2; Figure 1). The features for the model were then directly derived from the continuous monitoring signal. A first basic set of features (Table 1) were derived: the combined acceleration value of multiple points on the vicinity of the peak of the different TOF twitches (T1, T2, T3, T4) and the absolute TOFR value.

Figure 1. Normal and anomalous train-of-four (TOF) patterns; upper figures display normal TOF observations while bottom figures represent anomalies. Normality recordings are illustrated by the upper 2 patterns, where 4 clear peaks can be detected and that follow one another in a fixed time interval. The lower 2 patterns represent 2 simulated anomalies, where the 4 peaks cannot be clearly recognized from the TOF pattern; or where a wide gap in terms of time interval exists between peaks.

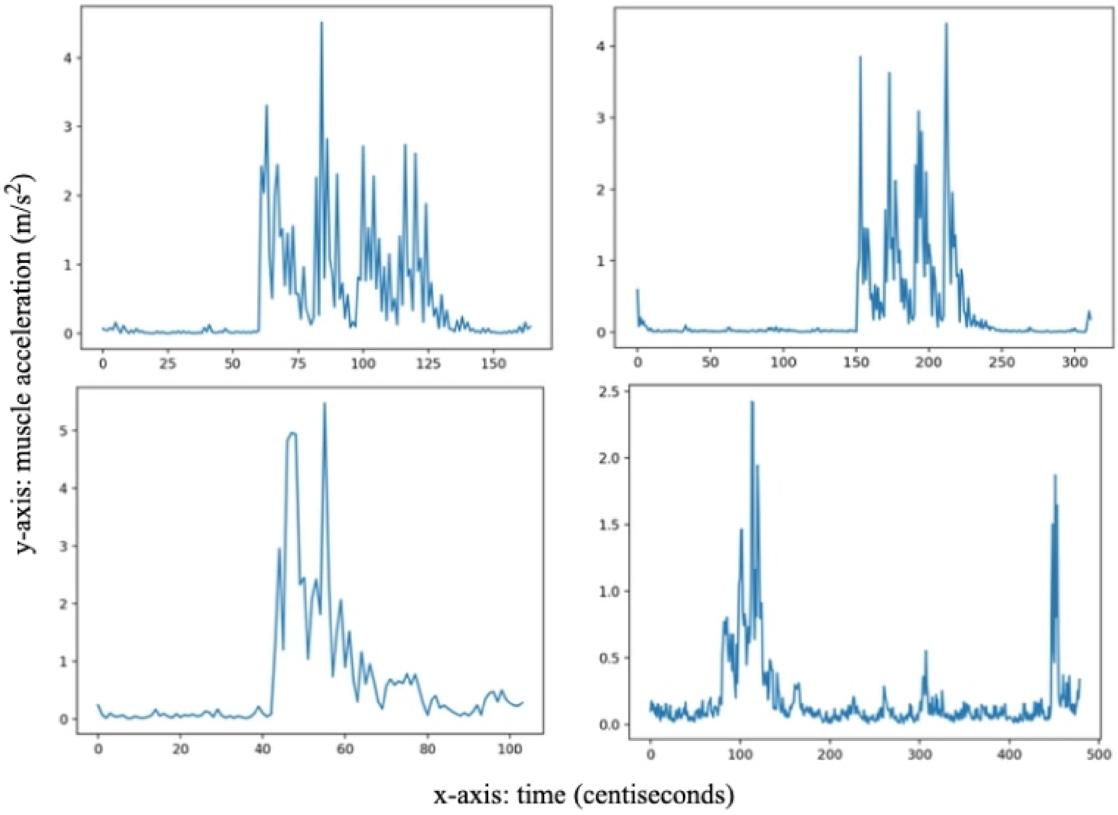

Table 1. Description of the basic features of data set. A train-of-four recording is defined as the integral combination of all acceleration/angulation points of T1, T2, T3, and T4.

Feature name	Description	n (count)
T1	First twitch of train-of-four response	533
T2	Second twitch of train-of-four response	533
T3	Third twitch of train-of-four response	533
T4	Fourth twitch of train-of-four response	533
TOFR[a]	Absolute ratio derived by dividing T1 with T4	533
AMG[b]_StdDev	Standard deviation of an AMG measurement	533
AMG_Mean	Arithmetic mean of an AMG measurement	533

[a] TOFR: train-of-four ratio.

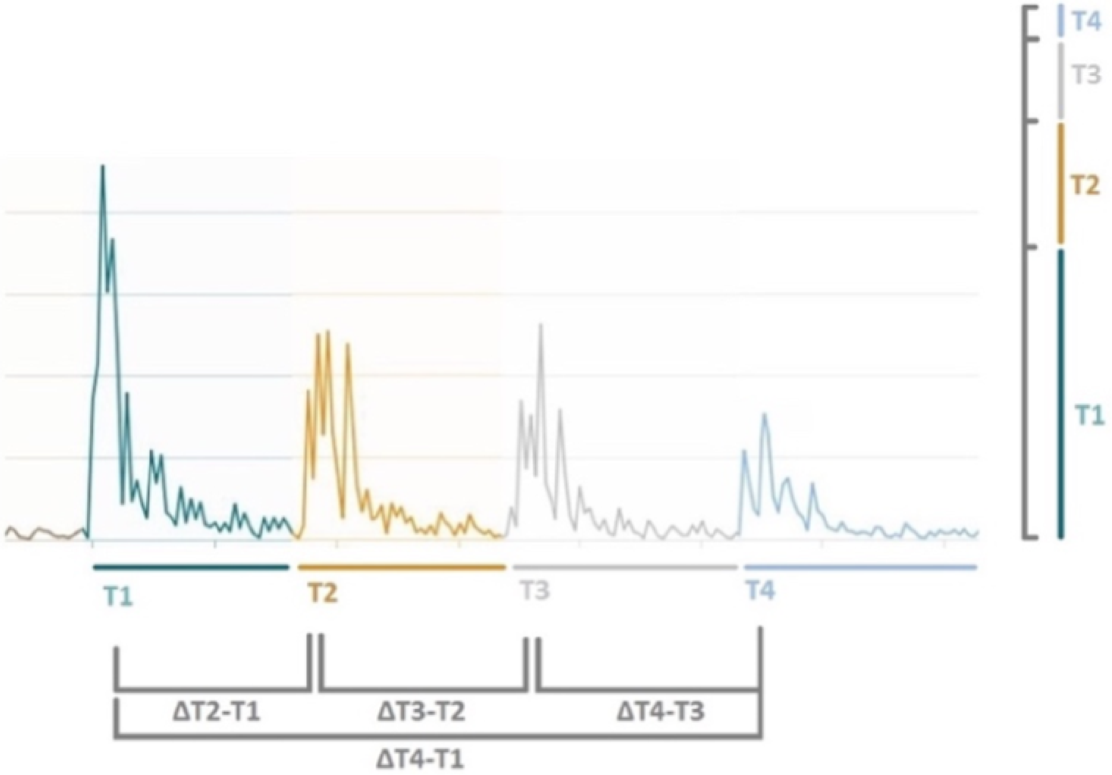
[b] AMG: acceleromyography.

Additionally, the arithmetic mean and standard deviation of the AMG values related to one measurement were computed in order to gain a better insight into the differences in variation between different AMG measurements. In order to avoid confusion with other descriptive statistics, these were labeled as “AMG_StdDev” and “AMG_Mean.” An additional set of features were engineered to assess specific TOF pattern characteristics (Table 2). Several of these were derived from the distance between the different TOF twitches (denominated with the prefix “delta”; Figure 2), whereas other features were based on the ratio of a specific TOF twitch compared with the mean of the respective TOF measurement (denominated with the prefix “ratio”). With a nonanomalous pattern, one would logically expect such a ratio to be exceedingly higher than the arithmetic mean of the TOF measurement. In total, 15 features were extracted and engineered to serve as input for the outlier detection models. We emphasize that the authors have deliberately designed the aforementioned features to detect an anomaly based on the signal characteristics of a specific measurement instance. Because of the limited size of the data set, there is no feature that takes into account any historical information of the TOF recording, administered drugs, or other patient-related parameters.

Table 2. Description of engineered features of data set.

Feature name	Description	n (count)
deltaT2_T1	Elapsed time (ms) between second and first twitch	533
deltaT3_T2	Elapsed time (ms) between third and second twitch	533
deltaT4_T3	Elapsed time (ms) between fourth and third twitch	533
deltaT4_T1	Elapsed time (ms) between fourth and first twitch	533
ratioT1	Ratio between first twitch and arithmetic mean	533
ratioT2	Ratio between second twitch and arithmetic mean	533
ratioT3	Ratio between third twitch and arithmetic mean	533
ratioT4	Ratio between fourth twitch and arithmetic mean	533

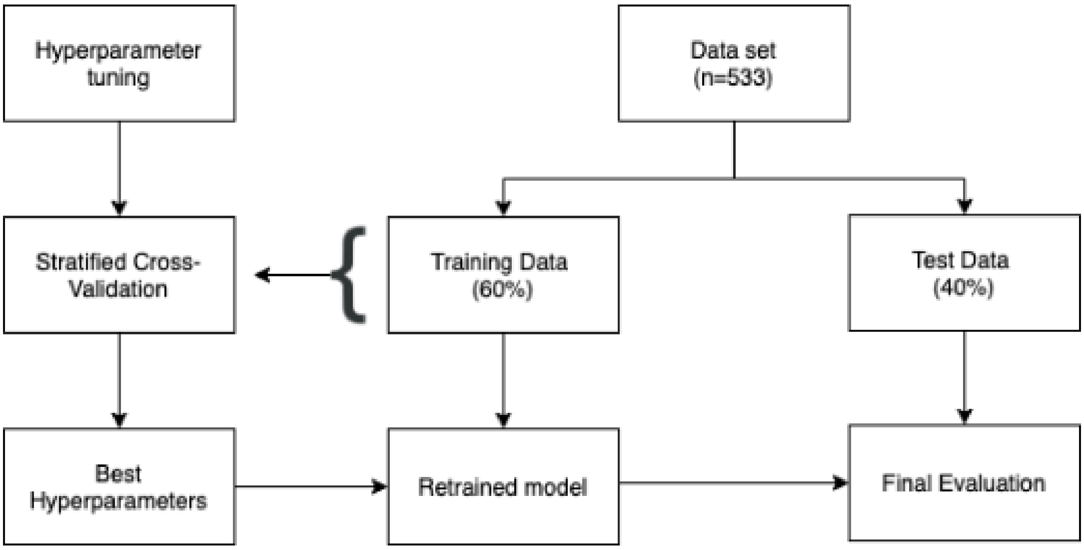
Figure 2. Basic and engineered feature illustration (x axis: time, y axis: combined angulation and acceleration). Each color represents an individual train-of-four (TOF) twitch. Each individual twitch (T1, T2, T3, and T4) is composed of multiple acceleration/angulation points during the corresponding contraction, and not solely by the highest value. The TOF recording is obtained by the summation of each individual twitch.



Model Development and Overfitting

Model development encompassed both the basic feature set and the engineered feature set. Because the study’s data set is composed out of labeled data with 2 distinct classes (normal observations and outliers), supervised learning can be applied in the form of a classification model. Because outliers are rare instances in the data, there is a class imbalance where the distribution between the normal observations and outliers is significantly skewed. To overcome the issue of class imbalance, a cost-sensitive learning technique was adopted, where the objective function of the classification algorithm is modified in order to weight the classification errors in a differential way for the normal and the less frequent class. This refers concretely to cost-sensitive logistic regression (CSLR), where a class weighting configuration is used to influence the amount of logistic regression coefficients that are updated during training. The weighting penalizes the model less for errors made on instances from the normal class, while maintaining a larger penalty for errors made on instances from the rare class. The result is a version of logistic regression that performs better on imbalanced classification tasks [17]. To avoid overfitting, a part of the available data set was held out as a test set during the data preprocessing phase (Figure 3). Moreover, in order to select the different hyperparameters related to our chosen models, a cross-validation strategy was adopted, more specifically in the form of stratified k-fold validation together with the hyperparameter optimization technique called grid search.

Figure 3. Overview of data set partitioning and model training.



Model Evaluation

To evaluate the effectiveness of the engineered features (Table 2), their performance was compared with that of the basic features (Table 1) and tested for significance. Therefore, 2 CSLRs were trained: one on the basic feature set and another on the engineered ones. All model performances were assessed on the same test set, which was composed of 40% of the total data and separated from the training set. The precision, recall, and the F1 score were chosen as performance evaluation metrics as these are best suited to evaluate data sets with class imbalance. Additionally, receiver operating characteristics (ROCs) and area under the curve (AUC) graphs were computed to characterize the performance of the models.

Statistical Analysis

Statistical analysis was performed with the open-source python library Scikit-learn [22]. Wilcoxon signed-rank test was adopted to compare the performance of the CSLR models, with $P<.05$ considered significant.

Results

Descriptive Statistics, Model Training, and Cross-Validation

The descriptive statistics of both feature sets are quantified in Table 3. The Python code related to hyperparameter optimization, training, and testing is presented in Multimedia Appendix 1. In contrast to the basic features, the engineered variables display a larger variation, as can be derived from their standard deviation. In fact, mainly the "delta" variables appear to be skewed. Figure 4 displays a scatter plot and a distribution plot of the basic features T1 and TOFR, and the engineered features ratioT1 and deltaT4_T1. While the outliers in the scatter plot of the basic features are more dispersed throughout the normal data, the outliers within the scatter plot of the engineered plots can more clearly be identified compared with the normal observations.

Concerning model training, the training data set (n=319) consisted out of 18 outliers, while the test data set (n=214) included 12 outliers. Both train and test data instances were chosen in a completely randomized manner by means of the train_test_split function of the scikit-learn library [22]. The division of data during cross-validation was performed solely on the segmented measurements (n=533). The split between train and test data has also been performed in a stratified way so as to guarantee the same class–imbalanced distribution of the entire data set. As for the stratified k-fold learning, 5 folds were chosen to split the training set, taking into consideration the size of the training set. In combination with cross validation, a grid search approach was employed to find the best hyperparameters for the L2 regularization coefficient and the appropriate class weights configuration for the imbalanced class distributions of our data set. All model training, cross-validation, and model evaluation were performed with the open-source library scikit-learn and the high-level programming language Python (version 3.8.2) [23].

Table 3. Descriptive statistics of basic features and engineered features.

Features	Mean (SD)	25%	50%	75%	Minimum	Maximum	Kurtosis	Skewness
T1	1.89 (1.13)	0.06	0.97	1.67	2.62	5.96	0.17	0.77

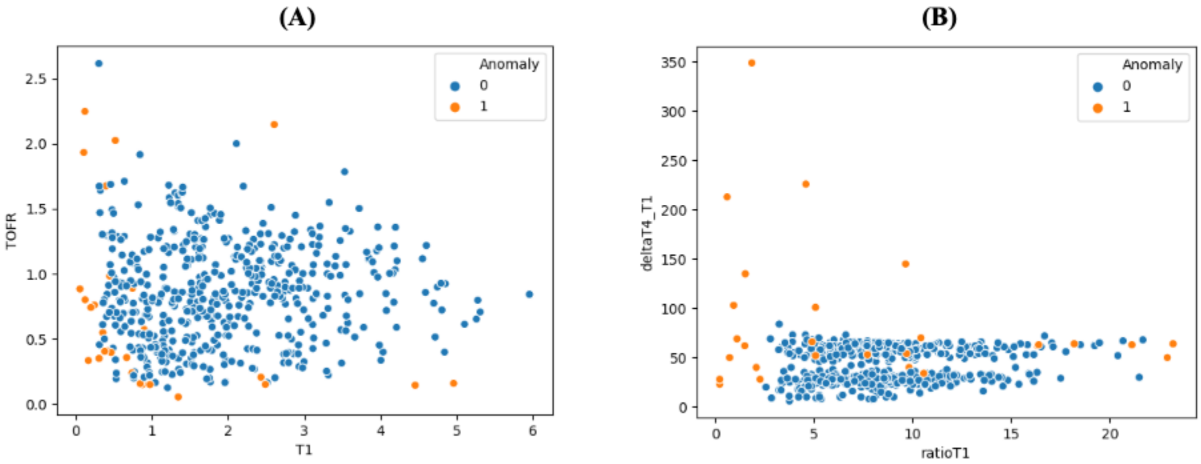
[a] TOFR: train-of-four ratio.

[b] AMG: acceleromyography.

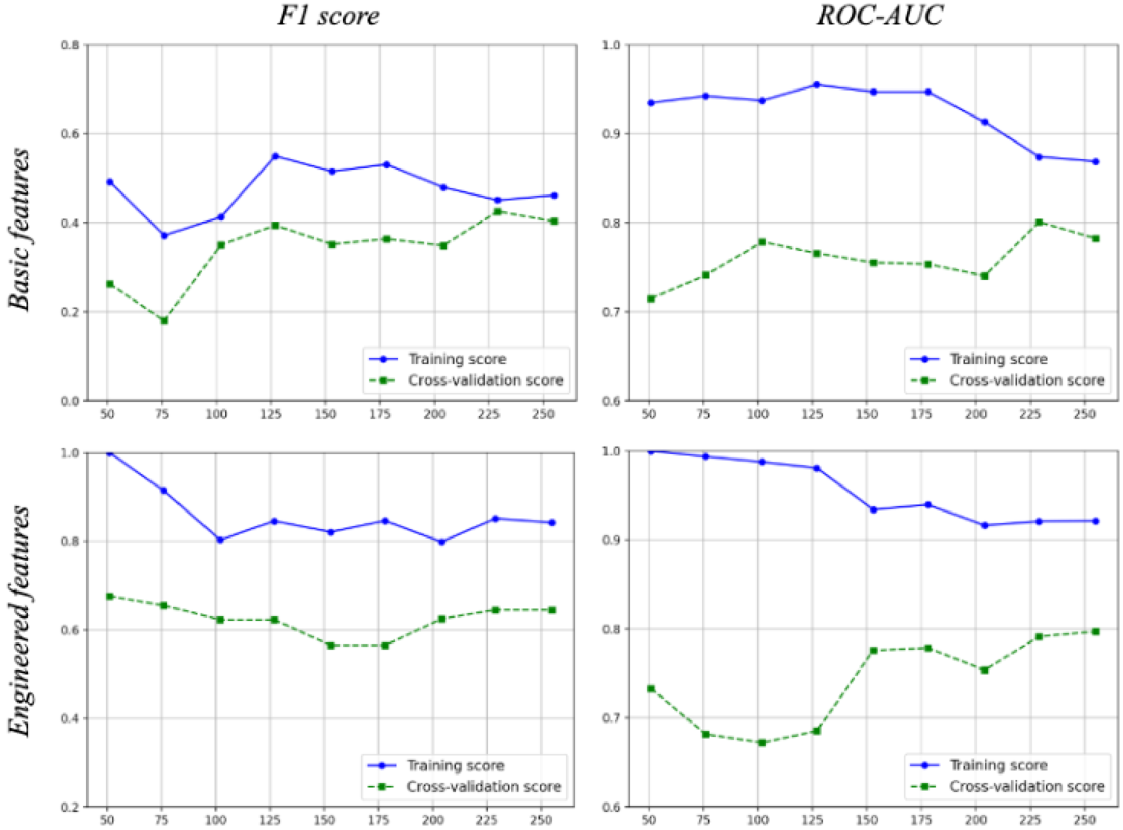
Figure 4. Panel A displays a scatter plot of train-of-four ratio (TOFR) and T1. Panel B displays a scatter plot of the features deltaT4_T1 and ratioT1. Scatter plot displays 1 as outlier, and 0 as a normal observation. TOFR in absolute units. DeltaT4_T1 in milliseconds. T1 in root-mean square angulation and acceleration.



Model Performance

Figure 5 presents the learning curves during model training and validation, for both the F1 score and ROC–AUC performance metrics. By plotting the model training and validation performances as functions of the training set size, high variance (ie, overfitting) or bias (ie, underfitting) can be assessed. While overall there seems to be a good bias–variance trade-off for both models, the CSLR based on the engineered features data set tends to overfit more than the model based on the basic features.

Figure 5. Learning curves of the cost-sensitive logistic regression models of the basic feature (above) set and the engineering feature set (below). Training and validation metrics are the F1-score and the ROC-AUC score (y-axis). X-axis represents the number of training instances.



In Table 4, the F1 score, the ROC–AUC, precision, and recall for the CSLRs of the basic features and the engineered features are presented. Performance metrics are given for the training and test data sets. The CSLR model with the engineered features on the test data has an improved performance compared with the metrics of the training data set, indicating that the model has not been overfit. For the CSLR model of the basic features, we observe the opposite. The F1 score (95% CI) was 0.86 (0.48-0.97) for the CSLR model with the engineered features, which was significantly larger than the CSLR model with the basic features (0.29 [0.17-0.53]; *P*<.001). ROC curves and AUC curve results are visualized in Figure 6. The CSLR model with the engineered features has the highest AUC (95% CI) with a score of 0.91 (0.72-0.97), significantly larger than the CSLR model with the basic features (0.86 [0.63-0.93]; *P*<.001).

Table 4. Performance metrics of the training data set and the test data set.

Data sets	F1 score, mean (95% CI)	ROC[a]–AUC[b], mean (95% CI)	Precision, mean (95% CI)	Recall, mean (95% CI)
Training data set (n=319)				
Basic features	0.47 (0.24-0.63)	0.78 (0.63-0.82)	0.43 (0.18-0.68)	0.55 (0.33-0.71)
Engineered features	0.65 (0.49-0.84)	0.80 (0.70-0.87)	1.00 (0.68-1.00)	0.50 (0.40-0.75)
Test data set (n=214)				
Basic features	0.29 (0.17-0.53)	0.86 (0.63-0.93)	0.25 (0.10-0.52)	0.33 (0.29-0.98)
Engineered features	0.86 (0.48-0.97)	0.91 (0.72-0.97)	1.00 (0.49-1.00)	0.75 (0.44-0.94)

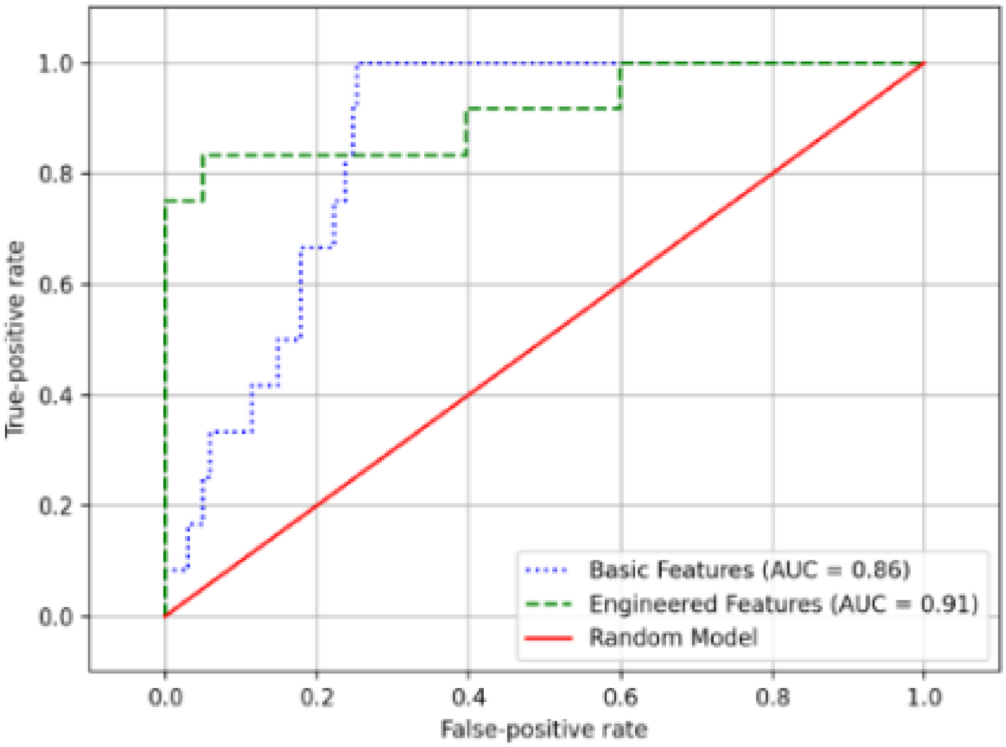
[b] AUC: area under the curve.

Figure 6. Receiver-operating characteristic curves displaying the ability of the algorithms to classify a train-of-four measurement as an outlier. AUC: area under the curve.



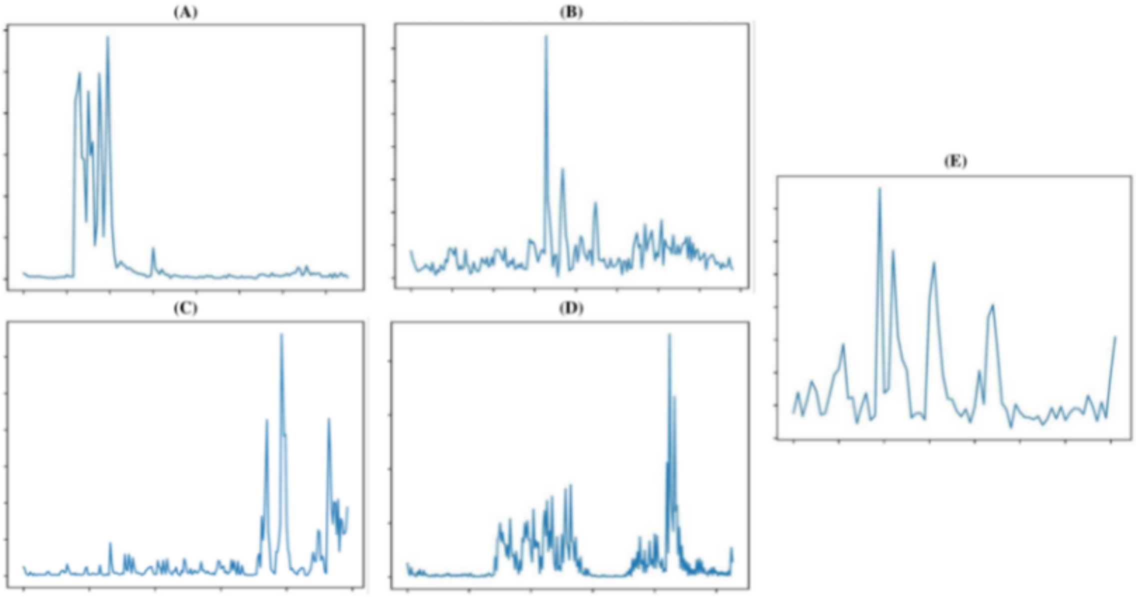
Discussion

Principal Findings

The herein obtained results demonstrate that engineered TOF features outperform basic and common clinically employed neuromuscular monitoring endpoints for automated outlier identification of intraoperative TOF measurements. In the test data set, the CSLR of the engineered variables correctly identified 9 out of 12 measurements as outliers, compared with the CSLR of the basic features, which only correctly flagged one-third of the outliers. Moreover, the basic feature CSLR displayed a high degree of false positives, where 12 TOF measurements were incorrectly labeled as outliers, as opposed to 0 false positives on the CSLR model with the engineered features. While the authors recognize that the current models are sedimented on a limited data set and that further development is necessary in order to arrive at a clinically deployable outlier detection algorithm, the performance of the engineered feature algorithm is promising for a possible clinical application. Various research efforts [8,15,24] have highlighted that quantitative neuromuscular monitoring is still suboptimally and reluctantly adopted by practicing anesthesiologists, among others, due to a low perceived usefulness and reliability of monitoring devices. Even when effectively available on request, perceived unreliability due to artifactual recordings has been shown to be a prevalent barrier and a technical hindrance toward consistent monitoring adoption [15]. Nevertheless, the measurement error (artifact) incidence rates of standard neuromuscular monitors are unknown, and for that matter, so is an encompassing formal description and corresponding physiological correlations.

Given the wide scope of anesthesia monitoring, the daily clinical relevance and eventual successful adoption of such an outlier analysis are certainly subject to debate. Nevertheless, the development of the CSLR models within this study is anchored on clinically grounded reported monitoring issues [7,8,15,25-29]. Figure 7 illustrates examples of flagged abnormal extraneural stimulation-induced moments. Although all have quantifiable and within-normality TOFR values, outliers are evident on closer inspection.

Figure 7. (A) Short 4-peak burst—rebound phenomenon TOF-like pattern after a single movement, short intertwitch distance; (B) T3 less than T2 and T4; (C) Almost equidistant oscillations; (D) Crescendo pattern; (E) Decrescendo but gross oscillations and variable interpeak distance. Some of the detected patterns have implications. y axis: muscle acceleration (m/s2), x axis: time (centiseconds). TOF: train-of-four.



The anchoring of such outlier analysis to the clinical context of neuromuscular blockade monitoring is yet to be done practically and prospectively. Although the authors anticipate the present offline analysis will improve both neuromuscular monitoring adoption and clinical errors when embedded into anesthesia monitors, this can only be speculated upon at the present stage of development. It should additionally be reiterated that the bottleneck issue of undereducation is not tackled by the present developments. In fact, phenomena such as the failure of T1% to reach its baseline levels of around 100% during EMG-based neuromuscular monitoring are frequently observed in clinical practice and similarly trigger distrust among anesthesiologists [15]. The importance of human factors on the effective implementation of recommendation software has been highlighted by a recent randomized pilot trial, where a rather widely deployable predictive algorithm—the Hypotension Prediction Index (Edwards Lifesciences Corporation)—has been shown to fail to engage anesthesiologists [30].

As reinforced in the latest perioperative neuromuscular management consensus statement, educational efforts constitute an important part of modern anesthetic neuromuscular monitoring [7]. On the authors' opinion, automated decision support software alone is expected to aid, but not solve or abolish, with the problem of suboptimal worldwide adoption of neuromuscular monitoring.

Considering the frequent and known artifactual biasing of kinetic data even with CE/FDA-labeled AMG/kinemyography/EMG neuromuscular monitoring devices [25-29], the added value of outlier analysis becomes especially relevant for reliability purposes. For instance, Liang et al [29] performed an ipsilateral comparison of AMG and EMG monitoring devices, concluding that AMG is less precise than EMG and overestimates the EMG TOFR by at least 0.15 units. A similar study performed by Kopman et al [28] found that AMG TOF values tend to overestimate the extent of EMG recovery, with a bias estimate of 0.125. However, both authors could not provide a cause to why these bias estimates between AMG and EMG devices were measured, stating that their lack of agreement cannot be explained by the imprecision of either device. Although outliers are not expected to explain such systematically reported intermethod precision differences when no technical issues are at hand, these do have the potential to compensate for small kinetic nuances such as overshoots, provided enough training data are available. In that sense, commonly applied AMG correction techniques such as normalization against baseline measurements could potentially be obviated. Nevertheless, based on the herein presented results, such potential is purely speculative.

Study Limitations

- It can be argued that the data set that was collected and applied to develop the algorithm within this study is of a somewhat limited sample size. In order to address this limitation and avoid overfitting, we chose a cost-sensitive learning technique for logistic regression, adopted a cross-validation strategy together with the grid search optimization technique, and implemented regularization training, commonly used in machine learning.
- While the presented CSLR model with our engineered features is capable of detecting outliers in the process of AMG neuromuscular monitoring, there is no correlation with a possible cause. Hence, except for a measurement repetition, it remains unclear how clinicians would act upon the warning given by the algorithm.
- The data of this study were collected through an AMG-based smartphone app specifically aimed to monitor the TOF movement pattern and to calculate the corresponding TOFR. This app is undergoing further refinement to facilitate neuromuscular monitoring and to provide clinical intraoperative decision support. While the quality of the recorded measurements of the device has been previously assessed within a clinical trial [16], it is

still possible that certain outliers are due to the nature of handheld devices themselves.

- We present a set of engineered features that have the potential for real-time detection of outliers within neuromuscular monitoring. Further analysis could reveal features that carry additional information for this purpose. Additionally, this study did not analyze (online) real-time streams of data to detect outliers.
- The algorithm developed depends on AMG neuromuscular monitoring devices. While these devices are still the most adopted quantitative neuromuscular devices in the domain of anesthesia [6], the developed algorithm does not tackle EMG-based devices [31].
- This study is not an intermethod validation study, but a precision increasing exercise that still warrants prospective intermethod comparison. This refers to its paired comparison with both AMG and EMG devices.

Conclusion

This study demonstrates that a set of engineered features has the ability to detect outliers from an AMG neuromuscular device based on intraoperative measurements. The development of the model based on these features displayed promising results toward the creation of an outlier detection technique for neuromuscular monitoring. With further research and additional training, an outlier detection algorithm can potentially be implemented within an AMG neuromuscular monitoring device to scan TOF measurements for outliers automatically while not relying on active input from medical providers.

Abstract

Background: Obsessive-compulsive disorder (OCD) is characterized by recurrent intrusive thoughts, urges, or images (obsessions) and repetitive physical or mental behaviors (compulsions). Previous factor analytic and clustering studies suggest the presence of three or four subtypes of OCD symptoms. However, these studies have relied on predefined symptom checklists, which are limited in breadth and may be biased toward researchers' previous conceptualizations of OCD.

Objective: In this study, we examine a large data set of freely reported obsession symptoms obtained from an OCD mobile app as an alternative to uncovering potential OCD subtypes. From this, we examine data-driven clusters of obsessions based on their latent semantic relationships in the English language using word embeddings.

Methods: We extracted free-text entry words describing obsessions in a large sample of users of a mobile app, *NOCD*. Semantic vector space modeling was applied using the Global Vectors for Word Representation algorithm. A domain-specific extension, *Mittens*, was also applied to enhance the corpus with OCD-specific words. The resulting representations provided linear substructures of the word vector in a 100-dimensional space. We applied principal component analysis to the 100-dimensional vector representation of the most frequent words, followed by k-means clustering to obtain clusters of related words.

Results: We obtained 7001 unique words representing obsessions from 25,369 individuals. Heuristics for determining the optimal number of clusters pointed to a three-cluster solution for grouping subtypes of OCD. The first had themes relating to relationship and just-right; the second had themes relating to doubt and checking; and the third had themes relating to contamination, somatic, physical harm, and sexual harm. All three clusters showed close semantic relationships with each other in the central area of convergence, with themes relating to harm. An equal-sized split-sample analysis across individuals and a split-sample analysis over time both showed overall stable cluster solutions. Words in the third cluster were the most frequently occurring words, followed by words in the first cluster.

Conclusions: The clustering of naturally acquired obsessional words resulted in three major groupings of semantic themes, which partially overlapped with predefined checklists from previous studies. Furthermore, the closeness of the overall embedded relationships across clusters and their central convergence on harm suggests that, at least at the level of self-reported obsessional thoughts, most obsessions have close semantic relationships. Harm to self or others may be an underlying organizing theme across many obsessions. Notably, *relationship*-themed words, not previously included in factor-analytic studies, clustered with *just-right* words. These novel insights have potential implications for understanding how an apparent multitude of obsessional symptoms are connected by underlying themes. This observation could aid exposure-based treatment approaches and could be used as a conceptual framework for future research.

Introduction

Background

Obsessive-compulsive disorder (OCD) is characterized by recurrent and persistent thoughts, urges, or images that are experienced as intrusive and inappropriate (obsessions) and that cause marked anxiety or distress and/or repetitive behaviors (compulsions) [1]. OCD has a lifetime prevalence of approximately 2%-2.3% worldwide [2,3] and is associated with functional impairment, poor quality of life, and increased use of health care services [4].

OCD symptoms can manifest in a variety of seemingly disparate ways [1]. Obsessions can be, for example, fears of contamination from one's immediate environment, ego-dystonic thoughts that one might harm someone else in a violent or sexual manner despite not having a desire or intent to do so, believing that one has done something blasphemous, excessive doubts or concerns about one's partner in a relationship, or having a difficult-to-describe need to feel that an object is placed *just right* in their environment. In response to these obsessions, patients might engage in different types of compulsive behaviors that could include, for example, handwashing, checking, praying, arranging items, mental self-reassurance, or avoiding situations that trigger obsessive thoughts.

This range of different symptoms has contributed to the notion that OCD may be a heterogeneous condition characterized by different *subtypes* [5,6]. If so, subtypes might have important implications for understanding the potentially different underlying neurobiology and may have clinical implications, such as different effective treatment approaches for different subtypes.

To date, multiple factor-analytic studies have been conducted on OCD to understand the aggregations of symptoms and establish different potential subtypes [7,8]. Most of these studies have focused on symptoms elicited from clinical interviews rather than underlying pathophysiological mechanisms or processes as the basis for subtyping [7]. Symptom category–based factor-analytic studies have demonstrated evidence for four dimensions or subgroups of obsessions: contamination, harming, symmetry or order, and hoarding (hoarding has since been reconceptualized in the Diagnostic and Statistical Manual-5 as a separate disorder) [9,10] or contamination or somatic, aggressive, sexual, or religious, symmetry or order, and hoarding [11,12]. Two studies found evidence for five latent structures: contamination, harming, symmetry or order, hoarding, and religious or sexual [13] or sexual or somatic [14]. Cluster analyses have also been applied to identify subgroups of OCD symptoms, with some finding similar results as the factor-analytic studies [15,16]; however, one analysis found evidence of additional obsessional symptom clusters of sexual or somatic and contamination or harming [17].

A meta-analysis of 21 studies and 5124 participants found four factors using category-level data: cleaning and contamination, aggressive, sexual, or somatic obsessions (*forbidden thoughts*), symmetry, and hoarding [8]. Using item-level data revealed a five-factor solution: symmetry, aggression or sexual or religious, contamination, aggression or checking, and somatic.

These studies and most approaches to assess OCD symptoms to date have relied on assessing the presence of symptoms by selection from the predefined sets of obsessions and compulsions, most commonly from the clinician-administered Yale-Brown Obsessive-Compulsive Scale Symptom Checklist (YBOCS-SC) [18]. The individual items on the YBOCS-SC and the clustering of these into 13 categories was originally established by clinical consensus. However, using a predefined list of symptoms may introduce bias as it could lead to patients and/or clinicians *fitting* the symptoms into the terms on the checklist, which are further arranged in predefined categories.

Apart from handwashing, the YBOCS-SC was shown in one study to have poor convergent validity with self-report measures [17]. However, this may be attributed to the incomplete representation of symptoms in the other self-report measures to which the YBOCS-SC was compared, which also has the limitation of having predefined checklists. For instance, relationship-related obsessions [19-24] pertaining to obsessions regarding the suitability of the relationship or the relationship partner are not in the YBOCS-SC. Another study found an incomplete correspondence between the YBOCS-SC and self-report measures [25]. Furthermore, its internal consistency reliability was low for symmetry or ordering and sexual or religious symptoms; however, it was adequate for contamination or handwashing and aggression or checking [26].

A potentially less biased approach to assess and classify the types of OCD symptoms could come from patients' free responses rather than relying on checklists. However, using free responses to understand the relationships among these symptoms to determine if categories or factors exist poses a challenge because of the vast number of different possible responses. Very large samples of responses, from large numbers of individuals, are likely required to identify stable patterns because multiple repeated terms, or terms representing similar semantic themes of symptoms, would be needed to separate signals from noise.

Such large samples could be obtained using digitally obtained data, such as from mobile apps used by individuals with OCD [27]. Mobile digital sources of free-entry text could provide a valuable resource for uncovering naturalistic, unrestricted, spontaneous, and therefore relatively unbiased patterns of responses.

Although they are more difficult to classify as compared with checklists, the semantic relationships of freely entered words representing obsessions can be analyzed for their clustering relationships in the English language. A tool to perform this clustering is natural language processing (NLP)—a branch of artificial intelligence that attempts to bridge the gap between computers and humans using the natural language [28]. Some common use cases of NLP include language translation apps such as Google Translate and computerized personal assistants such as Siri and Google Assistant. Each of these apps rely on NLP to decipher and understand human languages to complete a task. Approaches using NLP could provide a better understanding of latent semantic themes that could form the organizing relationships of groupings of protean individual obsessional examples. As a result, we apply NLP to characterize obsessions in this first-of-its-kind study.

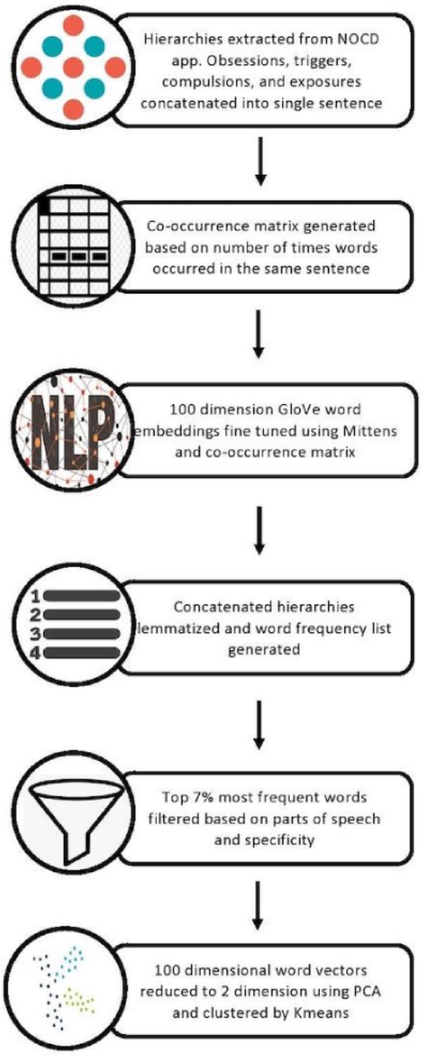
Objectives

To explore this approach, we obtained free-entry data for obsessions from a mobile health treatment platform developed by NOCD [29]. The NOCD app, among other functions, provides users with a platform for setting up customizable exposure and response prevention (a form of cognitive behavioral therapy for OCD) exercises. The primary objective of this study is to determine the number, types, and relationships of semantically organized clusters of obsessions in a data-driven manner. To this end, we applied an NLP technique called word embedding to a large data set of words from a large sample of individuals using the NOCD app.

Methods

An overview of the data extraction and following processing steps are shown in Figure 1.

Figure 1. Data extraction and processing steps. GloVe: Global Vectors for Word Representation; PCA: principal component analysis.



Data Extraction

We extracted data from freely entered words describing obsessions and their corresponding triggers, exposures, and compulsions by users of the iOS version of the mobile app NOCD who self-identified as having OCD (NOCD iOS app version 2.0.7-2.0.96). This app includes two features where users can input their current obsessions, namely, the “SOS” feature and the hierarchy, which can then be used for planned exposure exercises. Obsessions that had been inputted by users were assigned an anonymous user ID number, and all data were deidentified. NOCD users are required to be at least 17 years of age, but to preserve privacy, no specific demographic information was collected. Data were collected between March 22, 2018, and July 9, 2020.

Data Preprocessing

Obsessions and descriptions of obsessions from their associated triggers, exposures, and compulsions were grouped together into a singular phrase. In addition, phrases were cleaned to remove punctuation, special characters, and spelling errors.

Generating Word Embeddings—Global Vectors for Word Representation Algorithm and Mittens

A co-occurrence matrix of size N×N is generated by iterating over the aforementioned phrases and incrementing (i,j), where N is the number of unique words, and i and j correspond to two words that appear in the same phrase. Pretrained 100-dimension Global Vectors for Word Representation (GloVe) algorithm [30] word-embedding vectors were used in conjunction with the co-occurrence matrix as inputs to Mittens [31], which is an extension of GloVe for learning domain-specialized representations.

Thus, GloVe vectors, based on global word-to-word co-occurrence statistics from a 6 billion–word corpus, were fine-tuned based on the localized co-occurrence matrix. This provides a specialized representation of words and their relationships from the OCD-specific lexicon synthesized with pretrained representations from the general lexicon.

Data Processing

To identify the root forms of words that may be inflections of each other, we performed lemmatization using Stanford CoreNLP—natural language software [32]. The entries were first parsed into single words. These words were assigned a frequency as to how often they occurred across all individuals’ entries and then sorted by the frequency of occurrence. The top percentage of most frequently occurring words was chosen; the top 7% was selected as it captured the most commonly occurring words balanced with the ability to visualize the cluster graphs.

These words were then filtered based on the parts of speech: adverbs, modals, third-person singular present verbs, gerunds, past participle verbs, *to*, prepositions, subordinating conjunctions, and personal pronouns. In addition, a clinician (JDF) reviewed the filtered list to further remove nonclinically relevant words, resulting in a total of 430 words.

Clustering and Data Analysis

To visualize the 100-dimension latent semantic relationships of words in a 2D space, we applied principal component analysis to the 100-dimensional vector representation of the most frequent words and plotted the first two principal components. Furthermore, to identify clusters of related words in a data-driven manner, we performed k-means clustering. The optimal number of clusters was determined using the following heuristics: the silhouette coefficient [33], Elbow Method [34], Calinski-Harabasz Index [35], and the Davies-Bouldin index [36].

Once the optimal cluster number was determined, we compared the relative frequencies among the clusters of (1) unique obsessional words and (2) total obsessional words using the chi-square test.

Results

Characterization of the Data

We obtained 7001 unique words representing obsessions from 25,369 individuals aged 17 years and older, self-identified as having OCD across 108 countries. Most individuals were from the United States (18,315) with an additional 1335 North American entries from Canada and Mexico, 4134 from Europe, 557 from Asia, 100 from Africa, 137 from South America, and 791 from Australia and New Zealand.

In total, 94.99% (24,100/25,369) of users contributed no more than five obsessions each to the data set. Most users—16,988 (the mode)—contributed only one obsession; 4311 contributed two obsessions, 1861 contributed three obsessions, 854 contributed four obsessions, and 476 contributed five obsessions. There were two extreme outliers that contributed 120 and 174 obsessions. We removed these data before the analysis. In summary, although users could enter multiple words, given the large total number of obsessional words that were mapped and the fact that most users only entered one or two words, the overall results were unlikely to be biased by single users (Multimedia Appendix 1, Figure S5, shows a histogram of the number of word entries per user).

Determining Cluster Size

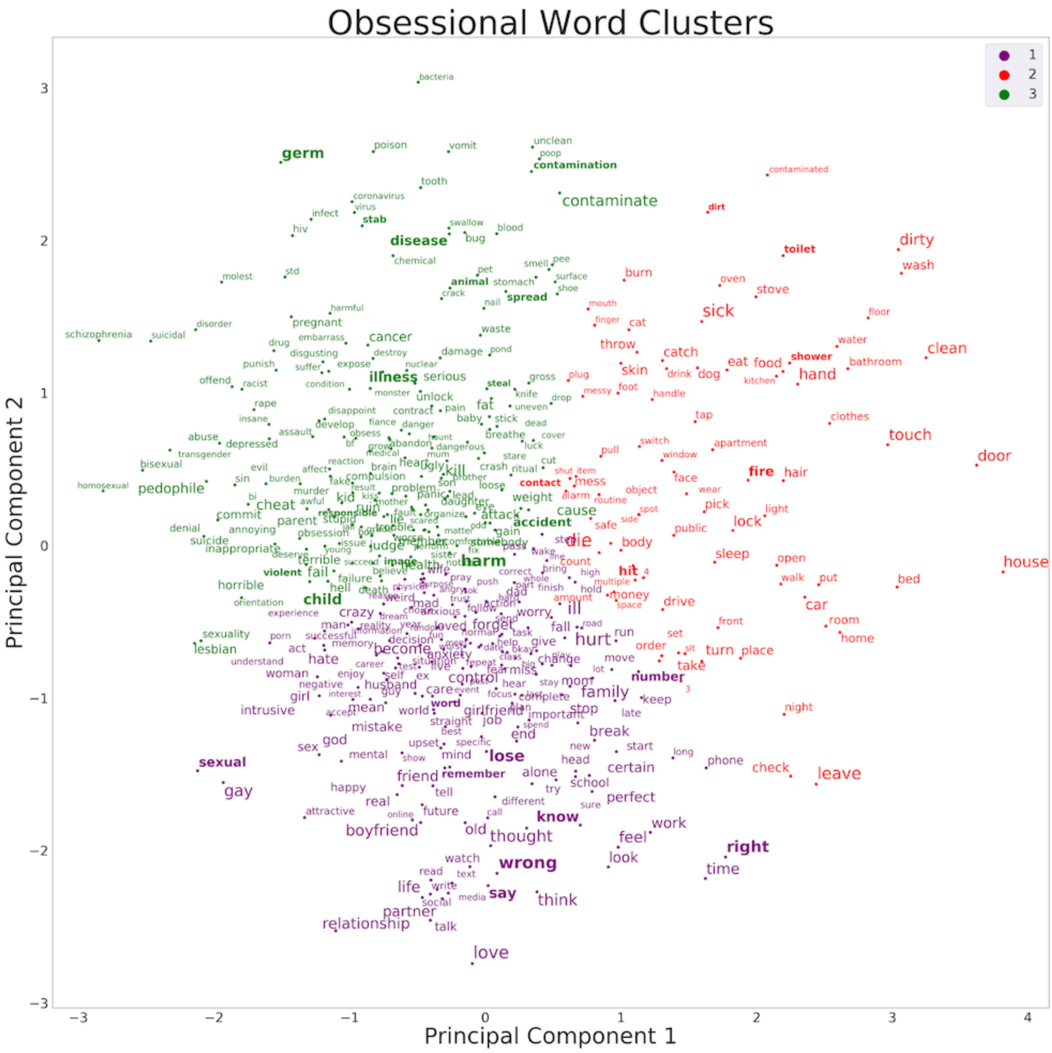
The silhouette coefficient yielded optimal clusters with sizes of 3 and 5. The Elbow Method, Calinski-Harabasz index, and Davies-Bouldin index all pointed to k=3 as the optimal number of clusters (Multimedia Appendix 1, Figure S5).

Relationships of Obsessional Words With Canonical OCD Symptom Factors

Next, we determined how the clusters of obsessions from our data-driven methods using freely reported obsessional words compared with previous factor-analytic and clustering studies that characterized symptom groupings based on rating scale checklists. To do this, we qualitatively examined which cluster appeared as OCD-specific words from the YBOCS-SC. We examined this for the optimal cluster solution of k=3 (Figure 2) [16] as well as for k=2, k=4, and k=5 clusters (Figure 3). Across all cluster solutions, there was a large, dense, central grouping with principal themes relating to harming of self or others (eg, *harm*, *accident*, and *hit*).

Furthermore, across k=3, k=4, and k=5 cluster solutions, the densest regions of each cluster were at a central convergence of the clusters, thereby suggesting closely grouped embedded relationships both within and across clusters (including on the borders between these clusters). Furthermore, cluster *3* in the k=3 solution that contained contamination and somatic-themed words (eg, *contamination*, *germ*, *disease*, and *illness*) and physical- and sexual-related harm words (eg, *harm*, *accident*, *child*, and *sexual*) split from each other in the k=4 solutions, suggesting that although these themes are related, distinctness is evident at the next level of separation.

Figure 2. Frequently occurring obsessional words and their clustering, based on semantic relationships. The word embedding was trained on the entirety of the data set and clustered using k-means with k=3 clusters. The font is scaled according to the frequency of occurrence of each word. For reference, bolded words are those that also appear in the Yale-Brown Obsessive-Compulsive Scale Symptom Checklist.



Split-Sample Repeat of the Clustering Analysis

We repeated the analysis in an equal-sized, nonchronological overlapping sample to control for any possible influences of minor changes in the NOCD app user interface that occurred during the period of data collection. The first sample was from March 22, 2018, to August 14, 2019 (11:18:04 PM), and the second sample was from August 14, 2019 (11:42:12 PM), to July 9, 2020, and each sample included 22,749 and 22,750 words, respectively.

The two aforementioned samples demonstrated similar clustering patterns, suggesting that the results were stable over time. To quantify this observation, we compared the 2D embeddings of the two groups by calculating the distance from a word to all other words on the graph. We performed this task for all words, creating a matrix of distances. Matrices for the two groups were compared using the Pearson correlation coefficient. Most correlations were above r=0.90, thereby demonstrating a high consistency of results across separate periods (Multimedia Appendix 1, Figure S14).

As the two abovementioned samples included some of the same individuals who entered obsessions in both the first and second periods, we additionally repeated the analysis in two nonoverlapping equal-sized user samples. The first sample contained 12,684 users with 22,510 obsessions and the second sample contained 12,685 users with 22,989 obsessions. By performing the same comparison of word-to-word matrices as for the chronological split sample, we found that the two split-by-users samples demonstrated very similar clustering patterns with the majority of correlations $r \geq 0.90$, suggesting that the results are reliable over subsets of users.

Relative Frequency of Obsessional Words by Cluster

Comparing the three clusters on the total number of obsessional words, we observed 169 words in cluster 1 (just-right and relationship themes), 86 words in cluster 2 (doubt or checking themes), and 174 words in cluster 3 (contamination, somatic, or harm themes). All three clusters were significantly different from each other ($\chi^2=34.2$; $P<.001$). Furthermore, cluster 1 was significantly different from cluster 2 ($\chi^2=27.4$; $P<.001$) and cluster 3 ($\chi^2=11.4$; $P<.001$). Cluster 2 was significantly different from cluster 3 ($\chi^2=29.4$; $P<.001$). Thus, contamination, somatic, or harm words were more frequent than the just-right and relationship words and the doubt or checking words, and the just-right or relationship words were more frequent than the doubt or checking words.

Discussion

Principal Findings

In this large data set, we applied a data-driven approach and the NLP technique of word embedding to understand commonly occurring semantic themes of obsessions, freely reported by individuals using an OCD app. The optimal number of independent clusters that represents the relationships of the most frequently occurring obsessions was 3. Notably, the embedding patterns revealed that most obsessional words were closely grouped within and across clusters, including on the borders between clusters. Moreover, the densest region of each cluster is at a central convergence of the three, with principal themes relating to harm. This suggests that, at the level of self-reported obsessional thoughts, most obsessions have close semantic links with each other. Thus, although unique obsessions are protean, many examples, even across cluster *subtypes*, may actually have underlying latent relationships with each other.

Observations of Semantic Themes of Clusters

To relate these findings to previous studies of OCD subtypes, we chose descriptive labels for the clusters from words from the widely used YBOCS-SC from six of the eight obsession categories: aggressive, sexual, religious, somatic, symmetry, and contamination (excluding hoarding and miscellaneous). Using these labels, the optimal cluster solution of three resulted in contamination-themed and physical- and sexual harm–themed obsessions occurring in the same cluster (cluster 3) and relationship and just-right themes occurring in the same cluster (cluster 1; Figure 2). Cluster 2 included many doubt-related obsessions typically associated with checking compulsions and a subset of contamination-related obsessions (eg, toilet, shower, sick, or dirty).

A notable overall observation is that the clustering algorithm produced topological patterns demonstrating a large but diffuse central cluster of harm-themed words, in addition to more diffuse and distanced words that represent contamination themes and doubt-related obsessions typically associated with checking compulsions (eg, fire, house, door, car, or lock). This is most readily apparent at the lowest level of clustering (k=2; Figure 3). As the number of clusters increases from k=3 to k=4 to k=5, some contamination-themed words joined with somatic-related themes (cluster 3 for k=3; Figure 3), which subsequently split into two different clusters (clusters 3 and 4 for k=4; Figure 3). At k=5, the original harm cluster from k=2 split into three clusters (clusters 1, 3, and 4), comprising words with themes related to sexual, sexual orientation, and relationships (cluster 1); *just-right* (cluster 3); and physical harm and a subset of doubt or checking (cluster 4).

This latter observation that a subset of doubt or checking words split off into two separate clusters at this level is consistent with a previous factor-analytic study finding that *aggressive* obsessions and checking compulsions tend to show instability on which factors they load on [37]. This progressive splitting of groups of obsessions as the cluster number increases provides unique insights into how closely some obsessional themes are related to each other based on their semantic relationships embedded in a 100-dimensional space.

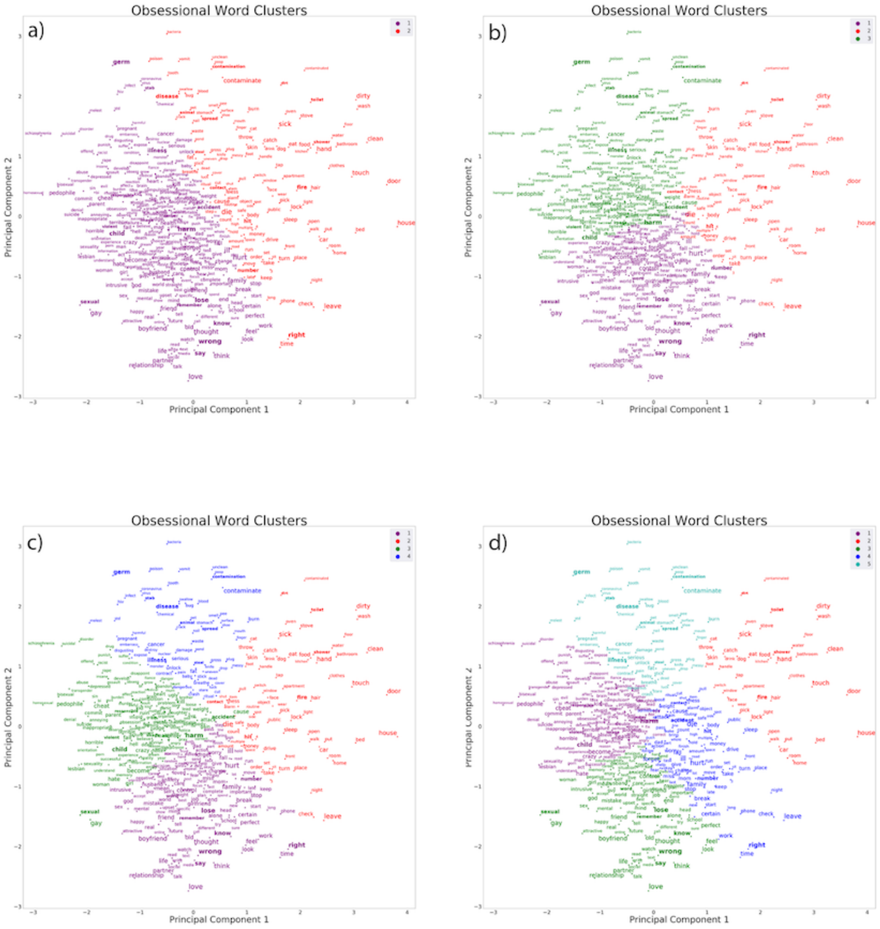
These results are largely consistent with the findings of previous factor-analytic studies. A previous meta-analysis [8] of factor-level results similarly suggested a three-factor solution (not including hoarding symptoms); however, the item-level results pointed to five factors. There are several possible reasons why results differ, at least partially, from previous studies. First, this study represents an obsession from a much larger sample size: 25,369 individuals. The previous meta-analysis included a total of 5124 individuals; yet, individual study sizes ranged from 45 to 615. Thus, this study might have sampled a broader population.

Furthermore, as described in the Introduction section, previous factor-analytic and clustering studies used data collected with existing scales that include predefined checklists and categories, often from the YBOCS-SC. This could have the effect of creating a conceptual framework into which patients (and clinicians and researchers) may *shoe-horn* their experiences and symptoms. In addition, if a patient has an obsessional preoccupation that is not listed on the scale, then the patient, clinician, or researcher may not identify it as an OCD symptom. Freely entered text, as the NOCD app allows, mitigates this limitation. Notwithstanding, many individuals using the app may have already been exposed to commonly used lexicons regarding OCD subtypes, from clinicians, educational material, the media, or even the NOCD app itself because the online *community* forum mentions OCD subtypes.

Additional factors might account for why results partially diverge from previous factor-analytic and clustering studies. Some patients may feel embarrassed, ashamed, or even fearful of the consequences of divulging certain *taboo* obsessional thoughts, such as blasphemous, pedophilic, other sexual, or violent themes in front of a clinician or researcher. Such individuals may find it easier to enter these, on their own, in an app. In addition, in the online community forum in NOCD, people can find others who share similar thoughts. Once they have identified that what they experience is likely an OCD symptom, because it is shared by others, this could facilitate them entering the obsessional words related to these themes in the *hierarchy* part of the app. In sum, this approach of mapping the embedded latent relationships of obsessions partially recapitulates factor-analytic studies' findings; yet, the differences might reflect a more unconstrained capturing of naturally occurring obsessions.

The split-sample test over time and across unique individuals demonstrated overall stable results. This stability across time suggests that the semantic themes of obsessional words entered by users are mostly invariant to periodic updates and fixes that happened with NOCD, as is standard with the most widely used mobile apps. In addition, early adopters of apps in general may have certain characteristics that differ from later adopters [38]. However, the stability across the split sample demonstrates that the results hold across these potentially different sets of individuals.

Figure 3. Frequently occurring obsessional words and their clustering, based on semantic relationships. The word embedding was trained on the entirety of the data set and clustered with k values of 2, 3, 4, and 5. The font is scaled according to the frequency of occurrence of each word. For reference, bolded words are those that also appear in the Yale-Brown Obsessive-Compulsive Scale Symptom Checklist. Observations of how the bolded words change clusters as k values change provide valuable insight into the similarities of OCD subtypes.



Relative Frequencies of Obsessions Across Clusters

Earlier studies that categorized patients with OCD according to primary compulsions observed that contamination obsessions were the most common [39]. A subsequent study found that cleaning compulsions (therefore most often associated with contamination fears) were almost twice as common as checking compulsions (most often associated with harm or doubt obsessions) and more than four times as common as obsessions without physical compulsions in people with OCD seeking treatment [40]. A community assessment of OCD from the National Comorbidity Survey Replication included 2073 people and administered the YBOCS [2]. The results suggested that obsessions leading to checking (typically caused by obsessional fear of harm or doubt) are more common than contamination fears. The latter finding could have included the types of harm obsessions that were found to be highly represented in this study's data set (clusters 2 and 3 in Figure 3), although it is unclear from the data collected in that study.

In this study's sample, obsessions with harm themes were represented in a much higher proportion than in previous studies. Although harm-, contamination-, and somatic-themed words were clustered together in the k=3 grouping, the harm and contamination or somatic themes split and harm themes were nearly twice as common (n=138) as contamination or somatic words (n=70) at k=4. As most individuals in the current sample contributed only one obsession, this might represent their primary symptom, although this was not specifically ascertained. One interpretation of this finding is that this could represent a truer reflection of the relative proportions of these obsessional themes in the larger population of those with OCD, particularly because this study had a sample size that was an order of magnitude larger than the National Comorbidity Survey

Replication. Furthermore, previous studies may not have found such relative proportions because of the limited thematic content of the YBOCS-SC or other instruments used to collect these data (as mentioned earlier). In addition, as mentioned earlier, *taboo* themes often relate to harming others and might appear more frequently in this data set obtained via relatively anonymous entry as compared with other data sets from population-based studies that involved researchers directly querying participants about subtypes.

An alternative interpretation is that there may be an overrepresentation of individuals who use the NOCD app who have harm obsessions. If this is the case, then it could be related to the stigmatization and *taboo* nature of these themes. Individuals with unwanted obsessional thoughts that are taboo in most societies and cultures, such as sexual thoughts about children, incest, physically harming someone, or blasphemous religious thoughts, may not readily share them with clinicians or researchers. However, they may feel more willing to share these in an app, which is a more anonymous experience. In addition, the NOCD app includes an online community forum in which other individuals share topics such as obsessional thoughts. This may help individuals not only realize that these thoughts could be related to OCD (they may not have found exact examples of their particular obsession elsewhere) but also the stigmatization of sharing them and entering them in the app could be reduced.

Another possibility that could lead to the overrepresentation of individuals with *harm* themes among NOCD users is that they might not have received effective treatment elsewhere and therefore gravitated toward NOCD as an alternative to try to find help. A study by primary care physicians demonstrated that OCD was misdiagnosed as either another psychiatric or psychological condition or no diagnosis 50.5% of the time [41]. Furthermore, in that study, obsessions related to homosexuality, aggression, and pedophilia were misdiagnosed ≥70% of the time. A similar study by clinical psychologists found that OCD was misdiagnosed 38.9% of the time and obsessions about the taboo thoughts of homosexuality, sexual obsessions about children, aggressive obsessions, and religious obsessions were more frequently misdiagnosed than contamination obsessions [42]. Even if diagnosed correctly, clinicians might find these types of symptoms difficult to understand and/or difficult to treat with exposure and response prevention because the themes are outside of the well-known *textbook* examples of contamination fears and checking compulsions, many of which have mental rather than physical compulsions or primarily engage in avoidance behaviors.

Relationship-Themed Obsessions

Obsessions related to relationships have recently received attention in clinical and research settings [19-24], spawning the term "relationship OCD." Although the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* [1] does not explicitly describe "relationship obsessions," it provides an example under Other Specified Obsessive-Compulsive and Related Disorder, "Obsessional jealousy...a nondelusional preoccupation with a partner's perceived infidelity." Other partner-centered obsessional themes include obsessions about a partner's flaws, such as intelligence, social aptitude, and morality [21]. Additional themes are centered on the relationship itself and can include obsessional doubting about whether one's relationship is a *good* or *ideal* relationship. In addition to having obsessional *thoughts* about relationships, this can also include intrusive images, urges, or *not right* feelings.

To the best of our knowledge, this study is the first to characterize relationship-themed obsessions using clustering or factor-analytic approaches. Many such relationship themes appear in the same cluster as "just-right" obsessions, sometimes referred to as "not-just-right-experiences" [43]. This suggests the possibility that a driving force for many with relationship-themed obsessions could be that something about it does not *feel right*, rather than, for example, other catastrophic or otherwise negative consequences related to the relationship itself or one's partner.

Potential Clinical Implications

There are several potentially important insights that this study provides to the semantic relationships of obsessional thoughts. These have potential clinical assessment and treatment implications for understanding how an apparent multitude of *surface* obsessional symptoms are connected by underlying themes. This could assist clinicians during the assessment phase to facilitate a more focused and personalized inquiry about the presence of additional obsessions that may be semantically related to those reported. This could be helpful, particularly because patients with OCD are sometimes unaware that a particular thought is an obsession. Otherwise, it is difficult and time consuming for a clinician to guess what other obsessions they might have or to present patients with an extremely long and unfocused list of obsessions to choose from.

The findings from this study could also aid in planning exposure-based treatment approaches, for example, therapists could potentially map their patient's primary obsessional themes to understand what are nearest-neighbor themes that might tap into a yet-unexplored core obsessional fear. A specific example of the potential utility of these findings could be to help clinicians explore whether the underlying feeling or emotion associated with a relationship-themed obsession is a not-just-right experiences versus the fear of a negative consequence of the relationship.

Limitations, Strengths, and Future Directions

One of the limitations of this study is that although the data come from individuals who sought out and used therapeutic tools on an OCD app, we cannot confirm whether they met the diagnostic criteria for OCD because they did not undergo a diagnostic evaluation. It would be useful to repeat the procedures and analysis in a clinically diagnosed OCD sample; however, achieving a similar sample size would be extremely challenging. Therefore, this study's results apply to those using the NOCD app, implying that they self-identify as having OCD or an OCD-like problem and could include those with other obsessive-compulsive and related disorders, for example, body dysmorphic disorder or other disorders with prominent obsessional thinking (eg, anorexia nervosa or illness anxiety disorder). This approach is in line with alternative transdiagnostic or dimensional strategies to study psychiatric illnesses, such as the National Institute for Mental Health's Research Domain Criteria [44] framework. Another limitation is that we only examined postings in English. Although the majority of postings were in the English language, there were postings in other languages as well because NOCD is available and used worldwide. Another limitation is that we had limited demographic information because the data were strictly deidentified, limiting our ability to characterize demographic subgroups of individuals with OCD or determine whether these data represented the same gender distributions that are observed in the population of those with OCD. A further limitation is that the sample was limited to those aged 17 years and older. Whether the results can be generalized to children with OCD is unknown.

Finally, because of the variable nature of OCD and variability in the number of obsessions a user will choose to enter in the NOCD app, there was a skewed distribution of the frequency of obsessions across users (Multimedia Appendix 1, Figure S1). Thus, a small number of users theoretically could have influenced the results both at the stages of Mittens enhancement of GloVe embedding and of the comparison of frequencies of obsessions among clusters. However, to mitigate this, we removed the two extreme outliers. Furthermore, the split-sample results across equal numbers of unique users showed stable clusters and relative frequencies of obsessions, so it is unlikely that the main outcomes were influenced by a small number of individual users.

There are several important directions for future research. To understand the dynamics of semantic themes—specifically, if and how they change over time within individuals—it would be useful to obtain longitudinal data. This would allow, for example, an exploration of whether obsessional symptoms are stable in individuals or stable within semantic clusters or whether they cross over into different semantic themes. In addition, semantically defined OCD subtypes could be used as a conceptual framework to explore whether there are corresponding differences in the underlying neurobiology.

Conclusions

In this study, we analyzed the semantic relationships of obsessional words freely entered in a mobile OCD app using a large data set. This novel, data-driven method provides unique insights into the relationships of obsessional themes and identifies potential OCD subtypes. This method is distinct from traditional characterizations of phenomenology in OCD; it is not easily achieved in clinical settings or in-person research settings and circumvents the limitations and biases of pre-existing clinical and research conceptualizations of established OCD subtypes.

Acknowledgments

Abstract

Background: Chemopreventive agents such as selective estrogen receptor modulators and aromatase inhibitors have proven efficacy in reducing breast cancer risk by 41% to 79% in high-risk women. Women at high risk of developing breast cancer face the complex decision of whether to take selective estrogen receptor modulators or aromatase inhibitors for breast cancer chemoprevention. *RealRisks* is a patient-centered, web-based decision aid (DA) designed to promote the understanding of breast cancer risk and to engage diverse women in planning a preference-sensitive course of decision making about taking chemoprevention.

Objective: This study aims to understand the perceptions of women at high risk of developing breast cancer regarding their experience with using *RealRisks*—a DA designed to promote the uptake of breast cancer chemoprevention—and to understand their information needs.

Methods: We completed enrollment to a randomized controlled trial among 300 racially and ethnically diverse women at high risk of breast cancer who were assigned to standard educational materials alone or such materials in combination with *RealRisks*. We conducted semistructured interviews with a subset of 21 high-risk women enrolled in the intervention arm of the randomized controlled trial who initially accessed the tool (on average, 1 year earlier) to understand how they interacted with the tool. All interviews were audio recorded, transcribed verbatim, and compared with digital audio recordings to ensure the accuracy of the content. We used content analysis to generate themes.

Results: The mean age of the 21 participants was 58.5 (SD 10.1) years. The participants were 5% (1/21) Asian, 24% (5/21) Black or African American, and 71% (15/21) White; 10% (2/21) of participants were Hispanic or Latina. All participants reported using *RealRisks* after being granted access to the DA. In total, 4 overarching themes emerged from the qualitative analyses: the acceptability of the intervention, specifically endorsed elements of the DA, recommendations for improvements, and information needs. All women found *RealRisks* to be acceptable and considered it to be helpful (21/21, 100%). Most women (13/21, 62%) reported that *RealRisks* was easy to navigate, user-friendly, and easily accessible on the web. The majority of women (18/21, 86%) felt that *RealRisks* improved their knowledge about breast cancer risk and chemoprevention options and that *RealRisks* informed their (17/21, 81%) decision about whether or not to take chemoprevention. Some women (9/21, 43%) shared recommendations for improvements, as they wanted more tailoring based on user characteristics, felt that the DA was targeting a narrow population of Hispanic or Latina by using graphic novel–style narratives, wanted more understandable terminology, and felt that the tool placed a strong emphasis on chemoprevention drugs.

Conclusions: This qualitative study demonstrated the acceptability of the *RealRisks* web-based DA among a diverse group of high-risk women, who provided some recommendations for improvement.

Introduction

Breast cancer is the most commonly diagnosed cancer among women in the United States and the second leading cause of cancer-related deaths; therefore, prevention of the disease would significantly improve public health [1]. An estimated 268,600 new cases of invasive breast cancer occur among women each year, and 41,769 women will die from the disease [1,2]. The United States Preventive Services Task Force recommends that clinicians offer chemoprevention as a primary prevention strategy to women at high risk of breast cancer and low risk of adverse effects from these drugs [3]. High-risk criteria for breast cancer are defined as a 5-year invasive breast cancer risk of ≥1.67% or lifetime risk score of ≥20% according to the Gail risk model, which accounts for age, race and ethnicity, benign breast disease, first-degree family history of breast cancer, and reproductive factors [4,5]. Chemopreventive agents such as selective estrogen receptor modulators (tamoxifen and raloxifene) and aromatase inhibitors (exemestane and anastrozole) have been shown to reduce breast cancer risk by 41%-79% among high-risk women [6]. Despite the risk-reducing benefits, chemoprevention uptake remains low in the United States, with fewer than 5% of high-risk women deciding to take the medication [4]. Racial and ethnic minority women are less likely to seek breast cancer preventive care [7,8], which contributes to higher rates of late-stage diagnoses, poorer clinical outcomes, and health disparities [9-11].

Patient-level barriers to chemoprevention uptake include inadequate knowledge and negative attitudes, the fear of potential side effects, and inaccurate perceptions of breast cancer risk [4,12]. Previous studies have found that some women are not aware of the availability of chemoprevention drugs, and less awareness has been noted among racial and ethnic minority women [12]. Women may also be skeptical about the efficacy of chemoprevention in reducing the risk of breast cancer [12]. Studies have found that the fear of the potential side effects of tamoxifen leads to negative attitudes toward chemoprevention, including perceptions that the increased risks of endometrial cancer, pulmonary embolism, stroke, deep vein thrombosis, cataracts, hormonal symptoms, and sexual problems outweigh the potential benefits of the drugs (ie, reduced risks of breast cancer and osteoporosis) [13-16]. In addition, when women view themselves as healthy and not at high risk of developing breast cancer, they are less likely to take chemoprevention drugs [17].

Women at high risk of developing breast cancer face the complex decision of whether to take selective estrogen receptor modulators or aromatase inhibitors for breast cancer chemoprevention [5,12]. The decision is complex because (1) the efficacy of these drugs in preventing breast cancer is limited to estrogen receptor–positive tumors, (2) there is an increased risk of developing serious medical conditions with the use of these drugs, and (3) the recommendations are different for pre- and postmenopausal women [5,12]. Therefore, the best choice for chemoprevention is not always clear, making this a preference-sensitive decision that takes into account how each individual values the relative potential benefits and harms [5,12]. Several interventions have been designed to increase chemoprevention uptake [14,15,18-20]. However, these interventions have been met with limited success, ranging from 0.5% to 5.6% chemoprevention uptake [14,15,18-20]. To address patient-related barriers to chemoprevention among racially and ethnically diverse women, our research team developed a patient-centered, web-based decision aid (DA), *RealRisks*, which is currently being tested in 3 clinical trials [4,21,22].

The purpose of this study is to understand the perceptions of women at high risk of developing breast cancer regarding their experience with using *RealRisks*—a DA designed to promote the uptake of breast cancer chemoprevention—and to understand their information needs.

Methods

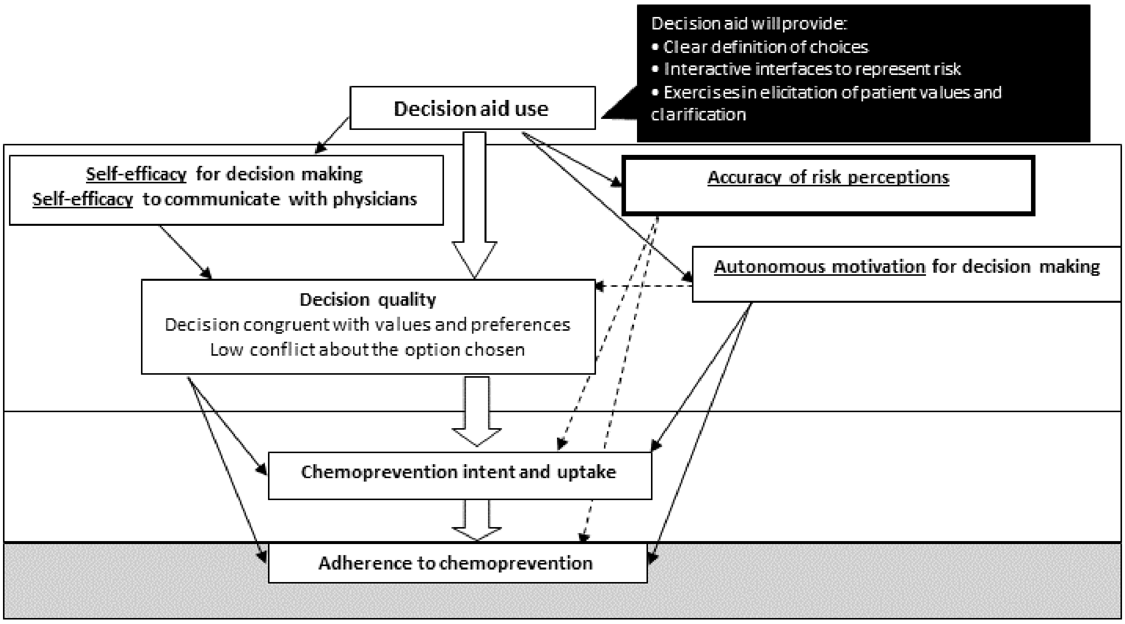
Study Design

We conducted a qualitative study to understand high-risk women's perceptions about *RealRisks*. This study was nested within a randomized controlled trial (RCT) that involved 300 high-risk women assigned to standard educational materials alone or in combination with *RealRisks* to determine chemoprevention uptake at 6 months (primary outcome) [4].

Intervention

RealRisks was designed to promote a woman's understanding of her breast cancer risk and to engage women in planning a preference-sensitive course of decision making about chemoprevention. This web-based DA incorporates 2 complementary theoretical frameworks—shared decision making [23] and self-determination theory (SDT) [24]—to engage women in planning a preference-sensitive course of decision making about chemoprevention. SDT has at its core the concept of autonomous motivation [24-26] and describes autonomous choices as those that a person could fully endorse upon reflection [27-29]. This is contrasted with behaviors or choices that feel *controlled* or coerced by another person. Fully autonomous choices involve reflecting on and integrating one's preferences and values. The key is to facilitate choice in the context of decisions concerning chemoprevention, in a manner such that the evidence presented is not experienced as coercive but as supportive of autonomous choice. As shown in Figure 1, the *RealRisks* DA is intended to promote the accuracy of breast cancer risk perceptions, autonomous motivation, self-efficacy for decision making, and chemoprevention uptake.

Figure 1. Multidisciplinary framework based on shared decision making and self determination theory.



The DA is delivered via audio files with Spanish translation and is organized into the following modules: (1) breast cancer risk (breast cancer risk factors, calculation of personal breast cancer risk, and interactive games on risk communication), (2) chemoprevention, (3) family history and genetic testing, and (4) lifestyle factors. The content in *RealRisks* has been tailored to a Hispanic or Latina group of women. Figure 2 shows the interactive components of the tool that the women complete during their engagement with the tool. The DA has been described in detail in previous publications [4,22].

Pros and Cons of Breast Cancer Risk-Reducing Pills

Your Risk

Based upon your breast cancer risk profile, you are eligible to take breast cancer risk-reducing pills to help lower your risk of breast cancer.

Drag the slider to reflect how you feel about each item.

In the previous section, you learned about the risks and benefits to choosing breast cancer risk-reducing pills. This section of RealRisks will give you an opportunity to explore your feelings and concerns about breast cancer risk-reducing pills and what is most important to you. Move the slider along the scale to indicate how you feel about each statement. There is no right or wrong answer. Use your responses to help you decide if starting breast cancer risk-reducing pills is right for you.

This is very important to me | This is somewhat important to me | This is not important to me

Taking this pill will help me prevent getting breast cancer

I will have difficulty taking or swallowing pills

I don't trust medications

The impact of breast cancer risk-reducing pills on my bone health will influence my decision

The impact of breast cancer risk-reducing pills on my cholesterol level will influence my decision

If I take a breast cancer risk-reducing pill, I will worry less about breast cancer

Risk Game: Breast Cancer Risk in the Next 5 Years

Of the 100 women below, some will have breast cancer but you won't know which ones. Click on the women until you find one with breast cancer. Women with breast cancer will turn red when you click on them.

Click the people until you find out!

5 Year Risk

The picture shows that for an average 50 year old woman, her 5 year risk of breast cancer is **1 in 100**

This game showed 5-year Breast Cancer Risk.

Start a new game with Lifetime Breast Cancer Risk

Participants and Settings

Interview participants were recruited from the intervention arm of the RCT. Participants were eligible if they (1) were English or Spanish speaking, (2) completed their 6-month survey, and (3) had access to the web-based *RealRisks* DA through the intervention arm of the RCT. Recruitment and data collection occurred between February and April 2020. Eligible participants were recruited via email and telephone interviews. The research team stopped recruitment efforts upon reaching data saturation—the point at which the collected data stopped producing novel insights [30]. The study protocol was approved by the institutional review board at Columbia University and Florida Atlantic University.

Data Collection

Eligible participants were invited to participate in a one-on-one semistructured interview conducted over the telephone or via

Zoom web conferencing technology (Zoom Video Communications). The interviews were audio recorded to ensure accuracy. A semistructured interview guide was developed with open-ended questions to explore women's perceptions and experiences using *RealRisks*. We explored participants' acceptability of the tool (what they liked or disliked about *RealRisks* and what new information they learned) and any unmet information needs after interacting with the tool. We also explored participants' access to electronic devices used to access the tool and any technological issues that participants may have encountered. In addition, we asked women about their decision making regarding chemoprevention, factors impacting their decisions, and their clinical encounters with their health care provider. A total of 2 versions of the interview guides were developed: one for women who used *RealRisks* and another for women who had never accessed the DA and could not recall using *RealRisks*. The interviews were conducted by TJ and AG and lasted between 20 and 60 minutes. The interviews were transcribed verbatim by a Health Insurance Portability and Accountability Act–compliant transcription company and compared with the original digital recording to ensure the accuracy of the content. This paper reports data on the perceptions, experiences, and information needs of high-risk women who were granted access to the DA through the intervention arm of the parent trial.

Data Analysis

Transcribed and deidentified data were analyzed using Dedoose software (SocioCultural Research Consultants). Content analysis was used to systematically describe the meaning of the qualitative data [31,32]. Data analyses were performed in several steps. First, the principal investigator (TJ) read the first 2 transcripts to gain familiarity with the data and used open coding to build a coding framework derived from the interview guide topics. Second, the analysis team, consisting of researchers trained in conducting qualitative research (TJ, AG, and TS), coded the first 2 transcripts independently using line-by-line coding and discussed code applications as a group to develop consensus. Third, the analysis team members used the Dedoose training center to evaluate interrater reliability by generating a pooled Cohen κ coefficient to assess coding precision [33]. The final pooled Cohen κ score was 0.86, which indicated a high level of coding agreement among the coding team [34]. Fourth, TJ and AG continued to code the remaining transcripts independently and used the memo feature in Dedoose to review each other's coding and to capture thoughts and observations within and between transcripts. Finally, the analysis team abstracted and interpreted the data to generate thematic domains. To ensure trustworthiness, direct quotations were provided to connect the results to the raw data. Ellipses were used (3 periods indicating a break within a sentence) to help minimize the length of the quotations. In addition, some larger quotations were presented to keep the context of the conversation intact.

Results

Participants and Interview Data

A total of 21 high-risk women participated in this qualitative study (Table 1). The mean age of the participants was 58.5 (SD 10.1) years. Our sample was racially and ethnically diverse, with demographics distributed as follows: 5% (1/21) Asian, 24% (5/21) Black or African American, and 71% (15/21) White. In addition, 2 participants were Hispanic or Latina. Most (15/21, 71%) participants had a family history of breast cancer, and all women (21/21, 100%) reported using *RealRisks* after being granted access to the DA. Interview data were categorized into 4 main themes: (1) the acceptability of the intervention, (2) specifically endorsed elements of the DA, (3) recommendations for improvement, and (4) information needs. Each theme comprised several subthemes, and exemplar quotes are presented to authenticate the overarching themes and subthemes. Themes, subthemes, and exemplar quotes are also provided in Multimedia Appendix 1.

Table 1. Study participant characteristics (N=21).

Characteristics	Value
Age (years), mean (SD)	58.5 (10.1)

[a] GED: General Education Development.

Theme 1: The Acceptability of the Intervention

Subtheme 1: General Perceptions

All women (21/21, 100%) who accessed *RealRisks* shared their general perceptions that they liked using the DA and considered it to be helpful. Almost 80% (16/21, 76%) of the women who were granted access to the DA through the intervention arm of the parent trial completed the tool. Some women (9/21, 43%) shared recommendations for improvement after using the tool. Overall, women from all 4 racial and ethnic groups represented in our study viewed the tool as acceptable. One of the women stated:

> *I felt that it was good for me to have done it [RealRisks]. And I do feel that I got information that I would not have gotten otherwise. I mean, I felt a little bit more informed. So, I'm happy about that.* [Participant #18]

Subtheme 2: Usability of the Intervention

Most women (13/21, 62%) felt that *RealRisks* was easy to navigate. For instance, women shared the following:

> *It was pretty simple and easy to do, and I didn't feel like there were a lot of issues with using the tool and taking the surveys at all...I didn't find it to be off putting. I didn't find it to be hard to do. I didn't find it to suck up a lot of my time.* [Participant #27]

> *It was easy to access. The instructions were pretty good...Simple and basic and not overwhelming and I like the fact that if you didn't know something you could just hover over a term and you could get a definition.* [Participant #26]

> *I liked the fact that it was quick. I was able to just go through it.* [Participant #21]

> *I thought it was easy to use. It answered the questions that I would have. Like it was very thorough in the questions, so I didn't have to wonder what it meant. It wasn't up for interpretation. I thought it was pretty clear.* [Participant #25]

None of the women who used the DA reported encountering any technological issues. One woman stated:

> *No. I was able to get in. I was able to answer all the questions. I don't remember any glitches at all.* [Participant #15]

Subtheme 3: User-friendly

Other women felt that the DA was user-friendly, straightforward, simple to follow, and easy to understand. They shared the following:

> *It was pretty easy to understand. I have no medical background and it gave, I thought, very clear, information about how different drugs could help. And then I could answer the questions that came next.* [Participant #23]
>
> *Pretty easy. Sort of user-friendly in terms of just accessing all the steps.* [Participant #18]
>
> *It was simple to follow-simple to use. It didn't take up too much time. I mean, it's been a while. It's been over a year, right? But I remember just being able to just quickly go on my tablet and answer the questions.* [Participant #7]
>
> *I thought it was easy to understand and to complete. I thought it was pretty user-friendly for someone like myself.* [Participant #5]

Subtheme 4: Easily Accessible on the Web

Most women (19/21, 90%) reported having access to technological devices such as cell phones, tablets, laptops, and desktop computers to access *RealRisks.* The exceptions were 2 Spanish-speaking participants who reported having no access to a computer at home and came to the hospital to receive in-person support to access the tool from one of our research team members. The women who had access to technology liked that the DA was web-based, which allowed them to access it on the web at their own convenience. For example, women shared the following:

> *It was easy because I could do it online. You know, I could like start it at work. I could finish it at home. I did not have to go back and re-answer questions. I thought it was user-friendly.* [Participant #1]
>
> *I could do it online, could start it at work and finish it at home.* [Participant #2]
>
> *It was good that it was online and it was easy to navigate.* [Participant #14]
>
> *I didn't really have any trouble following through. But, you know, I guess, with everything that's done online, you're doing it on your own time.* [Participant #18]

Theme 2: Specifically Endorsed Elements of the DA

Subtheme 1: Improved Knowledge

Most women (18/21, 86%) described gaining new knowledge after using *RealRisks*. A total of 11 women described learning new information about breast cancer prevention drugs. The participants described learning new information such as which chemoprevention drug was appropriate for them, for example, tamoxifen and other available drugs. Other women described learning which drug was appropriate for premenopausal and postmenopausal women. The women described the following:

> *New information was the information around the drugs to take. I can't remember what they were called, but the preventive, I guess that's what they are, drugs.* [Participant #5]
>
> *I knew about the existence of the drug, tamoxifen. I know it opposes estrogen. An anti-estrogen-type drug. I did not know about other drugs. So that was new information.* [Participant #24]

In total, 2 of these women explained that *RealRisks* reinforced some of the information that they had already heard from their health care providers, which contributed to an improvement in their overall knowledge:

> *Being diagnosed with the BRCA2 gene mutation, I was getting so much information at that time and doing so much research and meeting with so many different doctors because of trying to be very, very proactive about being diagnosed with the BRCA2 gene that it actually turned out to have been helpful in terms of reinforcing some ideas that I didn't necessarily—that hadn't quite sunk in yet.* [Participant #8]

A total of 8 women described learning about their *risk* of breast cancer. These women stated that they now understood the factors contributing to *risk*, such as genetics, personal history, family history, and lifestyle factors. One woman appreciated the way *RealRisks* presented *risk* information in a story format. Another woman who had a pathogenic variant in the *BRCA*2 gene felt that *RealRisks* was thought provoking. The women learned actions that they could take to reduce their risk and shared the following:

> *Oh, it made me think about what the risks are, specifically having to do with my situation and being in a high-risk category...Well, I guess I surmised that I was high risk, given my family history. But it solidified that, and it also taught me about options that were available to me should I choose them to reduce my risk.* [Participant #15]
>
> *I like the way that it was set up, as a possibility of being at risk, and that was for me, a sensitive issue...I remember there was a story—the way that it was presented by story. So it became more real rather than just the data, medical data, and to try to identify through the just numbers. It was like real.* [Participant #17]

Subtheme 2: Informed Decision Making

Most women (17/21, 81%) who used *RealRisks* reported that the DA played a role in informing their decision making about chemoprevention. The women reviewed the modules in *RealRisks* and became familiar with the options that exist to reduce their breast cancer risk, including developing an understanding of the benefits and risks of taking a chemoprevention pill. The women explained:

> *Yes, because the information that was provided was thorough. I mean, there was plenty of it. And I feel comfortable that—I've seen both sides of it. I could see why a person would take it. I believe I have made an informed decision.* [Participant #6]
>
> *I think it is because I did not know about it [chemoprevention] until I saw RealRisks. But definitely it played into it [my decision-making]. And I didn't really look into it because I thought I wasn't really the best person to be eligible for it. And now I know I do have an elevated risk.* [Participant #20]

Although 95% (20/21) of the women in the study viewed themselves as *healthy* and decided not to take chemoprevention, their experience with using *RealRisks* informed an autonomous decision about whether chemoprevention was the right choice for them:

> *I made a decision for who I am and what I want right now. So I didn't ask my doctor. I didn't ask anyone. I just made the decision by myself. I just took my decision because I don't want to put anything in my body. That's it.* [Participant #9]
>
> *I remember when they talked about the differing types of procedures you could go through to help prevent breast cancer. It was in-depth and I read it all but I was not in agreement with taking any kind of medicine...It was very informative, and I think if I was in poorer health, I would probably be willing to try anything. But my health is relatively good.* [Participant #22]

Theme 3: Recommendations for Improvement

In addition to positive perceptions about *RealRisks*, some women (9/21, 43%) pointed out aspects of the DA that they did not like and shared recommendations for improvement.

Subtheme 1: Tailored for a Hispanic or Latina Population

Some women (4/9, 44%) who were not of Hispanic or Latina descent were concerned that *RealRisks* appeared to be tailored for Hispanic or Latina women. The women recognized that it was difficult to design a tool for diverse target audiences, especially those with varying health literacy and numeracy. One woman felt that *RealRisks* was designed for people who were not native English speakers. Another woman who was not of Hispanic descent was confused as to why Hispanic characters were used in the illustrations. In addition, 3 women shared that the comics were not appealing to them:

> *It was trying so hard to be ethnically diverse. It felt like it might have been for people where English was not their original language.* [Participant #8]
>
> *Found it interesting that if you're going to draw pictures of—I actually discussed this with my doctor. If you're going to draw pictures of people, it's hard not to racially profile. Even though it was a line drawing, it clearly looked like a person of color. So I mean, not that it meant any good or bad to me.* [Participant #24]

A few women (3/9, 33%) felt that the DA made assumptions about where they were in the care continuum and did not give them the opportunity to input their own risk factors. For instance, women shared the following:

> *There was not an opportunity to discuss why I didn't think I was at risk. I felt that there were assumptions made about me without even simply asking. For example, cigarette smoking causes a great deal of cancers and I do not smoke.* [Participant #6]
>
> *Some of it did not apply to me because I was already under care. I was already diagnosed with a BRCA2 gene mutation and already had surgery and already in the middle of this. But it wasn't quite flexible enough...I sort of stepped into the RealRisks halfway through if you know—I didn't need to assess my risk.* [Participant #8]

Subtheme 2: Difficult Terminology

In total, 33% (3/9) of women felt that *RealRisks* included difficult terminology, and the content was not written in layman's terms. Of these 3 women, 2 (66%) stated that if they were not intelligent, it would have been difficult to understand the information in *RealRisks*. The participants explained the following:

> *I did find some of the terminology a little difficult, because I wasn't familiar with some things. I do remember like, having to look some things up, particularly when it came to the treatment options.* [Participant #7]
>
> *The language used in RealRisks was not layman's language. If I wasn't intelligent, I wouldn't have understood it all. Maybe it was like reading The Times paper.* [Participant #22]
>
> *For me, being a white, middle-class, Jewish college-educated woman, I had no trouble with it. But I wouldn't want to speak for other cultures. I am married to a Puerto Rican man and like I could see where his mother, if she were reading this, would've really—she might've struggled...I think it tried to be very clear and very easy to understand, but I don't know, I think it can be hard for people—sometimes the way people have a block on math, sometimes when they read about medical things they get a bit of a block.* [Participant #23]

Subtheme 3: Strong Emphasis on Chemoprevention

Overall, 22% (2/9) of women felt that the *RealRisks* DA placed a strong emphasis on chemoprevention drugs. Despite the importance of these drugs, these 2 women felt that they would have preferred more emphasis on the lifestyle and environmental factors affecting breast cancer risk:

> *I have two graduate degrees. I'm not saying this to brag. I taught college for many years. So I thought the graphics and the cartoons and all of that, were useful in general, not necessarily for myself. I felt a little bit that the chemoprevention was being pushed.* [Participant #5]

> *I felt, throughout the whole process that it was very much pushing some type of drug on me, that I felt I wasn't really ready to consider that.* [Participant #24]

Theme 4: Information Needs

Participants were asked "what additional information do you need to make decisions about reducing your breast cancer risk?" With respect to women's information needs, 33% (7/21) of women described at least one unmet need. One woman wanted to learn more about mammography screening:

> *I was having this conversation with my sister recently. Because so much of the information around mammography and the frequency of mammography is changing. And so I was just having this conversation with her, that, you know, should I still be getting a yearly mammogram, I know that, age-wise, I think someone my age, and probably, with our risk, we should be getting it. But I feel like, because a lot of the information is changing, there is some confusion in terms of trying to make a decision about certain things.* [Participant #5]

Other women were interested in learning more about breast cancer risk factors, including modifiable lifestyle factors. Some women still desired to understand their individual breast cancer risk and what puts a woman at high risk of developing breast cancer. For example, women shared the following:

> *Well, I think the only information I would need or want would be during the course of my visits with my doctor is to go over my lifestyle, and just to find out if there's any additional information that's become available. And if there's any additional thoughts on the benefits or risks of taking the medications. I would always consider it as I get older.* [Participant #26]
>
> *It's a good question. I guess, printed materials probably, maybe like how to avoid putting myself in harm's way, stuff that you can prevent. You know, I mean, of course there's a lot of stuff that you can't prevent. But I mean, if it proves that, if there was a reason for them to say, "Oh, yeah, you're at really high risk," I, you know, I would do whatever and apply what was suggested.* [Participant #4]
>
> *Probably just you know, a one-page outline of all the risks, you know, maybe just outlining everything in a concise way so that I could look at it and just know what the risks are and just have it—just be more conscious of what the risks are on a day-to-day basis and without having to go through a lot of reading and stuff.* [Participant #18]

Discussion

Principal Findings

In our racially and ethnically diverse sample of women at high risk of developing breast cancer, all participants reported that they used the web-based DA *RealRisks*. The high-risk women who participated in the intervention arm of the chemoprevention trial and were granted access to the DA reported that they generally liked the DA and considered it to be helpful. This result confirms the need for decision support for women at a high risk of developing breast cancer. In line with our objective to understand the perceptions of women at high risk of developing breast cancer regarding their experience with using *RealRisks*, our analysis generated 4 themes:

1. The acceptability of the intervention: women found the tool to be acceptable, easy to navigate, user-friendly, and easily accessible on the web.
2. Specifically endorsed elements of the DA: the DA was favored for its ability to improve knowledge and inform decision making.
3. Recommendations for improvement: participants wanted more tailoring based on user characteristics.
4. Information needs: participants reported wanting to learn more about mammography screening and breast cancer risk factors, including modifiable lifestyle factors.

Regarding theme 1, participants found *RealRisks* to be an acceptable intervention and had positive attitudes overall. The web-based nature of the intervention was very appealing to participants who appreciated being able to access the tool at their own convenience. In addition, the tool was acceptable to women in a variety of age groups, as the average age of our participants was 58.6 years (SD 10.1). Regarding theme 2, the women reported that *RealRisks* increased their knowledge about chemoprevention. This finding is aligned with the results of our pilot study, which found an increase in chemoprevention knowledge after exposure to *RealRisks* [22]. The observation that most women were autonomously motivated to make an informed decision to not take chemoprevention after using the *RealRisks* DA is aligned with the SDT, the underlining premise of the DA [35]. SDT, a theory of human motivation, emphasizes the extent to which behaviors are relatively autonomous, originating from oneself without pressure or coercion by interpersonal forces [35]. Therefore, implementing the DA in primary care may not be appropriate for all high-risk women and should be reserved for women who are undecided about taking chemoprevention and would like to further discuss the pros and cons and chemoprevention options with their primary care provider. Our results indicate that the DA offered great decision support to high-risk women, improved their knowledge, and informed their decision making about chemoprevention.

Regarding theme 3, despite the general acceptability of the DA, high-risk women wanted a more holistic approach to reducing their breast cancer risk based on tailoring that incorporates user characteristics [36]. The women felt that the DA was not personalized and made assumptions about where they were in the care continuum, which did not give them the opportunity to input their own risk factors. Other women felt that the DA placed a strong emphasis on chemoprevention drugs. Regarding theme 4, our results demonstrate that, based on the information needs reported, the high-risk women enrolled in our study wanted to learn more about general breast cancer risk factors and breast cancer screening strategies, including mammographic frequency, in addition to chemoprevention. Existing evidence suggests that interventions that are tailored based on unique characteristics and provide personalized feedback, guidance, and motivation to users might assist them in engaging in more active lifestyles [37-39] and are an effective method of promoting mammography adherence [40]. Therefore, based on our findings, future iterations of *RealRisks* may consider incorporating tailoring with a broader focus on breast cancer risk reduction and should incorporate guidance on other breast cancer risk factors.

Strengths and Limitations

Our study has several important strengths and limitations. A strength of this study is that we had about 40% (8/21, 38%) racial and ethnic minorities, which is representative of the US population. However, we only included participants from the intervention arm of the chemoprevention trial who had accessed the tool, on average, 1 year earlier and, therefore, may have experienced recall bias. In addition, this study was conducted at a large urban academic medical center, which may not be generalizable to other geographic and practice settings.

Future Work

Future studies should focus on developing interventions that target the knowledge gaps identified in this study and meet the needs of high-risk women to empower them to make informed decisions about reducing their breast cancer risk. Our research group is currently developing a breast cancer screening module to be added to *RealRisks*, which will provide evidence-based information on mammography screening and other methods of breast imaging.

Conclusions

This study has demonstrated the acceptability of the *RealRisks* web-based DA among a diverse group of high-risk women, with a few caveats and recommendations for improvement. Women's perceptions about *RealRisks* were influenced by the tool's ability to increase their knowledge about breast cancer risk and the pros and cons of taking chemoprevention drugs; they indicated that this information facilitated their informed decision making about taking chemoprevention. We found that after using the DA, women wanted a more tailored and holistic approach to reducing breast cancer risk. The findings will inform the future development of the web-based DA. Next steps include translating the results from this study into further development of the DA and optimizing the tool's module architecture to add a breast cancer screening module.

Conflicts of Interest

Abstract

Background: The health belief model explains that individual intentions and motivation of health behaviors are mostly subject to external cues to action, such as from interpersonal communications and media consumptions. The concept of mobilizing information (MI) refers to a type of mediated information that could call individuals to carry out particular health actions. Different media channels, especially digital media outlets, play an essential role as a health educator to disseminate cancer health information and persuade and mobilize cancer prevention in the community. However, little is known about calls to action (or MI) in online cancer news, especially from Asian media outlets.

Objective: This study aimed at analyzing cancer news articles that contain MI and their news components on the selected Malaysian English and Chinese newspapers with online versions.

Methods: The Star Online and Sin Chew Online were selected for analysis because the two newspaper websites enjoy the highest circulation and readership in the English language and the Chinese language streams, respectively. Two bilingual coders searched the cancer news articles based on sampling keywords and then read and coded each news article accordingly. Five coding variables were conceptualized from previous studies (ie, cancer type, news source, news focus, cancer risk factors, and MI), and a good consistency using Cohen kappa was built between coders. Descriptive analysis was used to examine the frequency and percentage of each coding item; chi-square test (confidence level at 95%) was applied to analyze the differences between two newspaper websites, and the associations between variables and the presence of MI were examined through binary logistic regression.

Results: Among 841 analyzed news articles, 69.6% (585/841) presented MI. News distributions were unbalanced throughout the year in both English and Chinese newspaper websites; some months occupied peaks (ie, February and October), but cancer issues and MI for cancer prevention received minimal attention in other months. The news articles from The Star Online and Sin Chew Online were significantly different in several news components, such as the MI present rates (χ^2=9.25, P=.003), providing different types of MI (interactive MI: χ^2=12.08, P=.001), interviewing different news sources (government agency: χ^2=12.05, P=.001), concerning different news focus (primary cancer prevention: χ^2=10.98, P=.001), and mentioning different cancer risks (lifestyle risks: χ^2=7.43, P=.007). Binary logistic regression results reported that online cancer news articles were more likely to provide MI when interviewing nongovernmental organizations, focusing on topics related to primary cancer prevention, and highlighting lifestyle risks (odds ratio [OR] 2.77, 95% CI 1.89-4.05; OR 97.70, 95% CI 46.97-203.24; OR 186.28; 95% CI 44.83-773.96; P=.001, respectively).

Conclusions: This study provided new understandings regarding MI in cancer news coverage. This could wake and trigger individuals' preexisting attitudes and intentions on cancer prevention. Thus, health professionals, health journalists, and health campaign designers should concentrate on MI when distributing health information to the community.

mobilizing information; online cancer news; quantitative content analysis; Malaysia; online news; cancer; infodemiology; media; digital media; digital health; health information; cancer health information

Introduction

Cancer is a pressing public health issue and does not discriminate whether in a developed or developing country [1,2]. Cancer, in fact, remains the second leading cause of death throughout the world. The World Health Organization [1] reported that in 2018, 9.6 million people were estimated to have died from cancer. In other words, 1 in 6 deaths is from cancer of some type. Lung, prostate, colorectal, stomach, and liver cancer are the most common types of cancers in men, while breast, colorectal, lung, cervical, and thyroid cancer are the most common among women [1]. According to a recent report from the International Agency for Research on Cancer [3], breast cancer occupied the first leading incidence rate in Malaysia (17.3%), followed by colorectal cancer (14.0%) and lung cancer (10.7%). Local cancer incidence was not equal across ethnic groups. In recent years, Malaysian Chinese have had the highest cancer incidence rate for the majority of leading cancers. It is more elevated than Malays and Indians [4,5].

Scientific findings showed that at least half of all cancers occurring today could be prevented if individuals adopted healthy lifestyles and behaviors, and many other cancers can be diagnosed through medical interventions in the early stages [6]. Hence, it is crucial to promote cancer prevention and early detection to the individuals. Essentially, cancer prevention is no longer treated as a health issue alone but a developmental issue for a nation. Health promotion regarding cancer issues involves collaborations from different stakeholders, which include conventional media and digital media.

The media provides various health resources [7]. In reality, media can be a vital health educator, bridging the information gap between health care practitioners and the public in cancer communication [8,9]. The media publicize activities or campaigns from medical or governmental sectors and translate medical language and other jargon into public language [10,11]. Nowadays, besides health professionals, the internet has become a popular source of health information [12]. It changes the way an individual makes health decision, perceives health issues, and interacts with health professionals [13]. Cancer-related topics are the most commonly searched health topics online [14], and cancer news coverage is one of the most consumed health news categories by online newsreaders [15]. The majority of online news sites contain specific sections for conveying health news coverage: it allows information-oriented news consumers and active health information seekers to obtain timely health information about issues that concern them [16,17].

The health belief model explains that individual intentions and motivation of health behaviors are mostly subject to external cues, such as interpersonal communications and media consumptions [18]. It was defined as a variable called cue to action [19]. Based on this viewpoint, Tanner and Friedman [20] linked the concept of mobilizing information (MI) onto the theoretical ground of the health belief model. Originally, MI was a type of information widely examined by scholars from political science and journalism studies [21,22]. By definition, in the realm of public health, MI refers to a type of mediated information that could call individuals to carry out particular health actions (eg, quit smoking) or trigger them to act on preexisting attitudes effectively. Preexisting attitudes involve one's overall evaluation on a subject matter which later forms preconceived notions even if they did not experience it personally [23]. Since health information from media channels is usually persuasive, it acts as an actuator for health behavior change [7]: when individuals encounter persuasive health information, especially MI, their cognition and memories related to the particular health issue would be evocated and, in turn, brought to further actions. Specifically, MI includes the venue, time, and contact information of a health campaign, detailed educational information of how to a prevent certain disease or reduce risks, and additional links to provide further readings or interactions [20,24]. The individuals could actively or passively engage with different types of health news content that contain a certain type of MI. Thus, MI can reach newsreaders easily during their routine news consumption.

Several studies have examined MI in different health news coverage, but previous researchers found that there was very limited MI presented in the news content. For example, one study found that there was only approximately 30% of chronic disease coverage presented MI in Canadian aboriginal newspapers [25]. Another study reported that only 3 in 10 online health news articles from American local television websites presented MI [20]. Moreover, previous studies treated MI as an affiliated coding variable, scrutinizing on the present rate or types of MI instead of investigating the in-depth relationships between MI and other news components, such as news source and news focus. Also, most of the past studies examining MI are from the Western and English media channels [26,27]; little is known about how the Eastern and non-English media provide MI in health news coverage.

In Malaysia, media channels practice multilingual media policy to serve different communities [28]; the characteristics of the local media industry differ from other countries. Even in the local Chinese society, the media preference varies based on the socioeconomic background or other factors [28]. Thus, it is research-worthy for analyzing and comparing the local media contents published in different languages. Scholars reported that the way the media cover cancer news depends highly on who the target audience is [29]. Therefore, the focal points of the approach of presenting MI on cancer issues might differ from the local English media and the Chinese media. Since Malaysian Chinese populations had the highest cancer incidence rate among 3 main ethnicities [5], it is vital to know how Malaysian English and Chinese online news sites cover cancer issues and how these news sites mobilize individuals to prevent cancer. To fill the abovementioned research gaps, this study aims to answer the following research questions:

- RQ1a: What are the present rates, patterns, and types of MI in cancer news coverage on an English news site and a Chinese news site?
- RQ1b: Are there differences in the present rates, patterns, and types of MI on cancer coverage between an English news site and a Chinese news site?
- RQ2a: What are the characteristics of news components (ie, cancer type, news sources, news focus, and cancer risk factors) in cancer news coverage that provided MI on an English news site and a Chinese news site?
- RQ2b: Are there differences in the characteristics of news components (ie, cancer type, news sources, news focus, and cancer risk factors) in cancer news coverage that provided MI on an English news site and a Chinese news site?
- RQ3: Are there associations in the cancer coverage presenting MI between news sources, news focus, and cancer risk factors on an English news site and a Chinese news site?

Methods

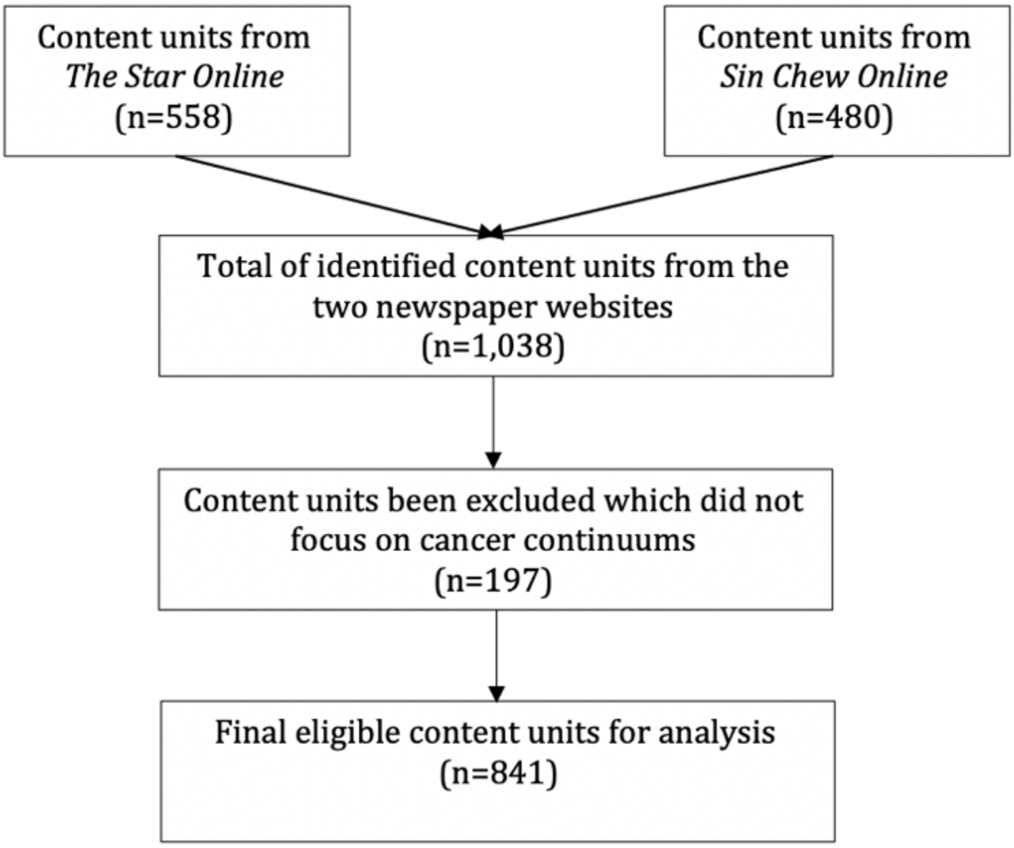
In this study, we applied quantitative content analysis to examine cancer news articles that contain MI on selected Malaysian English and Chinese newspapers with online versions and compare the differences between the newspaper websites.

Selection of Content Units

According to the Reuters Institute Digital News Report 2019 [30], The Star Online occupied 29% of the local weekly online news media use, which ranked the highest among all English newspaper websites. Sin Chew Online occupied 12% of it, which ranked the highest score among all local Chinese newspaper websites.

The unit of analysis of this study was the news article. News articles were retrieved using a keyword search of the homepages of individual newspaper websites. The keywords such as “cancer” OR “cancer prevention” OR “cancer treatment” OR “breast cancer” OR “lung cancer” OR “prostate cancer” OR “colon cancer,” etc, appearing in the headlines, subheadlines, first 3 paragraphs and lead paragraphs were used to find articles about MI on cancer prevention. We excluded news articles that covered obituaries of public figures who died from cancer and did not focus on cancer treatment or suggestions for cancer prevention. A total of 841 news articles were identified from 2017 to 2019. The process of selecting and excluding news articles for analysis is shown in Figure 1.

Figure 1. Process of selecting and excluding content units.



Research Instrument and Descriptions

Interrelated coding book and coding sheet were predesigned for the data collection purpose. There are 5 variables in the coding instruments that were conceptualized based on previous studies. There are several options under each variable; the number of options that should be chosen depends on the measurement and operationalization of each variable. All the variables were identified as nominal measurements. The operational definitions of each coding variable are shown in Multimedia Appendix 1.

Description of Cancer Type

Two categories of cancers (Multimedia Appendix 2) were examined in this study (ie, highly preventable cancers and highly detectable cancers). This description was adopted from Moriarty and Stryker's categorization of cancers [31], which was approved by the American Cancer Society. If an article covered any cancer-related topic without focusing on a specific type of cancer or covered more than one particular type of cancer, such as coverage on cancer care facilities' improvement, cancer-related health policy change, or statistic report on incidence rate/mortality rate, the article was then coded as cancer in general. Coders were requested to identify one type of cancer for a news article only.

Description of News Source

News source has a vital impact on health news coverage, and it is also a crucial variable for content analysis [32]. The description of news source in this study was adopted from past studies [33,34]. Six types of news sources were examined: medical journal, research institution, pharmaceutical company, government agency, nongovernmental organization (NGO), and other. Coders coded more than one news source for an article if applicable.

Description of News Focus

Different news articles cover an issue through different foci. The description of news focus was based on Tanner and Friedman's study [20]. There were 6 types of news focus under this study (ie, primary cancer prevention, secondary cancer prevention, medical treatment, social support/survivorship, medical research, and statistical report). Coders coded more than one type of news focus for an article if applicable.

Description of Cancer Risk Factors

This description aimed to identify the types of cancer risks mentioned in cancer news coverage. There were four categories of cancer risk factors that could be identified from cancer news articles, which are lifestyle risks, environmental/occupational risks, demographical risks, and medical risks. It was conceptualized and used in previous studies [35,36]. Coders coded more than one cancer risk factor for an article if applicable.

Description of Mobilizing Information

This description is the primary research focus of this study and includes 2 coding items (presence of MI and types of MI). First, the presence of MI in the news article was identified. Coders identified whether each article presented MI by coding present or absent in the coding sheet. If MI is absent from the article, the coders needed not to code the types of it.

If MI is presented in the article, then coders identified the types of MI in the article. There are 4 types of MI defined by previous research [20,21]: locational MI (ie, location of a hospital or event), identificational MI (ie, contact details of a health care provider), tactical MI (ie, suggestion or educational information regarding how to prevent cancer), and interactive MI (ie, hyperlinks for further readings). Coders coded more than one type for an article if applicable.

Intercoder Reliability

Two coders (the first author and a graduate student) randomly coded 10% of the identified news articles for intercoder reliability check. The graduate student received extensive training before coding the articles. We employed a Cohen kappa reliability test [37]. Based on the Altman strength of agreement, Cohen kappa value ranging from .61 to .80 indicates good agreement while values falling from .81 to 1.0 show very good agreement [38]. Our results demonstrated that some coding items obtained good agreement, such as tactical MI (k=.73, 95% CI .59-.87) and medical cancer risks (k=.74, 95% CI .59-.88), and the rest of items gained very good agreement between 2 coders, like cancer type (k=.89, 95% CI .78-.98) and presence of MI (k=.94, 95% CI .85-1.0).

Data Analysis

The obtained data were analyzed via SPSS (version 26.0, IBM Corp). First, we applied descriptive analysis and chi-square test to answer RQ1 and RQ2, including the frequencies, percentages, and differences of each news component. We then employed binary logistic regression (forward likelihood ratio method) to determine the associations between different news components and the presence of MI in online cancer news (RQ3). The level of significance in this study was set as $P<.05$.

Results

There were 585 out of 841 cancer news articles on The Star Online and Sin Chew Online provided at least one type of MI in a span of 36 months from January 2017 to December 2019 (Table 1). The overall present rate of MI was 69.6% (585/841), which means nearly 7 in 10 of cancer news articles provided MI. Specifically, 64.4% (283/436) of articles on The Star Online, and 74.6% (302/405) of news articles on Sin Chew Online provided MI. The present rate of MI on Sin Chew Online was higher than The Star Online (χ^2=9.25, df=1; P=.003).

Table 1. The presence of mobilizing information in cancer news coverage on The Star Online and Sin Chew Online (2017-2019; n=841).

MI[a] presence	The Star Online, n (%)	Sin Chew Online, n (%)	Overall, n (%)
Present	283 (64.4)	302 (74.6)	585 (69.6)
Absent	152 (35.6)	103 (25.4)	258 (30.4)
Total	436 (100)	405 (100)	841 (100)

[a] MI: mobilizing information.

The overall patterns of monthly distribution showed a fluctuation in both newspaper websites (Figures 2 and 3). The patterns of cancer news articles providing MI between the 2 news sites were slightly different. For The Star Online, the peak was in October 2019, and there were 18 cancer news articles contained MI. However, no cancer news article provided MI in July 2019. Sin Chew Online had 2 peak months, October 2017 and September 2019. There were 18 cancer news articles delivered MI in both months. The lowest month for Sin Chew Online was April 2017, which only had 2 cancer news articles that provided MI.

Figure 2. Numbers of cancer news articles provided mobilizing information on The Star Online from Jan 2017 to Dec 2019.

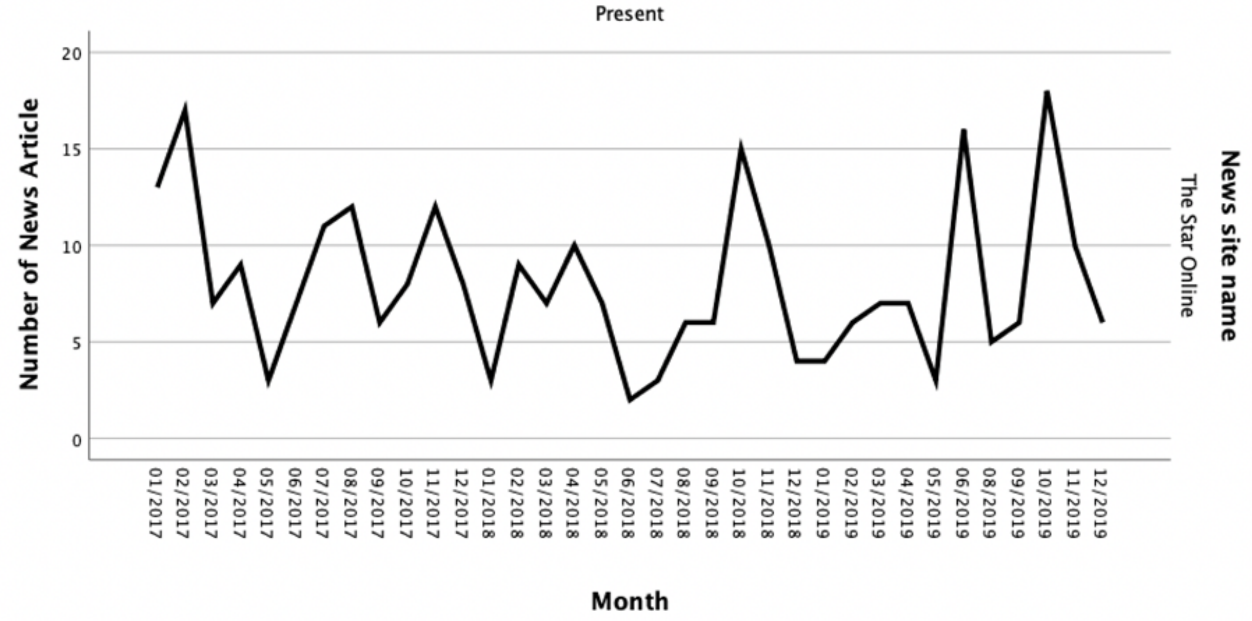


Figure 3. Numbers of cancer news articles provided mobilizing information on Sin Chew Online from Jan 2017 to Dec 2019.

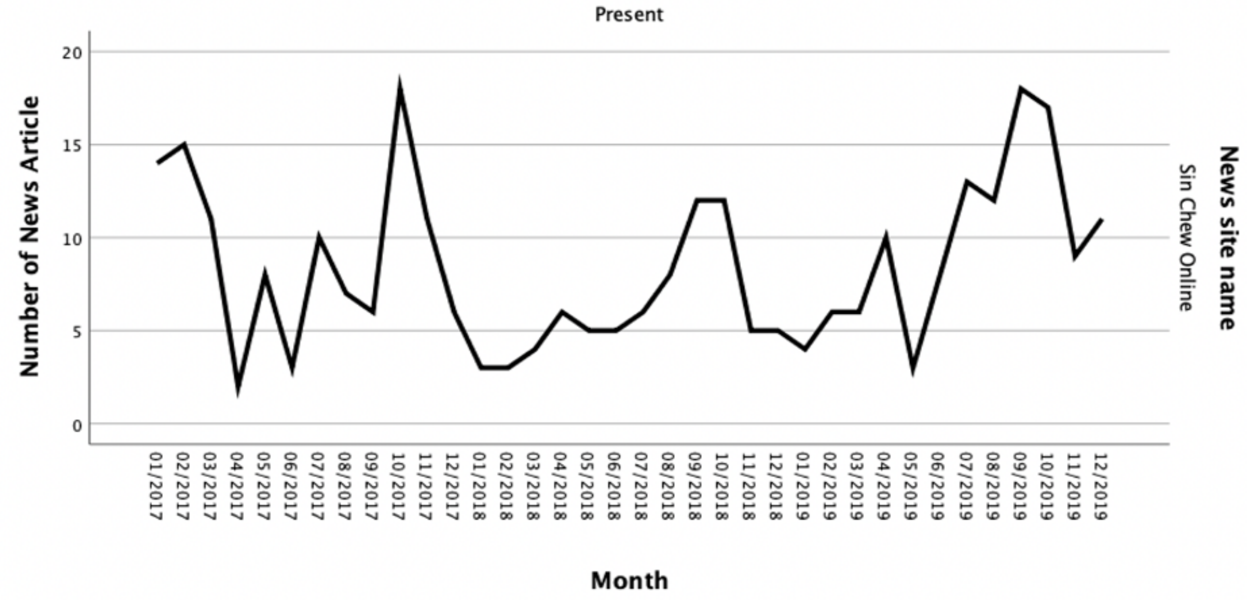

For the types of MI (Table 2), the majority of news articles (419/585, 71.6%) from both news sites provided tactical MI. Locational MI was the second most frequently presented in the news articles, which occupied 25.1% (109/585). Besides, there were similar patterns on providing identificational MI (96/585, 16.4%) and interactive MI (107/585, 18.3%), both provided by less than 20% of cancer news articles. The chi-square results indicated that news articles in The Star Online provided more interactive MI (χ^2_1=12.08, *P*=.001), while news articles in Sin Chew Online provided more identificational MI (χ^2_1=5.44, *P*=.03).

Table 2. Distributions of types of mobilizing information (n=585).

Type of MI[a]	The Star Online, n (%)	Sin Chew Online, n (%)	Overall, n (%)	χ^2	*P* value
Locational MI	91 (15.6)	109 (18.6)	200 (34.2)	1.0	.34
Identificational MI	36 (6.1)	60 (10.3)	96 (16.4)	5.4	.03
Tactical MI	192 (32.8)	227 (38.8)	419 (71.6)	3.9	.05
Interactive MI	68 (11.6)	39 (6.7)	107 (18.3)	12.1	.001

[a] MI: mobilizing information.

Descriptive analysis and chi-square test for each news component were conducted to answer RQ2a and RQ2b (Table 3). More than half of the cancer news articles that provided MI did not focus on a specific cancer (313/585, 53.5%), and there were overall 36.1% (211/585) of news articles focused on highly detectable cancers such as breast cancer, prostate cancer, liver cancer, and stomach cancer. Only 10.4% (61/585) of articles gave attention to highly preventable cancers such as lung cancer and cervical cancer. There was a significant difference between the websites in covering different cancer types (χ^2_1=8.05, *P*=.02).

Pertaining to news sources, more than half (333/585, 57%) of the cancer news articles that provided MI from both newspaper websites interviewed staff from medical institutions, followed by NGOs (208/585, 35.5%). Less than 20% of the news articles interviewed cancer patients, cancer survivors, or other individuals who did not belong to any institution (102/585, 17.5%) or government agency (97/585, 16.6%). Very few news articles cited medical journals (37/585, 4.7%) or interviewed pharmaceutical companies (8/585, 1%). The chi-square results indicated that there was a significant difference between newspaper websites and news sources used while reporting cancer news. (11.3% [66/585] vs 5.3% [31/585]; χ^2_1=12.05, *P*=.001). Specifically, Sin Chew Online skewed to refer to government agencies as the source in reporting cancer news.

As for news focus, the majority (410/585, 70%) of cancer news articles that provided MI focused on primary cancer prevention and almost half (285/585, 48.7%) focused on secondary cancer prevention. In addition, 28.0% news articles that focused on social support contained MI (164/585), followed by medical treatment (127/585, 21.7%), medical research (80/585, 13.7%), and statistical reports on cancer issues (69/585, 11.8%). The chi-square results showed that news articles in The Star Online were more likely to focus on medical treatment (13% [76/585] vs 8.7% [51/585]; χ^2_1=8.54, *P*=.004); news articles in Sin Chew Online were more likely to look at primary cancer prevention (39.3% [230/585] vs 30.8% [180/585]; χ^2_1=10.98, *P*=.001).

In terms of cancer risk factors, 63.0% (368/585) of cancer news articles that provided MI mentioned demographical risks, followed by medical risks (281/585, 48.1%) and lifestyle risks (236/585, 40.4%), respectively. Only 3.3% (19/585) of news articles gave attention to environmental/occupational risks that may cause cancer. The chi-square result showed that news articles in Sin Chew Online focused more on lifestyle risks than articles in The Star Online (23.6% [138/585] vs 16.8% [98/585]; χ^2_1=7.43, *P*=.007).

Table 3. Descriptive analysis of news components in cancer news coverage that provided mobilizing information (n=585).

Variable and category	The Star Online, n (%)	Sin Chew Online, n (%)	Overall, n (%)	χ^2	*P* value
Cancer type	—[a]	—	—	8.1	.02
General cancer topic	139 (23.8)	174 (29.7)	313 (53.5)	—	—
Highly preventable cancer	39 (6.7)	22 (3.8)	61 (10.5)	—	—
Highly detectable cancer	105 (17.9)	106 (18.1)	211 (36.0)	—	—
News source	—	—	—	—	—
Medical journal	21 (3.6)	16 (2.7)	37 (6.3)	1.1	.31
Medical institution	173 (29.6)	160 (27.4)	333 (57.0)	4.0	.06
Pharmaceutical company	5 (0.9)	3 (0.5)	8 (1.4)	0.7	.50
Government agency	31 (5.3)	66 (11.3)	97 (16.6)	12.1	.001
Nongovernmental organization	105 (17.9)	103 (17.6)	208 (35.5)	0.6	.49
Other individuals	53 (9.1)	49 (8.4)	102 (17.5)	0.4	.45
News focus	—	—	—	—	—
Primary cancer prevention	180 (30.8)	230 (39.3)	410 (70.0)	11.0	.001
Secondary cancer prevention	149 (25.5)	136 (23.2)	285 (48.7)	3.4	.07
Medical treatment	76 (13.03)	51(8.7)	127 (21.7)	8.5	.004
Social support	77 (13.2)	87 (14.8)	164 (28.0)	0.2	.71
Medical research	47 (8.0)	33 (5.6)	80 (13.6)	4.0	.05
Statistical report	34 (5.8)	35 (6.0)	69 (11.8)	0.03	.09
Cancer risk factors	—	—	—	—	—
Lifestyle risks	98 (16.8)	138 (23.6)	236 (40.4)	7.4	.007
Environmental/occupational risks	8 (1.4)	11 (1.9)	19 (3.3)	0.3	.65
Demographic risks	184 (31.5)	184 (31.5)	368 (63.0)	1.1	.35
Medical risks	142 (24.3)	139 (23.8)	281 (48.1)	1.0	.32

[a] Not applicable.

A binary logistic regression analysis (forward likelihood ratio method) was conducted to answer RQ3. Table 4 presents these results accordingly. First, the results indicated that news articles that interviewed NGOs and medical institutions were more likely to present MI (OR 2.77, 95% CI 1.89-4.05; OR 1.85, 95% CI 1.33-2.58, respectively). News articles that cited medical journals as the source were also more likely to present MI (OR 2.28, 95% CI 1.03-5.01), but the significant level was lower than NGOs and medical institutions (95% [*P*=.04] vs 99% [*P*=.001]). Therefore, NGOs, being the news source, obtained the strongest association with the presence of MI. There was no significant association found for other news sources, such as medical journals, pharmaceutical companies, or governmental agencies in the examined news articles.

Second, for news focus, the binary logistic regression results reported that news articles were more likely to present MI when they focused on primary cancer prevention (OR 97.70, 95% CI 46.97-203.24) and secondary cancer prevention (OR 22.12, 95% CI 12.16-40.22). However, news articles that focused on medical research were less likely to present MI (OR .33, 95% CI .12-.37). The equation model shows that articles that focus on primary cancer prevention obtained the strongest association with the presence of MI. Other news focus such as medical treatment, social support/survivorship, or statistical report were not significantly associated with the presence of MI.

In terms of cancer risk factors, the binary logistic regression results showed that all 4 types of cancer risk factors (ie, lifestyle, environmental/occupational, demographic, and medical) were positively associated with the presence of MI in the online cancer news. However, the significant levels varied. The news articles that reported lifestyle risks obtained the strongest association with the presence of MI (OR 186.28; 95% CI 44.83-773.96), followed by demographic risks (OR 8.97; 95% CI 6.08-12.25), and medical risks (OR 3.07; 95% CI 2.08-4.53). The news articles that reported environmental/occupational risks were also associated with the presence of MI (OR 3.83; 95% CI 1.15-12.76). However, when comparing to the other 3 risk categories, the significance level of the association between environmental/occupational risks and the presence of MI was relatively weak (only at 95%).

Table 4. Associations between news sources, news focus, cancer risk factors, and the presence of mobilizing information (n=841).

Discussion

Principal Findings

As the media has been instrumental in creating public awareness about cancer and chronic disease prevention, understanding the media's role in mobilizing the public regarding cancer prevention is of utmost importance. This study provides the first comprehensive and comparative assessment of MI in cancer news on the selected Malaysian English and Chinese newspapers with online versions. Of importance, our results show that there were nearly 70% of the online cancer news articles in The Star Online and Sin Chew Online presented at least one type of MI. It indicates that the selected Malaysian newspaper websites have an awareness of mobilizing and calling health behavior change for its readers. However, our findings are contrary to previous studies that examined MI in cancer coverage in Western countries [22,24-26]. Several possible explanations could support our findings. First, since the past studies that examined MI in cancer news coverage were conducted at least 10 years ago, the patterns of cancer news coverage have already changed, especially for online news media [22,24-26]. Second, Hoffman [20] introduced another type of MI called interactive MI, which is only applicable for online news content. This could be one of the reasons why online cancer news contained more MI as compared to print media. Third, the increasing rates of cancer incident and mortality around the world [1], the seriousness of the disease, health information needs among the people, and the media attention of cancer issues that differ from the past have become another dependable rationale to support our results. Fourth, culture and social background would give impacts to health coverage [39]. Thus, our results report that the characteristics of cancer news coverage in the selected Malaysian newspaper websites were quite different from the

Western countries. Of note, we also found that cancer news articles in Sin Chew Online were more likely to present MI than those in The Star Online. This may due to the increased cancer incident rate reported among the Chinese population [4,5], and Sin Chew Online realized that it is crucial to promote and mobilize cancer prevention to its targeted readers.

Our results illustrated that there was an unbalanced monthly distribution in terms of the number of cancer news articles that provided MI. In certain months, there were more cancer news articles found providing MI, such as in February, October, and November. This may due to the fact that World Cancer Day falls in February, Children's Cancer Awareness Month falls in September, and Breast Cancer Awareness Month falls in October. These occasions gained more media attention because of shared journalistic values; journalists usually cover health topics according to the allocation of relevant campaigns or events [40]. In the same vein, Varga and colleagues [40] reported that the media coverage on certain cancers mushroomed during their awareness months, such as breast cancer and prostate cancer, and especially on social media platforms. However, in certain months, there were fewer cancer news articles reporting MI, such as in June and July. These months are the busier months throughout the year as there are many local festivals and school holidays happen in these months. The Hari Raya Aidilfitri, Gawai Dayak, King's birthday, and Dragon Boat Festival happen in these 2 months. Negative news such as reporting cancer issues and related death tolls would likely give way to positive news and announcements such as big sales and discounts, tourism, and Open House. Hence, the news distribution of MI on cancer prevention was found less in June and July. Speaking of the types of MI, we found that the majority of cancer news provided tactical MI, which contained how-to health information and detailed suggestions about cancer prevention. Such news provides a clear picture to the readers of how to prevent cancers in their daily life.

We found several differences between The Star Online and Sin Chew Online regarding news components providing MI in online cancer news. First, the results indicated that there was a significant difference in terms of cancer types portrayed in the 2 studied online news websites. More than half of cancer news that provided MI focused more than one specific type of cancer. It mainly covered health campaigns or events related to cancer prevention, followed by highly detectable cancer and highly preventable cancer. This phenomenon is consistent with the previous study, which applied the same categorization of cancer types [31]. By comparison, cancer news from Sin Chew Online focused more on general cancer topics while The Star Online is more likely to cover highly preventable cancer issues.

For news source, the results showed that the majority of cancer coverage that provided MI interviewed professionals from medical institutions, such as public and private hospitals, universities or laboratories, followed by NGOs. This corroborates with previous studies that examined sourcing practices in various health coverage [41,42]. Interestingly, we found that cancer news articles that provided MI in The Star Online were more likely to cite medical journals from overseas countries, while those in Sin Chew Online were more likely to interview government agencies and NGOs from the local Chinese society, such as ancestral connective organizations and religious organizations serve for Chinese communities (ie, Chinese temples and Chinese-dominant churches). This shows that cancer coverage from different languages has varying source preferences subject to their journalistic values and social/cultural norms [39].

Pertaining to news focus, most cancer news providing MI focused on primary cancer prevention, such as local educational events or social marketing campaigns related to cancer issues, followed by secondary cancer prevention, like mobilizations on cancer screening for early detection and other medical interventions. Since the characteristics of MI include triggers and call the readiness among individuals, it is reasonable that the majority of cancer coverage that provided MI focused on prevention, rather than other topics like cancer treatment or cancer research [20]. We found that cancer news providing MI in The Star Online focused slightly more on topics related to secondary cancer prevention and medical treatment as compared to the coverage reported in Sin Chew Online, which was more likely to concentrate on primary cancer prevention and social support topics. This phenomenon reflects Malaysian media ecology when it comes to health news coverage.

As for cancer risk factors, our results showed different findings compared to the previous study where this description was adopted [35]. More than half of the examined news coverage mentioned demographic risks, like cancer-related with a specific gender or age. Most of these demographic risks pointed to female cancers, such as cervical cancer prevention, HPV vaccination, and breast cancer self-checking. Almost half of cancer news articles mentioned medical risks and lifestyle risks when providing MI. It corroborates the dominant characteristics of MI that promotes behavioral change on health issues [20], which advocates changes and adoptions of health behavior, as well as an understanding of medical knowledge and preventive strategies among the readers. However, it is worth noting that there was rarely cancer coverage that provided MI on environmental risks, such as natural resources pollutions, radiations, and occupational risks. The reason could be due to lack of knowledge on environmental issues and their association with cancer morbidity and mortality [43]. By comparing the two newspaper websites, we found that cancer news from Sin Chew Online was more likely to mention lifestyle risks when providing MI. It may subject to the cancer incidence in local Chinese communities; reducing risk lifestyle is one of the dominant approaches to avoid cancer occurrence [5,6].

The logistic regression analysis unveiled the in-depth findings of this study. This method is inspired by previous studies that used the same approach to analyze other media messages [34,44]. We examined the associations between 3 critical news components (ie, news sources, news focus, and cancer risk factors) and the presence of MI in online cancer news separately. For the news sources, our results illustrated that the cancer news articles were most likely to present MI when NGOs were interviewed as the source, followed by medical institutions and medical journals. This result agrees with a previous study finding that elite sources are the dominant news sources in health news coverage [32]. This study suggests that health journalists should be more active in engaging with NGOs and medical institutions. On this count, NGOs could bring up-to-date resources for events and campaigns regarding cancer prevention, and medical institutions can provide credible and applicable health information for cancer prevention.

A finding of interest was that MI was more likely to be presented in online cancer news when articles focused on primary cancer prevention, such as health education, consultation, health events or campaigns, followed by secondary cancer prevention, like promotions of early detection, screening, or diagnosis. On the other hand, MI was less likely to be presented when articles covered topics related to medical research. Thus, we recommend that health journalists should devote more attention on how to cover topics related to cancer education, local events, and campaigns, which would mobilize and persuade the newsreaders to take proactive actions to prevent cancer instead of merely providing medical research-related news retrieved from collaborative news agencies.

Regarding cancer risk factors, we found that even though every type of cancer risk was positively associated with the presence of MI, the probability level was different. The articles that reported lifestyle risks such as obesity, alcohol consumption, or smoking causing cancer were positively associated with the presence of MI in online cancer news. This is consistent with previous findings which showed that since various cancers occurring today are related to unhealthy lifestyles, cancer news coverage switched their major attention from highlighting environmental causes to discussing lifestyle causes [35]. Our results also showed that the mentions of demographic risks, like risks related to gender and age, were positively associated with the presence of MI. However, we found out that the majority of news articles that mentioned demographic risks pointed to females, which suggests that future events or campaigns could focus on mobilizing females to prevent breast and cervical cancer, as well as educating this target group to raise their awareness on cancers that most prevalent among females. There were limited news articles on demographic risks provided MI that targeted males even though prostate cancer and testicular cancer are two serious health issues for males [45]. We suggest that health journalists need to notice that cancer coverage should not skew to cancers related to females only. It is also essential to raise awareness and mobilize males to prevent cancers that are associated with them. The lack of coverage on cancers related to males calls for the need for research on effective strategies to reduce health information disparities among the male population.

Limitations

This study contains some limitations. First, we only applied a keyword searching strategy for searching online news articles, and we might have missed some relevant news articles due to human errors. Future researchers should improve news sample selecting strategy by applying technology-based approaches to minimize human errors. Second, we only analyzed MI in online cancer news from the selected Malaysian newspaper websites. We did not consider the cancer news published in Malay and Tamil newspaper websites, which are two other major languages spoken in Malaysia. The representativeness of this study, hence, is limited. More studies should give attention to cancer news published in Malay and Tamil; it would draw a more comprehensive picture in terms of covering cancer issues and providing MI in Malaysian media. Third, we determined the original definition of tactical MI is ambiguous, which points to “the explicit and implicit instructions for certain behavior” [19,20]. The understanding and operationalization of this concept highly depend on different researchers and newsreaders. Thus, communication scholars need to argue and re-theorize this definition in future studies. Fourth, it is worth noting that there is a lot of variation in the products and content of the agencies used as sources, such as their stature, professional staff, mission, and other characteristics that would explain or influence the variance in data collected. In this study, the researchers only categorized the sources in generic forms. Future studies could apply textual analysis, examining the latent content of news coverage or case study to explore these variations in detail. Fifth, this study did not compare the differences or correlations of representation of MI on the internet, print, and broadcast media. Hence, future research could examine whether if different types of MI are presented differently on different mediums. Last, our results only could represent the way of presenting MI by the online news media, but the effects of MI toward individuals are unknown. Future studies should examine the effects of MI and behavioral intention or outcomes among newsreaders.

Conclusion

This study is one of the first scholarly attempts to throw light on analyzing and comparing MI of cancer news on selected English and Chinese newspaper websites. The findings and discussions corroborate new practical, theoretical, and methodological knowledge in health communication and journalism that would help public health researchers, medical professionals, health journalists, health policymakers, and NGOs in their researches and decision makings. The comprehensive picture of this study shows the characteristics and in-depth relationships between MI and different news components. For future studies, researchers could focus on online cancer news in other languages and also compare the differences between those published in native/national language and English. Also, experimental designs should be developed to examine the effects of MI on cancer prevention among different individuals. Furthermore, our methodological use could be applied in future studies that examine other variables in health news coverage, such as frame building and supplemental information.

Abstract

Background: Reduced patient portal use has previously been reported among Black Americans when compared with that of the general population. This statistic is concerning because portals have been shown to improve the control of chronic conditions that are more prevalent and severe in Black Americans. At their very simplest, portals allow patients to access their electronic health records and often provide tools for patients to interact with their own health information, treatment team members, and insurance companies. However, research suggests that Black American patients have greater concerns over a lack of support, loss of privacy, and reduced personalization of care compared with other Americans, which results in a disparity of portal use.

Objective: This qualitative investigation of primary care experiences of Black Americans from across the United States who participated in remote focus groups in April and May 2020 aims to explore the use and perceived value of patient portals to better understand any barriers to optimized treatment in the primary care setting.

Methods: We performed an inductive thematic analysis of 8 remote focus group interviews with 29 Black American patients aged 30-60 years to qualitatively assess the experiences of Black American patients with regular access to portals.

Results: Thematic analysis uncovered the following interrelated themes regarding patient portals in primary care: the optimization of care, patient empowerment, patient-provider communication, and patient burden.

Conclusions: In contrast to what has been described regarding the reluctance of Black Americans to engage with patient portals, our focus groups revealed the general acceptance of patient portals, which were described overwhelmingly as tools with the potential for providing exceptional, personalized care that may even work to mitigate the unfair burden of disease for Black Americans in primary care settings. Thus, opportunities for better health care will clearly arise with increased communication, experience, and adoption of remote health care practices among Black Americans.

Introduction

Background

The use of electronic health records (EHRs) is rapidly becoming the norm for primary care services. The American Recovery and Reinvestment Act of 2009 attempted to provide access to EHRs for every American within 5 years through US $19 billion in incentives in the Health Information Technology for Economic and Clinical Health Act [1]. According to the most recent National Electronic Health Records Survey from the Centers for Disease Control and Prevention in 2017, 85.9% of office-based doctors use EHRs—up by 37.6% from the year the Health Information Technology for Economic and Clinical Health Act was passed [2,3].

Patient portals, which were first developed by software vendors and health care centers in 1999, provide patients access to their medical charts and other data from their EHRs [4]. Patient portals vary by provider but many also facilitate payments, scheduling, and medication refills; link patients to educational materials; and allow password-secured communications with providers [5,6]. These tools are associated with increased effectiveness in the comprehensive care of chronic diseases, including diabetes and hypertension [7], which are both more prevalent and result in more severe outcomes among Black Americans compared with the rest of the American population. This health disparity is likely due to the psychosocial and socioeconomic stresses associated with the structural racism that is evident across the United States [8]. Proactive, portal-based secure messaging from the treatment team to the patient between visits has been shown to increase patient engagement and self-management behaviors in the treatment of chronic disease [9]. Despite the rapid adoption of patient portals at clinics and the positive outcomes associated with patient portal use, only 24.9% of the National Health Interview Survey respondents engaged with patient portal tools in 2017 [10]. Black Americans were less likely to activate their portal account and log-in and even less likely to use portal tools (12.2% of the Black National Health Interview Survey respondents) such as appointment scheduling, regardless of income or education [10,11]. Among Black Americans who are not registered for portal access, some barriers to portal use include a lack of support (ie, technological support and interaction with the treatment team); concerns for the loss of privacy, which are likely influenced by historical injustices within the health care system; and reduced personalization of care [12,13].

COVID-19 and the need to implement physical distancing to limit the spread of the associated virus have reduced the availability of in-person visits for primary and nonemergent care since early 2020 [12]. As of the second quarter of 2020, office-based visits were reduced by 50.2% [14]. In-person preventive care, chronic disease follow-up, and visits related to other primary care concerns can often be adapted to virtual care, although the frequency of routine assessments might change [14,15]. In place of in-person visits, primary care providers have increasingly used telemedicine and secure messaging to meet and communicate with their patients [12,14,15]. For example, one large primary care system asked 59% of its primary care staff to work from home by the end of March 2020, resulting in secure messaging to and from their 58,000 patients to increase by 41% and 51%, respectively [15]. In addition, telemedicine is also likely to increase the overall utility of patient portals because an increasing number of portals allow scheduling of telemedicine visits, access to the visit summary, and information on any recommended follow-up steps [5,6,15]. Following in the footsteps of federal agencies (ie, Medicare), private insurance companies have recently responded to the COVID-19 pandemic by lifting previous restrictions on telemedicine and by reducing or eliminating co-pays for telemedicine visits [12]. Although telemedicine is more accessible, the sudden shift to it has decreased the total number of appointments in primary care by 21.4%, according to the IQVIA (formerly Quintiles and IMS Health, Inc) National Disease and Therapeutic Index [14]. The frequency of assessments of cardiovascular risk factors and the prescription of new medications have also been reduced [14]. As Black Americans are already less likely to schedule office-based preventive care visits with their primary care provider [11,16], the need to digitize routine visits presents another barrier to scheduling, assessment, and treatment [14]. Digitization of health care will likely continue to grow even beyond the COVID-19 pandemic; thus, the importance of effectively connecting Black Americans to digital health care services is overwhelmingly necessary [17].

Objectives

We used focus groups to understand potential barriers to optimized care for conditions disproportionately affecting Black Americans, and participants repeatedly noted the impact of using portals on their care. The perceived utility and value of patient portals were often integral to participant experiences with care and their relationships with providers, health care institutions, and their own health, as detailed herein.

Methods

Study Design

Self-identified Black American residents aged 30-60 years with regular access to primary care were recruited nationally using Craigslist and Research Match advertisements. Recruitment continued until thematic saturation [18] was reached. Interviews were conducted remotely through Webex (Cisco Systems) in April and May 2020, with both the study team and participants located in their own environments. The participants were sorted into focus groups on a first-come-first-serve basis. Individual phone calls were implemented to answer any participant questions, collect demographic data, and obtain verbal informed consent per the Oregon Health & Science University Institutional Review Board exemption guidelines.

Each interview was an hour long, with a maximum of 5 participants and 2-3 facilitators. One facilitator was responsible for primary facilitation and asking probing questions and at least one facilitator took notes. The focus groups began with the facilitators describing their role and any personal connection to the research and reminding participants that the information disclosed in the interview would remain confidential. The participants then introduced themselves and provided a first name or nickname for use in the focus group to engage with other participants; no other personal identifiers were provided during the session. The subsequent discussion was participant led. At least one facilitator self-identified as Black in every session. Interviews were recorded with video and audio, transcribed verbatim, and deidentified by the primary facilitator.

Data Analysis

Patterns within the data were analyzed and identified through inductive thematic analysis using NVivo software (version 12.0; QSR International) [19]. An intercoder reliability analysis was performed using percent agreement among the raters [20]. Respondent validation was not used because of the quick evolution of the COVID-19 pandemic and the onset of nationwide protests that have involved many in the Black community and may therefore affect perspectives on health disparities or COVID-19 transmission and add additional participant burden [21]. The development of the interview guide was informed by grounded theory (Table 1). Study design and interview analysis were reported using the Consolidated Criteria for Reporting Qualitative Studies 32-item checklist (Table S1 in Multimedia Appendix 1) [22].

Table 1. Interview guide for 8 remote focus groups.

Prepared question	Interview numbers
Briefly describe a typical appointment with your primary care provider.	Interviews 1-3
Discuss the relationship between you and your primary care provider.	Interviews 1-8
When you have an appointment, how are recommendations or other health information conveyed to you?	Interviews 1-8
What are some health conditions that you think Black Americans are the most at risk of developing?	Interviews 1-3
Imagine that your primary care provider offered a new treatment or drug designed solely for Black Americans. How would you respond?	Interviews 1-3
If your primary care provider offered you a holistic plan to treat, for example, high blood pressure, including drugs, physical activity, and nutrition, would you be receptive to this? Why or why not?	Interviews 4-8
What are your concerns in the prevention and care of COVID-19?	Interview 4 and Interviews 6-8

Theoretical Framework

A total of two theoretical frameworks were integrated to direct the discussion of emergent themes related to patient portal use among the participants: the technology acceptance model (TAM) and the health belief model (HBM) [23]. The TAM posits that the perceived usefulness and ease of use of a technology determines attitudes toward and actual use of that technology [23]. The HBM is used to predict health behavior and posits that individuals with high perceived personal risk of disease are more likely to seek health information and engage in health behaviors [24]. The integration of these models may predict the likelihood of adopting portal technology (TAM) to support an individual's health awareness and provider communication and their engagement in healthy behaviors (HBM), including the adoption of preventive measures and treatment [25].

Data and Materials Availability

The data that support these findings are available on request from the corresponding author, NPB; the data are not publicly available because of ethical restrictions.

Results

Overview

Eight focus groups engaged 29 participants (22 women) with a mean age of 40 (SD 8) years. Intercoder reliability was found to be in ≥95% agreement, such that secondary codes were not used in the analysis. Of the 29 participants, 22 (76%) discussed experiences related to patient portals. From the inductive thematic analysis, four themes emerged regarding patient portal use among Black Americans in primary care: optimization of care, patient empowerment, patient-provider communication, and patient burden. Table 2 provides the frequency of these four themes, and in the *Optimization of Care*, *Patient Empowerment*, *Patient-Provider Communication*, and *Patient Burden* sections, we provide some of the most salient individual examples that emerged from discussion in each of these themes.

Table 2. Frequency of identified themes in 8 focus groups.

Theme	Frequency values[a]
Optimization of care	29
Empowerment	15
Patient-provider communication	34
Patient burden	9

[a] Frequency was calculated as the total number of thematic endorsements of a particular code by an interviewee in any number of interviews.

Optimization of Care

Most participants described patient portals as a tool to keep both the doctor and patient informed and organized, as well as to connect with the treatment team. For many, patient portals are integrated into the appointment routine and are considered a *go-to* tool for patients before and after each visit. Before the appointment, these portals were used for scheduling, requests for tests, insurance navigation, and communications. Scheduling is often the first point of contact for patients:

> *[The portal is] a really convenient tool especially for this day and age. I think that the doctor is more accessible that way. It's a lot harder to have to schedule an appointment and have to go [in-person]. And then if something gets in the way and you have to reschedule, it could all be delayed.* [Participant 4, group 1, Portland, Oregon]

After scheduling, the portal helped patients to prepare for their next visit. As noted by 1 participant, physicians may respond differently to requests for tests. For this participant, use of the portal before appointments complemented her own engagement with her health, as well as her new physician's willingness to work with her to understand her symptoms:

> *[The portal is] typically how I get my information...When I was desperately trying to find out what is wrong with me, I was always going online or finding something that I thought I might have. Interestingly enough, I would email my primary care physician via the web portal, and he would say "okay, well we'll test you for this or test you for that..." My last experience before I switched primary care physicians was most harrowing: I didn't feel heard, and I'm sure a lot of people have had this experience as well where they say "oh, you have this so, here, get this prescription," or "do this," or "do that." So, it's been quite a journey to finally find a diagnosis for what I have...I like [my new physician's] approach because he is kind of like "let's rule it out" versus, you know, "let me figure it out or let me tell you what I think you have...."* [Participant 23, group 4, Fontana, California]

Communication with the treatment team before the appointment reduced the possibilities of the participants forgetting or becoming too nervous to address specific health concerns:

> *I think you just have more time when you're on the computer to think of what you really [want to] tell the doctor....* [Participant 3, group 1, Denver, Colorado]

During appointments, the participants reported the efficiency of having personal and family health histories centralized and readily available to the treatment team through their EHR:

> *[The portal] also makes things quicker because [the doctor] could just be like "alright from your last visit I see this, and let's go ahead and move forward with that." I think because the doctor already knows what they're dealing with it probably makes it easier for them to make a more informed decision about [my] care... [When I] switch doctors it kind of feels like starting over...I think it helps having these uniform systems [and patient] information in the portal so [the new doctor] can at least catch up.* [Participant 4, group 1, Portland, Oregon]

After the appointment, treatment teams often contacted patients first (through phone, text, or secure email) for next steps. Participant access to portals for after-visit summaries and treatment recommendations (eg, prescription dosages and blood assay results) streamlined visit follow-up. Some platforms allowed participants to make payments and view insurance information:

> *[The portal is] my best good friend, medically speaking, because it's what I prefer to use to check my results. [My provider] also follows up with conversations via the portal, so I use the portal quite a bit...from payment options, to referrals, to the information she conveys to me—any recommendations she makes [when] we are no longer face to face, that's my primary go-to.* [Participant 13, group 3, Pasadena, Maryland]

Centralized patient health records, accessible to both the treatment team and the patient, limited redundancies and mistakes:

> *The portal is a very simple system, but I'm very thankful for that. [My primary care physician and I] can go back-and-forth and then if she tells me a certain dosage, I can just look on the portal—"oh what did she say?"* [Participant 15, group 6, Staten Island, New York]

For participants with relatively few health concerns, portal use reduced the number of appointments because test results and prescriptions are accessible on the web:

> *We use the portal a lot; sometimes I'm like three or four back-and-forth. In my mind this would've been a doctor's visit back in the day, but we go back-and-forth.* [Participant 15, group 6, Staten Island, New York]
>
> *I rarely have any other visits in-between. I like being able to go get my physical and then almost instantaneously get those results...delivered to me via the portal.* [Participant 17, group 5, Nashville, Tennessee]

The participants generally appreciated the integration of portals into their treatment:

> *I remember the time that you had to ask them for your results and stuff like that. I think it adds [to my treatment] because then you already have a sense of—sometimes before the visit—of things you're going to talk about. So, I think it's more helpful and empowering for patients to have that access.* [Participant 14, group 4, Portland, Oregon]

Patient Empowerment

Distrust was a major topic in the discussion of treatments for diseases that disproportionately affect Black Americans. Distrust was founded primarily on historical, personal, and media-based accounts of malpractice. Providers ignoring medication allergies or preferences was a commonly reported cause for distrust and switching providers. Under these circumstances, portals may facilitate the transfer of records. Patient portals also play a unique role in mitigating distrust, as participants described the importance of personal and family health histories—instead of, or in addition to, racial identity—in the consideration of a new treatment or therapy:

> *I've been with my primary care [provider] for years and years and years and I've been very vocal about what my concerns are, my family history, and my culture, and I'm already putting that stuff out there. [If] they come back to me like "oh, I agree with you, and per this research...," I would be more receptive, because it's like, "okay, you actually heard where I'm coming from. And you're listening to what my concerns are and why I have these concerns, and*

> *you're trying to work with me to create a solution." But if it's definitely from a place of privilege where it's like "well, you know, you Blacks, the fried chicken and you got—" it's like "oop, sorry, new doctor! That's what you're not going to do."* [Participant 23, group 4, La Mesa, California]

This experience highlights the desire for personalized interactions among the participants and the importance of providing educational resources that connect previous discussions between the patient and provider to any new treatment recommendations. Educational resources were often provided digitally after appointments through secure messaging or portal-based visit summaries. Others obtained this information on their own through internet searches.

User-friendly portals also empowered the participants to discuss sensitive matters more transparently and to engage in their own health care more effectively. Most portal users reported benefiting from additional control of their appointments, although some participants viewed the portals as a hurdle between themselves and their provider rather than an additional avenue for communication (see *Patient Burden* section). Thorough reporting of health concerns through the portal was especially useful before the visit because crossing the digital divide served as an icebreaker in what can sometimes be timid interactions with the treatment team:

> *[The portal] lends a platform for being more honest and I think people in general are less uninhibited online. So, I think if you're a patient you're probably going to be a bit more forthcoming about what your symptoms are, or what you're experiencing, or what's going on in order for the doctor to better be able to assess what's happening...I think we've all been in those situations at the doctor's office and it's awkward especially if it is a new doctor and you don't know them really well. So, for me, I feel the need to be more detailed as well, because it is through text so I'm trying to make sure they can follow.* [Participant 4, group 1, Portland, Oregon]

The participants also stressed the importance of documenting health concerns on the portals to reduce in-person anxieties that may arise when under time pressure:

> *I agree with what [Participant 4] said...I just have more time to think it out, and can write it down, and really get maybe even better feedback. Or, at least feedback you can look back on and tell somebody else if you want a second opinion.* [Participant 3, group 1, Denver, Colorado]
>
> *I didn't use [the portal] as much before because I thought it was kind of impersonal and dismissive... [Now I don't] have to store [health concerns] in my mind and wait for an answer, because maybe I was a little bit anxious about whatever was going on with me...it's helped take some of the anxiety out of me, especially as I started to develop a relationship with my new primary care physician and the nurse.* [Participant 23, group 4, Fontana, California]

Other anxieties potentially resulting in the participants forgetting or dismissing relevant points during appointments were commonly attributed to distrust based on experiences of being pressured by members of the treatment team or intimidation by a doctor's demeanor.

According to the participants, physician accountability reciprocated patient accountability with regard to portal use. Many participants reported experiences in which their primary care providers would give the impression, either subtly or explicitly, that they did not have time for concerns beyond those routinely addressed in annual visits. The participants often avoided provider dismissiveness when they expressed their concerns through the portal before the visit:

> *I like to have [my health concerns] in writing and I feel like it's going to hold the doctor more accountable having it in writing...the doctor gets back to you quicker [over the portals].* [Participant 3, group 1, Denver, Colorado]

One participant highlighted this theme in her experience of advocating for the health of her mother, an older adult. In this example, her mother's treatment team was described as neglecting the patient, but the information stored in the portal served as a reference for her family members. Using her proxy access to her mother's up-to-date portal, the daughter was able to contact the treatment team and make the necessary requests for tests that had previously been neglected:

> *When [my mom] was dealing with the MediCal, the people were overworked and underpaid...so I would go into my mother's portal and health insurance and I would look for the doctors that she needs and then I would basically spell out everything for them... I'd write down dates and everything that I did so that they can't turn around and say "oh, I forgot all this..." I definitely had to be the proactive one to go after them to show them if they were being not only insensitive but also they were giving information which was basically the opposite of what they said before. They were saying she has kidney issues and her hemoglobin [A1]C is elevated but then they didn't follow up with her for four months. And I would say, "how didn't you follow up when her diabetes is out of control?" But then you're saying "you have to play a role; you have to take this medication..." I was like "that's just not right. [There] was a huge void and a huge gap, and it worried me...It helps me understand more why anybody, but especially Black people are with the highest rates of diabetes, kidney disease, and amputations, and problems and not getting care...I can be here for [my mom], but a lot of people don't have that because they're working, or their kids don't live with them, or they [just] don't know."* [Participant 18, group 6, San Diego, California]

As portals provide a way to conquer the digital divide, physicians may also be encouraged to obtain second opinions and other professional insights more readily. Thus, patient portals may increase transparency for both patients and their providers:

> *I imagine that [nervousness] is similar for the doctor, where if they're in a face to face visit with you, it might be more awkward if they need to Google something or call a colleague. But if they're not face to face with you, it does give them a little more time and anonymity and in being able to go consult with somebody if they need to.* [Participant 4, group 1, Portland, Oregon]

Health history stored on the portal underscored the value of transparency for increasing care satisfaction and patient engagement. Physician access to health records through EHRs tailored primary care visits to the specific health history of the patient. The ease of access to health information, such as test results and family health histories, complemented participant efforts to maintain accountability over their personal health outcomes:

> *I have, you know, parents, family health issues, and I want to make sure I'm not impacted. So, I try to stay a little more on top of things...I am a little more diligent.* [Participant 15, group 6, Staten Island, New York]

Reported lifestyle changes were most often dietary or exercise-related. Commonly reported steps to counteract increased health risk were typically related to conditions that participants knew disproportionately affected Black Americans. Participants were specifically aware of racial disparities in the prevalence of diseases such as COVID-19, cardiovascular disease, and diabetes, and accountability for health was usually attributed to the participants' personal and family history of disease. Chronic disease was common among participants and their family members, and EHRs documented and facilitated discussions of these health concerns. The accessibility of health records made possible through most portals enabled a level of patient accountability necessary to address increased health risks:

> *I don't have to feel like I have to play politics, particularly with my PCP... [Regarding portal use]. Usually I initiate, but they're willing to give me the information that I need or want and allow me, without trouble, to make decisions. They don't treat me like oh you're the patient and you can't make the decisions...* [Participant 18, group 6, San Diego, California]

Some participants wanting a new provider felt too invested to find one if their family health records were stored locally because sharing this information with a new physician might be time consuming, as previously noted. Digital records enabled participants to change physicians without communicating family and personal health histories anew (if transferring to an interoperable site) and to obtain second opinions easily.

Patient-Provider Communication

Some participants expected patient portals to reduce personalization of care but instead found that the portals supplemented their interactions with their treatment team. The accessibility of portal communications enabled many participants to address their concerns more thoroughly and accurately, increasing their engagement with their treatment plans. Participants with negative experiences regarding the portal were often dissatisfied with their treatment team at the time and were sometimes seeking a new primary care provider. Overall, communication through portals mirrored communication patterns already established between the patient and their provider (eg, efficient and accommodating or terse and impersonal):

> *[The portal is] a double-edged sword, right?...The best way of thinking of it I think is that [if] I'm texting with my doctor, you can either give me a short answer or just say "yes/no" without any other follow up or results. And there's other instances that people use that as a "hey, I saw your message, I actually wanted to give you a call. After I get off the phone with you, I'm going to send you another message and we'll check in..." So, it all depends really more so on the doctor. If they use that as another touch point to stay in touch, that's good.* [Participant 23, group 4, La Mesa, California]
>
> *Assessments that were performed that day [are] delivered to me via [the] portal...I've also given them permission to notify me by email and by text....I'll get a [text] message, that might say "you have a new test result" and I like that, and I find it very helpful...I like the connectivity...Whenever I've had to reach out to my primary care physician, I get a pretty good return rate. You know, usually within 24-48 hours if I ever have any questions....* [Participant 17, group 5, Nashville, Tennessee]

Provider response time was generally important to participants, as was the thoroughness of response:

> *Pretty rapid response time but very minimal in the communication. Just very, like, terse, which is what it is. That was the only method of communication.* [Participant 16, group 6, Portland, Oregon]

Although communication through patient portals was common, portal use failed to supplement in-person communication for some participants. Ineffective communication patterns and delegation of follow-ups from the provider to other treatment team members (eg, medical assistant or nurse) compromised satisfaction with portal-based communications. Portal use hindered effective communication in at least two scenarios. First, when a phone call was still necessary to fill the request or answer a question:

> *It's a longer process for them to get into the portal when I can just call and say what I have to say, instead of waiting a week to get an answer.* [Participant 22, group 5, St. Louis, Missouri]

Second, when digital responses from the provider are delayed, insufficiently detailed, or confusing:

> *When the replies are delayed, that kills me the most. Like, "hey, I sent a message on Monday. Here it is, now Monday the following week. What's up?"* [Participant 23, group 4, La Mesa, California]

For many participants, the nurse or medical assistant was in charge of much of the digital communication with the patients. Delegation to other treatment team members limited digital communication with primary care providers for some participants compared with those who received secure emails and phone call check-ins from their provider. Although some participants were indifferent to delegated communications, personalized messages from the primary care provider were especially appreciated. Weekend, after-hours, and between-appointment communications represented a level of care that exceeded expectations.

Patient Burden

Portals provide a variety of tools but also rely on the patient to take advantage of these tools outside of the appointment. Some participants had trouble adapting. In addition to technological setbacks, some participants described the portals as an extra step to contact their treatment team, especially in cases where a phone call is inevitable. The sophistication of the portal interface may also play a role in burdening the patient because some participants reported that messages are not forwarded to their email, requiring them to log in proactively to check their inbox. A Portland, Oregon, participant recalled that she had experienced this issue with her past primary care provider:

> *Everything was communicated through a portal. But I had to actively go into the portal to see if there were communications. It wasn't like if she sent me a message and that would show up in my personal email and then I would know—I had to really be looking and waiting.* [Participant 16, group 6, Portland, Oregon]

Many participants were aware of the lack of interoperability among portals and were frustrated at having to recount family health history to new providers when switching insurance networks or moving:

> *I bring everything back to my primary care doctor. There's not a lot of communication between specialists. They do have their own little charts [records] and that can be hard.* [Participant 18, group 6, San Diego, California]

In addition to changing appointment routines to adapt to the portal, some participants with long-term relationships with their providers noted the burden that portals placed on hospitals and treatment team members to learn how to implement them in their practice. This physician burden resulted in at least 2 participants losing their long-term primary care provider when the portal was introduced at their place of care:

> *This doctor retired and then, I don't know, he said he was kind of almost forced out a few years back when everything was going digital and he didn't. He's on the older side so he didn't kinda learn the new system and stuff...I did have to switch to someone in the meantime, and I got a referral for her from a family member. But, yeah, she wasn't as accommodating I'd say, and that's why I went back to my first doctor.* [Participant 5, group 2, Portland, Oregon]

The participant chose the existing rapport she had with her very accommodating provider over a digitalized form of their relationship. Another participant noticed that she rarely received responses to secure messages and wondered if her treatment team had any training on the use of portal-based communications.

Discussion

Principal Findings

In the past, structural barriers have limited the initial portal sign-on by Black Americans [11-13]. In our focus groups with Black primary care patients who do use patient portals, the most frequently referenced themes were (1) optimization of care, (2) patient empowerment, (3) patient-provider communication, and (4) patient burden. The two most common themes related to patient portal use in our focus groups, namely optimization of care and patient empowerment, suggest that experiences with patient portals are largely positive. The influence of patient portal use on patient-provider communication and patient burden was generally contingent on previously established communication patterns, as well as support from the treatment team. Similarly, previously identified barriers to portal use among racial minorities who had little or no history of portal use include expectations regarding technological support and the quality of portal-based communications [13].

Technology Acceptance and HBMs

Applying the TAM, the emergent themes in our focus groups suggest that when the perceived usefulness and ease of use of patient portals improve, attitudes toward portals improve and so does the actual use of patient portals among Black Americans [23]. The perceived usefulness of patient portals for optimized care among our participants is further explained by the integration of the HBM with the TAM. According to the integrated model, individuals with high perceived susceptibility to disease and high health consciousness are more likely to adopt technology that fulfills health information and communication needs or that supports health-seeking behavior [24,25]. Meeting such needs in a way that is perceived as both easy and beneficial subsequently influences and reinforces positive attitudes toward and increased use of health technologies [23,25]. Susceptibility to disease was a common concern among the interview participants. In the face of historical mistreatment and ongoing bias against Black Americans in health care settings, portals may offer Black patients control over their appointments while providing tools for personalized care to mitigate bias. This finding is consistent with a March 2020 survey [26] showing that Black Americans who viewed COVID-19 as a minor personal health threat (as opposed to no threat at all to personal health or a major threat for which in-person assessments may be necessary) had the highest use of telemedicine as a result of the pandemic compared with White respondents, despite anticipated barriers. This may be due to increased perceived susceptibility to COVID-19 among Black Americans, resulting in an abundance of caution regarding in-person visits compared with White Americans with the same level of perceived threat [26].

Although telehealth may replace some elements of in-person visits, the results from this study suggest that portals may be relied upon for the optimization of care before, during, and after appointments when used by Black Americans. Once a telehealth or in-person appointment is made, the personalization of care may still be limited by implicit bias against Black Americans. Patient portals may help reduce this disparity by holding providers accountable for addressing specific health concerns documented on the web, rather than requiring patients to quickly recall and disclose sensitive information in person. Patients run the risk of making mistakes, feeling uncomfortable, and even being traumatized by having to repeat health information every time they meet with a provider when their personal health information is decentralized (spread across multiple local EHRs) or if the patient lacks an EHR altogether [27]. Black patients may feel this distress more poignantly [27], compounding existing distrust that is common among Black Americans in health care settings because of interpersonal and institutional racial discrimination [17]. Furthermore, centralized and up-to-date EHRs facilitate provider treatment recommendations based on personal and family health records and on environmental factors that have been documented, thereby improving health outcomes [1].

Looking Beyond Race

In contrast, race is often leveraged to assess risk in the treatment of Black Americans for conditions that they are at heightened risk for developing severe symptoms, including COVID-19 [28,29]. Race-based medicine and common risk assessments that use algorithms adjusted by a patient's race are present in cardiology, endocrinology, nephrology, urology, oncology, obstetrics, and other specialties [29]. This practice of operationalizing racial and ethnic categories results in the differential prescription of specialty services (including assessments, treatments, and major surgical procedures) for Black patients and other racial or ethnic minorities [29]. The prescriptive use of race in clinics may exacerbate inequalities and perpetuate implicit bias at health care institutions [17,29]. This contrasts with the use of race in descriptive statistics, which are vital for identifying disparities in health and for beginning to understand the etiology of disease (including systemic racism) and subsequent downstream effects (such as reduced access to care or increased psychosocial and environmental stressors) [8,29].

The impacts of race-based risk assessments for Black Americans at clinics include under- or overprescription of pain medications, reduced options for life-saving surgeries such as cesarean sections during childbirth because of preoperative risk assessments, less aggressive screenings for bone disorders and some forms of cancer because of lower risk of developing the condition (eg, breast cancer), and increased or decreased likelihood of intervention resulting from a decreased likelihood of survival (eg, rectal cancer treatment, in which doctors may not recommend treatment to patients who are unlikely to survive and recover) [29]. Although risk-assessment algorithms intend to increase efficiency in diagnosis and decrease costs, without proper scrutiny and understanding of the distinctions between biological mechanisms of disease and social determinants [8,17], adjustments by race might be arbitrary or even harmful or fatal [29]. In other words, racial identity is certainly not a replacement for a patient's health records. In our study, the focus group participants generally felt empowered by access to their own health information, including test results. Provider familiarity (or lack thereof) with family health histories was important to the participants, especially those considering looking for a new provider. This priority is consistent with the outcome of a community-based intervention for cancer-risk perception in Black Americans that emphasizes family health history to assess objective risk [30]. After the intervention, wherein family health histories were disseminated to the participants, objective and subjective risk levels matched in most of the participants [30]. Contextualizing subsequent treatments for the patient would likely require further collaboration with the patient to understand the barriers to effective care.

Portal-based communications emphasize the communication patterns already established between a patient and their provider. To this extent, portals provide the treatment team with additional opportunities for exceptional and tailored care. Care centered on the unique needs and experiences of the patient may be an expectation for many patients, particularly those with access to their own health records [1], but Black patients experience unfair bias in medical settings [17,29]. Predisposition to chronic disease and implicit bias in the treatment of such diseases place pressure on Black Americans seeking care. Indeed, recent work suggests that Black patients in primary care may feel that they must take great care to protect themselves from the health effects of structural racism while also confronting family history of disease through lifestyle choices and engaging more with their health [26,28]. By matching patient accountability with a level of care that exceeds expectations, regular portal use by patients and their providers can reduce bias and therefore alleviate some of the burden of disparity from the shoulders of Black patients [9]. Specifically, setting realistic and informed goals and then checking in proactively with the patient between appointments may address barriers in primary care with tools and information readily accessible on patient portals [6,9,31].

Strengths and Limitations

The potential study limitations include generalizability to populations lacking health coverage, access to internet-compatible devices, or regular access to patient portals. The themes discussed in this paper should be confirmed using quantitative methods, especially considering the increased use of telemedicine over the last year [12,14,15]. Web-based recruitment, as well as the web-based format of the interviews, also limits generalizability to individuals who are less computer savvy. The participants were aged between 30 and 60 years because of the requirements of the parent study of this investigation. Age is a limitation because older patients are likely to interact with their treatment team more often and may have more visits to manage. Despite the benefits of portals in managing care among providers, older populations may use portals less often than our participants and would require even more technological support and coordination between providers and other members of the treatment team [13,14]. As lack of technological support contributes to lower use of patient portals among Black Americans generally, our focus groups show how increasing support, communication, and adoption of patient portals may provide opportunities for better health care among Black patients.

Acknowledgments

This work was supported by a research supplement to R01 HL142064, the parent grant (SAS). Support was also provided by KL2TR002370 (NPB) and the Oregon Institute of Occupational Health Sciences at Oregon Health & Science University through funds from the Division of Consumer and Business Services of the State of Oregon (ORS 656.630). The parent study received support from UL1TR000128 (Oregon Clinical & Translational Research Institute). The authors would like to thank Shelby L Watkins (Masters in Public Health), for providing NVivo training to OHO and assistance with coding; Martina A Shannon for help with interview transcription; and members of the PreSERVE Coalition for Black/African American Memory & Brain Health who helped inform the interview questions and provided resources for parent study recruitment.

Authors' Contributions

RLC was involved in designing the interview guide and providing valuable mentorship to OHO throughout the study. LDR was involved in interview facilitation and probing. SAS is the principal investigator of the parent study and provided mentorship to NPB and OHO. NPB was involved in project design, interview facilitation, coding, and manuscript writing, as well as primary mentorship for OHO. NPB and OHO conceived the project, and OHO was involved in project design, primary interview facilitation, transcription, coding, and manuscript writing. All authors read, edited, and approved the final manuscript.

Abstract

Background: Web-based time-use diaries for schoolchildren are limited, and existing studies focus mostly on capturing physical activities and sedentary behaviors but less comprehensively on dietary behaviors.

Objective: This study aims to describe the development of My E-Diary for Activities and Lifestyle (MEDAL)—a self-administered, web-based time-use application to assess diet and movement behavior—and to evaluate its usability in schoolchildren in Singapore.

Methods: MEDAL was developed through formative research and an iterative user-centric design approach involving small groups of schoolchildren (ranging from n=5 to n=15, aged 7-13 years). To test the usability, children aged 10-11 years were recruited from 2 primary schools in Singapore to complete MEDAL for 2 weekdays and 2 weekend days and complete a 10-item usability questionnaire.

Results: The development process revealed that younger children (aged <9 years) were less able to complete MEDAL independently. Of the 204 participants (118/204, 57.8% boys, and 31/201, 15.4% overweight) in the usability study, 57.8% (118/204) completed 3 to 4 days of recording, whereas the rest recorded for 2 days or less. The median time taken to complete MEDAL was 14.2 minutes per day. The majority of participants agreed that instructions were clear (193/203, 95.1%), that MEDAL was easy to use (173/203, 85.2%), that they liked the application (172/202, 85.1%), and that they preferred recording their activities on the web than on paper (167/202, 82.7%). Among all the factors evaluated, recording for 4 days was the least satisfactory component reported. Compared with boys, girls reported better recall ability and agreed that the time spent on completing 1-day entry was appropriate.

Conclusions: MEDAL appears to be a feasible application to capture diet and movement behaviors in children aged 10-12 years, particularly in the Asian context. Some gender differences in usability performance were observed, but the majority of the participants had a positive experience using MEDAL. The validation of the data collected through the application is in progress.

(J Med Internet Res 2021;23(6):e25794) doi:10.2196/25794

KEYWORDS

time use; web-based; diet; movement behaviors; usability; schoolchildren

Introduction

Background

The prevalence of obesity in children and adolescents has increased in recent decades, and this rising trend has surged in parts of Asia [1]. In addition to short-term health consequences, overweight and obese children have a greater risk of adverse psychosocial health conditions and earlier onset of noncommunicable diseases [2]. Understanding factors contributing to obesity risk in children, such as physical inactivity and poor diet, is critical to prevent the accelerating burden of chronic diseases in later life.

However, there is a lack of good quality and timely data on schoolchildren, particularly those aged 10-14 years [3]. Parents may help to report the health behaviors of their children at home but often are not fully aware of their activities out of home, especially when children are increasingly independent in their food and activity choices at this age [4]. Although questionnaires completed by children are valuable tools to collect health behavioral data, they have the following limitations: (1) they often focus on a single health behavior; (2) they typically involve long-term recall, which is cognitively demanding for children (eg, examine activities during the past 7 days or last month) [5,6]; and (3) they rarely capture emerging health behaviors, such as nonscreen time sedentary behaviors, light-intensity physical activities, outdoor time, and tasks done concurrently (eg, screen time and eating) [7,8]. Although objective methods of measuring health behaviors are increasingly being used, they do not provide information on the type of activity or food consumed [9,10]. To address these limitations, a growing number of studies have used the time-use approach in children to collect information on health behaviors [11].

Time-use diaries prompt users to provide an account of a series of activities in a 24-hour day through previous day recalls [11]. Children are not cognitively developed to recall well before 8 years of age, but by the age of 10 years, they have the independent ability to provide accurate reports [12,13]. In addition, they allow the simultaneous capture of multiple energy balance–related behaviors. Most existing studies rely on paper-based diaries [11], whereas recent studies have developed software-based diaries [14-17], which have been demonstrated to engage children more effectively. However, to our knowledge, these studies focus mostly on capturing physical activities and sedentary behaviors but less comprehensively on dietary behaviors; for example, types of food consumed [14,17] and food portions [15,16] were not collected. Furthermore, there is a lack of application containing databases of Asian foods and common activities of children within the Asian context, such as tuition, also known as shadow education, which is prominent in East Asian countries [18]. In addition, the location of activities has been less studied, and no study to date has collected data on simultaneous activities (eg, eating while studying) in children aged 10-14 years, which is valuable for a better understanding of the activity contexts in children [19].

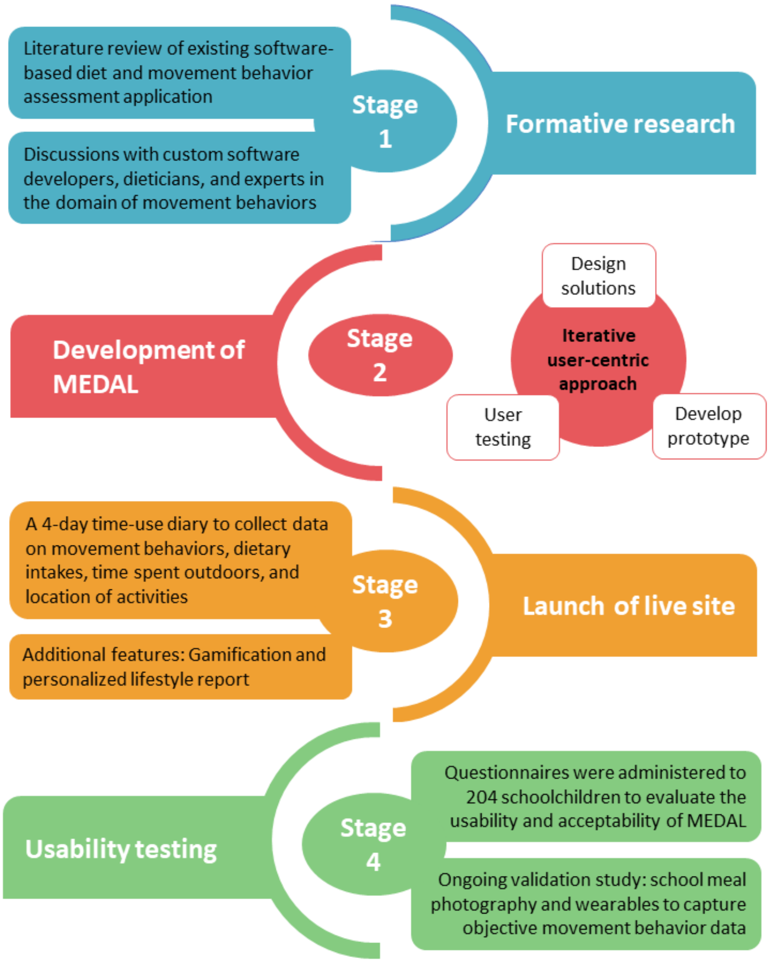
Objectives

To bridge these gaps, we developed a self-administered, web-based time-use application to assess diet and movement behaviors in schoolchildren: My E-Diary for Activities and Lifestyle (MEDAL). This study aims to describe the development of MEDAL and evaluate its usability among schoolchildren in Singapore.

Methods

The development of MEDAL was a multistage, user-centric process (Figure 1).

Figure 1. Flowchart illustrating the development process of My E-Diary for Activities and Lifestyle (MEDAL).



Stage 1: Formative Research

Several data sources were reviewed to identify the elements and requirements for developing a self-administered, web-based application for assessing diet and movement behaviors in schoolchildren. Both electronic and hand-searched strategies were adopted to identify existing software-based diet and physical activity assessment tools for schoolchildren. MyDailyMoves in the Netherlands [17], WebCAAFE in Brazil [16], Synchronised Nutrition and Activity Program in England [15], and Multimedia Activity Recall for Children and Adolescents in Australia [14] were evaluated. We also held interviews and meetings with experts from various knowledge domains, including custom software developers, experienced educators, and dieticians. The key points emanating were (1) application should be simple, easy to navigate, and take no more than 20 minutes per day to complete; (2) use of appealing visuals to engage children, and they prefer images to text and clicking instead of typing; and (3) enable children to report activities sequentially from wake-to-bed time (analogous to a time-use diary), so as to enhance recall—this method of *behavior chaining* has been shown to help children remember their activities [15]—and (4) complete the application at the end of each day to minimize omissions and intrusions [14,20]; children's accuracy in reporting has been shown to improve with shorter retention intervals (ie, time between event occurrence and reporting) [21].

Stage 2: Iterative User-Centric Development Process

On the basis of the formative research in stage 1, we adopted an iterative stepwise refinement approach to design, develop, and test features of the application [22]. User testing was conducted with children using methods such as paper-based simulations, audio clips, and mock-ups (ie, static wireframes) to understand the children's preferences for the interface and their comprehension of the task. At the end of user testing, user feedback was evaluated, and necessary improvements and amendments were conveyed to the software developers to inform the next development cycle. Multimedia Appendix 1 summarizes the key feedback and changes made during each development phase. Small groups of schoolchildren (aged 7-13 years), ranging from n=5 to n=15, were involved in all development stages to ensure that design decisions were tailored to their needs until the full functional system was launched. The sample sizes for each stage of user testing were adequate, as studies have shown that 80% of the usability problems were found with the first 5 users [23], and the diminishing return of uncovered problems was apparent when the sample size increased [24]. The key takeaways from the development phase were as follows: (1) recording should be limited to 4 days (similar to other diet and activity monitoring tools), as children found it tedious to record for 7 days; (2) prompts should be included to aid recall; (3) child-appealing visuals and intuitive designs should be used to ease navigation and motivate completion; and (4) younger children (<9 years) may need more assistance to complete MEDAL independently.

Stage 3: Launch of the Live Site

Technical Specifications

Multimedia Appendix 2 presents the major functionalities of MEDAL. MEDAL is a self-administered, web-based time-use application that takes users through the completion of a 4-day diary to collect data on movement behaviors, dietary intakes, time spent outdoors, and the location of these activities. It is written using the Yii Framework (version 1.0), PHP (version 5.6) as the application programming interface, Angular 2 (version 2) as the front end, MySQL (version 8) as the database, and hosted by the National University of Singapore. It is accessible on browsers such as Google Chrome, Microsoft Edge, Firefox, and Safari on devices such as tablets, laptops, and desktops.

Log-in and Registration

User-specific accounts are created by research administrators through the backend portal, and users can access MEDAL by logging on with a username and password given to them. Information on the date of birth and sex of the user is collected during the first log-in. MEDAL allows users to have the flexibility to record on any 4 days. Users can select if they are recording for the current day or the day before. The recall period is limited to the day before to minimize the retention interval and increase the likelihood of data validity [21].

Recording of Activities and Diet

Activities

Users are asked about the time they slept the night before and their wake-up time. Following this, users are asked to record their activities sequentially, with the end time of one activity leading to the start of the next, until the end of the day is reached (ie, bedtime). They can choose from 22 activities grouped into 6 broad categories: (1) shower or wash up, (2) eat and drink, (3) traveling, (4) sitting activities, (5) active activities, and (6) nap/sleep. For example, the traveling category included activities such as *walk*, *cycle*, *car/taxi*, and *bus/train*; sitting activities category included *reading/doing homework*, *hand phone/tablet*, *TV*, *video games*, *computer/laptop*, *board/card games*, *sit and chat*, and *tuition/music lesson*; and active activities included *run/jog*, *cycle/skate/scoot*, *ball games*, *martial arts*, *dance*, *neighborhood play, and water activities*. This list of activities was compiled from existing questionnaires examining the indoor and outdoor activities of schoolchildren [25]. Common activities listed in 7-day activity diaries completed by 200 children of a local multiethnic birth cohort study (Growing Up in Singapore Towards healthy Outcomes) [26] were also considered (Cheryl Zhang, MPH, unpublished data, May 2018). These activities were further grouped to reduce the number of response options (eg, basketball, handball, and football are collectively known as *ball games*), as a previous report showed that providing a large number of options for children was associated with poorer quality of data collected [27]. Children can specify activities that are not listed by typing in a free-text box labeled *other*.

When an *active activity* is selected, users will be questioned further about its intensity: “How tiring was the activity?” To aid children in conceptualizing activity intensity, 3 emoticons with captions illustrating different degrees of physical exertion are presented: (1) Just a little—you can sing and talk during the activity, (2) Quite tiring—you can talk but cannot sing during the activity, and (3) Very tiring—you cannot say more than a few words without pausing. Energy expended at each activity can be determined by multiplying the duration of the activity and its corresponding metabolic equivalent task, drawn from the Youth Compendium of Physical Activities [28].

Diet

When the category *eat and drink* is chosen, users will be asked to select the food and drink they consumed from 88 food items (icons) organized under 13 main food and drink groups (Multimedia Appendix 3). When necessary, items were placed in multiple food groups so as to enhance user accessibility (eg, French fries was located in the *noodle/pasta/potatoes* group and in the *fast food* group). Besides browsing the food and drink groups, users can perform a text search to display the food items as typed. The embedded fuzzy search feature allows items to be searched and displayed even when the food names are misspelled, thus greatly enhancing the ease of use of MEDAL for children. The list of food and drinks was compiled from commonly consumed foods identified from 3-day diet records of 360 local children of the Growing Up in Singapore Towards healthy Outcomes cohort [29] as well as discussions with experts in the field of dietary assessment. Users were also asked to choose the portion sizes of food that best corresponded to the amount they consumed from 4 pictorial options (shown simultaneously) per food item. A total of 4 pictorial options were provided, as this was found to be the optimal number of options for children to select from [20]. Moreover, the even-numbered options limit the middle option from being chosen out of convenience [30]. Simultaneous presentation of food images depicting increasing portion sizes is preferred over the sequential presentation for children to quantify their food intake more accurately [31] and within a shorter period [32]. For items that are not listed, users can type into the *other* textbox and indicate the amount consumed from the 4 options provided: half a portion, 1 portion, one-and-a-half portion, or 2 portions. Prompts for commonly forgotten foods “Did you forget to select any fruits, drinks, dessert, or supplements you have eaten?” were provided after each meal entry. Users also have the option to review and edit the food and drink items entered before recording the next activity.

Additional Features

MEDAL requests users to indicate activities that were performed simultaneously (eg, watching TV while having their meals), which may not be achievable in existing assessment tools [14-16]. Users were also prompted to enter the location of their reported activities (ie, home, school, student care, or others) and if they were done indoors or outdoors. Inquiry on location helps children to contextualize and recall the activities they did [15,20]. Following the selection of an activity, children were asked to record the end time of the activity. The recorded end time should be at least 5 minutes from the start time. The minimum time frame of 5 minutes was designed to allow children to record short bouts of activity [14]. To check for activities that may be missed out, prompts such as "That's an odd timing, are you sure you ended this at [time]?" will be provided if users recorded an activity that lasted for more than 3 hours. MEDAL automatically saves the user's responses and allows them to log in at any time of the day to continue recording or review and edit their activities if they are not able to complete in one sitting.

Gamification

Several game design elements were implemented to motivate children to complete MEDAL. Users can personalize the background interface and select their choice of avatar. The chosen avatar provides instructions and prompts in the form of visual texts and auditory dialogs, which serve to alert the user to action (ie, more reactive) and enhance user immersion in the MEDAL task [33].

Each completed day of recording rewards users with a gardening tool to nurture their virtual plant. At the end of 4 complete days of recording, a randomly assigned mystery fruit will be revealed to the user. These visual representations of achievements directly communicate the success or completion of the task and serve to evoke feelings of competence and efficiency in children [34]. The addition of the mystery element and randomization further aims to spark curiosity in children and motivate them to complete the task [35].

Personalized Lifestyle Report

On completing 4 days of recording, users will instantly receive a personalized lifestyle report. The report provides information on 4 components of movement behaviors—physical activity duration, outdoor duration, screen viewing duration, and sleeping duration—and evaluates the intake of 5 food groups—fruits, vegetables, whole grains, sugar-sweetened beverages, and dairy and dairy products. The mean durations or servings per day (ie, daily estimates) were calculated based on standardized algorithms and compared with the recommended guidelines [36-38]. Specific messages were delivered to users for each component based on the categories they belong: (1) met recommended guidelines, for example, "Terrific! Super-duper proud of you! You should continue to spend less time on the screen"; (2) nearly meeting guidelines, for example, "Almost there! Aim to spend less time on the screen. Keep going!"; or (3) did not meet guidelines, for example, "You should spend less time on the screen. Aim for less than 2 hours of screen time daily. Persevere! I believe in you!" Messages were gain-framed (ie, focused on attaining a desirable or positive outcome) and presented with graphical illustrations, as evidence from existing reviews and qualitative research has shown that this is effective in motivating children [39].

Stage 4: Usability Testing

Study Population

To test the usability of MEDAL, primary 5–level children (aged 10-11 years) from 2 coeducational government schools in Singapore were invited to participate in the usability study between April and August 2019. Children were eligible if they were able to understand and respond to the assessment in English. Of the 458 invited children from 13 classes (7 classes from school A and 6 classes from school B), 49.8% (228/458) were recruited. The main reasons for nonparticipation were *did not return consent form* (150/458, 32.8%), *parents did not consent* (46/458, 10%), *child was busy or not interested* (20/458, 4.4%), and *child was absent on the day of study* (14/458, 3.1%). The study was approved by the institutional review board of the National University of Singapore (Reference S-18-088). Approval was also obtained from the Ministry of Education, Singapore, to approach schools for participant recruitment (reference RQ17-18(02)B). Informed written consent was obtained from the parents or guardians, and all participants gave verbal assent.

Data Collection

Practical sessions were conducted for each class in the schools' computer laboratories by 2 trained researchers who demonstrated how to log in and navigate the MEDAL application. Participants started their first MEDAL entry using school computers and completed the rest of the day's entry at home. Participants were instructed to record their diet and activities over 2 specified weekdays and 2 weekend days. They were encouraged to complete the day's entry at the end of the day (ie, before bedtime) or the day after. The schools' computer laboratories were opened during recess and after school to allow participants with no access to the internet or computer at home to complete MEDAL. School meal photography during the recess period was also conducted, and devices to capture objective data on movement behaviors (ie, accelerometers) and outdoor time (ie, FitSight watch, which measures light intensity [40]) were provided for validation of data collected through MEDAL.

At the end of the study, participants were instructed to complete a 10-item usability questionnaire based on a 4-point Likert scale (strongly disagree, disagree, agree, and strongly disagree). The questionnaire was adapted from existing usability questionnaires [41,42] and kept short to avoid satisficing responses [43]. Questions were positively worded, direct, and specific to tailor to the children's cognitive and communicative capacities [27]. The key themes covered by the questionnaire included clarity of instructions, motivation to continue recording, ability to recall activities and food, recording duration, and overall experience of using MEDAL. Participants were also allowed to provide comments and suggestions at the end of the questionnaire.

Information on participants' sex and age was collected from MEDAL. The time taken for participants to complete MEDAL each day was calculated as the duration of the first and last entry input (ie, bedtime), summed and averaged over the number of recording days. Height and weight were measured biannually in schools, and the most recent records were obtained. Underweight (<5th percentile), normal weight (5th to 90th percentile), and overweight (>90th percentile) were classified according to the age- and sex-specific BMI reference of the local population [44]. Parents were asked to indicate their child's access to computers and the internet at home (yes or no) in the consent form.

Statistical Analyses

Participants' characteristics were summarized according to sex, and comparisons were assessed by the Fisher exact test (categorical) and Wilcoxon Mann-Whitney test (continuous). Differences in usability attributes between sexes were examined using the Fisher exact test. The usability questionnaire responses *agree* and *strongly agree* as well as *disagree* and *strongly disagree* were merged into 2 categories, *agree* and *disagree*, before analysis. The method has been shown to be more helpful in the description of Likert scale data [45]. All statistical analyses were performed using Stata 14 (StataCorp LP). Statistical significance was set at *P*<.05.

Results

Characteristics of Participants

Of the 228 participants, 204 logged on to MEDAL and completed the usability questionnaire and were included in the analysis (Figure 2). The cohort comprised 57.8% (118/204) boys, with a median age of 10.9 (25th percentile: 10.6 and 75th percentile: 11.2) years, and 15.4% (31/201) were overweight (Table 1). The median time taken to complete MEDAL was 14.2 minutes per day, and the proportion who completed 3-4 days of recording, 1-2 days of recording, and <1 day of recording were 57.8% (118/204), 20.1% (41/204), and 22.1% (45/204), respectively. Compared with boys, girls spent more time completing MEDAL (median 15 min per day vs 13 min per day; *P*=.03) and were more likely to complete 3-4 days of recording (*P*=.01).

Figure 2. Flowchart of participants. MEDAL: My E-Diary for Activities and Lifestyle.

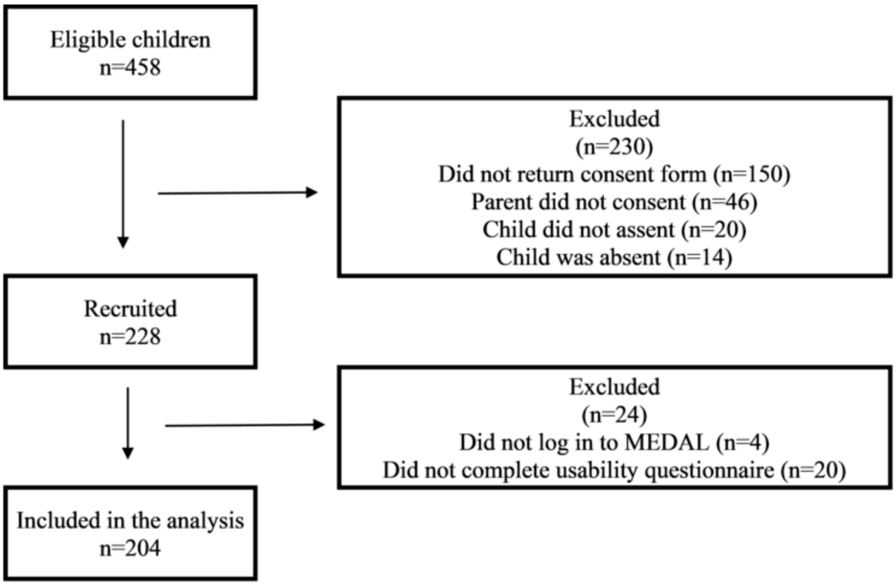


Table 1. Characteristics of participants summarized by sex (N=204).

Characteristics of participants	All (N=204)	Girls (n=86)	Boys (n=118)	*P* value[a]
School, n (%)				.07
School A	141 (69.1)	53 (61.6)	88 (74.6)	
School B	63 (30.9)	33 (38.4)	30 (25.4)	
Age (years), median (25th-75th percentile)	10.9 (10.6-11.2)	11.0 (10.8-11.2)	10.9 (10.6-11.1)	.03
Weight status, n (%)				.41
Underweight	25 (12.4)	12 (14)	13 (11.3)	
Normal weight	145 (72.1)	64 (74.4)	81 (70.4)	
Overweight	31 (15.4)	10 (11.6)	21 (18.3)	
Access to the internet and computer at home, n (%)				.99
Yes	170 (89.5)	73 (90.1)	97 (89)	
No	20 (10.5)	8 (9.9)	12 (11)	
Days completed, n (%)				.01
<1 day	45 (22.1)	12 (14)	33 (28)	
1-2 days	41 (20.1)	13 (15.1)	28 (23.7)	
3-4 days	118 (57.8)	61 (70.9)	57 (48.3)	
Average time taken to complete in minutes per day, median (25th-75th percentile)	14.2 (10.4-19.0)	15.0 (11.1-20.3)	13.1 (10.1-17.6)	.03

[a] *P* values were assessed by the Fisher exact test (categorical) and Wilcoxon Mann-Whitney test (continuous). There were missing data for weight status (n=3) and access to the computer and internet at home (n=14).

Usability of MEDAL

When assessing the usability of MEDAL, the majority (193/203, 95.1%) of participants agreed that instructions were clear, that MEDAL was easy to use (173/203, 85.2%), that they (172/202, 85.1%) liked the application, and that they preferred recording their activities on the web than on paper (167/202, 82.7%; Table 2). Recording for 4 days and ability to recall events were reported to be the least desirable among other factors (146/203, 71.9% and 154/203, 75.9%, respectively). Overall, the percentage agreement for the 10 questions ranged from 71.9% (146/203) to 95.1% (193/203).

Table 2. My E-Diary for Activities and Lifestyle (MEDAL) usability responses according to boys and girls.

Survey questions	Agree, n (%)[a]			*P* value[b]
	All (n=204)	Girls (n=86)	Boys (n=118)	
1. I understood the instructions for MEDAL[c] clearly	193 (95.1)	83 (96.5)	110 (94)	.52
2. It was easy to use and I do not require further instructions	173 (85.2)	76 (89.4)	97 (82.2)	.17
3. Earning tools to grow my plant makes me want to continue the game	159 (78.7)	75 (88.2)	84 (71.8)	.005
4. I was able to remember all the activities I did	154 (75.9)	70 (82.3)	84 (71.2)	.07
5. I was able to remember all the food and drinks I had	165 (81.2)	75 (87.2)	90 (76.9)	.07
6. The time I took to complete one day's entry was just right	149 (75.6)	71 (83.5)	78 (69.6)	.03
7. Recording for 4 days was just right	146 (71.9)	66 (77.7)	80 (67.8)	.15
8. I prefer recording my activities online than using paper	167 (82.7)	73 (85.9)	94 (80.3)	.35
9. I would play the game again	162 (79.8)	73 (85.9)	89 (75.4)	.08
10. Overall, I liked the game	172 (85.1)	76 (89.4)	96 (82.1)	.17

[a] Values shown are the sums of "Strongly agree" and "Agree."

[b] *P* values were assessed by Cochran-Mantel-Haenszel test. There were missing data for question 1 (n=1), question 2 (n=1), question 3 (n=2), question 4 (n=1), question 5 (n=1), question 6 (n=7), question 7 (n=1), question 8 (n=2), question 9 (n=1), question 10 (n=2).

[c] MEDAL: My E-Diary for Activities and Lifestyle.

Compared with boys, girls were more motivated by the gamification to complete recording on MEDAL (75/85, 88.2% vs 84/117, 71.8%; *P*=.005) and agreed that the time spent on completing 1-day entry was appropriate (71/85, 83.5% vs 78/112, 69.6%; *P*=.03; Table 2). Compared with boys, a higher proportion of girls reported being able to recall all the activities they did (84/118, 71.2% vs 70/85, 82.3%; *P*=.07) and food and drinks they consumed (90/117, 76.9% vs 75/86, 87.2%; *P*=.07).

Open-ended Suggestions

A total of 23 participants provided open-ended suggestions. Participants (n=8) who recorded MEDAL for ≤2 days preferred recording on paper rather than on the web (Textbox 1). It was also reported that there was insufficient time to complete MEDAL. For participants (n=15) who completed 3 or 4 days of recording, there were suggestions to include more food and activity options and to have the ability to edit timings of activities (n=3 girls). Participants also proposed to allow recording on MEDAL for more than 4 days (n=3 boys) and modifying the game design, such as inclusion of more avatars and games and wanting a reward that is different from a plant.

Textbox 1. Suggestions provided by 23 participants.

Participants Who Recorded for ≤2 Days (n=8)

- Prefer recording on paper rather than on the web
  - “We could use paper to do rather than online” [Girl]
  - “I do not want the activity online but in paper” [Boy]
  - “To use paper than online is easy. I don’t know” [Boy]
- Insufficient time to complete MEDAL
  - “This program is very interesting but a bit troublesome as I don’t have much time to finish the online diary” [Girl]
- Include more options
  - “More options. Like more activities.” [Boy]
  - “Study in school” [Boy]

Participants Who Recorded for 3-4 Days (n=15)

- Include more options
  - “Include more options for us to choose” [Girl]
  - “Have more food options” [Boy]
  - “Sometimes we just do nothing, so please add a button saying ‘nothing’” [Boy]
- Ability to edit timing of activity
  - “Delete stuff [cause (sic) I accidentally write what time I sleep wrongly but could not change]” [Girl]
  - “During the game, when putting in the timing slots, when I put some numbers in wrong it is impossible to change” [Girl]
  - “For example, if you forgot what you did but you suddenly remembered you can change what you wrote” [Girl]
- Allow recording on MEDAL for more than 4 days
  - “I would ask them if they wanted to do more” [Boy]
  - “Make the days longer” [Boy]
  - “The ability to do the entries for the days even further behind” [Boy]
- Modifying the game design
  - “Put more characters!” [Girl]
  - “I would change the reward given.” [Girl]
  - “...to do more and they could get another plant” [Boy]
  - “More games” [Boy]
- Allow recording of sleep past midnight
  - “Make time for 12 am when I sleep” [Boy]

Discussion

Principal Findings

In this study, we described the development and evaluated the usability of MEDAL—a 4-day web-based time-use application to assess diet and movement behavior in schoolchildren in Singapore. Approximately 60% (118/204) of the participants completed more than 3 days of recording, whereas the rest recorded for 2 days or less. The majority of the participants reported having a positive experience using MEDAL. Compared with boys, girls were reported to be more motivated by gamification, had better reported recall ability, and agreed that the time spent on completing 1-day entry was appropriate.

During the development process of MEDAL, we observed that the completion rate of MEDAL was significantly lower in younger children (aged 8-9 years) than in older children (aged 11-12 years). Younger children aged <9 years may need more assistance to complete MEDAL independently; thus, MEDAL is more suitable for children aged ≥10 years.

Response rates for multiday diaries have generally been an issue among children [46]. It is perceived as tedious to report for ≥2 days, especially when activity patterns were more or less similar on school days. Respondents may also report fewer activities on subsequent days as a means of decreasing the level of burden [47]. Indeed, in our study, we found similar issues with response rates, such that only 57.8% (118/204) of the participants completed 3-4 days of recording. Recording for 4 days was also the least satisfactory component reported in the usability assessment. To strike a balance between the reliability of data and minimizing respondent burden, the collection of 2 diary days for a large study (ie, 1 weekday and 1 weekend day) or 3 days for smaller-scale investigations (ie, 1 day from Monday to Thursday, Friday, and 1 weekend day) has been deemed adequate to obtain representative time-use data in children [14,46]. Large sample sizes may level out individual behavioral misclassifications that result from the short assessment period and would consequently give accurate population-level estimates [48]. For the next version of MEDAL, we plan to provide the flexibility to record between 1 and 7 days and optimize the application for mobile devices on both Android and iOS platforms to cater to the needs of different projects, and users can access the website on the go.

We observed that participants who recorded for <2 days were less likely to have access to a computer and the internet at home (*P*=.02, results not shown), and qualitative data showed that they preferred recording on paper rather than on the web. Participants (20/190,10.5%) with no access to the computer and internet at home may be less tech-savvy, thus exhibiting lower usability performance [16] and greater preference for print than digital. In the next version of MEDAL, we plan to integrate a frequently asked questions section to assist participants, especially those with lower computer knowledge and skills, to troubleshoot their problems and enable them to navigate the site with ease.

Existing studies have shown that recall ability is a common difficulty reported by children [14,16], although girls tend to outperform boys in episodic memory tasks (eg, everyday events) [49]. This is in line with our findings, where we observed trends toward greater reported recall ability in girls than in boys. Participants suggested including more food and drink and activity options and pictures (eg, household chores and shopping). This feedback will be incorporated into the next version of MEDAL, as images will be useful to serve as visual memory prompts to enhance recall in children.

Studies have shown that boys have lower attentional performance and poorer inhibitory control but perform faster than girls [50]. Consistent with these findings, we found that girls spent more time completing MEDAL (median 15 min per day vs 13 min per day), but they were more agreeable to the time spent on MEDAL compared with boys. Generally, the actual average time spent on MEDAL was comparable with similar questionnaires completed by children [15,16], which is sufficiently short to hold the users' attention [20,51].

With regard to gamification, existing studies did not include this element [14-17]. In our study, girls appeared to be more motivated by the virtual gardening game to complete MEDAL recording than boys. Some boys have suggested integrating more games and that they wish to do more so that they can receive more rewards. Introducing more games may distract users and steer them away from recording their daily activities attentively [52]. However, as most of the participants reported a positive evaluation for the in-built game, we plan to revise and accelerate the game progression rewards in the next version of MEDAL so that users are able to receive rewards more frequently. Users will be rewarded with gardening tools as they record their activities, and a mystery fruit will be revealed after each completed day of recording. On the basis of the feedback from the participants, we will also include more avatars and backgrounds for users to choose and personalize in the next version of MEDAL.

Strengths and Limitations

MEDAL is a novel and engaging application for schoolchildren aged ≥10 years. It includes a range of Asian food options that cater to the key ethnic groups in Asia and captures data on food portions, which allow us to have a detailed assessment of energy and nutrient intakes. This is useful, as evidence suggests that portion sizes among children are increasingly poorly regulated [53]. In addition to assessing dietary intake and movement behaviors, MEDAL also examines the location of activities and tasks performed concurrently to allow a better understanding of the context of the activities and enable interventions to be more targeted. The usability evaluation of MEDAL, including user testing during the development phase, involves several methodological strategies (eg, direct observation, interview, Likert scale questions, and open-ended feedback), which allowed us to obtain rigorous and detailed qualitative and quantitative data.

However, there are some limitations to this study. First, we did not have information on children's academic ability. However, our usability questionnaire showed that 95.1% (193/203) of the participants understood the instructions on MEDAL, which was not unexpected, considering that English is the main language of instruction in Singapore and primary education is compulsory.

However, we recognize that the cognitive abilities to recall events, capability to concentrate, and comprehension of questions may have an impact on usability testing [16] and acknowledge that children with poorer cognitive ability may experience some challenges in using MEDAL. Currently, users are only able to edit types of activities but not the timing of the activities. In addition, the current application prevents users from recording beyond 12 midnight. As late bedtimes have become pervasive in children [54], the ability to record activities beyond 12 midnight, along with the function to modify timing, will be made available in the next version of MEDAL. In addition, to cater to both observational and interventional study designs, we plan to incorporate the flexibility to hide the lifestyle report so that it will not induce behavioral change in participants of observational studies.

Conclusions

In conclusion, we developed MEDAL, which appears to be a feasible web-based time-use application for children aged 10-12 years and potentially useful for children above this age group. We observed some gender differences in usability performance, but the majority of the participants had a positive experience using MEDAL. The validity and reliability of MEDAL will be examined next, and the results of this study will be used to inform the next version of MEDAL to customize MEDAL for children in other parts of Asia, which includes translation to their native language and adaptation of application content to their local context.

Acknowledgments

The authors would like to thank the principals, teachers, and children from both primary schools for their participation and contribution to this study. The authors would also like to thank the Ministry of Education, Singapore, for their help in the recruitment of schools for this study. This study was supported by the National University Health System Summit Research Program Partnerships-Office of Deputy President Research and Technology; Saw Swee Hock School of Public Health; and Yong Loo Lin School of Medicine, National University of Singapore. Additional funding was provided by the corresponding authors' National University of Singapore start-up grant. The funders had no role in the design of the study; collection, analysis, and interpretation of data; or writing the manuscript.

Authors' Contributions

MFFC, FMR, SMS, and LPS conceived and designed the study. ARC and SYXT designed and developed MEDAL with inputs from PN, FMR (content related to movement behaviors), CL, SMS (content related to location), MJC, MTC, JYT, and MFFC (content related to diet). SYXT, MNJSC, and ARC collected the data with assistance from MJC, MTC, and JYT. MNJSC and ARC performed statistical analyses. ARC drafted the manuscript with inputs from MFFC, FMR, SMS, SYXT, JYT, PN, and CL. All authors read and approved the final manuscript.

Abstract

Background: Improving clinical reasoning skills—the thought processes used by clinicians to formulate appropriate questions and diagnoses—is essential for reducing missed diagnostic opportunities. The electronic Clinical Reasoning Educational Simulation Tool (eCREST) was developed to improve the clinical reasoning of future physicians. A feasibility trial demonstrated acceptability and potential impacts; however, the processes by which students gathered data were unknown.

Objective: This study aims to identify the data gathering patterns of final year medical students while using eCREST and how eCREST influences the patterns.

Methods: A mixed methods design was used. A trial of eCREST across 3 UK medical schools (N=148) measured the potential effects of eCREST on data gathering. A qualitative think-aloud and semistructured interview study with 16 medical students from one medical school identified 3 data gathering strategies: Thorough, Focused, and Succinct. Some had no strategy. Reanalysis of the trial data identified the prevalence of data gathering patterns and compared patterns between the intervention and control groups. Patterns were identified based on 2 variables that were measured in a patient case 1 month after the intervention: the proportion of Essential information students identified and the proportion of irrelevant information gathered (Relevant). Those who scored in the top 3 quartiles for Essential but in the lowest quartile for Relevant displayed a Thorough pattern. Those who scored in the top 3 quartiles for Relevant but in the lowest quartile for Essential displayed a Succinct pattern. Those who scored in the top 3 quartiles on both variables displayed a Focused pattern. Those whose scores were in the lowest quartile on both variables displayed a Nonspecific pattern.

Results: The trial results indicated that students in the intervention group were more thorough than those in the control groups when gathering data. The qualitative data identified data gathering strategies and the mechanisms by which eCREST influenced data gathering. Students reported that eCREST promoted thoroughness by prompting them to continuously reflect and allowing them to practice managing uncertainty. However, some found eCREST to be less useful, and they randomly gathered information. Reanalysis of the trial data revealed that the intervention group was significantly more likely to display a Thorough data gathering pattern than controls (21/78, 27% vs 6/70, 9%) and less likely to display a Succinct pattern (13/78, 17% vs 20/70, 29%; χ^2_3=9.9; *P*=.02). Other patterns were similar across groups.

Conclusions: Qualitative data suggested that students applied a range of data gathering strategies while using eCREST and that eCREST encouraged thoroughness by continuously prompting the students to reflect and manage their uncertainty. Trial data suggested that eCREST led students to demonstrate more Thorough data gathering patterns. Virtual patients that encourage thoroughness could help future physicians avoid missed diagnostic opportunities and enhance the delivery of clinical reasoning teaching.

Introduction

Background

Clinical reasoning skills are defined as the thought processes used by clinicians to formulate appropriate questions and diagnoses and, therefore, are critical to providing quality health care [1,2]. Poor clinical reasoning skills have been associated with missed diagnostic opportunities and poor patient outcomes [3-6]. To address the need to improve clinical reasoning skills, there has been a call for more explicit teaching of clinical reasoning skills in undergraduate medical education [7,8]. However, the optimal method of teaching clinical reasoning skills is not well understood because of the complexity of the skills and how they vary depending on context, knowledge, and experience [1,2]. Traditional methods of teaching clinical reasoning skills, such as clinical placements, place a considerable burden on faculty time and resources. Furthermore, growing numbers of students can result in fewer opportunities for exposure to a variety of clinical cases [9-11].

The use of digital teaching methods has been recommended to address gaps in clinical reasoning skills teaching and complement traditional face-to-face methods [8,12-15]. Virtual patients, a specific type of computer program that simulates clinical scenarios, has been recommended as an effective method [9,16,17]. Virtual patients allow students to be exposed to a large number of varied patient cases, which can help them develop their knowledge and create more complex mental representations of illnesses [18,19]. Learning through experience, reflection, and deliberate practice can also help students to develop and retain their skills [12,20,21]. Virtual patients are also becoming increasingly similar to clinical practice, as more consultations are being undertaken on the internet [22-25].

The Electronic Clinical Reasoning Educational Simulation Tool

To address the need for more structured clinical reasoning training using digital methods, electronic Clinical Reasoning Educational Simulation Tool (eCREST) was developed by the authors and web designers, Silver District [26], and is reported in detail elsewhere [27]. eCREST sought to influence 3 cognitive biases that have been found to influence clinical reasoning: the unpacking principle, confirmation bias, and anchoring [28-30]. The unpacking principle is the tendency to not elicit the necessary information to make an informed diagnosis. Confirmation bias is the tendency to seek information only to confirm a diagnosis. Anchoring is the tendency to stick to an initial diagnosis despite contradictory information [31]. To address these biases, eCREST was primarily focused on improving data gathering skills and flexibility in thinking about diagnoses rather than all clinical reasoning skills. In eCREST, students were presented with 3 videos of virtual patient cases. These patients presented to primary care with nonspecific respiratory symptoms, such as cough, which could be indicative of serious conditions such as lung cancer. The students were required to ask the patient questions from a list, received a video response, and formulated diagnoses and a management plan. To address potential biases, reflection was prompted at regular intervals throughout the case by asking students to revise their diagnoses, and they received feedback at the end of each case [32].

A trial evaluated eCREST in 3 UK medical schools to test feasibility and acceptability and is described in detail elsewhere [33]. This trial found that eCREST appeared to influence students' data gathering but had less impact on flexibility in thinking about diagnoses. Students in the intervention group appeared to show a more thorough data gathering pattern than controls, as they did not miss important information, but there was suggestive evidence (not statistically significant at 5%) that they may ask more irrelevant questions than controls. However, the quantitative data from the trial provided little further insight into how students gathered information while using eCREST and other data gathering patterns. In addition, little is known about how students gather information from previous clinical reasoning studies, as paper vignettes were used that did not require students to gather information [34,35]. A greater understanding of how students gather data when using virtual patients in real time will inform educators about how they can best support students in developing these skills. It could also help developers to design virtual patients that provide better training on data gathering skills. Therefore, this study aims to:

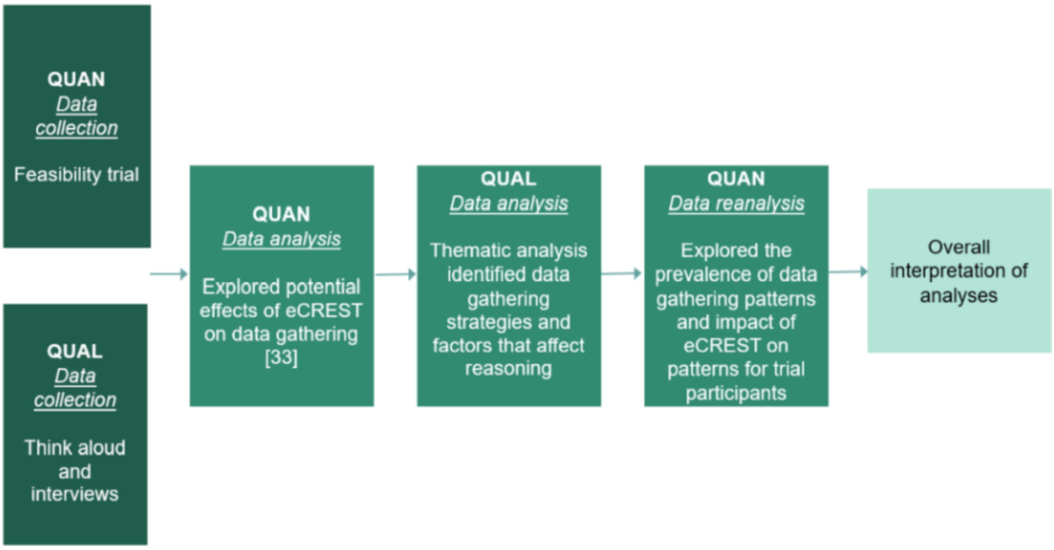
1. Understand how medical students gather information and reach diagnostic judgments when interacting with virtual patients.
2. Identify students' data gathering patterns while using virtual patients.
3. Examine whether eCREST changes the data gathering patterns of students.

Methods

Design

This study used a mixed methods design, as shown in Figure 1 [36-38]. The quantitative method was of equal priority to the qualitative method, and data collection was carried out concurrently and analyzed sequentially. Initially, a trial of eCREST was conducted to explore its potential effects on data gathering. The results of the trial's feasibility and effects on data gathering are reported elsewhere [33]. The methodological details of this study are also summarized in the sections below. During the trial, think-aloud protocols captured students' reasoning during eCREST and their reflections on the task. Following the initial analysis of trial data, qualitative data were thematically analyzed and distinct planned strategies of gathering data and factors that affect these strategies were identified (aim 1). This led to a reanalysis of the trial data to identify the prevalence of different data gathering patterns or behaviors among trial participants (aim 2). Finally, an exploratory analysis was undertaken to examine the effects of eCREST on data gathering patterns (aim 3).

Figure 1. Process of the mixed methods approach. QUAL: qualitative; QUAN: quantitative.



Setting

The trial took place at 3 UK medical schools, with full details reported elsewhere [33]. The concurrent qualitative study took place at one of the UK medical schools participating in the trial, with students who were not part of the trial. Ethical permission for the qualitative study was granted by the University College London (Ref. 9605/001; September 08, 2017).

Participants

For the trial, 18.16% (264/1454 of all eligible) final year medical students were recruited and randomly assigned to an intervention or control group. A total of 148 students (78 in the intervention group and 70 in the control group) remained in the trial after 1 month [33]. For the qualitative study, 16 final year medical students were recruited through a peer-assisted learning scheme, where the students opted to undertake a project in medical education, via newsletters and snowball sampling. All students were informed that their data would be anonymized and that their participation was voluntary, and they provided written consent. They were incentivized to participate with a voucher.

Procedure

Quantitative Data Collection and Initial Analysis

In the trial, the intervention group received 3 patient cases via eCREST that they had 1 week to complete while receiving teaching as usual. The control group received teaching as usual without access to eCREST until the end of the trial. Clinical reasoning skills outcomes were compared between the groups after 1 month through an additional eCREST patient case. Multimedia Appendix 1 shows a flowchart of the trial. The results indicated that eCREST may encourage more thorough data gathering patterns [33].

Qualitative Data Collection and Analysis

We used a think-aloud study design followed by semistructured interviews [39,40]. The think-aloud tasks involved observing students verbalizing their thoughts in real time while completing one patient case in eCREST. This method can provide insights into the clinical reasoning of medical students, as it provides access to their conscious thought processes [13,39,41,42]. A practice think-aloud task was given before the main task to ensure that students were comfortable with the process. Nondirective prompts, such as *keep talking*, were used if students were silent for a significant amount of time. Semistructured interviews were conducted after the think-aloud task to gather students’ retrospective thoughts [39,40]. A topic guide was developed for the interview and piloted with 2 medical students. Each session took approximately 1.5 hours per student.

All 16 think-aloud tasks and semistructured interviews were transcribed and imported into NVivo Version 12 (QSR International) software [43]. We used thematic analysis following the approach of Braun et al [44] and extended upon by Swain [45]. First, we developed deductive codes based on our research aims and initial findings from the trial data. We then familiarized ourselves with the data and developed inductive codes. A codebook was generated by one researcher (RP). To ensure the validity of the coding framework, 3 additional researchers (MK, APK, and JT) used the coding framework to guide their coding of a transcript and generated their own additional codes. We grouped similar codes into themes. Themes were validated in meetings with a wider research team where discrepancies were discussed, and a consensus was reached. Data were analyzed iteratively until the themes reached saturation. The results relating to how students gathered data (aim 1) informed the identification of students’ data gathering patterns in the larger quantitative data set obtained from the trial.

Reanalysis of Quantitative Data

Informed by the qualitative findings, we used data from the trial to estimate the prevalence of 3 data gathering patterns (aim 2) and to understand if eCREST may have changed these patterns (aim 3). Student data on an eCREST patient case completed by both interventions and controls 1 month after registration were used to assess clinical reasoning. As described in the trial paper, we constructed variables from these data to capture elements of clinical reasoning skills, such as data gathering ability and flexibility in thinking [33]. In this study, we focused only on the variables related to data gathering skills, as these were found to significantly differ between groups in the trial and the focus of this research was on data gathering skills. We assessed *essential information identified* (Essential) by measuring the proportion of essential questions they asked the patient and patient examinations undertaken, out of all possible essential examinations and questions identified by experts. This measure captured how complete data gathering was irrespective of whether irrelevant questions were also asked. The *relevance of history taking* (Relevant) was measured by assessing the proportion of all relevant and essential questions they asked the patient and patient examinations undertaken, out of the total number of examinations undertaken and questions asked. This measure was an indicator of the specificity of information gathered. Students could select a total of 70 questions and examinations. Experts defined 29 Essential items as a question or an examination that would change the differential diagnosis of the patient case, allow for differentiation as much as possible between alternative diagnoses, and reveal the key symptoms that might be indicative of sinister diagnoses. A further 10 questions were considered by experts as *relevant*, that is, clinically appropriate to ask but would not reveal key information to derive all important possible diagnoses. The remaining 31 questions were defined as *irrelevant*.

To identify the data gathering patterns displayed by students, the quartiles for the Essential and Relevant variables were calculated. Those who scored in the top 3 quartiles on both variables were classified as having a Focused pattern. Those who scored in the top 3 quartiles for Essential but in the lowest quartile for Relevant were classified as having a Thorough pattern. Those who scored in the top 3 quartiles for Relevant but in the lowest quartile for Essential were classified as having a Succinct pattern. Those whose scores were in the lowest quartile on both variables were labeled Nonspecific. Sensitivity analyses showed that other cutoff values below the lowest quartile had insufficient numbers for each pattern to conduct the chi-square analysis and compare scores between the intervention and control groups. We examined whether the use of different data gathering patterns varied between the intervention and control groups using a chi-square test. Analyses were conducted using STATA Version 15 with $P \leq .05$, considered statistically significant [46].

Results

Sample Characteristics of Qualitative and Quantitative Studies

Table 1 describes the participant characteristics of those in the trial at baseline and the think-aloud study. In the trial, most participants were 23 to 24 years of age (152/264, 57.6%) and were male (142/264, 53.8%). The age and gender of the think-aloud participants were similar: 81% (13/16) were 23 to 24 years old and 56% (9/16) were male.

Table 1. Participant characteristics at baseline in the trial and think-aloud study.

Characteristics	Trial			Think-aloud study
	Intervention group (n=137), n (%)	Control group (n=127), n (%)	*P* value[a]	Whole group (n=16), n (%)
Age (years)				
20-22	4 (2.9)	1 (0.8)	N/A[b]	0 (0)
23-24	73 (53.3)	79 (62.2)	N/A	13 (81)
25-26	39 (28.5)	29 (22.8)	N/A	2 (13)
27-28	11 (8)	10 (7.9)	N/A	1 (6)
>29	10 (7.3)	8 (6.3)	.49	0 (0)
Gender				
Female	64 (46.7)	58 (45.7)	N/A	7 (44)
Male	73 (53.3)	69 (54.3)	.87	9 (56)

[a] Comparisons between the intervention and control groups for the trial were made using chi-square tests. $P<.05$ was considered significant.

[b] N/A: not applicable.

How Students Gathered Information and Reached Diagnoses

From the qualitative think-aloud data, 4 major themes were identified relating to how students gathered information: data gathering strategies, structure of eCREST, diagnostic hypotheses, and confidence and uncertainty.

Theme 1: Data Gathering Strategies

Students had different data gathering goals and strategies for gathering information.

Being Thorough

Some students reported that they aimed to be thorough when gathering data and were aware of the potential pitfalls of the unpacking principle and not gathering all necessary information. Consequently, they asked many questions to reassure themselves that they had not missed any relevant information and symptoms indicative of serious disease. However, they acknowledged that this approach to data gathering could be lengthy and possibly led to them asking irrelevant questions:

> *I should probably go through those but I don't know, I do feel like I like to be thorough and I do want to ask all of the questions.* [P4]
>
> *I think I could be more concise. Cos, I just kind of ask everything just in case.* [P16]

Being Focused

Other students reported that they aimed to be focused when investigating the patient's symptoms and wanted to ensure that all the information they asked for was relevant to the patient case:

> *I don't really want to ask any more of these I mean partly because I feel like...I want to be focused, so I'm not really going to ask the rest of these which are potentially not that related.* [P10]

Being Succinct

Some also described that they aimed to be succinct and limit the number of questions they asked the patient, possibly because the way eCREST was structured or perhaps to be more time efficient. This shows that some students were less aware of the potential negative consequences of the unpacking principle and the importance of gathering all relevant information:

> *Maybe I should have not tried to limit myself to a specific number and asked what I thought was actually appropriate.* [P2]

Random Selection

Some students reported that they were asking questions randomly and had no discernable reasoning behind the way they gathered information. Students may have adopted this seemingly random approach because they were less engaged with patient cases in eCREST:

> *So these questions I guess aren't like very helpful but because they're there I'm going to ask them anyway.* [P11]

Theme 2: Structure of eCREST

The way in which eCREST was structured appeared to be one mechanism by which eCREST influenced how students gathered information. Students perceived eCREST to have both positive and negative effects on how they gathered information.

Organized Data Gathering

Students reported that the structure of eCREST helped them organize the way they gathered information by asking students to chunk their history taking into sections and regularly visualizing their diagnostic hypotheses. This helped them to hone their questions toward their diagnoses and may have helped some students to overcome the unpacking principle to take a more focused approach:

> *I guess it's good because it makes you streamline your thoughts regarding diagnosis after you have limited information available and I think that probably helps time management within GP settings, because it's making you streamline your questions.* [P9]
>
> *I think it was useful even for me to just like, to see when I'm taking the history, I think that...I don't really write down...the top five differential diagnosis when I'm taking history...Yeah, just better at visualizing it, and organizing it.* [P13]

Some appeared more focused in their approach to gathering data, as they thought of their own relevant questions first and then used eCREST as a checklist to confirm that they had not missed anything:

> *It's probably useful to try and think about this before I look at the list.* [P1]

Unrealistic Data Gathering

However, others reported that the list of questions in eCREST led them to ask questions more randomly and less strategically than they would in a real consultation:

> *I think it just biased the way in which I asked the questions. Because I wouldn't have just kind of gone through it and clicked on it as I went through.* [P2]

Some students felt that the lack of open questions in eCREST hindered their ability to gather information and felt open questions would have offered more relevant information in real life:

> *It's quite useful to make you think about the questions but because I don't ask questions in that, I feel like my own style is quite different to the way it's set out here...I'd be quite like open with the patient. I'd be like "tell me more." And then I'd be able, I'd have some better idea, I'd have a better timeline of the things.* [P15]

Theme 3: Diagnostic Hypotheses

The way in which eCREST guided how students generated and reassessed diagnostic hypotheses appeared to be another mechanism by which eCREST influenced how students gathered information.

Early Generation of Diagnostic Hypotheses

Some students found that eCREST helped them to think of diagnoses at an earlier stage than they usually would, which potentially helped them to avoid anchoring on a particular diagnosis early in the consultation and had an impact on the questions they asked:

> *Usually I don't really think about differentials so early on in a consultation...so this encouraged me to rule out different diagnoses from a very early point.* [P12]

Cognitive Biases

Some students became fixated on one or two initial diagnoses (anchoring) and would consequently seek information to confirm the diagnosis and stopped investigating other causes of the symptoms (confirmation bias). This may explain why some students took a more succinct approach to gathering information:

> *[Question: what will you try to improve?] Consider everything the patient has said and I think just not try to make diagnosis fit, like the COPD that I was trying to make her fit.* [P7]

Two students showed awareness of confirmation bias during the task and made a conscious effort to seek other information but consequently may have asked too many irrelevant questions and led to students taking a thorough approach to gathering data:

> *I think I normally like to sort of focus on a system, so do almost a respiratory thing and then move on to cardiac...although I shouldn't get too into confirming about, I'll just ask about any other symptoms.* [P4]
>
> *Often I ask confirmatory questions...and just exclude things that I just know weren't on my differential and so my differential didn't really change.* [P11]

Reflection

A few students reported that they found it useful that eCREST gave them time to pause, think, and reflect on their diagnoses because in clinical practice this is not always possible. The opportunity to reflect may explain why students were able to demonstrate the use of focused data gathering strategies and avoid some cognitive biases in eCREST:

> *It's nice to just click the questions, and then spend five minutes thinking about it. I think when you're actually seeing patients there's emphasis on it being slick.* [P14]

Alternative Diagnoses

There was evidence that eCREST helped students to avoid anchoring and confirmation bias, as most students reported that the prompts in eCREST to reassess diagnoses helped them to consider alternative diagnoses and reflect on the information they were gathering. This may have helped students to take a more focused approach to gathering data:

> *The fact that it makes you reconsider...your diagnosis after asking questions, asking a set number of questions is good practice for reality, when you should be doing that but you probably don't.* [P10]
>
> *It makes you like re-evaluate your ranking of diagnosis because then you actually have think about the questions and why you're asking them in the first place.* [P10]

However, some students demonstrated a random approach to reassessing their diagnoses and reported that the prompts to revise their diagnoses did not always help them to consider alternative diagnoses and stay open minded.

> *I'm just going to put in, arbitrarily, asthma...ischemic heart disease.* [P8]

A few students felt that the process of continually reviewing their diagnoses was too structured and some forgot information they gathered earlier in the case, which may have explained why their data gathering strategy appeared random:

> *It did perhaps make me think in that kind of modular way...each time I only considered the six questions that had been before. And forget about what had happened before that. So, like less of a kind of continuous set of questions and more like, oh, in the last six questions she said she like didn't have a fever.* [P16]

Theme 4: Confidence and Uncertainty

The way in which eCREST influenced students' confidence and level of uncertainty in their clinical decision-making skills appeared to be another potential mechanism by which eCREST influenced how students gathered information.

Creating Uncertainty

Some students reported that the structure of eCREST created some uncertainty, as the lists of diagnoses and questions encouraged them to reconsider diagnoses and think of the reasons behind choosing a diagnosis. This again suggests that the prompts to review diagnoses and reflect might have helped students to avoid anchoring and have a focused approach to gathering information from the patient:

> *I liked that there were all the differentials, you thought you knew but you still, it put that sort of seed of doubt in your mind. So in a sense...even though maybe I wasn't as flawless in terms of safety netting and making sure I didn't miss things, I think it forced you think okay well could it? And...constantly, by making you reconsider your diagnosis it did really make you think harder about each one.* [P4]

Managing Uncertainty

Some students talked about needing more confidence in their decision making to help them manage their uncertainty when gathering information from the patient:

> *Maybe I should just have more confidence in saying that, okay this is what I think and it's still consistent you know.* [P12]

Students also recognized a tension between making confident judgments about the most likely diagnosis and fearing serious consequences for the patient if they missed a more serious diagnosis. This may explain why some students adopted a thorough approach to gathering information and potentially used this approach to manage their uncertainty. There was also evidence from students' reflections that they were starting to manage this uncertainty by taking a more focused approach to gathering data and using safety netting:

> *You can give every investigation and then be sure, but actually realistically when you're trying to think well I can't get every single blood test in the world, this is the initial management...at the moment I feel I have to be quite brave, because you think well what if I do miss something that's terrible? But then I*

> *suppose it's easy to think okay, well what are the absolute terrible things? Make sure that I don't miss those, so for example an x-ray would cover a lot of bases in a sense.* [P4]
>
> *Learning to be comfortable...with a degree of uncertainty is important to GP and several other specialties. I will need to learn from more experience how much safety netting and investigation for other possible differentials is appropriate.* [P3]

Some students felt that eCREST and simulations were a way to practice taking responsibility for decisions and managing their uncertainty. It was suggested that being more engaged with the simulation helped students to adopt more focused or thorough data gathering patterns and avoid the unpacking principle, as it made them feel more responsible for the *patient* and motivated them to not miss any serious conditions:

> *I think every time I do...cases like this, and certainly when I see real patients, like I'm on GP at the moment...I'm going to try and think about it, to approach it as though I was the GP seeing the patient alone, and you're their only point of care...and therefore fully responsible for them. Which forces you to really think carefully about differentials and things not to miss.* [P4]

Some students felt reluctant to make decisions they would not be responsible for in real life and were perhaps less engaged with the simulation and the opportunity to practice managing uncertainty:

> *I would probably review him in the week, oh wait, actually, I don't know. I want to consult with my senior first but it's hard to say. I mean just to be...I mean if, in real life given, if I don't have any senior to talk to and if I don't know whether he has any back pain just to be safe I would probably just refer him, just to be sure, I guess.* [P13]

A few students felt that investigating rare and unlikely diagnoses was unrealistic and were perhaps less engaged with the simulation. This may have led to some students adopting more succinct data gathering approaches that just focused on common illnesses and led them to be more susceptible to cognitive biases:

> *I appreciate that...what they've said about all of their diagnoses but...in real life, what happens is: you make a working diagnosis, and everything else is left behind—you don't continue those, generally. There might be some things you safety net, but by and large, when it's clear cut—as that was—you would almost take that, go with it, do a few things, just to be sure. Where I am—and I know this is a GP situation, but in A&E, if you said, 'Oh, my fifth diagnosis of this patient is "Addison's Disease,"' I think you'd...be laughed out of the department, realistically.* [P1]

Identifying Data Gathering Patterns

The qualitative data showed that students aimed to apply 3 distinct data gathering strategies while using eCREST. It suggested that these strategies may manifest in the quantitative data as different data gathering behaviors and indicated how eCREST might influence them. As described in the *Methods* section, we sought to observe these data gathering patterns in the trial sample by using trial students' scores on the Essential and Relevant variables. Figure 2 summarizes the characteristics of the data gathering patterns. Those who displayed Focused and Thorough patterns tended to elicit the most essential information and take a more complete patient history. However, those who showed Thorough patterns also tended to gather more irrelevant information. Those who displayed a Succinct pattern or a Nonspecific pattern did not elicit enough essential information from the patient and took a less complete history from the patient. However, those who showed Succinct patterns also did not gather much irrelevant information.

Figure 3 shows a scatter plot of the trial students' scores on the Essential and Relevant variables by the trial group and whether their scores fell on or below the lowest quartile for each variable, which determined the data gathering pattern they were identified as displaying. The data show most students displayed Focused patterns, but a significant proportion displayed other patterns and the prevalence appeared to differ by the trial group.

Figure 2. Characteristics of data gathering patterns based on the “Essential” and “Relevant” variables.

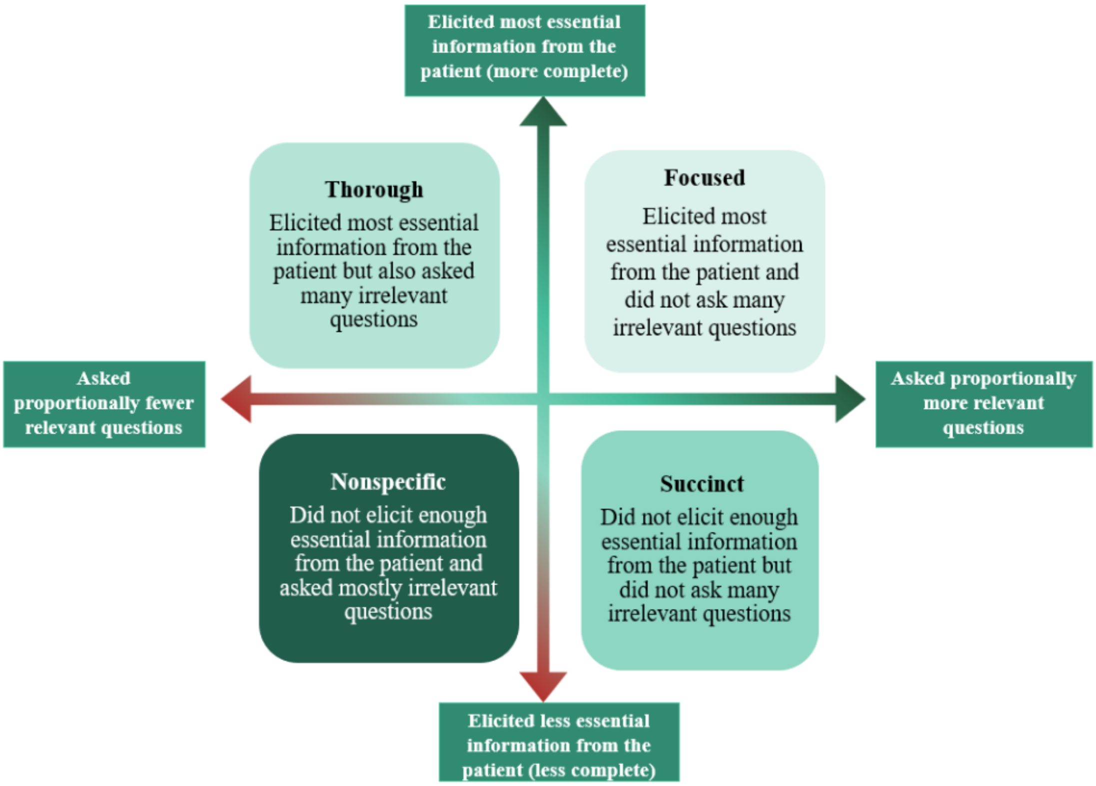


Figure 3. Scatter plot showing students’ scores on the “Essential” and “Relevant” clinical reasoning measure in the trial.

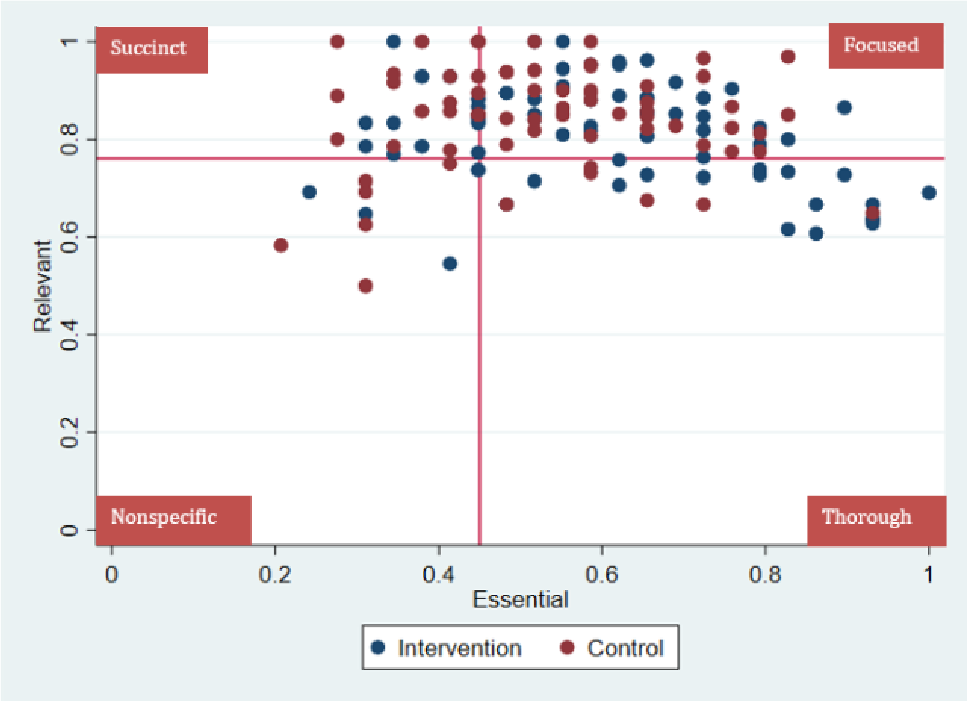

Impact of eCREST on Data Gathering Patterns

In the trial, there was a significant difference between the intervention and control groups in the type of data gathering pattern used (χ^2_3=9.9; *P*=.02; Table 2). Those in the intervention group were much more likely to show a Thorough pattern compared with the control group (21/78, 27% vs 6/70, 9%) but less likely to demonstrate a Succinct pattern (13/78, 17% vs 20/70, 29%). The likelihood of showing Focused or Nonspecific patterns were similar between the intervention and control groups (40/78, 51% vs 38/70, 54% and 4/78, 5% vs 6/70, 9%, respectively).

Table 2. Data gathering patterns observed in the electronic Clinical Reasoning Educational Simulation Tool in the trial data.

Data gathering pattern[a]	Intervention (n=78), n (%)	Control (n=70), n (%)	Total (N=148), n (%)
Thorough	21 (27)	6 (9)	27 (18.2)
Succinct	13 (17)	20 (29)	33 (22.3)
Focused	40 (51)	38 (54)	78 (52.7)
Nonspecific	4 (5)	6 (9)	10 (6.8)

[a] Patterns were significantly associated with the trial group; χ^2_3=9.9, *P*=.02 (as in the main text of the paper).

Discussion

Principal Findings

This study identified a range of data gathering patterns that students applied when generating data from virtual patients. The qualitative data indicated how eCREST can help students to take a more thorough approach, and potentially reduce the impact of cognitive biases, through continuous revision of diagnoses and allowing students to practice managing their uncertainty. Quantitative data from the trial indicated that eCREST influenced students to demonstrate more Thorough data gathering patterns.

This study showed how virtual patients such as eCREST can be used to address the cognitive biases of the unpacking principle, confirmation bias, and anchoring by continuously prompting students to reflect throughout a patient consultation. The qualitative data showed that these prompts encouraged many students to investigate patients more thoroughly and re-evaluate their diagnoses. This may have helped them to overcome the potentially negative consequences of these biases, such as missing serious diagnoses [32,47]. The trial data also indicated that students who had used eCREST before exhibited more Thorough data gathering patterns than controls, which may have helped them to address these biases [33]. We have no empirical data to suggest that any data gathering pattern is better than another and in which clinical circumstances they might be most appropriate. In clinical practice, a more Focused approach where most of the important information is gathered without gathering too much irrelevant information may be ideal, particularly given time constraints in real consultations. Policy and clinical guidelines in the United Kingdom and elsewhere are increasingly recommending more focused and thorough investigations of patients to avoid missing red flag symptoms, particularly in primary care for serious conditions such as cancer [8,25]. Thus, the data gathering pattern that eCREST is encouraging is in line with recommendations from health policy and may be particularly appropriate for the investigation of conditions such as cancer.

A unique contribution of this study is the use of a mixed methods approach. The qualitative data showed distinct data gathering strategies that students aimed to undertake and how eCREST influenced how they gathered information. We gained insight into students' rationales for their data gathering strategies. Those who reported wanting to be Thorough explained that they used this strategy to avoid missing key information about a serious diagnosis and because they felt uncertain about the case. The students who reported wanting to be more focused verbalized the importance of asking only relevant questions. Those who aimed to be more succinct reported wanting to limit the information they gathered. This was perhaps because in real consultations, students would only have limited time with a patient, but this may have led them to be susceptible to biases and miss symptoms indicative of a serious disease. We also found that some students were less engaged with eCREST and randomly clicked on questions and made decisions. Further research is needed to understand which students might not benefit from clinical reasoning teaching delivered via virtual patients and how it can be further adapted to students' needs.

Similar to previous literature on clinical reasoning, we identified a central theme for managing uncertainty [48,49]. The qualitative data showed how eCREST created uncertainty by prompting students to reconsider diagnoses. It also offered students an opportunity to practice managing their uncertainty by conducting thorough investigations and safety netting for the worst-case scenarios [48]. Therefore, eCREST may have helped to calibrate students' confidence. Previous studies have shown that there is little correlation between confidence and diagnostic accuracy in students or physicians and that overconfidence increases with more difficult cases [49-51]. Given that the cases in eCREST were relatively complex for students, it is perhaps a positive result that many students reported uncertainty and a lack of confidence while making diagnostic decisions in eCREST, suggesting that it might help reduce overconfidence in difficult cases.

This study also showed the potential impact of virtual patients, such as eCREST, on medical education. Given the increasingly limited exposure to real patients, virtual patients can provide students with some form of clinical experience [9]. They also provide an opportunity for educators to observe in real time students' data gathering strategies and patterns of behavior and inform the formative assessment of students' clinical reasoning skills. Previous research in education has used inventories to identify students' approaches to studying, such as the Approaches and Study Skills Inventory for Students [52-55]. Approaches and Study Skills Inventory for Students helps educators and students to identify general patterns on how students approach learning in certain circumstances and allows educators or computer programs to offer advice on other approaches that could be used. Similarly, educators could use data from eCREST in a reflective way and as a basis to provide feedback on data gathering patterns that might help students to improve their reasoning [21].

Limitations

Our study was limited to medical students, but we are undertaking further research with a range of health care professionals and students to understand how eCREST can be used more widely in clinical education. Students volunteered to take part in the trial and think-aloud study; therefore, this sample might have been different from those who did not volunteer, leading to possible selection bias. In addition, in the think-aloud study, students varied in their ability to verbalize their thoughts and the sample was not representative; therefore, it is likely that not all patterns and rationales for investigations were identified [56,57]. In common with all think-aloud and interview study designs, participants were observed and prompted to speak; therefore, students may have attuned their responses because of social desirability, and they were more reflective than they would have been if unprompted or unobserved [56,57].

Conclusions

This study found that students displayed a variety of data gathering patterns while using virtual patients. Data from the trial indicated that virtual patients such as eCREST might influence students to be more thorough in their data gathering. The think-aloud interviews suggested the mechanisms by which eCREST influenced students included helping them to continuously reflect on their diagnoses and manage uncertainty. These findings suggest that virtual patients, which increase the thoroughness of data gathering, could help future physicians to reduce missed diagnostic opportunities during future consultations. Virtual patients could also provide medical educators with a more accessible way of observing and identifying students' data gathering patterns, which may enable them to provide more tailored feedback on reasoning. Further research is needed to understand how data gathering patterns relate to existing clinical and pedagogical practices and vary across clinical contexts.

Abstract

Background: With the rapid development of information technology and web-based communities, a growing number of patients choose to consult physicians in online health communities (OHCs) for information and treatment. Although extant research has primarily discussed factors that influence the consulting choices of OHC patients, there is still a lack of research on the effects of log-in behaviors and web reviews on patient consultation.

Objective: This study aims to explore the impact of physicians' log-in behavior and web reviews on patient consultation.

Methods: We conducted a longitudinal study to examine the effects of physicians' log-in behaviors and web reviews on patient consultation by analyzing short-panel data from 911 physicians over five periods in a Chinese OHC.

Results: The results showed that the physician's log-in behavior had a positive effect on patient consultation. The maximum number of days with no log-ins for a physician should be 20. The two web signals (log-in behavior and web reviews) had no complementary relationship. Moreover, the offline signal (ie, offline status) has different moderating effects on the two web signals, positively moderating the relationship between web reviews and patient consultation.

Conclusions: Our study contributes to the eHealth literature and advances the understanding of physicians' web-based behaviors. This study also provides practical implications, showing that physicians' log-in behavior alone can affect patient consultation rather than complementing web reviews.

Introduction

Background

With the development of Health 2.0 technologies, the number of people using the internet to meet their health-related needs is increasing [1]. Online health communities (OHCs) have become prevalent in recent years, and research has focused on two of them: web-based physician-patient communities and web-based patient communities. A web-based physician-patient community is a platform that connects physicians with patients where patients can consult physicians on health issues and disease treatments anytime and anywhere. The object of this study is this kind of OHC, namely, the web-based physician-patient community.

Unlike other types of services, health care services have several characteristics. First, the disease of each patient is unique [2]. Second, life and death matter [3]. Third, serious information asymmetry exists between physicians and patients [4]. The choice of an appropriate physician has always been the focus of research in the health care field. The emergence of OHCs has effectively alleviated the problem of information asymmetry between physicians and patients. Unlike traditional health care services, OHCs give patients the opportunity to review the abundant amount of information about various physicians and then use this information to choose the physician whom they want to consult [5]. Although numerous studies have explored the factors that influence patients' choices of consulting [5-14], they are not the only ones; thus, more research is needed.

As health care service providers, physicians' web behaviors, such as knowledge-sharing behaviors [9], interactions with patients [5,6], and written and telephone consultations [13], provide important information when patients make consulting choices. However, for physicians, the premise of providing web-based health care services and conducting these behaviors involves logging into their accounts of the OHC. As physicians work full time in hospitals or clinics [14], they can only use off-duty hours to provide web-based services [15], which suggests that there are different log-in patterns in OHCs. Web-based behaviors reflect the degree of the physician's activeness and effort, as well as the quality of the service process [5,6,14,16]. In addition, as one kind of information generated by patients who have experienced health care services, web reviews can reflect the service outcome [14,16] and influence patients to make consulting choices [8-10]. The assessment of service quality should focus on both the outcome and delivery process they receive [17]. Log-in behavior and web reviews were evaluated in this study. Therefore, whether log-in behavior is related to patient consultation and its relationship with web reviews is worth studying.

As a web-based health platform may provide multiple signaling mechanisms simultaneously [18], there are multiple signals that influence patient consultation. This study focuses on both web-based and offline signals. According to the signaling theory [19], which indicates how the information receiver interprets signals along with information from the sender, log-in behaviors and web reviews can be considered as two web signals provided by a physician to assist patients in making consulting choices [6,11,20]. In addition, considering that people live in a mixed environment comprising web-based and offline worlds, the status of a physician's offline world (ie, offline status) as an offline signal may affect the relationship between web signals and patient consultation.

The objective of this study is to investigate how a physician's log-in behavior and web reviews affect patients' choices for consultation using data from a Chinese OHC. The main research questions are as follows:

1. How does a physician's log-in behavior affect patient consultation in OHCs?
2. How does a physician's log-in behavior and web reviews complement each other in affecting patient consultation?
3. How does the offline status of physicians moderate the effects of web signals (ie, log-in behavior and web reviews) on patient consultation?

To answer these three research questions, we collected data from 911 physicians over five periods and proposed a research model based on the signaling theory.

Related Research

With the development of information technologies, many physicians and patients are using OHCs. An OHC is a web-based community that presents a medical ecosystem, including patients and physicians, and is a core communication platform wherein patients can obtain physicians' web-based services, knowledge about diseases, and emotional support [20,21]. As health care service characteristics [2-4], the patient's choice of an appropriate physician for health care consultation has been the focus of research in the health care field. Table 1 summarizes the studies on patient consultation with OHCs. Although there are many factors that influence patients' choices of consulting [5-14], not all of them have been studied. More research is needed to better understand how information affects patient consultation in OHCs.

Table 1. Studies of patient consultation in online health communities.

Wu and Lu [13]	N/A	Written consultation, telephone consultation, and doctor reputation
Yang et al [14]	Signaling theory	System-generated information and patient-generated information

[a] ELM: elaboration likelihood model.

[b] N/A: not applicable.

An OHC is a web-based platform wherein physicians can provide more types of health care services than offline hospitals or clinics [22], such as network consultation, phone consultation, and appointment registration. Furthermore, physicians can update their personal information, publish articles, respond to consultations, and manage patients. In the literature, many scholars have investigated physicians' web-based behaviors, such as knowledge-sharing behaviors [9,23,24], interactions with patients [5,6], written and telephone consultations [13], and contribution behaviors [25-27].

Although several web-based behaviors of physicians have been studied, not all of them have been evaluated. Log-in behavior is a web-based behavior of physicians that involves launching profile home pages in health websites and logging into their accounts. Log-in behavior is the first step for physicians to participate in OHCs and conduct other web-based behaviors. Many physicians offer services in both OHCs and hospitals or clinics. Owing to the heavy workload at hospitals or clinics (offline services), they can only use their spare time to provide patients with web-based services [15]. Thus, physicians have unique log-in behaviors. Previous research has shown that information about physicians' web-based behaviors is an important factor influencing patients' consultation choices [5,6,13]. However, less attention has been paid to log-in behaviors in OHCs. Therefore, the aim of this study is to explore physicians' log-in behaviors and their roles in OHC consulting choices.

Research Model and Hypotheses

Signaling Theory

The signaling theory is used to describe the behaviors of two parties (individuals or organizations) when accessing different information and has been applied in studies of investment decisions, entrepreneur-investor relationships [4], and web-based social trading [28]. The primary parties in the signaling theory include signalers and receivers as well as the signal itself. A signaler sends signals to the receiver to reflect quality [19]. The receiver evaluates the quality of the signaler and acts. As the two parties hold different amounts and levels of information, significant information asymmetry exists between the signalers and receivers [29]. Hence, the signal conveyed by signalers affects the degree of information asymmetry and can affect the receivers' behaviors.

Parties in OHCs include physicians and patients. Patients are at a disadvantage, as they must rely on physicians to provide health care services [30]. Physicians, as signalers, can provide information (eg, titles, workplaces, web-based behaviors, or reviews) to receivers (patients) [11], which can help patients choose physicians to serve their needs. Referring to past studies [11,14], this study used the signaling theory to explain the effects of log-in behavior and web reviews on patient consultation choices.

Log-in Behavior and Web Reviews

For patients, web-based behavior is often an important factor in choosing a physician. On the one hand, web-based behavior indicates the level of active participation that stems from internet motivation within the web-based community. Activeness has a certain influence on the number of patient consultations [9]. On the other hand, web-based behavior is a positive indicator of a physician's effort and popularity. Patients can gain insight into a physician's past efforts through web-based behaviors, which may influence their attitudes toward the physician, thereby influencing the likelihood of selecting that physician [6]. Most importantly, physicians' web-based behaviors are important cues for evaluating service process quality [14,16]. Combined with health care service characteristics [2-4], patients prefer to choose physicians who can provide a high-quality service process.

As the web-based behavior of a physician, log-in behavior reflects the degree of active participation in the OHC and the physician's efforts. Given that a physician may log in many times each day to check for new messages, log-in is the basis for any active actions for physicians in OHCs. Li et al [31] believed that log-in behavior belongs to the central working sphere, and log-in patterns could indicate a physician's central efforts related to the work, as well as the physician's attitude toward service provision, participation degree, and responsibility. Bitner et al [32] revealed that customers' perceptions of service depend on service providers' efforts, and their behaviors will raise the purchase intentions or continuous purchase intentions of customers [33], thus having a positive effect on marketing sales or organizational performance [34]. Physicians as providers of web-based health care services also apply to this phenomenon [9]. On the one hand, physicians with a higher-frequency log-in are more likely to make more task-related efforts to attract a greater number of patients, and subsequent patients would consider this for references. On the other hand, a higher-frequency log-in appears to be more responsive and involved than others [35], with those physicians logging in more frequently being more likely to ensure timeliness in service delivery, leading to attracting more patients. Therefore, the following hypothesis is proposed:

> *Hypothesis 1: a physician's log-in behavior has a positive effect on patient consultation.*

Web reviews are a particular type of user-generated content or electronic word-of-mouth, are the most important information source in customers' decision-making processes [36], and are deemed more successful in influencing customer behaviors than traditional marketing, information provided by products or service providers, or promotion messages from third-party websites [37-39].

OHCs provide a feedback channel where patients can express their views on the physician's service and share treatment experiences on the web. This information can help patients understand a physician's service quality at a minimal cost. In OHCs, web reviews are generated by patients who have experienced health care services. The more web reviews about a physician presented in the OHC, the more patients have selected the physician for consultation [16]. The web reviews generated by patients with similar experiences are more objective and credible signals than traditional information from acquaintances [40], which can increase other patients' trust in the physician and reduce perceived risks [41]. Web reviews are signals that reflect a physician's service outcome [14,16].

Positive web reviews mean a higher outcome quality of the physician, which has been shown to influence patients to make consulting choices [5,8,9,12,14].

The coexistence of log-in behavior and web reviews may complement each other in driving patient consultation. As service is delivered via the interaction between the service provider and the receiver, the assessment of service quality includes not only the delivery process but also the outcome [17]. As per the preceding discussion, log-in behavior may send web signals reflecting the service delivery process from the physicians themselves. A physician with a positive log-in behavior is usually associated with a positive attitude toward the consultation service. Furthermore, web reviews send another web signal from patients who have visited the physician before, which represents the service outcome. A physician with positive web reviews is usually associated with positive outcome quality. On the basis of the characteristics of health care services [2-4], patients judging a physician rely on two types of web signals: service process quality (ie, log-in behavior) and service outcome quality (ie, web reviews). Physicians with both high outcome quality and process quality are scarce resources [18], and the demand of these physicians on the platform should be large, so a large number of patients choose these patients. As a result, log-in behavior and web reviews should complement each other. From the preceding discussion, we propose the following hypothesis:

> *Hypothesis 2: a physician's log-in behavior and web reviews have a complementary relationship that affects patient consultation.*

Moderating Effect of Offline Status

Offline status reflects a physician's abilities and performance in providing health care services in hospitals or clinics [11,13], referring to a physician's career titles, ranking, and position in the hospital [11,42]. Such information can help patients evaluate a physician's offline competence [9].

In traditional health care services, patients can only judge a physician's ability through limited information. In the case of other factors being considered to be the same, patients tend to choose physicians with a higher status or professional titles [18]. To a certain extent, physicians with a high-level offline status might have a heavy workload but not enough time to contribute via the internet [18]. For this reason, the log-in behaviors of physicians with high-level offline statuses have a weaker impact on patient consultation. Therefore, the following hypothesis is proposed:

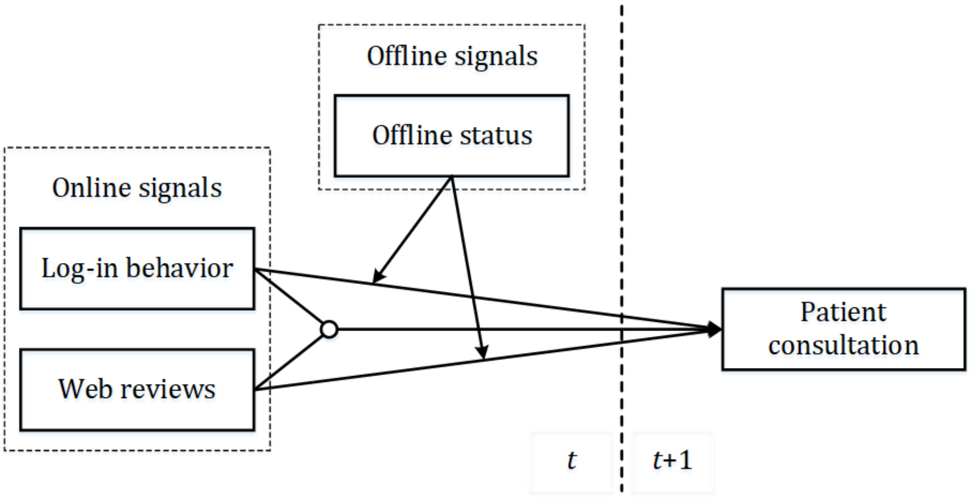
> *Hypothesis 3: the relationship between log-in behavior and patient consultation is negatively moderated by the physician's offline status.*

When patients choose physicians on the web, they rely mostly on offline and web signals. However, most patients regard offline signals as more reliable sources and treat web signals as additional information sources that supplement offline signals. Status may have a negative moderating effect on web signals [18]. When a physician has a high status, the offline signal will be sufficient for patients to make a decision. People are willing to accept the services of physicians with a high-level status as *credence services* instead of considering the service outcome reflected in web signals [25]. As physicians with high-level statuses may attract more patients, the effect of web reviews on patient consultation will be weakened. Hence, the following hypothesis is proposed:

> *Hypothesis 4: the relationship between web reviews and patient consultation is negatively moderated by a physician's offline status.*

The research model is shown in Figure 1.

Figure 1. Research model.



Methods

Research Context and Data Collection

The data used in this study were collected from Good Physician Online, which is one of the most popular and professional OHCs in China. It was founded in 2006 and, currently, more than 8000 hospitals and 500,000 physicians' information is presented on this website. Studying such a large and popular OHC can increase the generality of the results. Moreover, physicians registered on the Good Physician Online website have a profile home page, which contains information, such as physicians' background (name, medical title, academic title, hospital department, specialty, brief introduction, etc), patients' reviews, and information about web-based services. The information in a physician's profile home page is considerable and can help patients understand the physician and make a decision. Figure 2 shows an example of physician information shown on the OHC.

Figure 2. An example of physician information in online health communities.

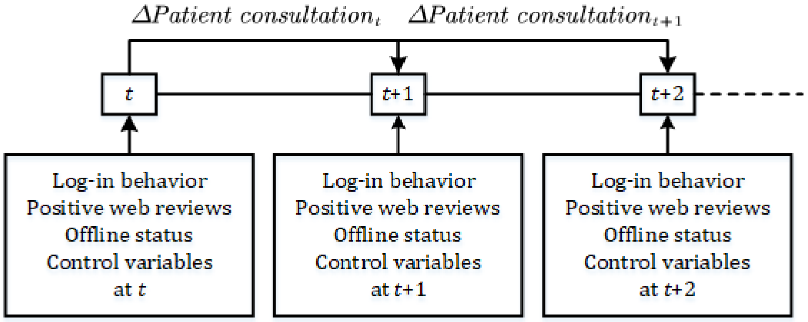
To reduce the influence of disease types, we only included physicians who treated patients with coronary heart disease as our sample. Using web crawler technology, we collected data from February 2019 to July 2019 (once every month during these six periods), which covered public information of hospitals and physicians presented on this website. We designed a longitudinal study to investigate whether a physician's log-in behavior and web reviews would change patient consultation choices. The data collection process is illustrated in Figure 3. After deletion of invalid data, short-panel data from 911 physicians over five periods were obtained for a total of 4555 physician data points. These physicians were currently active on the website, and the most recent log-in time was within 1 month.

Figure 3. Data collection and processing.



Variable Measurement

Table 2 presents the variable description. The dependent variable in this study was patient consultation. We used the number of patients before time *t* as a proxy for patient consultation, in accordance with previous research [5,14]. The number of patients included those who only consulted via the internet and those who consulted again after offline consultation. This study used the difference between the two periods as the dependent variable to reduce the causal relationship between the dependent and independent variables.

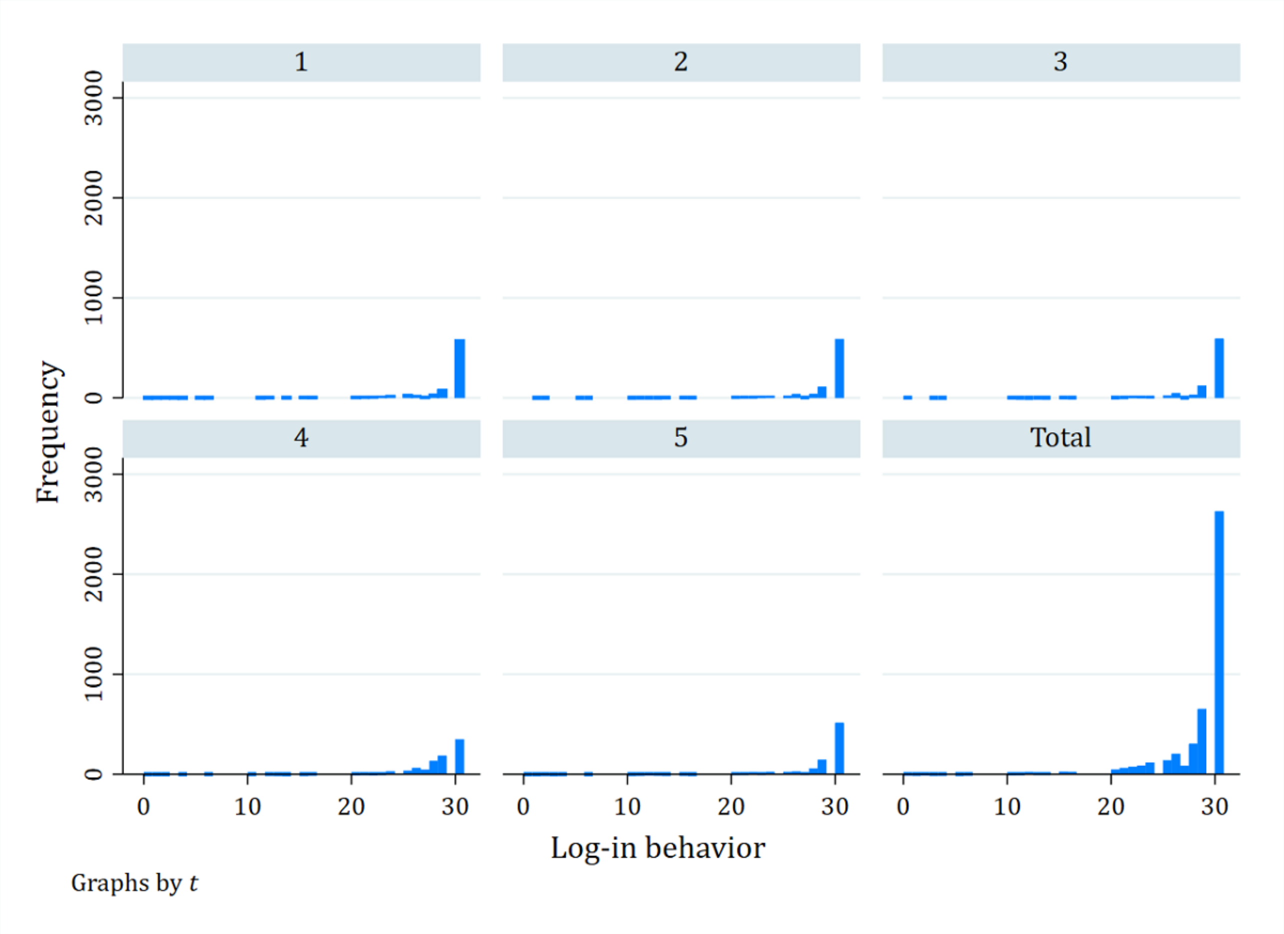
Table 2. Variable description.

Variables	Description	Proxy
Dependent variable		
Patient consultation	Patients evaluate the information about a physician and make the decision to consult online.	Patients
Independent variable		
Log-in behavior	One kind of online behavior that a physician launches his profile home page and log-ins his accounts.	Last web date
Positive web reviews	Positive reviews written by patients who have experienced a physician's health care service.	Thank-you letters
Moderating variable		
Offline status	The offline prestige of a physician in the career.	Medical title, academic title, or hospital ranking
Control variable		
Gender	The gender of a physician, 0 is male, 1 is female.	Gender
Usage years	The number of years that a physician using the OHC[a].	Usage years
Visits	The number of patients for visiting a physician’s profile home page.	Visits
Articles	The number of articles that a physician post on his or her profile home page.	Articles
Service stars	The number of service stars displayed on a physician’s profile home page.	Service stars
Written consultation	One type of online service. If a physician provided online written service, then 1; If not provided then 0.	Written consultation
Phone consultation	One type of online service. If a physician provided online phone service, then 1; If not provided then 0.	Phone consultation

[a] OHC: online health community.

The independent variables included physician’s log-in behavior and positive web reviews. In this study, log-in behavior was measured by the last date a physician was on the web at time *t*. If the physician logged in today, the log-in behavior is marked as 30; if the last on the web date is 30 days ago, the log-in behavior is marked as 0. The values are decremented individually. Figure 4 shows the frequency statistics of physicians’ log-in behaviors over five periods. It can be seen that physicians’ log-in patterns are different, and it is worth studying.

Figure 4. The frequency of physicians’ log-in behaviors in online health communities.



After the web-based consultation on the Good Physician Online website, patients can express their satisfaction or dissatisfaction with the physician’s service by sharing their treatment experience and writing a thank-you letter. The difference between a treatment experience and a thank-you letter is that the latter is a positive web review, and the patient who chooses to write a thank-you letter is definitely satisfied with the physician’s service. Referring to previous research [14,27], we used the number of thank-you letters a physician received from patients at time *t* to measure the physician’s positive web reviews.

The moderating variable in our research model is offline status, which mainly reflects the offline prestige in the physician’s career. According to previous research [27,42], we used the physician’s occupational title ranking and hospital standing at time *t* as a proxy for physicians’ offline status. A physician’s occupational title indicates the duties of a physician in a hospital, which is a manifestation of the physician’s professional expertise, health knowledge, and experience. A physician’s occupational title ranking includes medical title (chief physician, deputy chief physician, attending physician, and resident physician, coded from 4 to 1) and academic title (professor, deputy professor, and lecturer, coded from 3 to 1). Hospital standing can reflect an advantage in human capital, experience, health facilities, and technology, which is ranked as 3, 2, and 1. According to the methodology of previous research [43], this study integrated three variables to represent offline status. We standardized three variables by subtracting the means and dividing by the SEs, as shown in equation (1). Thus, the offline status of a physician was measured using equation (2).

Offline status = STD [STD (medical title) + STD (academic title) + STD (hospital ranking)] **(2)**

The control variables included the physician’s gender, usage years, number of visits, articles, service stars, written consultation, and phone consultation provided before time *t*. This information about the physician has been shown to be relevant to patients making consulting choices [5,7-9,13,14]. Gender is coded with “0” for male and “1” for female. Usage years are measured by the difference between the launching time of a physician’s personal website and time *t*. The number of visits, articles, and service stars is the information displayed on the physician’s profile home page before time *t*. Written consultation and phone consultation are two important types of services that physicians can provide on the Good Physician Online website. As the distributions of visits and articles are nonnormal, *ln* (*x*+1) transformations were also used for them.

Results

Descriptive Statistics and Correlation Results

Tables 3 and 4 show the descriptive statistics and correlations of variables, respectively. As shown in Table 4, log-in behavior is positively correlated with patient consultation and positive web reviews, and the β coefficients were .169 and .219, respectively. Log-in behavior and web reviews have positive correlations with offline status, with β coefficients of .047 and .284, respectively.

Table 3. Descriptive statistics of variables (n=4555).

Variables	Values		
	Mean (SD)	Min	Max

Estimation Model

As can be seen from Table 3, the dependent variables (patients) were nonnegative integers and their variance was greater than the mean; therefore, the negative binomial regression model was suitable for this study. The negative binominal probability function is as shown in equation (3), which has two parameters, θ and λ. Parameter θ captures overdispersion in the data, and parameter λ is the expected value of the distribution.

To test the hypotheses, the negative binomial regression model with fixed effects is explicitly expressed as shown in equation (4).

$$\triangle Patient\ consultation = Patient\ consultation_{i,t+1} - Patient\ consultation_{i,t}$$

$$= \alpha_0 + \alpha_1 Gender_i + \alpha_2 Usage\ years_{i,t} + \alpha_3 ln(Visits_{i,t} + 1) + \alpha_4 ln(Articles_{i,t} + 1) + \alpha_5 Service\ stars_{i,t} +$$

$$\alpha_6 \mathit{Written\ consultation}_{i,t} + \alpha_7 \mathit{Phone\ consulatation}_{i,t} + \alpha_8 \mathit{Log\text{-}in\ behavior}_{i,t} + \alpha_9 \mathit{Positive\ web\ reviews}_{i,t} + \alpha_{10} \mathit{Service\ stars}_{i,t} \times \mathit{Positive\ web\ reviews}_{i,t} + \alpha_{11} \mathit{Offline\ status}_{i,t} + \alpha_{12} \mathit{Log\text{-}in\ behavior}_{i,t} \times \mathit{Offline\ status}_{i,t} + \alpha_{13} \mathit{Positive\ web\ reviews}_{i,t} \times \mathit{Offline\ status}_{i,t} + \varepsilon_{i,t} \quad \mathbf{(4)}$$

Let i=1, 2, 3,..., n be the index of physicians. For equation (4), α_0 to α_{13} are the parameters to be estimated.

Regression Results

This study estimated the models using STATA software version 15.0 (StataCorp). The result of the Hausman test (χ^2_{14}=534.0; P<.001) indicated that the fixed effects model was suitable for this study. Table 5 shows the results of the fixed effects model hierarchically. Model 1 contains only constant and control variables, and model 2-model 5 add independent variables and interaction terms.

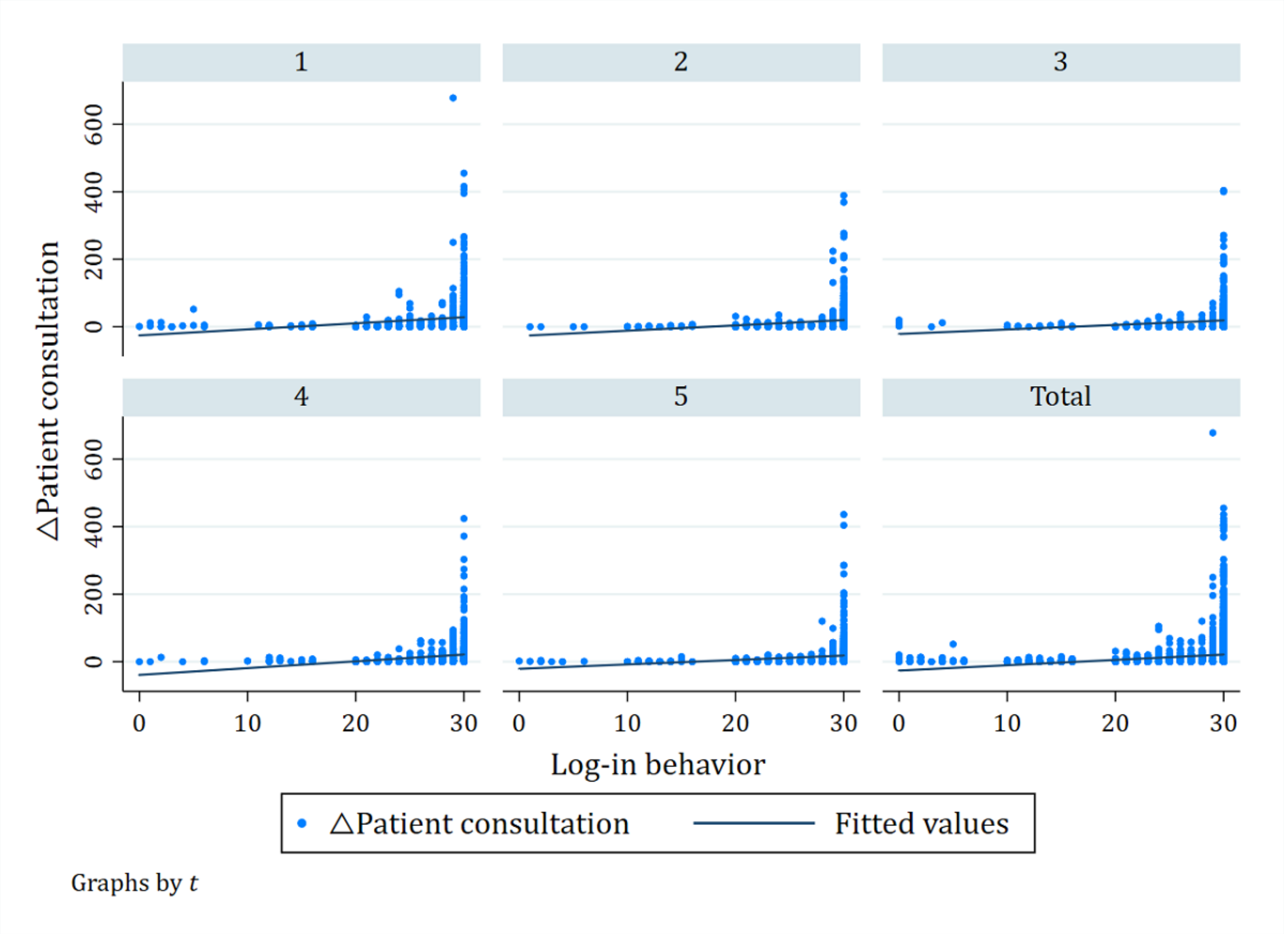
[a] Coefficient of the variable.

[b] Not applicable.

[c] Positive reviews: positive web reviews.

From model 2, the coefficient of log-in behavior (α=.016; P<.001) is positive and statistically significant, which supports hypothesis 1. The effects of log-in behavior on patient consultation are shown in Figure 5. As the number of log-in behaviors increases, the number of △patient consultation increases. When log-in behavior was less than 10 or 15, △patient consultation was 0 or <0. A comprehensive view of the regression lines of the five periods shows that the value of log-in behavior is ≤10, with the lowest number of patients making consulting choices.

Figure 5. The effect of log-in behavior and patient consultation on online health communities.



The results of model 3 show that the interaction between log-in behavior and web reviews (α=.001) is positive but not significant. This finding suggests that log-in behavior and web reviews do not have a complementary relationship that affects patient consultation. Therefore, hypothesis 2 is not supported.

The results of model 4 show that the interaction between log-in behavior and offline status (α=−.001) is negative but not significant. This means that the relationship between a physician's log-in behavior and patient consultation is not negatively moderated by offline status. Therefore, hypothesis 3 is contradicted.

The results of model 5 show that the interaction between web reviews and offline status (α=.070; *P*=.009) is positive and significant. This finding means that the effect of web reviews on patient consultation is stronger for physicians with a high status. Therefore, hypothesis 4 is contradicted.

Robustness Check

This study added the time effect to the estimation model, equation (5), and used the two-way fixed effects model to recheck the robustness of the results. Time is defined as a dummy variable, and $t1$ (February 2019) is used as the base period. The new estimation model is shown in equation (5). Table 6 shows the results of the robustness check, which are consistent with the results of the previous model (Table 5). In addition, the joint significance of the time dummy variable was tested, and it was confirmed that the time effect should be included in the estimation model. The robustness check results suggest that hypothesis 1 is supported.

$$\triangle Patient\ consultation = Patient\ consultation_{i,t+1} - Patient\ consultation_{i,t}$$

$$= \beta_0 + \beta_1 Gender_i + \beta_2 Usage\ years_{i,t} + \beta_3 ln(Visits_{i,t} + 1) + \beta_4 ln(Articles_{i,t} + 1) + \beta_5 Service\ stars_{i,t} + \beta_6 Written\ consultation_{i,t} + \beta_7 Phone\ consulatation_{i,t} + \beta_8 Log\text{-}in\ behavior_{i,t} + \beta_9 Positive\ web\ reviews_{i,t} + \beta_{10} Service\ stars_{i,t} \times Positive\ web\ reviews_{i,t} + \beta_{11} Offline\ status_{i,t} + \beta_{12} Log\text{-}in\ behavior_{i,t} \times Offline\ status_{i,t} + \beta_{13} Positive\ web\ reviews_{i,t} \times Offline\ status_{i,t} + \beta_{14} t_2 + \beta_{15} t_3 + \beta_{16} t_4 + \beta_{17} t_5 + \varepsilon_{i,t} \quad \textbf{(5)}$$

Let i=1, 2, 3,..., n be the index of physicians. For equation (5), β_0 to β_{17} were the parameters to be estimated.

Discussion

Principal Findings

In contrast to previous studies on physicians' web-based behaviors, our research focused on log-in behavior and found that it had a positive effect on patient consultation. The results were consistent with those of Li et al [31], who believed that physicians with higher-frequency log-ins are more likely to attract patients, because they seem to be more responsible and have a timely service process. The results also indicated that physicians' web-based behaviors positively influence patients' consulting choices [6,9,13], including log-in behavior. Our research also found that when a physician did not log in to the OHC for more than 20 days, the number of patients who chose them was small, even 0.

Our research used web reviews generated by patients after receiving health care services as a web signal to represent service outcomes. Our research found that a physician's log-in behavior and web reviews did not have a complementary relationship in affecting patient consultation, which was different from the findings of previous research on service quality [12,14]. On the one hand, it may be that log-in behavior and web reviews have separate effects on patient consultation, and patients do not consider both. On the other hand, although log-in behavior is a web-based behavior, it may not be directly related to the delivery process of a physician's response to consultation.

Patients mostly rely on both offline and web signals to choose a physician. This study found that web reviews were positively moderated by offline status. This is inconsistent with the findings of previous research, which suggests that web signals should be negatively moderated by offline signals [18]. However, offline status cannot moderate log-in behavior. A possible explanation is that most patients view offline signals as a more reliable source than web signals. Compared with the degree of initiative and effort, offline prestige (ie, offline status) in a physician's career can better reflect the service outcome quality.

Theoretical Implications

This study offers theoretical contributions in the following ways. First, previous studies have explored the influencing factors related to patients' consultation choices, including some web-based behaviors of physicians, such as publishing articles, providing written consultation, and phone consultation. However, the literature on the role of physicians' log-in behavior is inadequate. Logging is the central working sphere and is the first step for a physician to provide health care services. Log-in behavior represents the central effort, activeness, and service process quality. Our research found that log-in behavior could influence patients' consulting choices. This finding extends the understanding of physicians' web-based behaviors and may also be used in other service fields.

Second, although some signaling literature in the context of eHealth has discussed web reviews, no research considers web reviews as service outcomes with the log-in behavior of physicians. However, this study found that log-in behavior and web reviews did not have a complementary relationship that affected patient consultation. Therefore, these findings contribute to research on patient consultation in OHCs.

Third, a clear distinction exists between web and offline signals. This study investigated the main effects of web signals (log-in behavior and web reviews) and their interactions with offline signals (offline status). The results revealed that the moderating effects of offline status on these two signals were different. From this perspective, this study extended the understanding of multiple signal interactions.

Implications for Practice

This study has several practical implications. First, for health care service providers, our evidence-based research demonstrates that log-in behavior is also an important factor in influencing patients' choice of consultation. Apart from other web-based behaviors, patients can judge a physician's activeness, efforts, and service process quality by relying on their log-in behavior. Physicians should value their web-based behaviors and log in to OHCs proactively, transmitting signals of active participation and timely responses to patients. Furthermore, operators of OHCs should pay attention to physicians' log-in issues. The more actively physicians participate in web-based platforms, the more successful the OHCs will be.

Second, the results show that log-in behavior and web reviews do not have a complementary relationship that affects patient consultation. Physicians should distinguish between log-in behavior and other web-based behaviors. Although web-based behaviors can reflect a physician's activeness and effort, there may be differences in service process quality.

Third, the results show that multiple signals from different signaling mechanisms affect patient consultation. Offline signals can have positive moderating effects on web signals. Hence, physicians should value the impacts of both web-based and offline service quality, and offline service quality is more credible than web-based service quality for patients.

Limitations and Future Research

This study has certain limitations. First, this study used physician data from only one OHC and one disease type. However, interpretation of the results may be limited. Therefore, it is necessary to collect data from physicians with various expertise on different platforms simultaneously to further verify the research model. Second, the study used the physician's last date displayed on the web on the day of crawling data to measure log-in behavior, which has certain limitations. In future research, we could measure log-in behavior through other methods, such as counting physicians' log-in times within a month. Third, the control variables selected in this study may have ignored some important variables, especially those related to patients. As websites tend to obscure customer names to protect privacy, it is difficult to obtain these data from the website.

Conclusions

Drawing on the signaling theory, this study explores the effects of physicians' log-in behavior and web reviews on patient consultation in OHCs. This study hypothesized that two signals (ie, log-in behavior and web reviews) and their interaction affect patients' consultation choices, and the relationships between web signals and patient consultation were moderated by offline signals (ie, offline status). Short-panel data over five periods were used to test these hypotheses. Our research found that a physician's log-in behavior positively affects patient consultation, and a physician's no–log-in days should be no more than 20 days. Log-in behavior and web reviews had no complementary relationship that affects patient consultation. Furthermore, offline status could only positively moderate web reviews instead of log-in behavior.

Abstract

Background: Automated insulin delivery (AID) systems have been shown to be safe and effective in reducing hyperglycemia and hypoglycemia but are not universally available, accessible, or affordable. Therefore, user-driven open-source AID systems are becoming increasingly popular.

Objective: This study aims to investigate the motivations for which people with diabetes (types 1, 2, and other) or their caregivers decide to build and use a personalized open-source AID.

Methods: A cross-sectional web-based survey was conducted to assess personal motivations and associated self-reported clinical outcomes.

Results: Of 897 participants from 35 countries, 80.5% (722) were adults with diabetes and 19.5% (175) were caregivers of children with diabetes. Primary motivations to commence open-source AID included improving glycemic outcomes (476/509 adults, 93.5%, and 95/100 caregivers, 95%), reducing acute (443/508 adults, 87.2%, and 96/100 caregivers, 96%) and long-term (421/505 adults, 83.3%, and 91/100 caregivers, 91%) complication risk, interacting less frequently with diabetes technology (413/509 adults, 81.1%; 86/100 caregivers, 86%), improving their or child's sleep quality (364/508 adults, 71.6%, and 80/100 caregivers, 80%), increasing their or child's life expectancy (381/507 adults, 75.1%, and 84/100 caregivers, 84%), lack of commercially available AID systems (359/507 adults, 70.8%, and 79/99 caregivers, 80%), and unachieved therapy goals with available therapy options (348/509 adults, 68.4%, and 69/100 caregivers, 69%). Improving their own sleep quality was an almost universal motivator for caregivers (94/100, 94%). Significant improvements, independent of age and gender, were observed in self-reported glycated hemoglobin (HbA_{1c}), 7.14% (SD 1.13%; 54.5 mmol/mol, SD 12.4) to 6.24% (SD 0.64%; 44.7 mmol/mol, SD 7.0; *P*<.001), and time in range (62.96%, SD 16.18%, to 80.34%, SD 9.41%; *P*<.001).

Conclusions: These results highlight the unmet needs of people with diabetes, provide new insights into the evolving phenomenon of open-source AID technology, and indicate improved clinical outcomes. This study may inform health care professionals and policy makers about the opportunities provided by open-source AID systems.

Introduction

Background

Despite significant advances in health care, pharmaceuticals, and technological developments, type 1 diabetes remains a challenging chronic condition to manage, impacting life expectancy and diminishing quality of life [1-3]. Only a small proportion of people with type 1 diabetes achieve glycated hemoglobin (HbA_{1c}) levels below 7.0% (58 mmol/mol), as recommended by therapeutic guidelines to reduce the risk of long-term diabetes-related complications [4-6]. The complexity of diabetes self-management bears a high cognitive load and can cause distress in everyday life, with approximately 40% of people with type 1 diabetes reporting distress and/or depressive symptoms, particularly prevalent among adolescents and young adults [7-10].

In addition to optimizing glucose levels and variability, diabetes technologies have the potential to ease complex decision making and thereby reduce the cognitive and emotional burden of diabetes self-management. The latest advances in diabetes therapy combine sensors for continuous glucose monitoring and insulin pumps with computerized control algorithms, thereby enabling automated adjustments to insulin delivery in response to the user’s changing glucose levels. Automated insulin delivery (AID) systems, also known as *artificial pancreas* or *(hybrid) closed-loop* systems, are in various iterations of development and automaticity. Although a variety of commercial AID systems are under development, and some have recently become available in a limited number of countries, they are not universally available, accessible, or affordable.

To fill in the gap, open-source AID systems, also called *Do-It-Yourself* Artificial Pancreas Systems (DIYAPS), have been created by people with diabetes, in the web-based community behind the hashtag #WeAreNotWaiting, with instructions and codes for these systems available freely and widely via open-source platforms. Although anyone can access this, each user has to take responsibility to build their individual system and use it at their own risk. Initial observational studies have described significant improvements in glycemic outcomes in smaller cohorts of open-source AID users of all age groups, including children and adolescents whose caregivers build and maintain these systems on their behalf [11-15]. Further studies reported improved sleep quality and uninterrupted sleep, in particular, reduced burden of diabetes management, increased confidence in achieving diabetes management goals, increased energy, and reduced mood swings among open-source AID users [15]. An in-silico study of the AndroidAPS algorithm showed similar glycemic improvements and concluded that this algorithm is both safe and effective [16].

Despite the potential benefits of open-source AID systems, little is known about the reasons why people with diabetes initially chose to use this technology. It is important to determine the lessons to be learned from the #WeAreNotWaiting movement, especially for stakeholders involved in research and commercial product development and regulation, such as academia, industry, health care professionals, governance, and regulatory bodies.

Objectives

As part of the OPEN (Outcomes of Patients’ Evidence with Novel, Do-it-Yourself Artificial Pancreas Technology) Project, the aim of this study is to investigate motivational factors for building, using, and maintaining an open-source AID system among adults with diabetes (type 1, 2, and others) and caregivers of children and adolescents with diabetes, as well as their self-reported clinical outcomes, through a population-based survey [17].

Methods

Study Design and Participants

From November 2018 to March 2019, we conducted a web-based, cross-sectional survey titled *DIWHY* (Multimedia Appendices 1 and 2). The survey design was created by the patient-led OPEN consortium [17], in collaboration with open-source AID users, and piloted by a small number of them before the final release. The Checklist for Reporting Results of Internet E-Surveys was used to guide survey development [18]. The survey was approved by the Charité–Universitätsmedizin Berlin Ethics Committee (EA2/140/18). Participants were eligible if they were adults (aged >18 years), living with diabetes (type 1, 2, or other), or being caregivers of a child or an adolescent with diabetes using an open-source AID system.

Procedures

Participants were invited through public announcements on the OPEN Project website, in the Facebook groups *Looped* (>6000 members) and *AndroidAPS users* (>1800 members, November

2018), other regional subgroups on Facebook, and by public posts on Twitter using the hashtags #WeAreNotWaiting and #DIYAPS. All posts were organic, meaning there was no paid promotion or targeted advertising of posts on any platform. All participants gave their consent electronically. Participation was anonymous and voluntary; no financial or other compensation was provided. Participants were able to choose between 2 language options (English and German). There was a version for adults with diabetes and one for caregivers. Data were collected and managed using secure Research Electronic Data Capture electronic data capture tools hosted at Charité [19].

Measures

Initial questions focused on demographics, the type of open-source AID systems used, estimated commencement date, and 3 HbA_{1c} values each preinitiation and postinitiation of open-source AID (self-reported for adults; for caregivers, their child's). In addition, participants were asked to provide their or their child's average time in range (TIR; sensor glucose 70 mg/dL/4.0 mmol/L-180 mg/dL/10.0 mmol/L) before and after the commencement of open-source AID.

Subsequently, participants' motivation to build an open-source AID was assessed with a single question: "What motivated you to build a Do-It-Yourself Artificial Pancreas system for yourself? Indicate your level of agreement with each statement." A total of 14 fixed-choice statements followed to conclude the stem "I built a DIYAPS..." (eg, "...to achieve better glycemic control," "...to improve my own sleep quality"). For each statement, a 5-point Likert-type scale was used (*fully applies* to *does not apply at all*). In addition, participants could indicate further motivational factors using free text.

Quantitative Analysis and Statistical Testing

To ensure the reporting of robust parameters regarding HbA_{1c} levels, entries with more than one missing HbA_{1c} value either before or after open-source AID implementation were not considered in the calculation of arithmetic means, SDs, and statistical tests related to HbA_{1c}. The reduction in the average HbA_{1c} levels before and after open-source AID implementation was assessed using the Wilcoxon signed-rank test (*P* value threshold of .05, paired: *TRUE*, and alternative hypothesis: *greater*). Entries not providing TIR values before and after open-source AID implementation were not considered for the computation of TIR-related descriptive statistics and testing for the increased TIR after open-source AID implementation (same statistical test as for HbA_{1c}, with alternative hypothesis set to *lower*). Quantitative analyses were conducted within the R programming framework (v4.0.2; R Core Team), and the ggplot2 package was used to generate figures.

Content Analysis

Content analysis was performed to analyze responses to open-ended questions [20]. A total of 3 researchers coded data and analyzed the responses thematically in 2 rounds. After the first round, which was open, inductive, and independent, 3 lists of codes were merged and combined into a final version. The second round of coding was deductive, and each of the coders assessed the content according to the final list of codes. The interrater reliability (percentage agreement for multiple raters) method was used to calculate the level of agreement between coders, and the final list of the most frequently discussed codes was generated [21]. Codes were then compared with assess the level of similarity, for example, an interrater reliability result of 100% indicated that all codes generated by individual coders matched.

Results

Characteristics of the Study Cohort

A total of 1125 individuals participated in the *DIWHY* survey. After excluding 25.6% (288/1125) incomplete responses, data from 897 individuals over 35 countries were analyzed. Detailed demographic characteristics are shown in Table 1. Participants were mostly from Europe (691/897, 77%), whereas 14% (125/897) were from North America, and 9% (78/897) were from other continents. Most adults (599/722, 82.9%) and caregivers (153/175, 87.4%) had a university degree or higher. Of the respondents, 26% (236/897) had a professional background in information technology and 19% (170/897) in biomedicine or health care. Furthermore, 82% (736/897) of the participants reported out-of-pocket expenses, with an average of US $530 and a maximum of US $1000 per year. In both groups, various types of open-source AID systems were used regularly, with Loop being the most popular system in North America and AndroidAPS being the most frequently used system in Europe. Otherwise, the geographical location and household income did not indicate any specific patterns.

Table 1. Participants' demographic and self-reported clinical characteristics.

Participant demographics	Children and adolescents (n=175)	Adults (n=722)	Total (N=897)
People with diabetes, gender, n (%)			
Female	83 (47.4)	311 (43)	394 (43.8)
Male	92 (52.6)	411 (56.8)	503 (55.9)
Other	0 (0)	2 (0.3)	2 (0.2)
People with diabetes, average age, years (SD)	9.7 (4.0)	41.8 (11.8)	35.6 (16.7)
Type of diabetes, n (%)			
Type 1	174 (99.4)	714 (98.9)	888 (98.9)

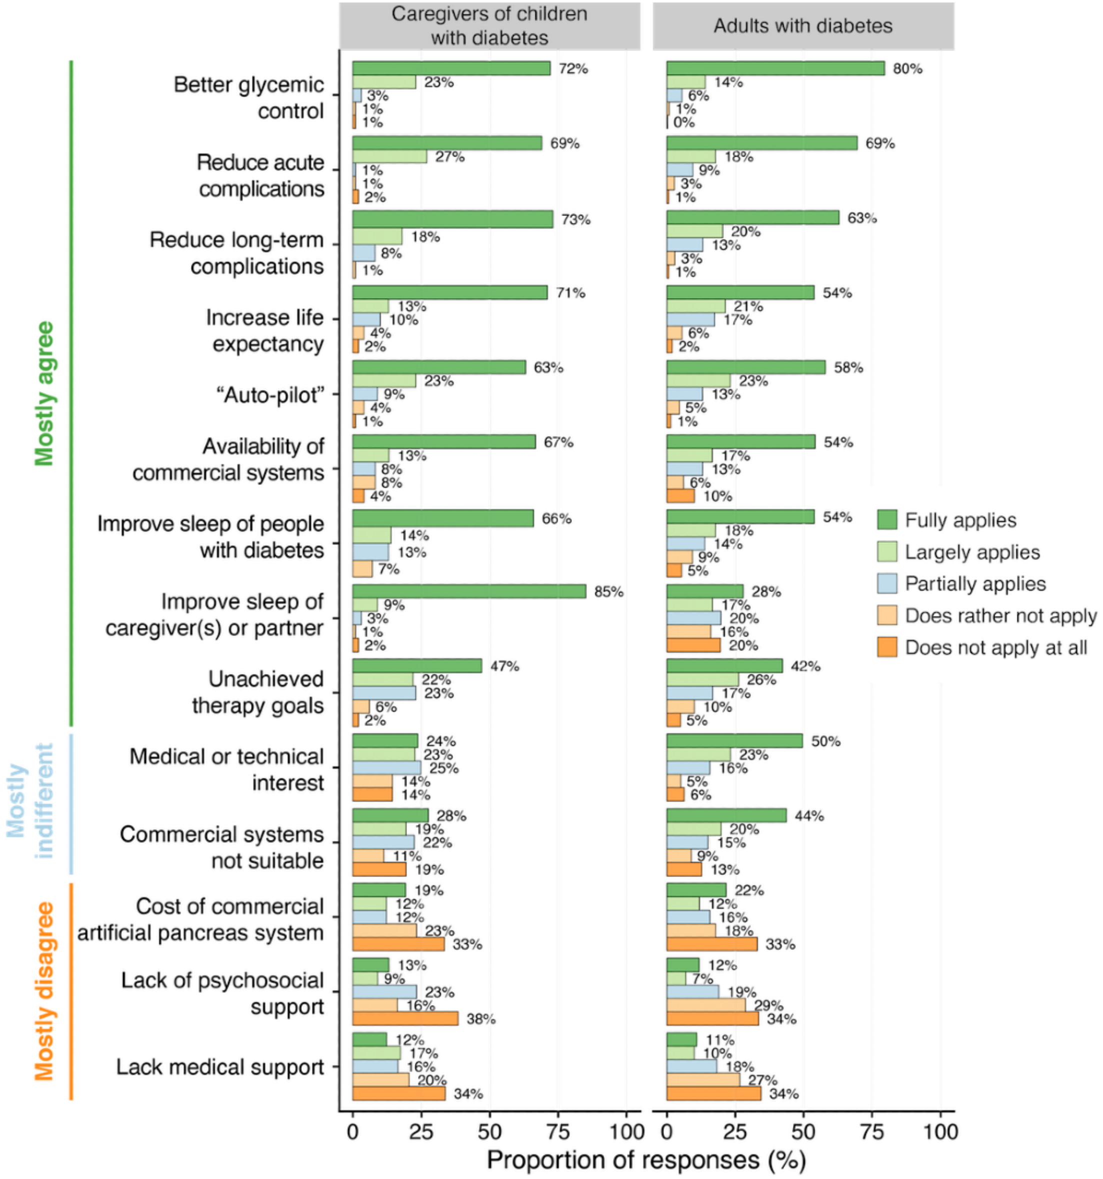
[d] Hong Kong, Kuwait, Palestine, and Singapore.

[e] For adults: own; for caregivers: caregivers.

Motivations to Commence Open-source AID Use

As shown in Figure 1, the most frequently endorsed motivations of adults as well as caregivers (as *fully applies* or *largely applies*) were to improve the overall glycemic control (476/509 adults, 93.5%; 95/100 caregivers, 95%), reduce the risk of acute (443/508 adults, 87.2%; 96/100 caregivers, 96%) and long-term complications (421/505 adults, 83.4%; 91/100 caregivers, 91%), put diabetes on *auto-pilot* mode and interact less frequently with diabetes technology (413/509 adults, 81.1%; 86/100 caregivers, 86%), increase their own or their child's life expectancy (381/507 adults, 75.1%; 84/100 caregivers, 84%), and improve their own or their child's sleep quality (364/508, adults 71.7%; 80/100 caregivers; 80%), because of the lack of commercially available closed-loop systems in their countries (359/507 adults, 70.8%; 79/99 caregivers, 80%) and unachieved therapy goals with the therapy options available to them (348/509 adults, 68.4%; 69/100 caregivers, 69%).

Figure 1. Motivations for building an open-source automated insulin delivery system. The x-axis shows the percentage of responses for each motivation question (y-axis). Bar colors represent the degree of relevance ranging from "does not apply at all" to "fully applies." The left and right columns show the responses of caregivers of children with diabetes and adults with diabetes, respectively. Responses are ranked from the most frequently endorsed motivations (top) to the less frequently endorsed (bottom).



Overall, the motivations of adults and caregivers of children and adolescents with diabetes were largely similar. As the most noticeable difference between the 2 groups, improvement in their own sleep quality (94/100, 94%) was a stronger motivation for caregivers compared with adults with respect to their partners or families (225/505, 44.6%). Curiosity (medical or technical interest) was endorsed more frequently by adults with diabetes (367/503, 73.0%) than by caregivers (45/97, 47%). Some believed that commercial systems did not suit their own or their child's individual needs, more frequently reported by adults (316/498, 63.5%) than by caregivers (46/98, 47%). Out-of-pocket costs related to the use of commercially available systems (166/496 adults, 33.5%; 31/99 caregivers, 31%) played a subordinate role. Lack of adequate medical support (105/501 adults, 21.0%; 29/98 caregivers, 30%) or psychosocial support (94/501 adults, 19.0%; 22/99 caregivers, 22%) were less frequently endorsed as motivating factors, although caregivers more frequently indicated a lack of medical support.

Further Motivations

In addition to the 14 predefined items, participants could indicate further motivation in an open-text field. In total, 127 participants (103 adults and 24 caregivers) provided a free-text response. Textbox 1 provides a list, as well as representative quotes, of the respondents. In the independent coders' selection of first-choice codes, there was an 83% interrater agreement between them (Multimedia Appendix 3).

Textbox 1. Illustrative quotes from adults with diabetes and the caregivers of children or adolescents with diabetes, highlighting additional motivation factors to build an open-source automated insulin delivery system.

Improving Diabetes Management

> *The psychological benefits of being able to significantly improve active control over diabetes and outcomes, rather than being more passively subjected to it.*
>
> *Another important reason for me is that I FINALLY have an overview of all data combined for later analysis but also direct decisions (values instead of opinions).*

Improving Quality of Life or Reducing the Burden of Diabetes Management

> *I chose DIY to decrease the demands of living with diabetes every day, around the clock. I also needed help consistently combatting the dawn phenomena, where I would wake up either too high, or too low from overcorrecting.*
>
> *His quality of life (staying with friends, knowing we can remotely monitor and assist, knowing that loop will help correct if he makes a mistake, attending sports training independently) is vastly improved. We can sleep! A happier, healthier family.*
>
> *Freedom to participate in normal 8 year old life eg play dates without having to pre-plan everything.*
>
> *Management of diabetes is helped by support but it is very much a self managed disease and requires 24/7 attention. Closed looping makes it just so much better, much of the time I can leave AAPS to take care of basals by itself. Quality of life is so much better. I can sleep without worrying about not waking up because of a bad hypo.*
>
> *We only wanted the best for our son. He should get exactly the same chances in life as his friends/children of the same age.*
>
> *To improve constant feeling of failure.*

Diabetes Distress or Burnout

> *Tired of diabetes after almost 30 years [...] The first real relief for me in my everyday life as a single mom.*
>
> *To reduce psychological distress, to be able to take responsibility for the course of diabetes, to enjoy life more since you are not torpedoed by Hypos and Hypers. Freedom despite technically higher dependency.*
>
> *There was no other way. The available treatments just did not control my diabetes sufficiently. The pressure and hopelessness of that scenario caused major mental health problems.*
>
> *I've lived my whole life [like] this & can't take it anymore. Too hard to do. Worst problem is "brain fog" & lack of energy due to blood sugar swings & hypoglycemic unawareness. I carry guilt for causing my family to lose sleep & carry the burden of diabetes [...]. [The] burden of diabetes is terrible.*

Autonomy

> *I feel so empowered by building my own system and taking control of my T1D. It's an awesome feeling!*
>
> *Daughter has learning difficulties, to make life easier for her and be less dependent on support, which in turn allows her to live a more independent life.*
>
> *To regain a sense of control on my diabetes management. I felt I was becoming dependent on my specialist for interpreting the adjustments needed for my insulin regime.*
>
> *Independent sleepovers with friends (without parents).*
>
> *To expand our daughter's independence and make her therapy decisions easier.*

Dissatisfaction With Available Technology, Choice and Health Care

> *Out of frustration with the existing designs seeming to have prioritized all stakeholders other than patients.*
>
> *Commercial closed loop systems do not allow users to specify a custom target BG but instead hard wire an unambitious target more concerned with legal liability that doesn't respect the autonomy, needs and wishes of the user.*
>
> *Dissatisfied with commercially available options and choice in the market space. No other option is appealing or provides the level of control and true artificial pancreas functions OR user interface.*
>
> *Doctors and hospitals have been telling me for years that things are simply fluctuating for me (hormones, stress, sensitivity to movement) and that you can't do anything about it. 'Resistant to all treatment options' and well-educated. Unfortunately with no success.*
>
> *We were desperate for something to use all the CGM data without sending our child crazy with in[sistent] requests for the pump to set low temps etc. We were infuriated by the business based decisions around closed loop in Australia - only the 640G was available and it was the worst decision for management and burden that we ever made. Now (as*

> *in within this fortnight) the 670G is available but still, no one can get training or sensors. We have been looping for nearly 3 years. If we hadn't then we would still be waiting today.*

Improving Sleep Quality

> *Sleep was the main reason followed by time in range. However, after all these years I still wake up but go back to sleep quickly.*
>
> *Frequently woke up from sensor alarms, make corrections and still wake up in the morning with a high or low glucose. Since closed looping, I get into bed knowing that Loop will keep me in range and I will wake up with a neat glucose. The only alarms I would ever get during the first period of closed looping were compression lows, and with the experience of loop keeping me in range I am now even confident enough to shut down all CGM alerts. Makes a huge difference for both me and boyfriend now that we start our days well rested. Every single day.*

Safety or Reducing Severe Hypoglycemia

> *Too many overnight hypos that require help.*
>
> *My child was overdosed on insulin twice by untrained teacher aides at school and if it was not for DIY looping technology- I would not have known about this at all until too late. Seeing the boluses appear on nightscout on real-time allowed me to question the dose and sugar treatment could commence preventatively than child actually going into severe hypo.*

"DIY mindset" or Early Adopter of Technology

> *I was going to build my own and found existing projects.*
>
> *Early adopter of all diabetes technologies. Turns disadvantage into a challenge.*
>
> *I love tinkering and making things. I'd always rather DIY, in many aspects of life.*
>
> *I initially built a closed DIY APS for a hackathon project out of pure tech curiosity. I planned to use the system for only 12 hours and then give a presentation to other employees at our company involved with the hackathon. After 12 hours, I realized I was never going to stop using it. Once on the system, almost every single one of the survey questions above are a "Fully Applies" as to why I decided to stay on the DIY APS.*
>
> *I'm a doctor and I'd like to test the closed loop first for myself and then use it in the future in my patients' treatment.*

Community Spirit

> *Being part of the community of selfless, generous, caring, and talented people willing to volunteer their time, knowledge, skills and experience to the benefit of the community.*
>
> *Something that also influenced me to move to a DIY system was the support from the community, and the general feeling that the community gives. It feel like I am part of a big people- powered movement. It feels like a revolution.*
>
> *I felt a strong moral and ethical imperative that technology should serve people.*
>
> *Help others to have healthier life.*

Comorbidities

> *I started on AndroidAPS when I was diagnosed with cancer needing chemotherapy. I found it extremely beneficial especially for those times when I was at my lowest and unable to control my BGs in the old way because of insulin resistance. Also when I was admitted to hospital because of infections and sepsis it was a godsend.*
>
> *More beneficial sexual activity, PDE-5 inhibitors no longer required.*
>
> *Because of other conditions, I have to take cortisone in different doses on a regular basis. This has made my diabetes management so difficult. The loop absorbs my BG fluctuations much better.*
>
> *Achalasia (food gets stuck in the esophagus at night), making blood sugar uncontrollable.*
>
> *I have been on a pump since 1992. I was on the 670G for over a year, and I felt helpless in my efforts to achieve excellent glycemic control while still living my random and not standardized life, where I eat when I am hungry, or forget to eat, and where pre-bolusing is dangerous, because I also have ADHD and I have forgotten to eat many times. My insulin needs vary depending on what I do in terms of activity, but also randomly on the day of the week, the time of the month and many other factors that i don't understand. On the 670G every weekend of high physical activity was followed by a couple of days of high BGs due to the user's inability to interact with the proprietary algorithms (Oh I am so done with Medtronic now).*

Diabetes-Related Complications

> *After 29 years of MDI and [...] retinopathy I decided to improve my health. I've researched several ways to improve control. Ultimately autonomy is the box I needed ticked! AAPS ticks that box 100%.*

> *Gastroparesis, I barely had nights where I wasn't over 200 half the night. With the G5 I was woken up at 170 and was able to intervene. Since the loop and some completed goals, I fall asleep again because the loop prevents the uncontrollable rise!*
>
> *Heart operation after 30+ years of poorly controlled diabetes.*

Female Health

> *Wanted better control for pregnancy.*
>
> *As someone whose hormone levels are not considered standard and rapidly change, the ability to [have] a helping hand to smooth out these Diabetes related complications (notably hyperglycemia episodes) was very important to me, as the situation is never the same twice and requires different treatment on a day-to-day basis.*
>
> *Deteriorating* HbA_{1c} *due to puberty and insulin resistance. Massive amounts of insulin needed giving unpredictable blood glucose.*
>
> *After manifestation of T1D, we made very high demands on* HbA_{1c} *and TiR for the benefit of our daughter...but with the onset of puberty, this led to an almost impossible workload (correcting 10-15 times at night).*
>
> *To have more insight as to why my blood glucose was so volatile due to changing hormones (menopause).*

Out-of-Pocket Expenses

> *It was questionable whether I would meet the health insurer's criteria for the Minimed 670 system for reimbursement. I don't have a CGM either, just the Freestyle Libre with an additional transmitter.*

Improving Performance

> *To improve my work at the office.*
>
> *To improve athletic performance by controlling night time blood sugars.*

Curiosity

> *To learn more about my diabetes in general. You have to acquire a lot of knowledge (technical as well as physiological aspects) before you start looping, and you get excellent support from developers and the community.*
>
> *The fact alone that you can be curious again about something new to the diabetes field, to see a form of therapy as an exciting challenge, plus the (so far not yet fulfilled hope) to finally better control the hardly controllable variating [postprandial] values.*

Most of the indicated *other motivations* provided greater details about the 14 predefined statements. The most frequently mentioned motivations for all—adults and caregivers—were *better management* and *reducing the disease burden*. The first motivation appears consistent with several statements related to hypoglycemia and hyperglycemia and risk reduction, whereas the second motivation may correspond with *to put diabetes management more on auto-pilot and interact less frequently with the therapy system*. This aspect and sleep quality are understood as the quality of life gains. Of motivations not covered by the predefined responses, the most frequently mentioned was *autonomy gain* in both adults and children or adolescents, as indicated by the caregivers. All these aspects were associated with improvements in family life:

> *This is for my wife. She wants me to live forever, this is as close as I can do for her.*

Psychosocial aspects, ranging from diabetes burnout and distress to a desire to improve athletic performance to increasing efficacy at work, were also identified as important motivating factors. The following comments illustrate the wide-ranging benefits experienced by many participants after adopting the technology:

> *Management of diabetes is helped by support, but it is very much a self-managed disease and requires 24/7 attention. Closed looping makes it just so much better, much of the time I can leave [AndroidAPS] to take care of basals by itself. Quality of life is so much better. I can sleep without worrying about not waking up because of a bad hypo. [...] I am so grateful to all the software developers who have freely given their expertise and time to make this possible.*

As highlighted in the example above, an important role was played by the *community spirit* and peer support in social networks:

> *Something that also influenced me [...] was the support from the community, and the general feeling that the community gives. It feels like I am part of a big people-powered movement. It feels like a revolution.*

Not only a *Do-It-Yourself* mindset and being *early adopters* of technology but also being motivated and empowered to improve one's life were frequently mentioned:

> *Because it's the most natural thing to do, after getting to know that it's possible. Because I could.*

Some motivations included other health-related aspects such as improving the management of existing diabetes-related complications and increasing safety by avoiding severe hypoglycemia. Other comorbidities, such as cancer, sexual health difficulties, or conditions requiring cortisone treatment, were also mentioned:

I have to take cortisone in different doses on a regular basis. This has made my diabetes management so difficult. The loop absorbs my BG fluctuations much better.

Women and caregivers of female children highlighted female health aspects such as hormone-related changes in insulin sensitivity, family planning, and pregnancy as reasons to commence open-source AID:

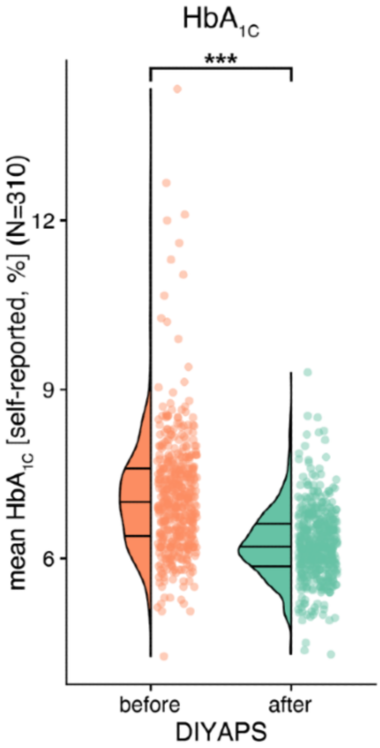
> *To have more insight as to why my BG was so volatile due to changing hormones (menopause).*

For some, special features were only offered by open-source AID and not by commercial systems, that is, customizable targets and the option to bolus from a smartwatch. For caregivers, remote real-time access to their child's data and the option to remotely control their child's AID system have been frequently described.

Improved Glycemic Outcomes Across All Age Groups and Genders

To assess glycemic outcomes, participants were asked to report their or their child's 3 most recent HbA_{1c} results before as well as the first 3 HbA_{1c} results after commencing the open-source AID. HbA_{1c} levels decreased significantly following open-source AID implementation ($P<.001$) from an average of 7.14% (SD 1.13%; mean 54.5 mmol/mol, SD 12.4) to 6.24% (SD 0.64%; mean 44.7 mmol/mol, SD 7.0), with an effect size of −0.9% (Figure 2).

Figure 2. Positive effects of open-source automated insulin delivery on clinical outcomes: average self-reported glycated hemoglobin (%; y-axis) for all 310 respondents, before and after open-source automated insulin delivery (x-axis) distinguished by orange and green colors, respectively. The left side is displayed as a density plot, with horizontal lines indicating quartiles. The right side depicts the data as a scatter plot. DIYAPS: Do-it-Yourself Artificial Pancreas System; HbA_{1c}: glycated hemoglobin.



The average self-reported TIR across adults and children with diabetes significantly increased by +17.4%, from 62.96% (SD 16.18%) to 80.34% (SD 9.41%; $P<.001$; Figure 3). Similar outcomes were observed separately for adults and children with diabetes (Multimedia Appendix 3) and were independent of age and sex (Figure 4). Overall, 92.3% (286/310) of the respondents reported a decreased average HbA_{1c} level (Figure 5).

Figure 3. Self-reported time in range (%; x-axis) of adults and children with diabetes, before and after implementing an open-source automated insulin delivery system. The left side is displayed as a density plot, with horizontal lines indicating quartiles. The right side depicts the data as a scatter plot.

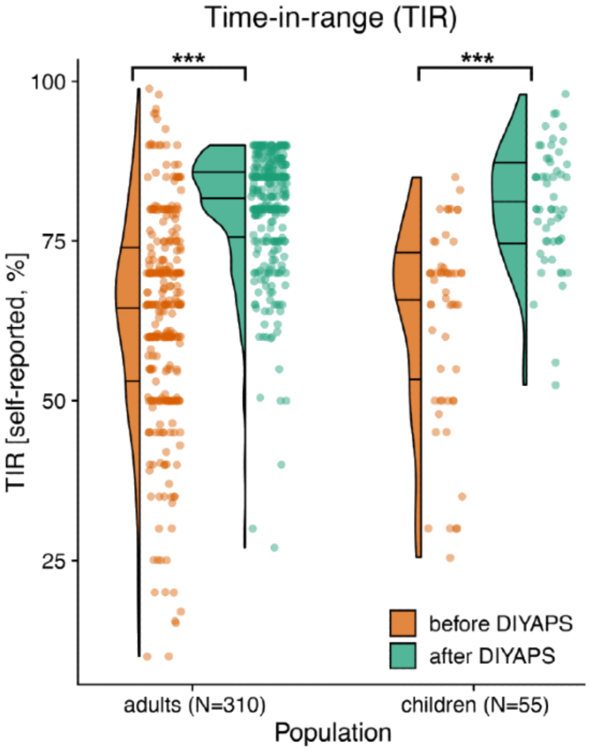


Figure 4. Improvements in self-reported glycated hemoglobin levels associated with open-source automated insulin delivery, independent of age or gender: relation between average glycated hemoglobin levels (%; y-axis) and age (x-axis), shown separately for female and male respondents (top and bottom rows, respectively). Colors separate average glycated levels before (orange) and after (green) open-source automated insulin delivery implementation. Each point represents one respondent after filtering of responses (the Methods section). Solid lines and their gray areas represent the trend and standard error for the respective groups. AID: automated insulin delivery; HbA_{1c}: glycated hemoglobin.

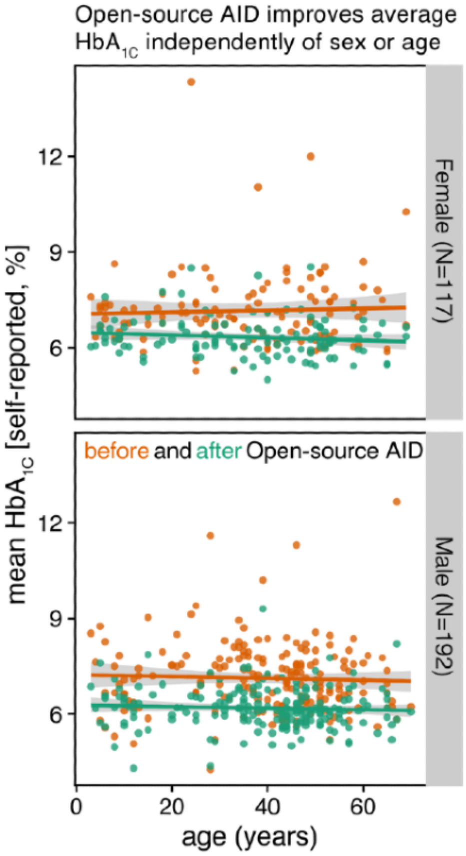

Figure 5. Improvements in self-reported glycated hemoglobin levels associated with open-source automated insulin delivery, independent of age or gender: the y-axis shows the difference of average glycated hemoglobin levels after open-source automated insulin delivery, compared with before its implementation. Colors distinguish respondents with reduced average glycated hemoglobin (blue) from those with unchanged or increased glycated hemoglobin (red). AID: automated insulin delivery; HbA_{1c}: glycated hemoglobin.

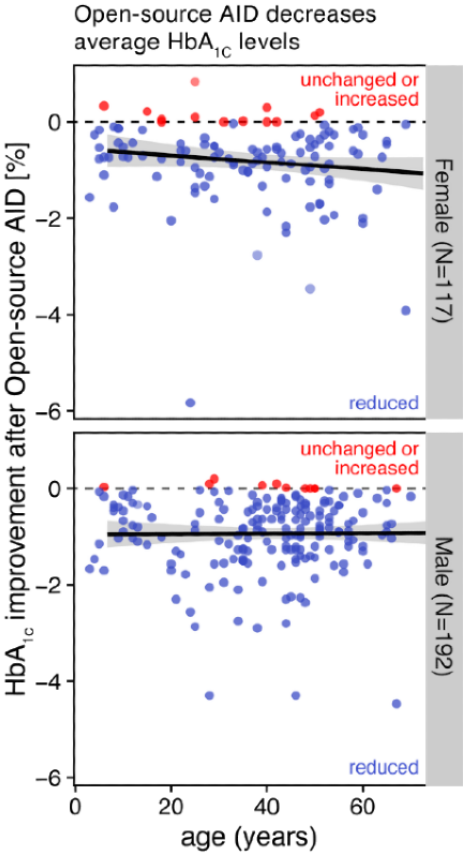

Discussion

Principal Findings

This study is the first to systematically analyze the motivations found within the #WeAreNotWaiting movement of people with diabetes, who have built and maintained their open-source AID systems and created their own ecosystem of international self-support networks. To the best of the authors' knowledge, this is also the largest study reporting the self-reported clinical outcomes of open-source AID users across several continents. We found large effect sizes for self-reported improvements in HbA_{1c} (−0.9% on average) and TIR (+17.4% on average), indicating considerable biomedical benefits associated with open-source AID, which were independent of sex and age.

Why #WeAreNotWaiting: Main Motivators to Choose an Open-source AID

The main motivators for adults were improvements in overall glycemic and long-term outcomes and quality of life, whereas the strongest motivation for caregivers was improvement of their own sleep, followed by improved glycemia of the child and possibility of remotely controlling glycemia and insulin delivery via the internet. The results indicate that motivations are configured differently among caregivers and that other motivations also scored a high level of consensus among the respondents. These findings suggest that motivation to transition toward open-source AID is multifaceted and complex, with reasoning and decision making bound up with the psychological and social intricacies of individuals' lives.

Improvement in Sleep Quality

Caregivers experience reduced sleep quality because of fear of hypoglycemia, which often requires them to regularly check their child's glucose levels overnight [22]. In our study, caregivers reported experiencing fewer demands and less apprehensiveness regarding their child's glucose levels at nighttime. As shown in the free-text responses, open-source AID also appears to offer caregivers with the reassurance necessary to provide their child more autonomy and engage in activities that might otherwise present a risk, such as having *a sleepover* with friends. Previous studies in adults using open-source AID have shown self-reported improvement in sleep quality [23,24]. These initial findings indicate a substantial benefit for users and caregivers for sleep and most likely for their psychological and physical well-being. Poor quality of sleep negatively affects the psychological well-being, cognitive functioning, and a diverse range of hormones that affect the regulation of appetite and our homeostatic systems as well as the immune system [25-34]. Recent research also points to sleep as impacting the actual maintenance of the brain and our DNA regenerative systems [35]. Thus, AID may play an important role in improving the psychological and physical health of people with diabetes and their family members. However, it has been noted elsewhere that the potential discomfort or inconvenience of wearing devices and overnight alarms may also hamper the benefits for some users [36].

The Importance of Customizability: One Size Does Not Fit All

The majority of participants reported that currently approved and available commercial therapy options may not be sufficiently flexible or customizable to fulfill their or their children's individual needs. Among caregivers, features only available in open-source AID, in particular, the possibility of remote management was the main additional motivation. A wider range of features and adjustable settings to improve user experience may be beneficial for people with diabetes of all ages, which mirrors a recent study in very young children using a commercial AID [36]. Interestingly, for many adult respondents, *curiosity* was cited as an important motivation. In contrast, curiosity was a much lower motivating factor for caregivers who chose to build a system for more practical or psychosocial reasons.

Do-it-Yourself Is Not Do-it-Alone: The Impact of Peer Support

The ability to receive and provide support within the do-it-yourself (DIY) community and observe the success of others was an important motivating factor associated with opting to use open-source AID for some. Obtaining and exchanging information and advice from open forums limits the spread of misinformation because other users constitute a community of inquirers ready to challenge and correct spurious or misleading information [37]. Although open-source AID is individualized and patient focused, it is also a grassroots community-driven movement. The number of responses to our survey reflects the enthusiasm and importance of open-source AID. In challenging traditional top-down hierarchies in medicine, open-source AID presents a patient-focused initiative that serves to empower people with diabetes through personalized technology. Because of the availability of current technology and individualized innovations, open-source AID has previously been described as having the potential to democratize health care, revolutionizing treatment and the way people with diabetes as well as other stakeholders such as care teams, researchers, and device manufacturers view chronic conditions such as diabetes [38]. The importance of peer support in the context of open-source AID use has recently been highlighted elsewhere, and a sense of community underpinning the development and diffusion of open-source AID has been emphasized by individual users [39]. Further research should consider community phenomena as an integral part of the DIY experience.

Strengths and Limitations

This study is the first to investigate motivations of users and caregivers to build and use open-source AID. In addition, this is the largest study that reports self-reported clinical outcomes of open-source AID users globally and adds to the existing evidence base around glycemic outcomes in smaller cohorts [11-15]. At the time of data collection, it surveyed the majority of open-source AID users worldwide, with 897 respondents of a population estimated in 2018 (N=1500). The sample is impressive not only in size but also because people with diabetes from various continents and regions of the world are represented. Of other strengths, this study has been conducted by an interdisciplinary consortium, with members of the diabetes community directly involved. However, this firsthand experience should be acknowledged as a potential bias. In addition, a key limitation of the study is the fact that self-reported outcomes have not been corroborated by clinical records. Some may consider this has potential for inaccuracy, that is, by lacking precision as witnessed by the overaccumulation of rounded TIR values or to be biased by the specificity of the population that participated. However, other studies have found that real-world data are robust and reliable [40]. We acknowledge that open-source AID users constitute a specific group of people with diabetes who may be highly motivated, engaged, and willing to improve the quality of their diabetes care and life, limiting the scope of our findings to this group. However, a recent study of newly available commercial AID systems indicates that users are similarly motivated to achieve the best possible outcomes but are dissatisfied with postprandial glycemic outcomes under commercial AID systems [41]. The earliest adopters of available commercial AID technology may be more similar to the group of people with diabetes choosing open-source AID in terms of motivation and engagement than expected. The lack of widespread availability of AID technology in general, including commercial systems with regulatory approval, at the time of the study likely influenced the perspectives of people with diabetes choosing open-source systems. In the future, wider availability—and, importantly, better funding or insurance coverage of commercial AID systems—may further influence this cohort. Similarly, it remains to be seen if the predicted *second generation* of commercial systems—with a hypothesis of increased sophistication or improvements on the first-generation devices and algorithms—will enable people with diabetes to achieve results similar to those they are currently achieving with their chosen open-source AID system.

It should also be noted that those who benefit from and continue to use open-source AID may be motivated to share their positive experiences. Although the survey was open to people with type 2 and gestational diabetes, it was completed almost exclusively by adults and caregivers of children with type 1 diabetes. This is likely a reasonable reflection of the DIY community, but efforts need to be made in the future to encourage participation of those with other types of diabetes. The high percentage of respondents from Europe may be influenced by the fact that the majority of the research team is EU based, which may be another bias. This may also be explained by the characteristics of the European health services provision and reimbursement of diabetes-related technology, which may provide a greater degree of accessibility of the underlying components needed (eg, pumps and continuous glucose monitors). Language barriers may have limited responses from other parts of the world as the survey was only available in 2 languages. Finally, the majority of participants had a university degree, suggesting that open-source AID uptake is more common among people of higher socioeconomic status. Increasing socioeconomic inequalities in access to the underlying technologies needed to build an open-source AID system may help to explain some of these variations. Thus, further investigation into how the wider diffusion of open-source AID is conditioned by factors such as social class, gender, age, and geographic location is required.

Conclusions

This study provides new insights into the factors that motivate people to adopt *DIY* solutions in relation to their diabetes and beyond. Our findings contribute to a better understanding of the unmet needs of people with diabetes and some of the current challenges in the uptake of AID technology. This study, alongside other efforts in the DIY community space, can help key stakeholders, including academia, the medical device industry, regulators, health care providers, and care teams, to better address some of the fundamental gaps and needs that still exist for people with diabetes worldwide, even with the advent of first-generation commercial AID systems. The DIY movement has resulted in impactful solutions addressing the unmet needs of people with diabetes and represents an exemplary case of how informed and connected patients are shaping the direction of technological innovation in diabetes care and potentially for other areas of health care in the future.

Acknowledgments

The authors would like to thank the #WeAreNotWaiting and DIY community that supported and greatly contributed to this study. The OPEN project has received funding from the European Commission’s Horizon 2020 Research and Innovation Program under the Marie Skłodowska-Curie Action Research and Innovation Staff Exchange grant agreement number 823902. J Speight and CH were supported by the core funding to the Australian Center for Behavioral Research in Diabetes provided by the collaboration between Diabetes Victoria and Deakin University. KB received the funding from the Berlin Institute of Health Digital Clinician Scientist Program and the SPOKES Wellcome Trust Translational Partnership Program. The funding sources had no involvement in the study.

Authors' Contributions

KB was the guarantor of this study. KB, DL, TS, HL, KR, J Schipp, KAG, CH, and BC performed the literature search. KB, SO, BC, A Tappe, DL, and KR designed the survey. KB collected the data. KB, DL, SO, TF, KAG, and BC analyzed and interpreted the data. A Thieffry conducted quantitative analyses and produced the associated figures. KB, DL, SO, and BC prepared the initial draft. All authors reviewed the manuscript, contributed revisions, and approved the final version.

Conflicts of Interest

All authors have completed the Unified Competing Interest form and declare the following: KB has received research grants from the Berlin Institute of Health, SPOKES Wellcome Trust, Stiftung Charité, and the German Diabetes Association (Deutsche Diabetes Gesellschaft). She has served as a speaker and advisory board member for Medtronic Diabetes and Hi.Health and received fees for medical consulting and public speaking from Roche Diabetes Care, Dexcom, Medtronic Diabetes, Diabeloop, BCG Digital Ventures, and Bertelsmann Stiftung, outside the submitted work. DL reports grants from the Robert Wood Johnson Foundation, JDRF, personal fees from Lilly, Diabeloop, Roche Diabetes Care, and Novo Nordisk and Tandem, outside the submitted work. J Speight has served on advisory boards for Janssen, Medtronic, Roche Diabetes Care, and Sanofi Diabetes; her research group (Australian Centre for Behavioural Research in Diabetes) has received honoraria for this advisory board participation and has also received unrestricted educational grants and in-kind support from Abbott Diabetes Care, AstraZeneca, Medtronic, Roche Diabetes Care, and Sanofi Diabetes. J Speight has also received sponsorship to attend educational meetings from Medtronic, Roche Diabetes Care, and Sanofi Diabetes and consultancy income or speaker fees from Abbott Diabetes Care, AstraZeneca, Medtronic, Novo Nordisk, Roche Diabetes Care, and Sanofi Diabetes, all outside the submitted work. KR is an advisory board member of Lilly Diabetes Care and Abbott Diabetes Care outside the submitted work. KB, DL, SO, A Tappe, and KAG are members of the open-source AID web-based community. All other authors have no conflict of interest to declare.

Abstract

Background: Adolescents with irritable bowel syndrome (IBS) are increasingly seeking and sharing information about their symptoms in web-based health care forums. Their posts and those from their parents contain critical insights that can be used by patients, physicians, and caregivers to manage IBS symptoms.

Objective: The aim of this study is to examine the posts from adolescent patients and their parents in a health forum, IBS Group, to better understand the key challenges, concerns, and issues of interest to young patients with IBS and their caregivers.

Methods: Using topic modeling and social network analysis, in this study, we analyzed all the messages (over 750 topics and 3400 replies) posted on the IBS Group forum from 2010-2019 by adolescents with IBS aged 13-17 years and parents having children with IBS. We first detected 6 major topics in the posts by adolescent patients and parents on teenagers' IBS symptoms and the interaction between the topics. Social network analysis was then performed to gain insights into the nature of web-based interaction patterns among patients and caregivers.

Results: Using the Latent Dirichlet Allocation algorithm and a latent Dirichlet allocation visualization tool, this study revealed 6 leading topics of concern in adolescents with IBS: school life, treatment or diet, symptoms, boys' ties to doctors, social or friend issues, and girls' ties to doctors. The top 6 topics in the parents' discussions were school life, girls' issues, boys' issues, diet choice, symptoms, and stress. The analyses show that the adolescent patients themselves are most concerned about the effect of IBS on their everyday activities and social lives. For parents having daughters with IBS, their top concerns were related to the girls' school performance and how much help they received at school. For their sons, the parents were more concerned about the pain and suffering that their sons had to endure. Both parents and adolescents gained social support from the web-based platform. Topic modeling shows that IBS affects teenagers the most in the areas of pain and school life. Furthermore, the issues raised by parents suggest that girls are bothered more by school performance over pain, whereas boys show exactly the opposite: pain is of greater concern than school performance.

Conclusions: This study represents the first attempt to leverage both machine learning approaches and social network analysis to identify top IBS concerns from the perspectives of adolescent patients and caregivers in the same health forum. Young patients with IBS must face the challenges of social influences and anxiety associated with this health disorder in addition to physical pain and other symptoms. Boys and girls are affected differently by pain and school performance and view the IBS impacts differently from the parents.

Introduction

Background

More than 58 million Americans are affected by irritable bowel syndrome (IBS) [1], a gastrointestinal disorder that causes abdominal pain, bloating, gas, and diarrhea or constipation. However, IBS in adolescents is a less known problem than it is among adults, although 6% of middle school students and 14% of high school students in the United States have symptoms indicative of IBS [2]. Patients with IBS, similar to others with chronic medical conditions, are increasingly seeking and sharing health information through web-based health care forums to manage their symptoms [3]. The forums, functioning similarly to online support groups, have served as a critical source of health information for patients and caregivers. On the internet, patients with gastrointestinal disorders could seek social, emotional, and peer support in addition to the real-time exchange of information related to medical concerns and symptom management [4].

Using data from the IBS Group forum, prior studies have investigated how the ways in which patients with IBS sought out or offered social support affected their behavior toward others on the forum [3,5]. For instance, expressing one's emotions in a post during support seeking significantly increases the likelihood of receiving social support from others who are active in the web-based forum, but reciprocating support with a fixed set of peers discourages individuals from continued social support to others in the larger community [3]. User participation in the forum discussion was found to follow a power law, meaning that a small number of users on the forum became opinion leaders and generated most of the activity on the forum.

IBS in Adolescents

IBS symptoms can be destructive to both adolescents and adults. Despite the serious impact of IBS on patients' quality of life, this gastrointestinal disorder remains a clinical challenge that lacks diagnostic, radiologic, or laboratory markers [3]. To continue this stream of research, this research proposes to use probabilistic topic models for text summarization and topic detection by analyzing an unlabeled corpus of adolescent patients' posts on their IBS symptoms and their parents' posts on how their children coped with IBS. Specifically, we use the latent Dirichlet allocation (LDA) approach, a generative unsupervised probabilistic algorithm that isolates the top K topics in a data set, as described by the most relevant N keywords [6]. Thus, the posts and replies to them in the corpora are treated as random mixtures of latent topics, where each topic is characterized by a latent Dirichlet distribution over a fixed vocabulary. Here, the word *latent* means that topics must be inferred from keywords rather than directly observed.

Using the LDA topic modeling method [7], in this research, we first detected major topics in parents' posts on the IBS Group forum discussing the IBS symptoms experienced by their teenaged sons and daughters. All the topics uncovered in the LDA analyses were analyzed and visualized to explore the relationships among the topics, whose results would assist in medical decision making for the teenagers, their parents, and health professionals. A social network analysis was also performed to gain insights into the nature of web-based interaction patterns.

The remainder of this paper is organized as follows. The next section provides the research background by reviewing the related literature. In the following section, we discuss the research questions (RQs) and explain the methodology. Subsequent sections present the main results and conduct a social network analysis. On the basis of the analyses, the findings and their implications, including the limitations, are examined in the *Discussion* section. Interventions have been proposed to mitigate IBS symptoms in adolescents. Finally, the conclusions are presented in the final section.

IBS Diagnosis

IBS diagnosis is currently based on a symptom complex, and there is no definitive diagnostic test. In children and adolescents, the prevalence of IBS-associated abdominal pain ranges from 6% to 17% and 13% to 38%, respectively [2,8-10]. Previous studies of information flow on public patient-centered health care forums—namely, forums initiated and maintained by patients—have suggested that patients with IBS rely on health information on such forums to evaluate their medical decisions, health risks, and treatment options as well as seeking emotional support [11].

Children and adolescents are particularly vulnerable to IBS. Compared with adult patients, children and adolescents with IBS are distinct in the prevalence of IBS subtypes [12] and are typically prescribed with different pharmacologic and dietary management plans than adult patients [13]. Hence, physicians have difficulty in confirming their diagnoses [14] and may overlook some of the associations among multiple symptoms and facets of this health problem. The limited long-term treatment options deemed safe for younger patients, coupled with the intermittent and unpredictable recurrence of symptoms, result in a chronic state of uncertainty that has profound and formative impact on children's and adolescents' school performance and their quality of life, particularly in eroding younger patients' self-esteem and magnifying their insecurity as *misfits* in schools and society. Although a large amount of work has been devoted to understanding IBS issues in adult patients, challenges in managing pediatric IBS symptoms are only beginning to garner the attention of researchers and health care practitioners.

Previous studies on adolescents' IBS issues are helpful in understanding the pathophysiology of the disease and the etiology of abdominal functional pain, food-induced gastrointestinal symptoms, and other dietary consequences [2]. However, with rare exceptions [15], most studies did not consider possible complications that arise from the symptoms and everyday management of IBS during vulnerable developmental phases, such as childhood and adolescence. The novel aspects of our work are that it is the first study to leverage both machine learning approaches (eg, LDA [7,16]) and social network analysis to identify top IBS concerns from the perspectives of children, adolescents, and caregivers on web-based health forums. Such state-of-the-art approaches should be able to provide novel data-driven insights into factors that facilitate and impede the translation and uptake of health care knowledge and practices.

Therefore, this study proposed the following RQs to explore informational insights by analyzing the posts of adolescents with IBS and their parents who discussed the impact of IBS on young patients:

- RQ1. What are the top 6 topics in parents' posts regarding the impact of IBS on their children?
- RQ2. What are the top 6 topics in teenagers' posts on IBS symptoms?
- RQ3. Are there any sex differences between the concerns that parents post on the forum about their male and female children?
- RQ4. What is the nature of the interactions in the social network on the IBS health forum and what insights can we learn from it?

Methods

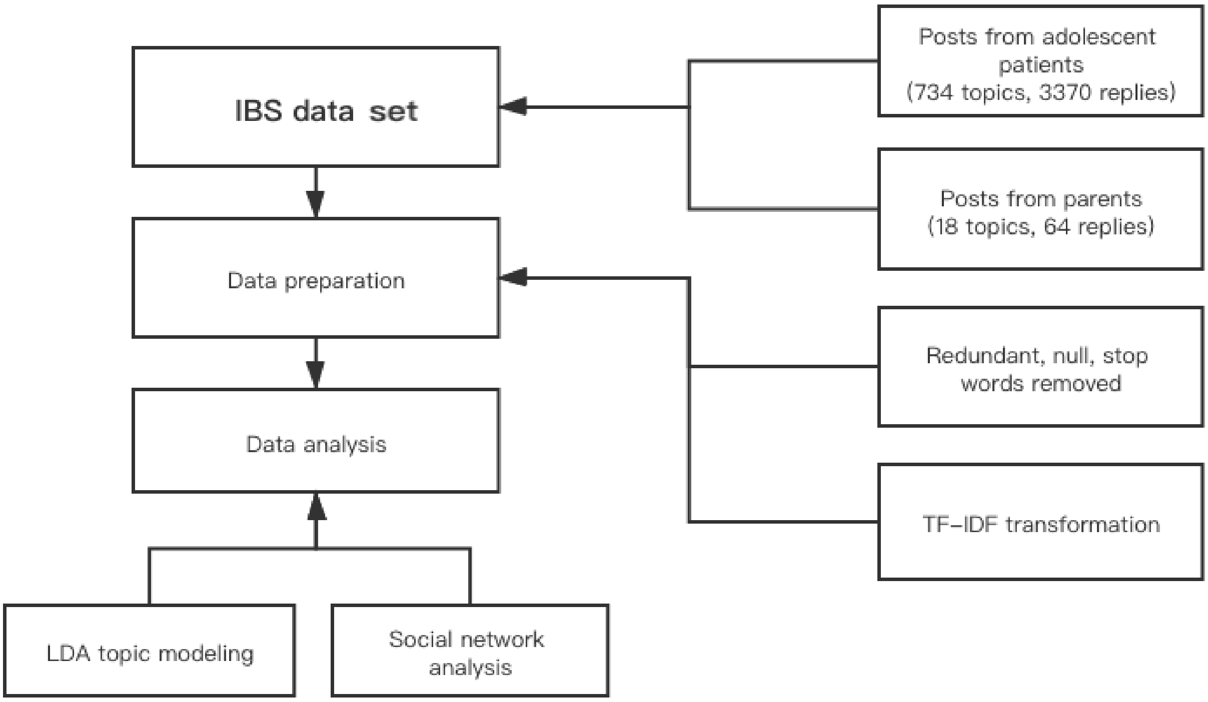
Sampling

In this study, we analyzed the topics in web posts from 2010 to 2019 from adolescents with IBS and the parents' posts concerning the IBS symptoms experienced by their teenaged daughters and sons. The data for this study were retrieved in June 2019 from the subforum discussing *Teens and Children's Issues* on the IBS Group forum [17]. All 734 topics in 3370 replies posted were collected and analyzed for adolescent patients. A preliminary analysis centers on identifying the topics when parents discussed the IBS issues experienced by their children aged between 13 and 17 years [18], involving 18 forum topics with 64 replies in this subforum. The LDA approach identified 6 major distinctive topics in their web-based discussion, as the analyses showed that if the number of topics was greater than 6, significant overlap could occur among them in the corpora.

Social Network Analysis

For social network analysis, we parsed all posts to identify the links that arose when a pair of users participated in a discussion about a subject on the same thread. These links were further dissected to identify the most active users on the forum and the nature of the interactions among them. We also plotted the social network graphs for this data set and performed further analyses. To clean the data, we first removed the null and duplicate posts. Then, we also deleted common stop words such as *this*, *that*, *a*, and *the*. We first built a document-term matrix (eg, an N×M document-term matrix D is a matrix with N documents and M terms). We then applied term frequency-inverse document frequency to process the data so as to eliminate the weight for high-frequency words appearing in every document and add weight for words appearing only in a few documents. Scikit-learn and pyLDAvis libraries were then used to perform topic modeling analyses in Python. Figure 1 shows the data collection and analysis process.

Figure 1. The process of data collection and analysis. IBS: irritable bowel syndrome; LDA: latent Dirichlet allocation; TF-IDF: term frequency-inverse document frequency.



Results

Overview

In this section, we first report the results from the *Parent's Discussion* subforum and then those from the *Teens' and Children's Issues* forum.

Parents' Perspectives on Their Children's IBS Issues

In the subforum of *Parent's Discussion* under the *Teens and Children's Issues* forum [18], we obtained 18 forum topics (or threads) and 64 replies after removing the duplicate, null, and invalid posts. A total of 82 posts were finally retrieved, including several comments from parents in the main forum: *Teens and Children's Issues*. Hence, we wanted to separate the parents' posts from those of the children. Parents' posts usually refer to their children as daughters, sons, he, and she. By looking for such posts, it is possible to determine whether they were made by a parent or caregiver and also the sex of their children. On the other hand, posts by children or teenagers usually do not refer to their own sex and, with some exceptions, it is usually not possible to determine the sex of the person making the post. By searching for sex-specific keywords, we identified and manually transferred 455 posts from the main forum into the parents' discussion subforum so that there were a total of 537 posts for analysis. The 6 topics that were discovered with 10 keywords each are listed in Table 1.

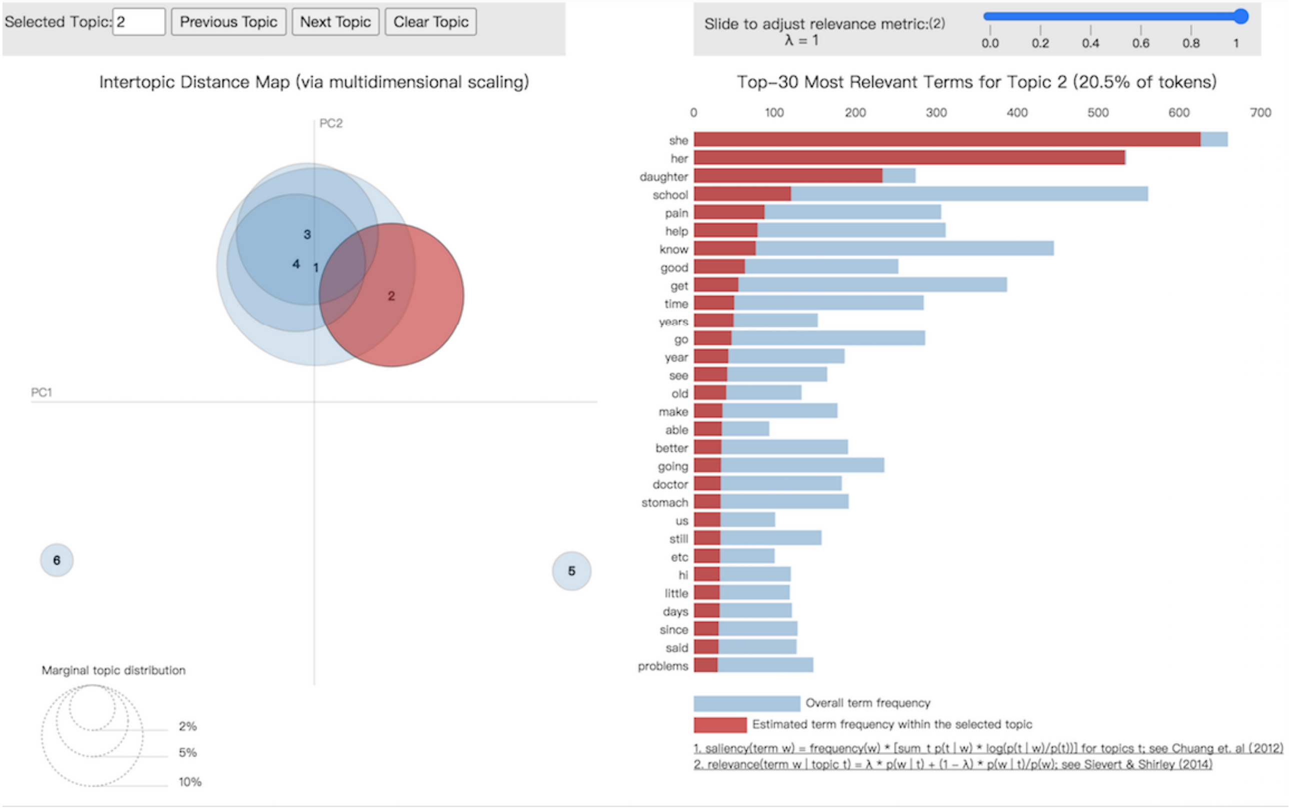
We used the keywords to assign appropriate topic names to each detected topic. We also used the modified pyLDAvis library to generate an overview and visualization of the topic distribution regarding girls' issues (Figure 2) and boys' issues (Figure 3). In the figures, the sizes of the circles represent the relative importance of topics and the distances between the topics reflecting their similarity to one another [19].

Table 1. The top 6 topics in the parents' discussion of their children's irritable bowel syndrome issues.

Topic number	Topic[a]	Keywords
1	School life	*school, know, like, feel, people, think, time, stomach, want, tell*
2	Girls' issues	*she, her, daughter, school, pain, help, know, good, get, time*
3	Boys' issues	*he, son, his, pain, school, help, year, doctor, old, know*
4	Diet choice	*foods, diet, like, eat, food, try, lot, gas, good, help*
5	Symptom	*person, she, say, everything, problem, better, life, week, never, symptoms*
6	Stress	*worse, think, keep, diet, stress, pain, bad, say, started*

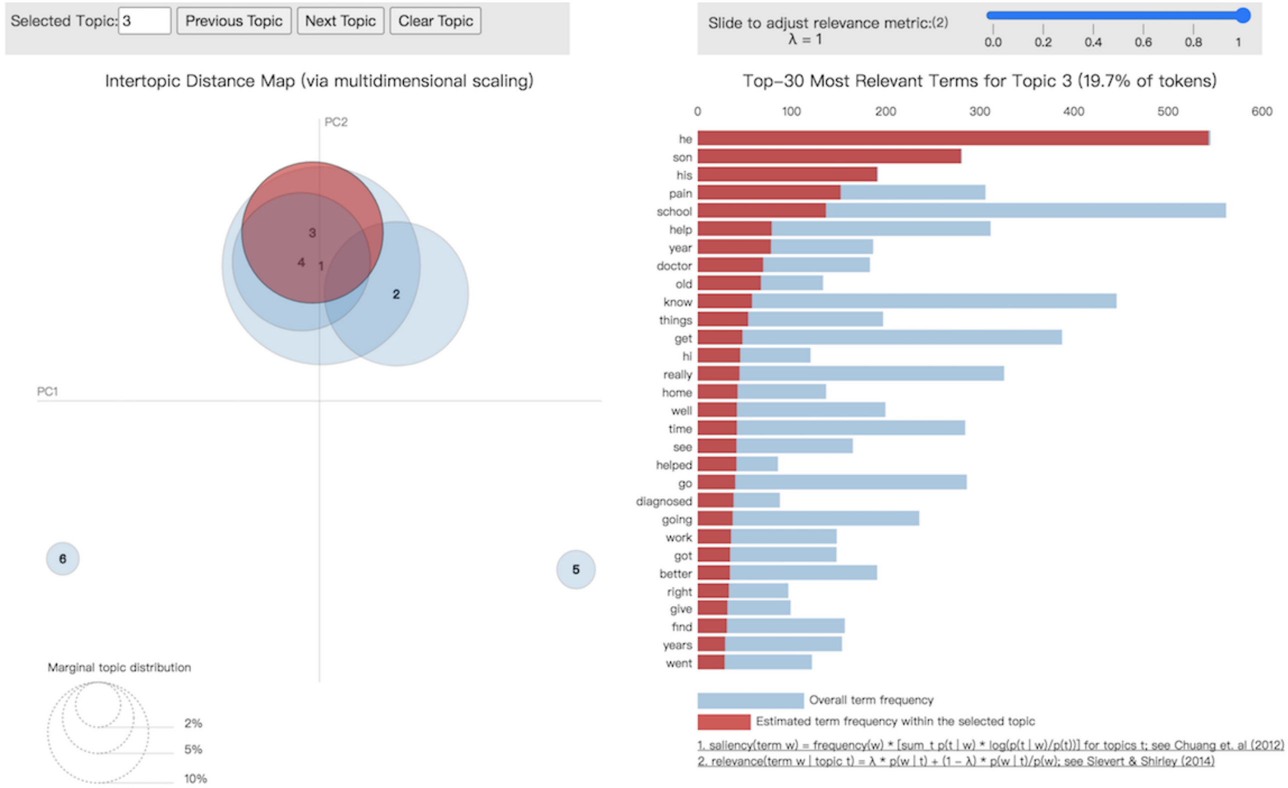
[a] The topic order is based on the total number of posts and replies each topic had from 1 (highest) to 6 (lowest).

Figure 2. Latent Dirichlet allocation visualization of topic 2 (girls' issues) in parents' subforum.



1. saliency(term w) = frequency(w) * [sum_t p(t | w) * log(p(t | w)/p(t))] for topics t; see Chuang et. al (2012)
2. relevance(term w | topic t) = λ * p(w | t) + (1 – λ) * p(w | t)/p(w); see Sievert & Shirley (2014)

Figure 3. Latent Dirichlet allocation visualization of topic 3 (boys' issues) in parents' subforum.



As shown in Figures 2 and 3, for parents, their adolescent girls' and boys' issues related to IBS fell into two major topic groups. The girls' issues, according to keywords representing the topic, are closely related to their school performance. Ignoring the frequently used keywords such as *she*, *her*, *daughter*, the other keywords indicate that parents seem to worry most about *school behavior* and the need of their children for *help*. Parent concerns about school attendance also appeared in their discussion on the subforum. An example post is as follows:

> *I know where we live, the schools get paid by the state based on how many days the kids are in school. So, this is why they are so concerned about the missed days. If I were you I would get a note from the doctor and bring it down to the school in person. Give a copy to the Principal, the Teacher and the School Nurse and explain the situation to them. This should help both your daughter and the school. Hopefully they will become a little more sympathetic to your daughter's needs and she will feel better about going to school overall. Don't let them bully you. Best of Luck and I hope your daughter starts feeling better soon.*

Furthermore, parental worries about their daughter missing classes appeared in the discussion, as indicated by the following post:

> *See if you can get a 504. I have a similar problem, and when I first asked to start a 504, the school counselor said she is fine and doing well and doesn't need one. She has not gotten into trouble for missing school, however, it causes both of us a lot of stress. I will be working on getting her a 504 next week so she will have it in place for high school. (A 504 is a plan for students who don't qualify for an IEPER but still have "disabilities" that impair their normal every day activities.)*

In contrast to the parents' worries about their daughters' school performance, for their sons, they appeared to be most concerned about their experience of pain and other symptoms brought on by IBS. This type of reaction can be seen in the discussion through posts such as the following:

> *My boy had a very strong reaction to the fructose solution. But none to the lactose. This was the only test in the long litany of tests around this miserable thing we call IBS that actually came out with an abnormal result. As a result he is on a low fructose and no fructan (fructans are in wheat and in the onion family especially). He has Post infectious IBS which was very severe during the first year of having it (he was treated by a chronic pain team in the end). Currently he has months when he is OK, normal really then the bowel problems always come back after a virus involving a sore throat.*

Some other examples of parents discussing treatment of their child's pain problems are as follows:

> *He is now on a very limited diet but his symptoms are so much better. He no longer has diarrhea or constipation on a regular basis, his stomach is no longer distended and best of all he hardly ever complains of stomach pains. We were also able to take him off all medications which treated symptoms but were not treating the cause of the pain. I suggest you see a good GI and have her tested for lactose*

> *intolerance and fructose malabsorption through Breath test and consider and endoscopy. Hope this helps and best of luck. I know it can be horrible to see your child in pain and feel you can't do much about it.*

> *My son has had for over 2 weeks pain in his stomach and usually in the middle and he goes to the bathroom but not a lot. It's not hard and not really diarrhea but I think he has been backed up. He has had nausea and a headaches with this. He either is really hungry or not into eating at all.*

Some other keywords also appeared in the discussion related to boys, such as *doctor* indicating parents' excessive attention to doctors' advice, diagnosis, and treatment, as it relates to boys. For example:

> *Now if your son is going to attend school great for him! I have a couple tips that might help him out with bathrooms etc. Go first to your doctor or specialist, have them fill out a form for IBS or a Doctor's note that say the YES he does have IBS.*

Adolescent Patients' Perspectives on Their IBS Issues

In the *Teens and Children's Issues* forum [17], discussion occurred among the adolescents who were themselves the patients. We crawled 734 topics (or threads) with 3370 replies on this forum. After deleting the null and duplicate data, 2410 comments remained. Then, we removed the former 455 parents' comments, which were transferred to the parents' discussion; thus, the comments of the 1955 teenagers and children were left for further analysis. As done before, we cleaned the data and applied the LDA method. This generated 6 main topics, which are listed in Table 2. We also created visualizations for the topics as shown in Figure 4.

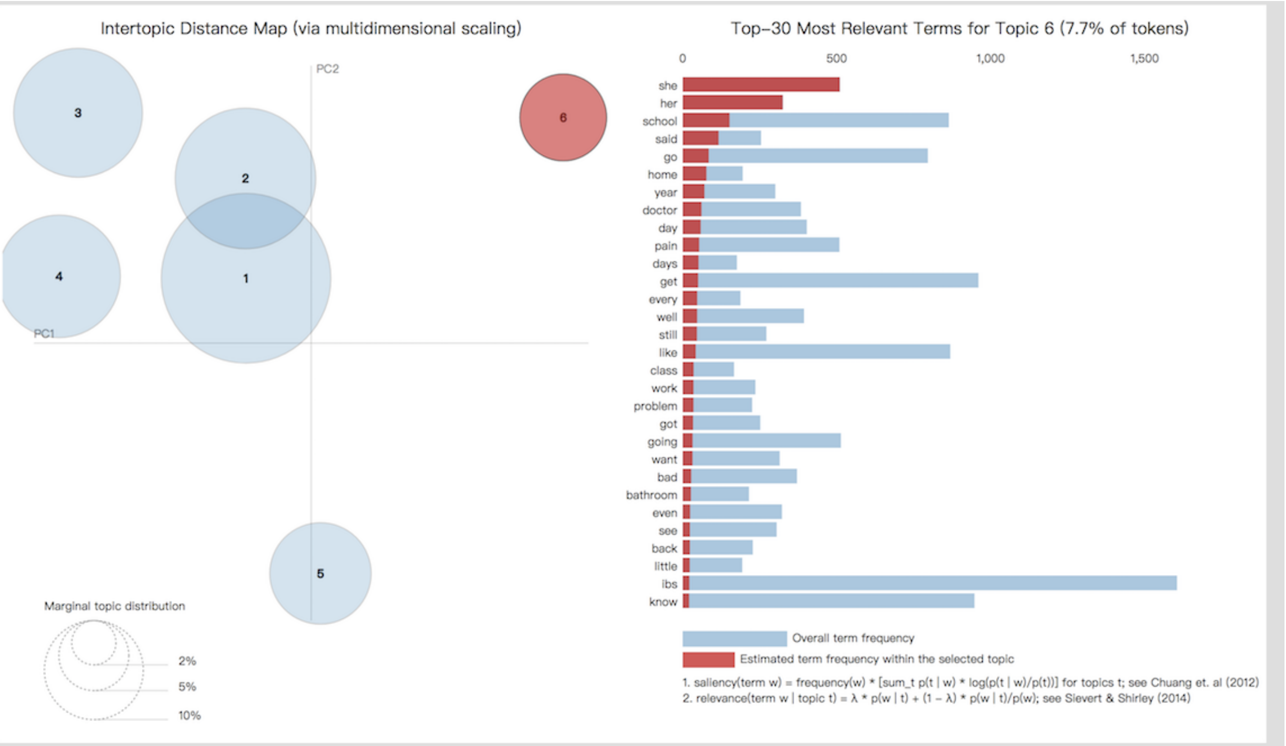
Table 2. The top 6 topics in the adolescent patients' discussion of their irritable bowel syndrome issues.

Topic number	Topic[a]	Keywords
1	School life	*IBS*[b], *school*, *know*, *life*, *try*, *think*, *hard*, *stress*, *want*, *need*
2	Treatment or diet	*eat*, *day*, *time*, *stomach*, *bad*, *IBS*, *sick*, *think*, *lot*, *little*
3	Symptoms	*IBS*, *pain*, *symptoms*, *diet*, *try*, *foods*, *help*, *food*, *find*, *thanks*
4	Boys' ties to doctors	*he*, *help*, *doctor*, *feel*, *need*, *pain*, *know*, *IBS*, *try*
5	Social or friend issues	*friends*, *know*, *school*, *feel*, *talk*, *understand*, *time*, *hope*, *think*
6	Girls' ties to doctors	*she*, *her*, *school*, *home*, *doctor*, *pain*, *class*, *work*, *problem*

[a] The topic order is based on the total number of posts and replies each topic had, ranging from 1 (highest) to 6 (lowest).

[b] IBS: irritable bowel syndrome.

Figure 4. Latent Dirichlet allocation visualization of the top 6 topics in the posts from adolescent patients.



As shown in Table 2, we concluded based on the LDA topic modeling analysis that there were 6 main topics in the posts. The first topic was calculated with keywords such as *IBS*, *school*, *know*, *life*, *try*, *think*, *hard*, and *stress*. We named this topic *school life*. The second topic was calculated with keywords such as *eat*, *day*, *time*, *stomach*, *bad*, *IBS*, *sick*, and *think*, and we named this topic *treatment or diet*. The third topic was calculated with keywords such as *IBS*, *pain*, *symptoms*, *diet*, and *try foods*, and we named this topic *symptoms*. It should be noted that schools, symptoms, and treatments were the most mentioned topics.

Among the symptoms, keyword frequencies showed that *stomach* and *pain* issues are the most devastating and irritating symptoms bothering patients in their daily lives. It is evident that for proper treatment, *food* and *diet* must be carefully planned. Eating more or less, quantity and diet choices are most frequently mentioned as ways to alleviate the problem in the diet options–related discussion. However, different patients have very personalized situations that they must pay attention to. Some discussed whether chocolate is suitable for patients with IBS, for example:

> *I feel your pain on not eating chocolate, but I'm so used to not getting to eat good food' anymore that I just kind of pass right by it and don't notice. Others concluded, on no junk food, for example: "no junk food, fried foods, dairy products, chocolate, soda...nothing!" Some patients seek help from doctors, some get advice from nutritionist, suggesting that "Often times it's your diet, and a nutritionist can really help you in figuring out what foods are causing these problems."*

School performance was also an important topic for young patients and a cause of stress. They encountered difficulty in *fitting* into society, some mentioning experiences such as:

> *In high school I missed 1.5-2 days a week, and it was even more embarrassing because people noticed I frequently took days off and when I did show up the teachers, students used to brazenly point out my attendance (good to see you! followed by laughter). I avoided school even more. I wanted so desperately to graduate and not be forced to sit in a classroom.*

Evidently, it was hard for them to be understood by their peers and teachers in school, with some complaining as follows:

> *Missing school is the worst as I know that nobody really understands what I'm going through.*

One theme consistent in both the parents' and teens' forums is that although both worried and suffered stress or anxiety from IBS, their emphases differed. For parents, the stress was mostly related to IBS symptoms, such as pain, whereas for teenagers and children, it came from school and social activities. This means that parents should be encouraged to become more closely involved in the psychological and social impact of IBS on their children's daily lives.

Social Network Analysis

The purpose of the social network analysis was to understand the patterns of interaction among the users on this forum and extract insights from them. An interaction occurs between a pair of users when both are involved in the same thread by making posts related to the same topic, say, in response to a question raised on the forum. We found that there were 3010 unique interactions in all the posts on the *Teens and Children's Issues* forum, including the parents' subforums. After excluding the responses by the same author who created the thread, there were 2053 interactions. On examining the data more closely, we found that user *Kathleen M*, one of the top content contributors, was an IBS expert who also participated in the IBS forum for adults.

Next, we plotted the top 30 most active users who contributed the most to the forum (Figure 5). The plot shows a typical power law pattern, where most of the contributions come from a small number of users and the participation of the remaining users is very small. This is also consistent with the pattern observed for the adult forum in our previous study [20,21].

Next, we used the Gephi tool [22] to create a social network graph of all interactions (Figure 6). This graph shows that there is a strongly connected core at the center from which there are connections radiating to the other nodes. The nodes on the outside have weak connections with each other. In this graph, there are 1165 nodes and 2020 edges. The edges are weighted by the number of exchanges that occur between the pair of users on the 2 sides. The weights vary from 1 to 5. The graph is undirected, so an edge with weight 1 represents the flow of a message in both directions. The density of the graph is 0.001, and its diameter is 16. The average degree of this graph is 1.734, and the weighted degree is 2.411. The clustering coefficient is 0.034.

Figure 5. Plot of number of posts made by the 30 top content contributors.

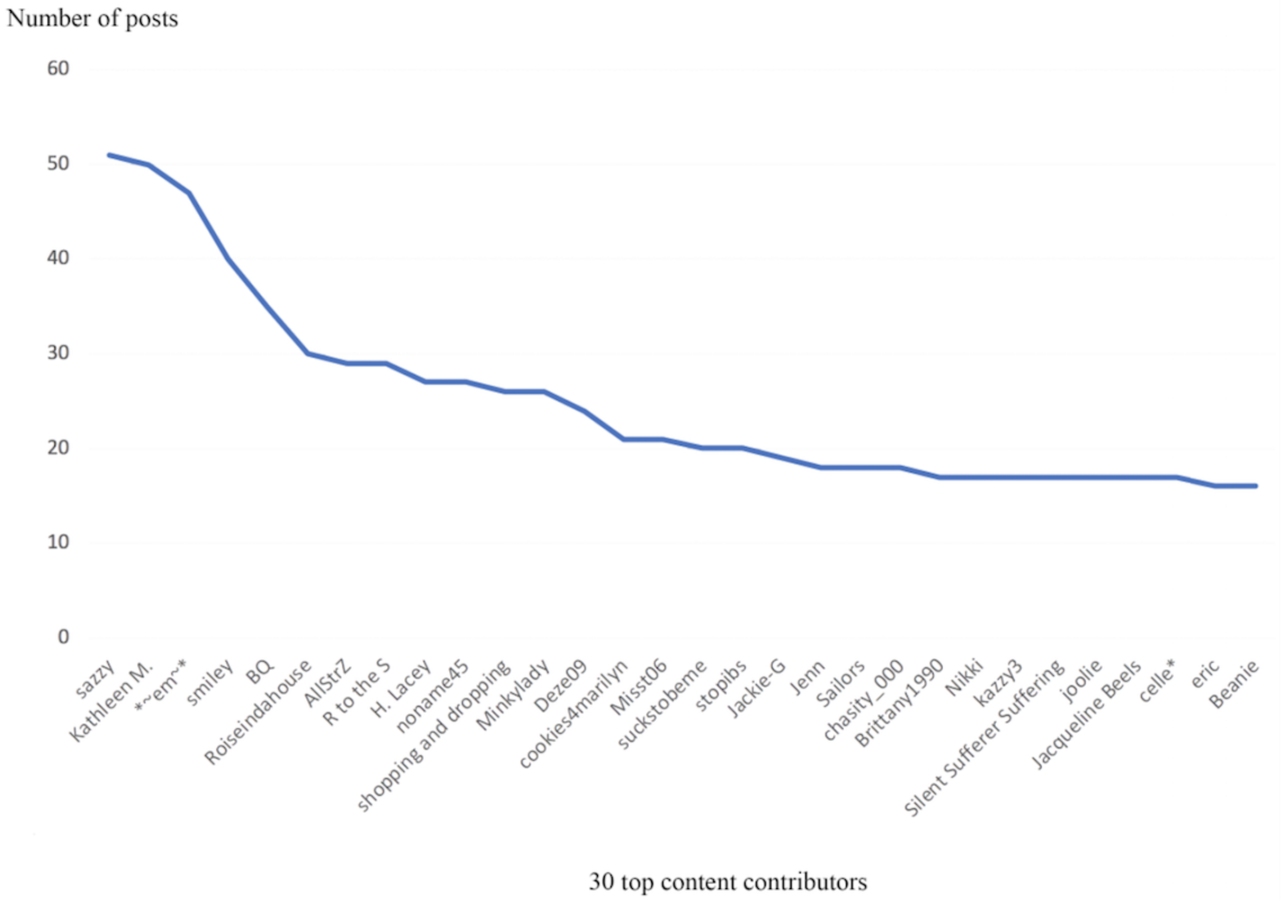


Figure 6. A full social network for all 2053 interactions on the forum.

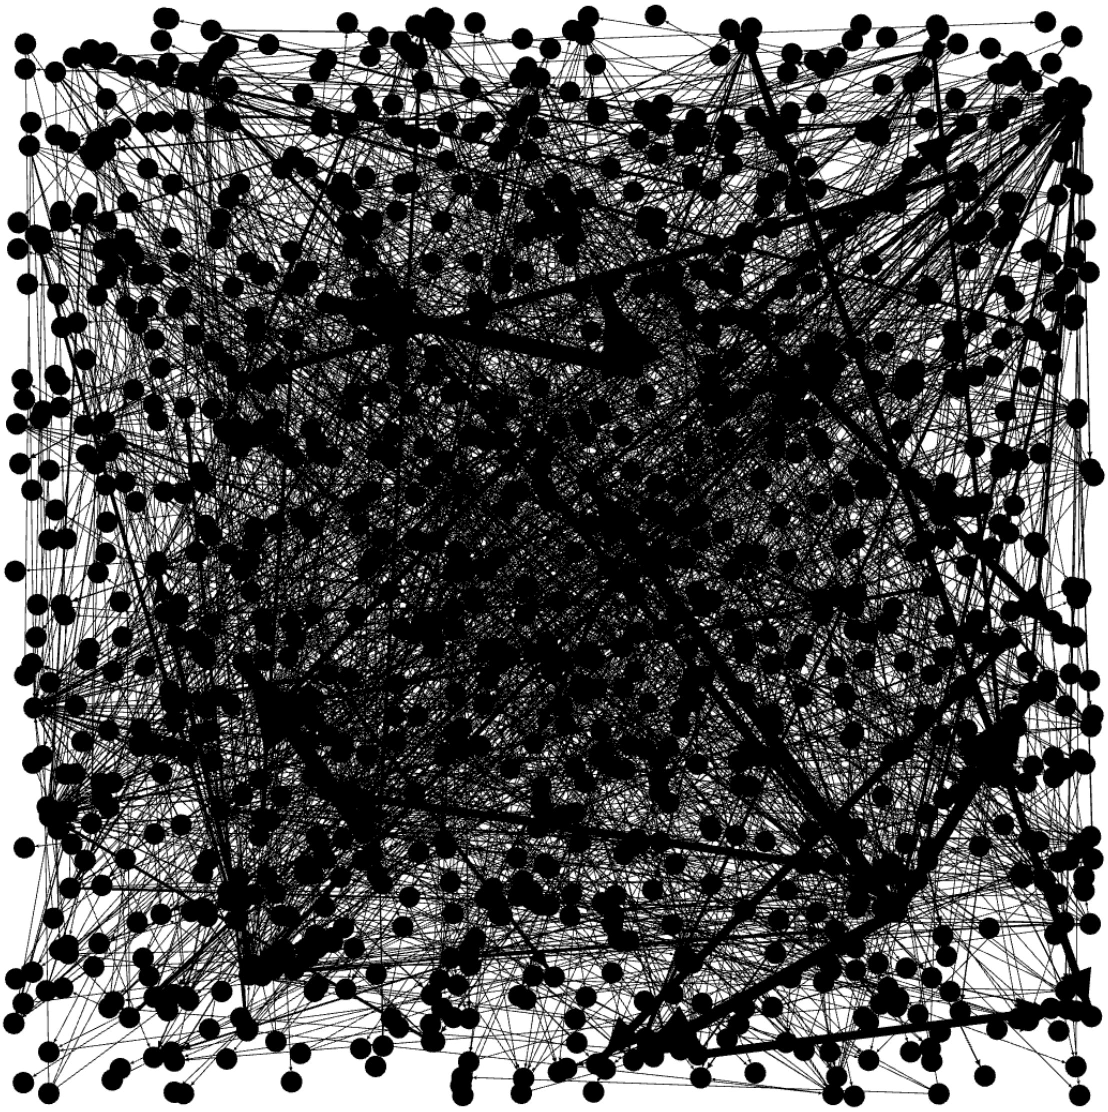
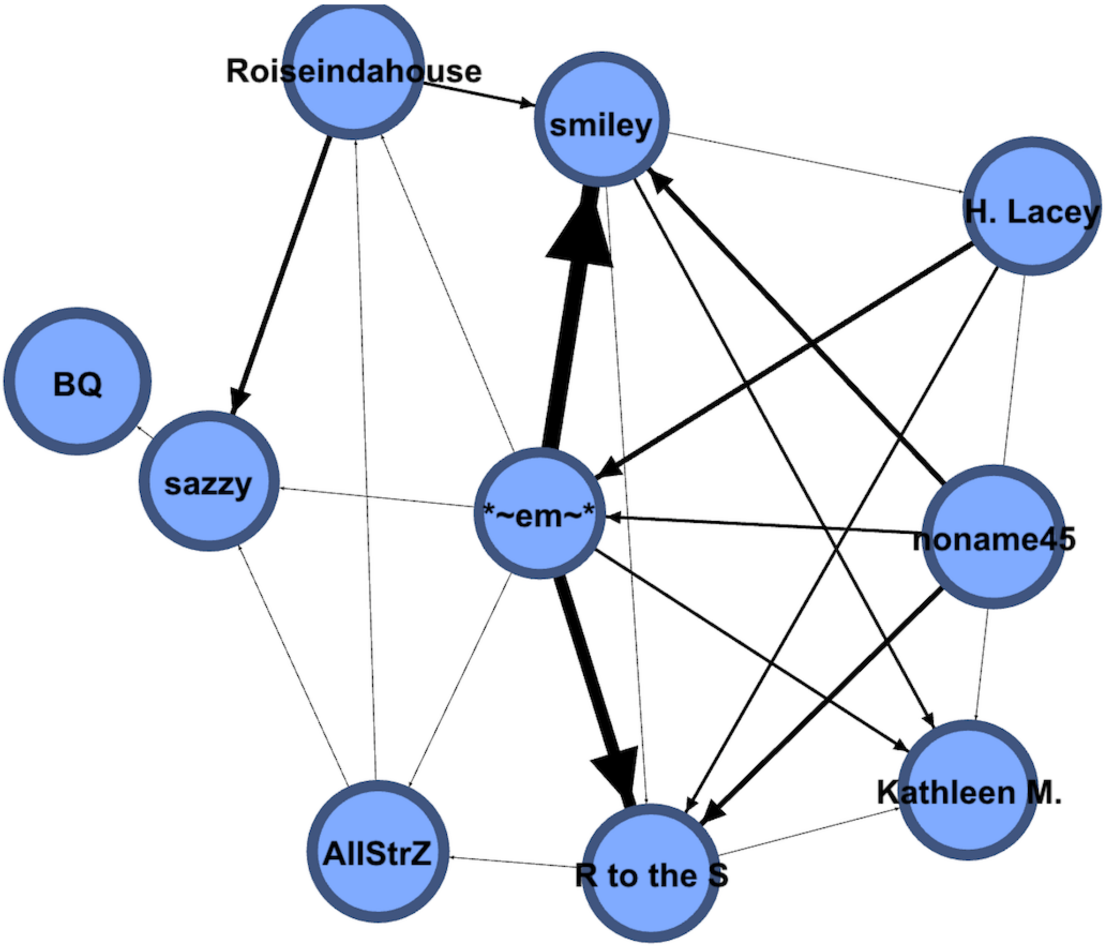


We also show a smaller filtered version of this graph in Figure 7. We deleted self-connected edges and showed a graph with nodes of degree >25 using the filter feature of Gephi to focus on the links among the most prolific contributors. The degree of a node in a social network is the number of connections it has to other nodes, and the degree distribution is the probability distribution of these degrees over the entire network, including both out degree, or the number of edges leaving a vertex, and in degree, which is the number of edges entering a vertex. The analyses show that this is a more tightly connected graph, as expected. The average degree of this graph and the average weighted degree are 2.6 and 4.867, respectively. The diameter is much smaller at 5, and the density is higher at 0.186. The clustering coefficient is 0.233.

As Figure 7 shows, the top contributors to the content in the forum had more interactions among themselves than with all other users in the same network. Among the top contributors, *Kathleen M* was found to contribute the most. It is important to note that this user or node did not have the highest closeness centrality, which reflects the inverse of one node’s average distance to all other nodes [23] and is one of the most important centrality indices in a network for the nodes [24]. Rather, *Kathleen M* was the top commentator on posts of others who did not post any inquiries in the forum. Other top content contributors, such as **~em~** and **sazzy**, posted inquires and comments on others’ messages and had the highest betweenness centrality in the forum, which is a key measure of distance in a network for a node that is calculated as the number of shortest paths going through a node. For **~em~**, the degree is 62, the closeness centrality is 0.275, and the betweenness centrality is 11,816.665, whereas for **sazzy**, the degree is 54, the closeness centrality is 0.168, and the betweenness centrality is 9749.487. These users were the 2 nodes with the highest degrees, closeness centrality scores, and betweenness centrality scores, even higher than those of the top content producer *Kathleen M* (degree=50, closeness centrality=0, and betweenness centrality=0). The results show that *Kathleen M* replies to many posts but did not post in this forum section, whose out degree is 0 and in degree is 50.

Figure 7. The social network of users with high-degree nodes (degree >25).



Discussion

Principal Findings

This study has discovered that IBS can be a sensitive topic for younger patients, particularly adolescents who are already undergoing myriad other critical developmental changes that deter them from sharing their feelings and emotions with adults, including their parents, caregivers, and teachers. Given the increasingly dominant role played by web-based platforms as a source of information exchange in this digital age, especially among adolescents [25], it is critical to harness information from web-based patient- and caregiver-centered forums to better understand key challenges, concerns, and issues of interest to younger patients with IBS and their caregivers; examine how health information, including misinformation and obsolete health care practices, is propagated and perpetuated via web media; and how the rates of information propagation and dissemination depend on the sentiments underlying health-related messages and links among forum members.

To date there is no definite cure for IBS, and hence, health care forums for IBS are very helpful to adult patients in exchanging medical information about their conditions and obtaining emotional support from others. Our semantic analysis of the posts reveals that adolescent patients with IBS and their parents also benefit from raising their issues and concerns regarding a forum dedicated to them. Physicians often advise them to follow a diet low in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols and avoid *trigger foods* [13]. It is also important for teenagers to learn how to manage pain and stress, which are known to worsen the symptoms [26].

Previous research has found that adult patients tend to focus on gastrointestinal discomfort in their posts, and the top three causes were psychological factors, food, and allergens [27]. Using the LDA algorithm and an LDA visualization tool, we identified and visualized 6 main topics in our study from 2 health forums, one for discussion among the parents who cared for teen patients with IBS and another for discussion among the adolescent patients themselves. For parents, a top concern was the school performance of their daughters and how much *help* they got at school. For their sons, they were more concerned about the pain and suffering they had to endure. Teenagers themselves are most concerned about the effect of IBS on their everyday activities and social lives.

Although both sexes faced worries and anxieties from IBS, boys and girls responded differently to IBS symptoms, especially abdominal pain. It is evident that both teenagers with IBS and their parents valued the social support they received from web-based health care forums enormously. Our findings should also assist medical professionals and school administrators in enacting better health policies and lead to sound decisions and higher care quality for patients with IBS. A better understanding of the impact of IBS on young patients' social and school lives can provide powerful support to both adolescents' caregivers in self-caring IBS symptoms. Such self-management techniques based on the information shared on health forums are known as *a web intervention*, which have positive outcomes for patients with IBS [28]. Our research adds fresh evidence of the effectiveness of such a web intervention.

Going beyond previous studies on patients with IBS that seldom analyzed sex differences, we identified three reasons for the sex differences that were observed on the forum. First, girls found it difficult to describe their IBS issues to others to seek help and support. Some even became more reticent and felt humiliated easily. For instance, one adolescent was asked in front of her parents whether she was pregnant. Second, some young women have been brought up by parents to follow social norms and expectations, more so than boys. Third, the tolerance of pain varies between females and males with girls being more capable of enduring pain than boys. The findings reveal that in addition to coping with IBS symptoms, young patients have to face the challenges of social influences and anxiety associated with this health disorder in addition to physical pain and other symptoms. Boys and girls are affected differently by pain and school performance, and their views are different from those of parents.

Our social network analyses have identified multiple prolific users in the forum who contributed most content, such as posts and replies, in the forum. They functioned like opinion leaders in the network that could strongly influence other users' health information processing concerning IBS. Their posts and replies could be the major drivers that kept the conversation of adolescent IBS symptoms going among the users, which also added value to the information flow. It is important to note that this study has found that one of the top content contributors such as *Kathleen M* did not post any messages but commented and replied to others' posts. Without the social network analysis, it was impossible to know that the top content contributor achieved the status by writing replies and comments only, who was more influential than many other users who posted inquires and comments about IBS. Other influential users in this network, such as users *sazzy*, **~em~**, and *smiley*, posted inquires and commented on messages from their peers. This finding has important implications for users and caregivers when they exposed, accessed, and accepted the health information circulated in the forum. Without this study, average users would not know the veiled features of the information flow from the top contributors in the health forum.

Several limitations must be considered when interpreting these findings. First, the results may not be representative of the entire population of adolescents with IBS even when this study analyzed all the posts and replies from adolescent patients and parents on the IBS Group forum. Second, we cannot recognize the sex of the parents based on their posts and can only indirectly identify some of the adolescents' sex by pronouns used, which may not be completely accurate. Third, because this is an anonymous forum, little information can be collected about the users, such as age, school year, health history including diagnoses, medicines, tests, allergies, immunizations, and treatment plans. All these factors make it difficult to fully understand their medical conditions, and thus, only limited insights may be revealed.

Conclusions

IBS among children and teenagers is an underappreciated problem in the medical and school communities, although about 1 of every 7 adolescents suffers from it. This research uses a novel machine learning approach called the LDA algorithm to perform topic analysis on 2 forums—one for parents and another for teens to discuss their IBS problems. One of the important findings is that certain IBS concerns in teenagers are sex specific, which is not so apparent among adult patients. Parents have different issues that bother them for their sons or daughters. Some issues among girls and boys who suffer from this condition are also different. Both parents and children derive considerable medical and emotional benefits from IBS forums. Our study shows that this condition is very debilitating for adolescents, and in many cases, it has a devastating effect on their everyday activities and social lives with potentially lifelong consequences. This study represents the first attempt to leverage both machine learning approaches and social network analysis to identify top IBS concerns from the perspectives of adolescent patients and caregivers on the same web-based health forums. The insights revealed in this study, especially the social influences of IBS-related concerns, should help adolescent patients manage their symptoms and school lives. Moreover, caregivers, teachers, and school administrators should also benefit from the findings of this study.

Abstract

Background: Antibiotic misuse is a serious public health problem worldwide. National health authorities release clinical practice guidelines (CPGs) to guide general practitioners (GPs) in their choice of antibiotics. However, despite the large-scale dissemination of CPGs, GPs continue to prescribe antibiotics that are not recommended as first-line treatments. This nonadherence to recommendations may be due to GPs misunderstanding the CPGs. A web interface displaying antibiotic prescription recommendations and their justifications could help to improve the comprehensibility and readability of CPGs, thereby increasing the adoption of recommendations regarding antibiotic treatment.

Objective: This study aims to design and evaluate a web interface for antibiotic prescription displaying both the recommended antibiotics and their justifications in the form of antibiotic properties.

Methods: A web interface was designed according to the same principles as e-commerce interfaces and was assessed by 117 GPs. These GPs were asked to answer 17 questions relating to the usefulness, user-friendliness, and comprehensibility and readability of the interface, and their satisfaction with it. Responses were recorded on a 4-point Likert scale (ranging from “absolutely disagree” to “absolutely agree”). At the end of the evaluation, the GPs were allowed to provide optional, additional free comments.

Results: The antibiotic prescription web interface consists of three main sections: a clinical summary section, a filter section, and a recommended antibiotics section. The majority of GPs appreciated the clinical summary (90/117, 76.9%) and filter (98/117, 83.8%) sections, whereas 48.7% (57/117) of them reported difficulty reading some of the icons in the recommended antibiotics section. Overall, 82.9% (97/117) of GPs found the display of drug properties useful, and 65.8% (77/117) reported that the web interface improved their understanding of CPG recommendations.

Conclusions: The web interface displaying antibiotic recommendations and their properties can help doctors understand the rationale underlying CPG recommendations regarding antibiotic treatment, but further improvements are required before its implementation into a clinical decision support system.

KEYWORDS

clinical decision support system; visualization; usability; clinical practice guidelines; antibiotic; primary care

Introduction

Antibiotic misuse is a serious public health problem worldwide [1,2]. It exposes patients to the risk of adverse effects and complications, including death [3,4], as well as bacterial resistance [5]. Most antibiotic prescriptions are made in primary care settings. In this context, the choice of antibiotic is usually empiric (ie, without identification of the causative bacterium) and depends on various microbiological, epidemiological, pharmacological, patient condition–, and general practitioner (GP)-related factors [6].

National health authorities release clinical practice guidelines (CPGs) to guide GPs in their choice of antibiotics. CPGs contain evidence-based recommendations from a group of experts based on scientific publications. However, despite the large-scale diffusion of CPGs, GPs continue to prescribe antibiotics that are not recommended for first-line treatment (eg, broad-spectrum antibiotics) [7,8]. This noncompliance with recommendations may be due to the GPs misunderstanding the CPGs or their lack of confidence in these guidelines [9,10]. Indeed, it has been shown that GPs are suspicious of the content of CPGs; they believe that the recommendations are driven by economic issues rather than a desire to improve patient care and that there is a lack of evidence to support the recommendations [11]. They also find the guidelines unclear, ambiguous, incomplete, complex, and unusable in clinical practice [11].

An antibiotic prescription web interface displaying not only recommendations of antibiotics but also their justifications could help improve the GPs’ comprehensibility and readability of CPGs, thereby increasing the adoption of recommendations regarding antibiotic treatment. The justifications for antibiotic recommendations can be found within CPG documents, but they are often *lost* or *hidden* in large amounts of text [12,13]. A qualitative analysis of CPGs [12,13] for antibiotic treatment showed that these justifications were based on antibiotic properties [14,15]. For example, fosfomycin trometamol is recommended for the treatment of uncomplicated cystitis because of the following properties: short-duration protocol, few side effects, and little collateral damage. The display of antibiotic properties in an easily accessible and understandable manner could therefore help improve the comprehensibility and readability of CPGs for GPs, thereby increasing the chances of them successfully adopting those recommendations.

It is not easy to display the recommended antibiotics and their properties in a readily usable interface [16,17]. In the context of antibiotic treatment, several kinds of interface have been used, including textual formats [18,19], tables [19], diagrams [20], hypertextual links [21], and tick boxes [18]. Outside the domain of medicine, e-commerce interfaces (such as those used by e-commerce organizations like Booking, eBay, and Amazon) are widespread and make it possible for consumers to compare particular parameters between products. However, surprisingly, interfaces of this type are rarely used in the medical domain. Such e-commerce interfaces could be an effective way of displaying both antibiotics and their properties.

In this study, we aim to (1) design a web interface for antibiotic prescription presenting recommendations and justifications, in the form of an e-commerce interface displaying antibiotics and their properties, and (2) evaluate the readability and utility of this interface for improving the GPs’ comprehension of CPGs.

Methods

Interface Design

The elements involved in medical decision-making for antibiotic prescription have been previously identified based on analyses of clinical guidelines [14] and clinical expertise [6].

The best way to organize these elements into the proposed web interface was determined by reviewing and analyzing the content of the following:

1. Health care interfaces: However, no interface with a design similar to that of an e-commerce interface was retrieved.
2. Several well-known e-commerce websites for booking trips or hotels and web-based stores: A panel of websites were reviewed and the interface of four selected e-commerce websites (ie, Booking, Amazon, Tripadvisor, and LeBonCoin) were analyzed in greater detail. This analysis revealed that these interfaces contained three common main sections: a summary section, a result section, and a filter section (Figure 1). The same partitioned sections were then used to organize the elements involved in medical decision-making and to design the web interface.

The *summary* section of e-commerce interfaces usually displays the search criteria entered by the user when searching for a product (eg, “hotels in Paris from 21/12/2020 to 26/12/2020”). In our web interface, the elements “patient profiles” and “diseases” (eg, adult pharyngitis) were considered as search criteria.

The *filter* section of e-commerce interfaces usually displays optional parameters that users can click to filter the products selected in response to the initial search criteria (eg, hotel price). In our web interface, elements relating to certain generic patient conditions that are taken into account during drug prescription (eg, renal failure) were considered as optional parameters.

Finally, the *result* section of e-commerce interfaces usually displays the products recommended after both the search criteria and the optional parameters entered by the user have been taken into account. The characteristics of the products are usually also displayed in the form of icons to facilitate product comparison (eg, an icon for a swimming pool). In the web interface, the elements “antibiotic” and “antibiotic properties” were considered as products and characteristics, respectively. The antibiotics recommended in CPGs and the properties used by CPG experts to make those recommendations would then be displayed. A previous study identified seven preference properties (eg, “convenient protocol”) that are currently used by experts for making recommendations [14]. Antibiotics satisfying these properties are preferred over others, depending on the clinical situation (eg, in women with uncomplicated cystitis, fosfomycin trometamol is preferred over other antibiotics because it has the property “convenient protocol”). For each preference property, two junior doctors reviewed the icon web sites and designed personalized icons using Inkscape. The seven preference properties, as described by CPG experts, are shown along with the representative icons in Table 1.

Figure 1. Basic wireframe of e-commerce interfaces compartmentalized into sections.

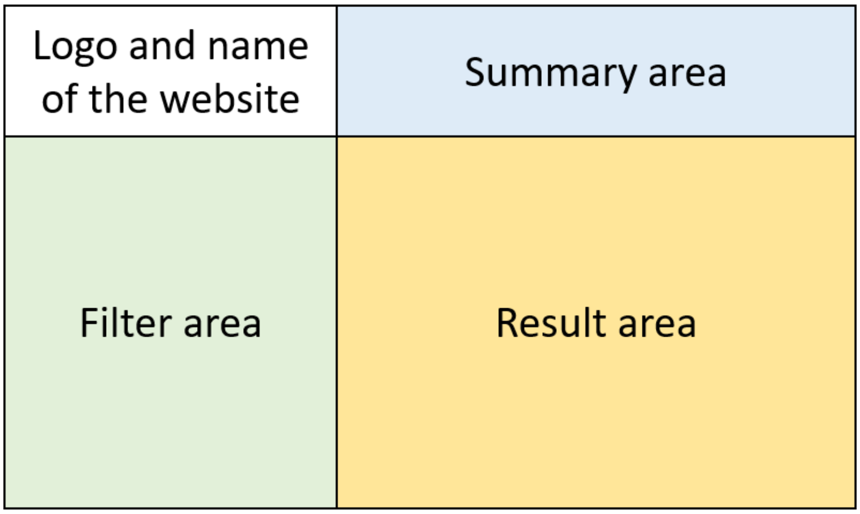

Table 1. Icons used for displaying antibiotic properties.

Preference property	Definition[a]	Icon description	Icon
Convenient protocol	If the antibiotic is prescribed orally and for less than Z days[b]	Symbolized by a capsule placed on a hand	
Absence of serious and frequent side effects	If there is no risk of serious side effects and the frequency of side effects is sufficiently low to allow prescription	Symbolized by a face with skin rash with an interdictory stroke	
Nonprecious class	If the antibiotic does not belong to a class of drugs that must be preserved for more serious infections	Symbolized by a diamond with an interdictory stroke	
Narrow antibacterial spectrum	If the antibiotic is described as having a narrow antibacterial spectrum	Symbolized by mass spectrum graph	
Low level of ecological adverse effects	If the antibiotic is described as having a low risk of promoting bacterial resistance	Symbolized by a recycling icon	
High level of efficacy	If the antibiotic is described as very effective (eg, high clinical cure percentage)	Symbolized by brachial biceps with a boxing glove	
Acceptable taste	If the antibiotic is described as having an acceptable taste for oral administration	Symbolized by a face with tongue emoji

[b] Z: the period depends on the clinical situation.

Interface Assessment

The utility of the interface for improving GPs’ comprehension of CPGs and their readability was evaluated using a questionnaire tailored to the study.

GP Recruitment

GPs were contacted via emails sent to medical networks in the Île-de-France region (including Paris) and by word of mouth, between March 25 and April 25, 2018. A reminder was sent 15 days after the first contact was made. For inclusion in the study, GPs had to be in training or practicing in primary care. The evaluation was voluntary and anonymous.

Study Design

A web-based evaluation was carried in three steps. First, the participating GPs were asked to answer five sociodemographic questions. Their responses were rendered anonymous. Next, the GPs were asked to use the web interface for the use case “young adult woman with uncomplicated pyelonephritis.” The information displayed on the web interface was derived from a knowledge base describing 11 infectious diseases, 50 antibiotics, and 21 patient profiles, constructed based on French CPGs and clinical expertise (a description of this knowledge base is available in the literature [14]). Then, the GPs were asked to answer 17 questions relating to usefulness (3 questions), user-friendliness (3 questions), satisfaction (3 questions) and comprehension (8 questions). The responses were recorded on a 4-point Likert scale (ie, “absolutely disagree,” “tend to disagree,” “tend to agree,” and “absolutely agree”). At the end of the evaluation, GPs were provided with an opportunity to write optional free comments.

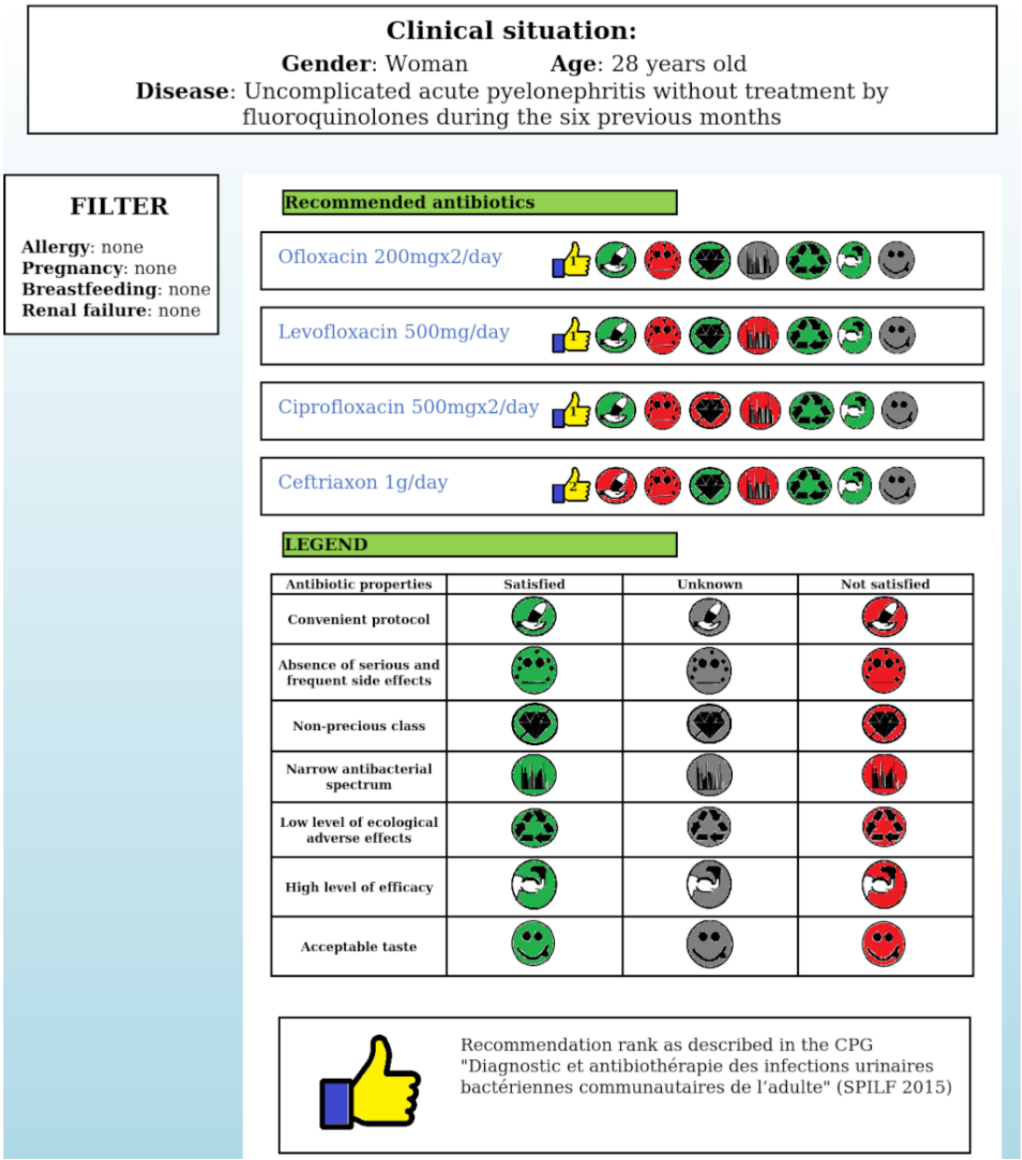
Results

Web Interface for Antibiotic Prescription

The web interface for antibiotic prescription was divided into three main sections, as in most e-commerce websites (Figure 2):

1. The *clinical summary* section, located at the top of the interface, displays a short summary of the clinical situation defined by both the disease and the profile of the patient (eg, sex, age).
2. The *filter* section, located at the top left of the interface, can be used to filter the recommended drugs according to patient-specific conditions such as drug allergies, renal failure, pregnancy, and/or breastfeeding.
3. The *recommended antibiotics* section, located in the center of the interface, displays the recommended drugs, with justifications in the form of drug properties. These preference properties are represented by seven icons. Each icon is shown in a different color, as follows: green, if the recommended antibiotic satisfies the property; red, if the recommended antibiotic does not satisfy the property; and grey, if no information is available. For each recommended drug, the recommendation rank is displayed with a numbered thumbs-up icon, as per the CPGs.
4. The *legend* located at the bottom of the interface highlights the icons used in the recommended antibiotics section and displays hypertextual links to the original CPGs.

Figure 2. Web interface for antibiotic prescription displaying recommended drugs and their properties.



Clinical situation:

Gender: Woman **Age**: 28 years old

Disease: Uncomplicated acute pyelonephritis without treatment by fluoroquinolones during the six previous months

FILTER

Allergy: none
Pregnancy: none
Breastfeeding: none
Renal failure: none

Evaluation of the Antibiotic Prescription Web Interface

Characteristics of Participating GPs

Given the opportunistic nature of the recruitment method used, it is difficult to estimate accurately how many GPs received the invitation email. The number of GPs contacted was estimated to range between 850 and 880.

In total, 117 GPs working within distinct GP surgeries accepted the invitation and assessed the web interface. More than half (73/117, 62.4%) were female. More than three-fourths (104/117, 89.0%) were under 40 years of age and had been in practice for less than 10 years. More than half (77/117, 65.8%) were working in private practice (Table 2).

Table 2. Sociodemographic characteristics of the general practitioners (GPs) (N=117).

Characteristic	Value, n (%)
Sex	
Female	73 (62.4)
Male	44 (37.6)
Age (years)	
20-30	42 (36.0)
30-40	62 (53.0)
40-50	7 (6.0)
50-60	3 (2.5)
>60	3 (2.5)
Professional status	
GP with an MD thesis	74 (63.3)
GP without an MD thesis	39 (33.3)
GP in training	4 (3.4)
Time in practice (years)	
<5	81 (69.2)
5-10	20 (17.1)
10-20	10 (8.5)
>20	6 (5.2)
Practice type	
Private	77 (65.8)
Salaried	15 (12.8)
Mixed	25 (21.4)

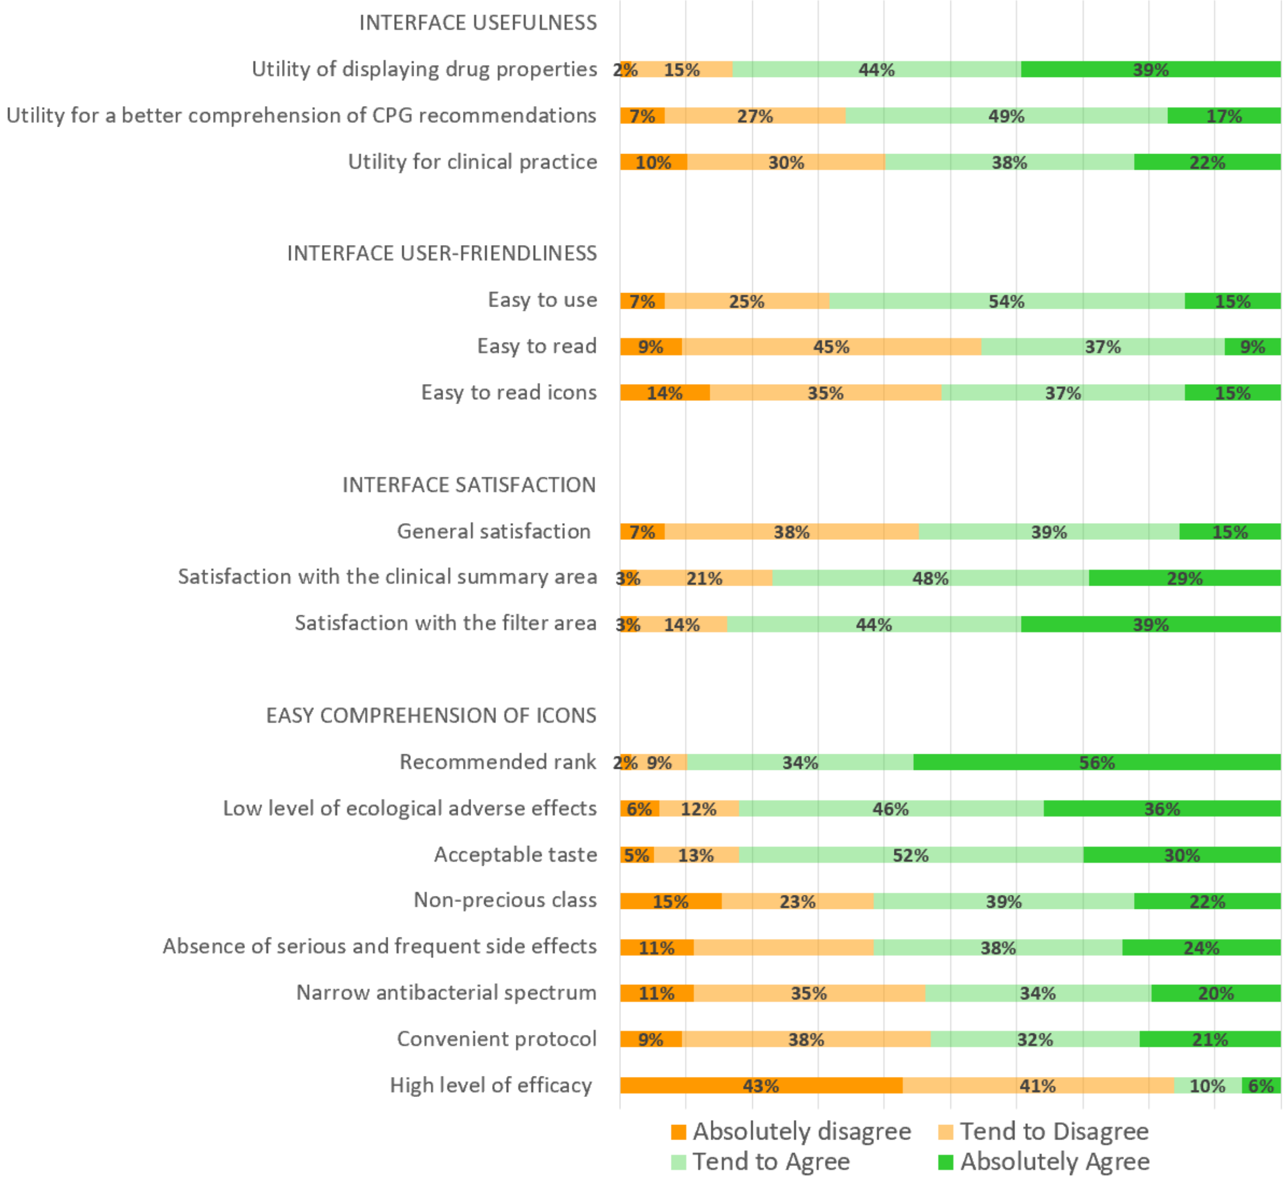
Satisfaction, Usefulness, Comprehensibility, and Readability of the Web Interface

Overall, 82.9% (97/117) of GPs found the display of drug properties useful (95% CI 76-90); 65.8% (77/117) reported that the interface improved their understanding of CPG recommendations (95% CI 57-74), and 59.8% (70/117) considered the interface useful for clinical practice (95% CI 51-69), as shown in Figure 3.

Only 54.7% (64/117) of all GPs were satisfied with the global interface (95% CI 46-64), probably because of dissatisfaction with some of the icons. Indeed, the majority of GPs appreciated the clinical summary (90/117, 76.9%) and filter (98/117, 83.8%) sections, whereas 48.7% (57/117) of them reported difficulties understanding some of the icons (Figure 3).

Five of the eight icons were considered sufficiently readable. The icons for recommended rank, ecological adverse effects, and taste were considered easily understandable by more than 80% of GPs; both the precious class and the side effects icons were considered comprehensible by more than 60% of all GPs. By contrast, three icons were not sufficiently readable; icons for antibacterial spectrum and convenient protocol were considered poorly understandable by nearly half the GPs and that for efficacy level was considered poorly understandable by about 84% of GPs (Figure 3).

Figure 3. Satisfaction, usefulness, readability, and comprehensibility of the web interface according to general practitioners. In the questionnaire, each item was turned into an affirmative sentence to be graded on a 4-point Likert scale ranging from “absolutely disagree” to “absolutely agree” (eg, the item “Utility of displaying drug properties” was converted to the statement “I found the display of drug properties useful” and this affirmation was then graded).



Areas for Improvement

Some GPs said that they found the web interface interesting but that it could take time for them to get familiar with it. They suggested several areas for improvement (Table 3).

For the clinical summary section, GPs suggested displaying more details about the probable causal microbes, patient history, treatment, and signs of gravity. For the filter section, they suggested adding filters for hepatic conditions and galenic forms. Regarding the recommended antibiotics section, the GPs thought it included too much information and needed to be simplified to improve readability. For example, some GPs said that only the most important properties should be displayed and that other properties should be hidden and accessible only on request (eg, nonprecious class, efficacy level, and taste). Surprisingly, some GPs reported that some properties were not important for the choice of antibiotic, whereas these properties were used by CPG experts in the formulation of recommendations (eg, ecological adverse effects, activity spectrum, antibiotic taste). Other GPs also had doubts about the nonprecious class property because they did not understand what this meant. Conversely, other GPs suggested including additional properties such as drug cost, drug-drug interactions, and contraindications. Some others said that some of the icons were not sufficiently intuitive and required revision. They suggested, for example, replacing the efficacy level by a graduated scale, speedometer, or weapon symbol. Finally, some GPs said that they thought the web interface could be useful for shared decision-making with patients.

Table 3. Areas for improvement extracted by analysis of free comments by general practitioners (GPs) (N=117).

Interface section and suggested improvement	GP, n (%)
Clinical summary	
Add more information about patient history and current treatment	9 (7.7)
Add more information about clinical signs of gravity	1 (0.9)
Add details about the suspected causal microbes	1 (0.9)
Filter	
Add hepatic condition filter	1 (0.9)
Add galenic form preference (eg, syrup, pill)	2 (1.7)
Recommended antibiotics	
Improve readability	31 (26.5)
Add some properties (eg, duration, cost)	8 (6.8)
Specify important patient contraindications for each antibiotic	2 (1.7)
Specify drug-drug interactions	3 (2.6)

Discussion

Principal Findings

An interface for antibiotic prescription displaying the recommendations and their justifications was designed and assessed. The web interface was divided into three main sections: a clinical summary section, a filter section, and a recommended antibiotics section enlisting recommended antibiotics and their properties displayed as icons. Overall, 82.9% of participating GPs found the display of drug properties useful, and 65.8% of them reported that the interface helped to improve their understanding of CPG recommendations. Nevertheless, the interface requires further improvement before its implementation in a clinical decision support system (CDSS).

Limitations

Interface Design

Icon Design

Despite 82.9% of the GPs reporting that they found the display of antibiotic properties useful, 48.7% reported difficulty in reading the corresponding icons. Starren et al [22] described five kinds of presentation for displaying medical data (ie, table, list, graph, generated text, and icon). We believed that icons were the most suitable presentation for displaying the antibiotic properties because they are small pictorial symbols that are particularly well adapted for displaying qualitative data within computer interfaces [22]. Furthermore, they are already widely used for displaying medical data such as for medication administration or patient events [22]. Iconic languages [23-25] have even been developed in the medical domain, such as the Visualisation des Connaissances Médicales (Visualization of Medical Knowledge [VCM]) language [25,26], which is used to represent signs, diseases, physiological states, life habits, and drugs. However, as there were no existing icons for representing antibiotic properties, the icons for this interface were designed by ourselves. Designing unambiguous icons for displaying precise concepts, such as “low level of ecological adverse effects” or “narrow antibacterial spectrum” was not an easy task, and it can take time for the GPs to become familiar with these icons. In our study, GPs discovered the icons for the first time during the evaluation period, with no prior tutorial or training, potentially accounting for their lack of satisfaction with the existing icons. The next step will be improving the design of some icons in accordance with the suggestions made by the GPs participating in this study (eg, “efficacy level” could be represented by a graduated scale). A tutorial and interactive information bubble will also be added to improve the readability of icons.

Missing Elements

The interface displayed the recommendations and the elements required for antibiotic prescription according to the experts writing CPGs. However, the qualitative analysis of the free comments highlighted the following: (1) some properties were considered important by CPG experts but not by GPs (eg, CPG experts considered antibiotic taste to be important for improving treatment adherence, whereas this was not the case for all GPs); (2) GPs considered other properties not mentioned in CPGs to be important (eg, some GPs reported needing to visualize drug interactions, which are seldom dealt with in CPGs); and (3) some properties are currently used by CPGs experts but are not understood by GPs (eg, the property nonprecious class). This gap between real-life practice and writing CPGs should be considered when designing CDSS interfaces. Thus, interfaces should also include the properties used by GPs in real-life practice, even if the evidence for their use is poor or not given in CPGs. For example, with regard to antibiotic prescription, Krishnakumar et al [6] developed a model of the rationale used by GPs for antibiotic choice. Some of the factors included in this model, such as drug pharmacokinetics, marketing authorization, and drug cost, will be included in the web interface in the future.

Interface Evaluation

The participating GPs were recruited via emails sent to medical networks and by word of mouth. This mode of recruitment was chosen because it is faster and cheaper than traditional approaches [27,28]. However, it may have introduced a selective participation bias [28] (eg, by selecting GPs keen on the use of new technologies). This bias was limited by using large mailing lists (>850 GPs), including GPs working in various health care centers, from a large French region (including Paris). The readability of the interface and its utility for improving GPs' comprehension of CPGs were also evaluated. Assessments of readability and comprehensibility are part of the software lifecycle and may prevent serious usability problems, which often occur during the design of new technologies [29]. Early testing makes it possible to identify serious issues and to improve the interface before its implementation in a CDSS.

Comparison With Previous Work

Comparison With Other Drug Comparison Interfaces

Other types of interfaces have been developed for comparing drugs in medical domains. With regard to Dopamine [30], for instance, double-entry tables were used to compare the contraindications and side effects of drugs. More sophisticated tables, including the possibilities of overlapping data and interactions, have also been developed, such as Twinlist [31] for medication reconciliation or rainbow boxes [32,33] for comparing drug information such as contraindications or side effects. Rainbow boxes were previously adapted for use in antibiotic prescription [34]; the resulting rainbow interface was perceived as easy to read for 27.5%-64% of GPs, depending on the clinical situation. However, as smartphones are increasingly being used by medical doctors for learning, information retrieval, and/or clinical decision support [35-38], it is important to consider interfaces more suitable for use with a smartphone. Tabular representations take up a large amount of space and are therefore more suitable for computer interfaces [39,40]. Here, an e-commerce interface adaptable for smartphones was designed as a means of overcoming this limitation. *Graphs* have also been used for drug comparisons, such as Rxplore [41] for the rapid review of potential drug events caused by drugs and Network graph [42] for chemotherapy treatment. However, in these cases, graphical representations were interesting because of the need to add quantitative information such as the results of clinical trials [42]. As antibiotic properties are qualitative data, graphical representations were not considered appropriate for this situation.

Comparison With Other Antibiotic Prescription Interfaces

Other interfaces have been developed for the empiric prescription of antibiotics in primary care, for example, IAAP Smart phone [43], ARI Smart Form [44], and ABX TRIP [21] for acute respiratory infections. These interfaces display antibiotic recommendations without their justifications—that is, only the recommended antibiotics are displayed in a textual format without their properties. This type of presentation suffers from "the black box effect" [45] and may make GPs passive in their decision-making process, simply accepting the decision suggested by the CDSS. GPs may also be suspicious of the recommendations due to a lack of understanding of the suggestions made by the CDSS. In our proposed interface, drug properties were displayed to involve GPs in the decision process. This improves their understanding of the underlying reasons for recommendations and enables them to compare the advantages and disadvantages of the recommended antibiotics. Preserving GP autonomy is an important factor to be considered when trying to increase the chances of CDSS being successfully adopted [46].

Conclusions

A web interface for antibiotic prescription presenting drug recommendations and their justifications was designed following the basic framework of an e-commerce interface. The justifications of CPG recommendations were displayed in the form of antibiotic properties, which was considered useful by more than three-fourths of GPs and helpful for understanding CPGs by two-thirds of GPs evaluating the interface. Further improvements are required before the implementation of this interface in a CDSS.

Acknowledgments

We thank the GPs for taking time to participate in this study despite their heavy workload. This study was funded by the Agence Nationale de Sécurité du Médicament et des Produits de santé (ANSM). APP 2016 – RaMiPA Project (Raisonner pour Mieux Prescrire les Antibiotiques or Reasoning for better antibiotic prescription) led by RT.

Authors' Contributions

RT led the project. RM and RT designed the study. RM, AU, DI, and RT designed the web interface.
RM and RT analyzed and interpreted the data. RT wrote the manuscript. All authors critically edited and approve the final version of the manuscript.

Abstract

Background: Phenotypes characterize the clinical manifestations of diseases and provide important information for diagnosis. Therefore, the construction of phenotype knowledge graphs for diseases is valuable to the development of artificial intelligence in medicine. However, phenotype knowledge graphs in current knowledge bases such as WikiData and DBpedia are coarse-grained knowledge graphs because they only consider the core concepts of phenotypes while neglecting the details (attributes) associated with these phenotypes.

Objective: To characterize the details of disease phenotypes for clinical guidelines, we proposed a fine-grained semantic information model named PhenoSSU (semantic structured unit of phenotypes).

Methods: PhenoSSU is an "entity-attribute-value" model by its very nature, and it aims to capture the full semantic information underlying phenotype descriptions with a series of attributes and values. A total of 193 clinical guidelines for infectious diseases from Wikipedia were selected as the study corpus, and 12 attributes from SNOMED-CT were introduced into the PhenoSSU model based on the co-occurrences of phenotype concepts and attribute values. The expressive power of the PhenoSSU model was evaluated by analyzing whether PhenoSSU instances could capture the full semantics underlying the descriptions of the corresponding phenotypes. To automatically construct fine-grained phenotype knowledge graphs, a hybrid strategy that first recognized phenotype concepts with the MetaMap tool and then predicted the attribute values of phenotypes with machine learning classifiers was developed.

Results: Fine-grained phenotype knowledge graphs of 193 infectious diseases were manually constructed with the BRAT annotation tool. A total of 4020 PhenoSSU instances were annotated in these knowledge graphs, and 3757 of them (89.5%) were found to be able to capture the full semantics underlying the descriptions of the corresponding phenotypes listed in clinical guidelines. By comparison, other information models, such as the clinical element model and the HL7 fast health care interoperability resource model, could only capture the full semantics underlying 48.4% (2034/4020) and 21.8% (914/4020) of the descriptions of phenotypes listed in clinical guidelines, respectively. The hybrid strategy achieved an F1-score of 0.732 for the subtask of phenotype concept recognition and an average weighted accuracy of 0.776 for the subtask of attribute value prediction.

Conclusions: PhenoSSU is an effective information model for the precise representation of phenotype knowledge for clinical guidelines, and machine learning can be used to improve the efficiency of constructing PhenoSSU-based knowledge graphs. Our work will potentially shift the focus of medical knowledge engineering from a coarse-grained level to a more fine-grained level.

Introduction

When people are sick, their bodies present a series of observable or perceptible abnormalities, which are called phenotypes. In medicine, the phenotype concept covers signs and symptoms, laboratory test results, and imaging findings [1]. Phenotypes characterize the clinical manifestations of diseases, which provide important clues for diagnoses. Knowledge about disease phenotypes is usually documented as free text in medical textbooks or clinical guidelines, and such knowledge forms are hard for computers to use. Therefore, it is essential to transform phenotype knowledge into a machine-understandable format to facilitate the development of automated systems that could improve health care [2].

To date, many structured knowledge bases, such as WikiData [3], MalaCards [4], and DBpedia [5], have been constructed for disease phenotypes. In these knowledge bases, the phenotype knowledge of a disease is represented as a list of phenotype concepts or terms (Multimedia Appendix 1). However, such a concept-based representation only focuses on the presence or absence of a phenotype but neglects its contextual properties [6,7]. The description "sudden, severe abdominal pain in the lower right abdomen," for example, names three attributes of abdominal pain, including the onset pattern (sudden), severity (severe), and quadrant pattern (lower right abdomen). These attributes are valuable for diagnosis but missing in the provided concept-based representation. Due to the neglect of phenotypic details, current phenotype knowledge bases only characterize disease manifestations at a very coarse-grained level [8], which is considered to be "sloppy and imprecise" [9,10].

To precisely represent phenotype knowledge in clinical guidelines, it is necessary to introduce fine-grained semantic information models [11], which consider phenotypes and attributes simultaneously. The currently available semantic models for representing phenotype information include but are not limited to clinical element models (CEMs) [12], the Health Level Seven fast health care interoperability resource (FHIR) model [13], and the clinical quality language model [14]. All these models can be viewed as standard entity-attribute-value structures, which represent phenotype information with sufficient details by using various attributes and qualifier values. For example, a CEM model considers 17 attributes associated with phenotypes, such as phenotype severity, laterality, and duration. Although semantic information models such as CEM and FHIR have defined many attributes for phenotypes, it should be noted that these attributes are mainly designed for recording phenotypic information in electronic medical records. However, the logic underlying phenotypic descriptions in clinical guidelines is quite different from that in electronic medical records. For example, clinical guidelines usually describe the frequency of a phenotype in a population (eg, 30% of patients may have a loss of smell); however, this attribute is not defined in CEM and FHIR models. In addition to the frequencies of phenotypes, other often used attributes such as temporal patterns (eg, acute, chronic) and pain characteristics (eg, sharp, dull) are also neglected by the CEM and FHIR models. Therefore, it is necessary to optimize the attributes included in current information models to make them more suitable for representing phenotype knowledge in clinical guidelines.

In this work, we aimed to develop a semantic information model that could effectively characterize the details of disease phenotypes for clinical guidelines. A semantic information model named PhenoSSU (semantic structured unit of phenotype) was developed based on the clinical guidelines for 193 infectious diseases from Wikipedia. A total of 12 attributes were included in PhenoSSU, which characterized the details of phenotypes from various aspects. Based on PhenoSSU, we constructed fine-grained phenotype knowledge graphs for these infectious diseases. Considering the increased annotation costs associated with the introduction of PhenoSSU, we also explored the potential of machine learning for performing automatic recognition for PhenoSSU based on free text. It is hoped that our work will contribute to the large-scale construction of fine-grained phenotype knowledge graphs for more diseases.

Methods

Materials

We collected the clinical guidelines for 193 infectious diseases from Wikipedia [15] as the corpus for constructing fine-grained phenotype knowledge graphs. In Wikipedia, the phenotypic knowledge of infectious diseases was usually buried in a section named signs and symptoms (Multimedia Appendix 1). Although Wikipedia is created and edited by volunteers worldwide, many studies have proven the high quality of its biomedical content [16,17]. In addition, phenotype knowledge graphs for WikiData [3] and DBpedia [5] were also constructed based on clinical guidelines from Wikipedia.

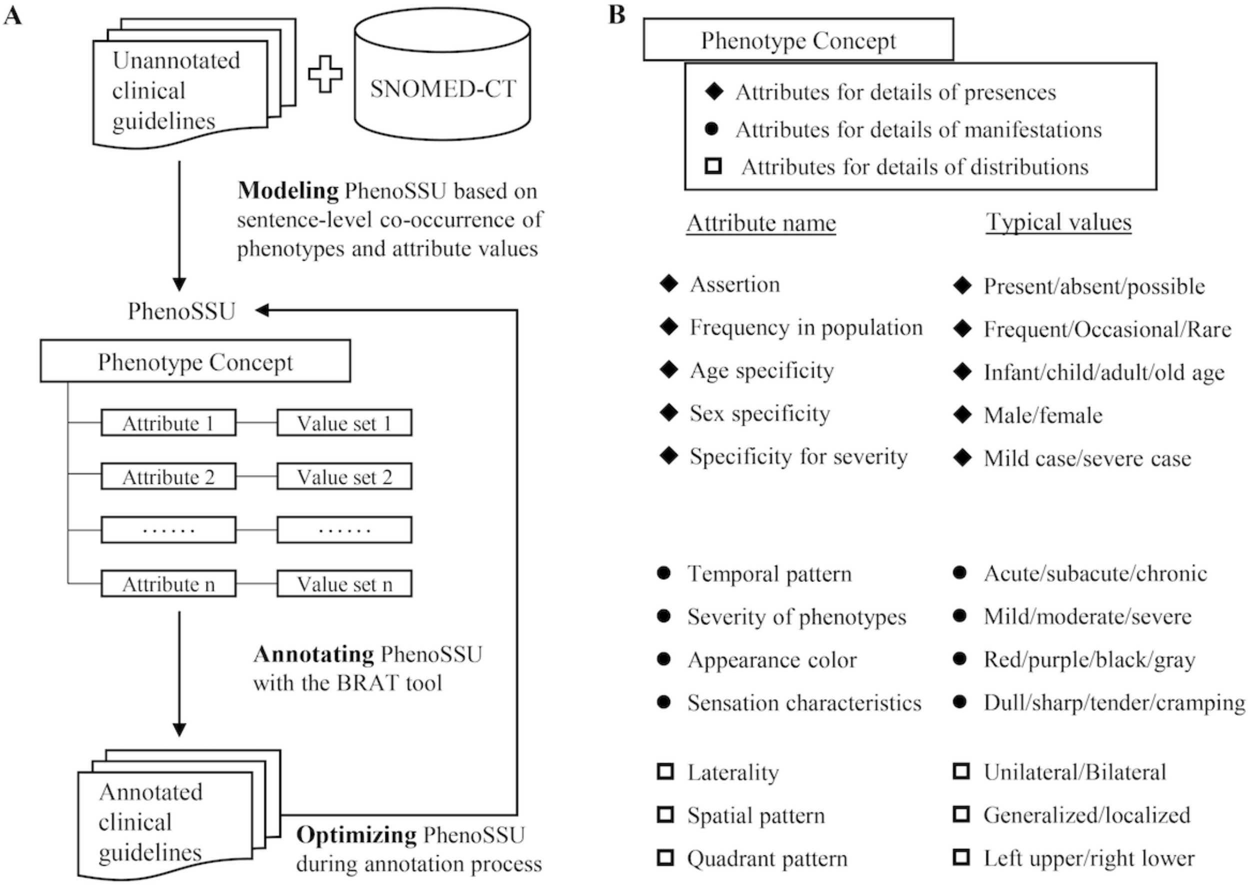
Design of PhenoSSU

PhenoSSU, by its very nature, is an entity-attribute-value model that consists of a phenotype concept along with a collection of attributes. Determining the attributes associated with various phenotypes is the key to the design of PhenoSSU. Four inclusion criteria for attributes were considered in this study:

- Introduced attribute and value set should come from a standard medical ontology to avoid the arbitrariness of defining new attributes. Systematized Nomenclature of Medicine–Clinical Terms (SNOMED-CT) [18,19], one of the most comprehensive clinical terminology databases in the world, was selected as the standard for normalizing both phenotypes and attributes.
- Introduced attribute should be a modifier associated with phenotypes rather than an entity independent of phenotypes. The concepts found in SNOMED-CT were organized into 19 distinct hierarchies. Phenotypes and attributes were mainly located in the clinical finding and qualifier value hierarchies, respectively (Multimedia Appendix 1).
- Value set of the introduced attribute should contain categorical variables with limited dimensionality. For example, the severity attribute in SNOMED-CT contains a value set including mild, moderate, and severe. This criterion is for convenience when configuring attributes in the brat rapid annotation tool (BRAT) [20] (Multimedia Appendix 1).
- Introduced attribute should occur at least once in the studied corpus. This criterion is for reducing redundancy when introducing many unused attributes.

To effectively find the attributes associated with various phenotypes, we developed a simple co-occurrence–based method for attribute filtering (Figure 1A). Specifically, the phenotypes in the corpus were annotated with the MetaMap tool [21], a state-of-the-art concept recognizer, and the values of the attributes in the corpus were annotated with the Flashtext tool [22], a string-based concept recognizer. If an attribute co-occurred with any phenotypes in at least 2 sentences from the whole corpus, we selected the attribute as a candidate that was potentially associated with phenotypes. Then, we manually filtered the attributes that were truly related to phenotypes and built an initial version of PhenoSSU. The initial PhenoSSU model was optimized during the annotation process. When annotators found a new contextual property associated with phenotypes, we searched for its existence in SNOMED-CT and added the standard attribute corresponding to that contextual property into the initial PhenoSSU model.

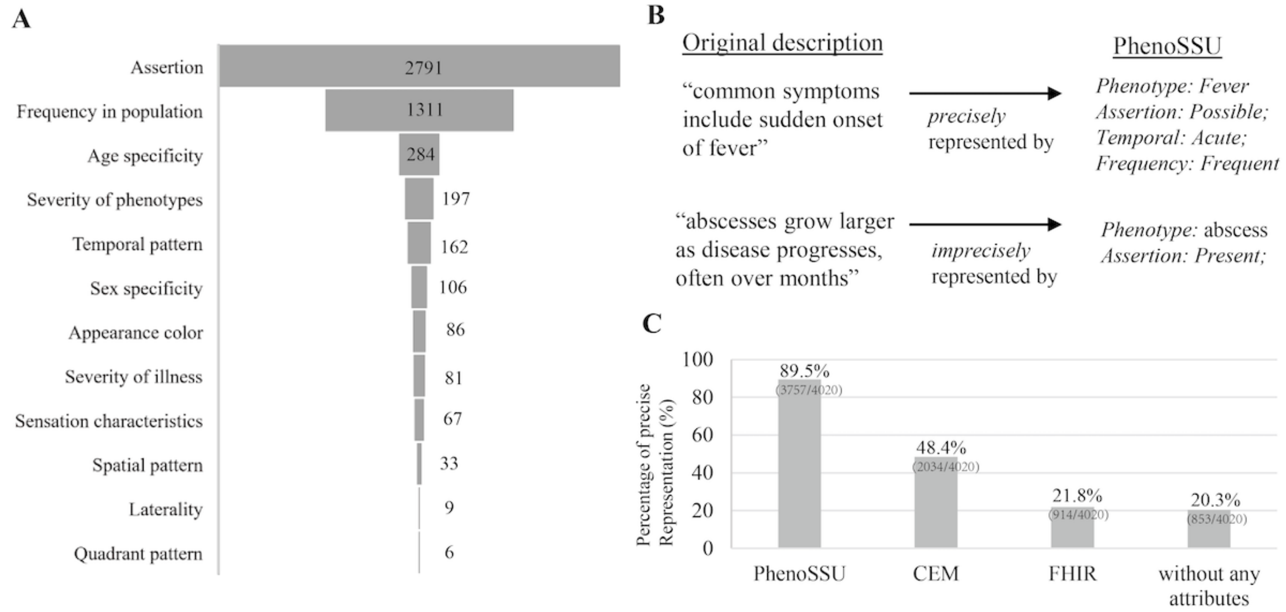
Figure 1. Modeling process of PhenoSSU: (A) modeling PhenoSSU based on sentence-level cooccurrences of phenotype concepts and attribute values in clinical guidelines and (B) components of the PhenoSSU model consist of a phenotype concept and 12 attributes.



The final PhenoSSU model contained 12 attributes, which could be classified into 3 categories according to the phenotypic details they characterized (Figure 1B): (1) details about the presence of phenotypes, including a phenotype's assertion, frequency in a population, age specificity, sex specificity, and specificity regarding the severity of illness; (2) details about the manifestations of phenotypes, including a phenotype's temporal pattern, severity, appearance color, and sensation characteristics;

and (3) details about the spatial distributions of phenotypes, including a phenotype's laterality, spatial pattern and quadrant pattern. The SNOMED-CT codes, definitions, and value sets of these attributes are listed in Multimedia Appendix 1. The distribution of these 12 attributes in the studied corpus is shown in Figure 2A.

Figure 2. Expressive power of PhenoSSU: (A) prevalence of the 12 attributes in the studied corpus, (B) examples of precise and imprecise representations for original phenotype descriptions with the PhenoSSU model, and (C) comparisons of precise representation percentages among different information models.



Annotation and Normalization of PhenoSSU

The annotation task of PhenoSSU can be divided into 2 steps: annotating a phenotype and annotating the attributes associated with that phenotype. Some annotation examples of different phenotypes attributes defined in PhenoSSU are presented in Multimedia Appendix 1. The clinical guides of 193 infectious diseases were annotated with the BRAT (Multimedia Appendix 1). To facilitate the annotation process, we preannotated the phenotypes found in clinical guidelines with the MetaMap tool. Then, two annotators (TY and SL) independently annotated the 193 clinical guidelines by following the annotation guide developed by LD and TJ. Their independent annotations were merged and visualized in the BRAT. To mark inconsistent annotations, we introduced a virtual attribute named agreement into PhenoSSU. Two independently annotated PhenoSSU models were regarded as consistent when both their phenotypes (text spans) and associated attribute values were the same. If there were inconsistencies in any part of a PhenoSSU model, the value of the agreement attribute was set to disagreement. The initial interannotator agreement at the PhenoSSU level was calculated with a Cohen kappa statistic [23] of 0.861. All inconsistent annotations were solved by an adjudication process (TJ).

The phenotypes annotated in BRAT were normalized with SNOMED-CT. To facilitate the normalization process, we also leveraged the MetaMap tool to obtain candidate concepts from the SNOMED-CT database and then manually selected the concept corresponding to each query phenotype. There was no need to normalize the attribute values because they were already normalized in SNOMED-CT.

One aspect to note about the normalization process is the special treatment used for finding sites of phenotypes. Finding sites were not explicitly included in the PhenoSSU model because they are entities independent of phenotypes. In SNOMED-CT, there were more than 39,000 concepts of finding sites in the body structure hierarchy, and these were hard to set as a value list in the BRAT. However, finding sites are indispensable information for describing phenotypes. Therefore, we also annotated the entities of finding sites associated with phenotypes. Taking the annotation of "bleeding from the nose and gum" as an example, the entities of the phenotype (bleeding) and two finding sites (nose, gum) were annotated separately and connected with a relation curve named locate (Multimedia Appendix 1). If a phenotype had an associated finding site, the phenotype together with the finding site was regarded as an integral concept in the normalization process. For example, the annotation of "bleeding" associated with "nose" was normalized as "249366005|epistaxis," which shared the same codes as the annotation of "bleeding from nose." If a composite concept could not be normalized as a whole (eg, "rash associated with hands"), we standardized the phenotype and its corresponding finding site separately and combined them into a postcoordination expression [24] (eg, "271807003|Rash": "33712006|Skin structure of hand"; Multimedia Appendix 1). In summary, information about finding sites was implicitly considered an integral part of a phenotype concept rather than its attribute.

Automatic Recognition of PhenoSSU

The manual annotation of a PhenoSSU model is a very time-consuming process because annotators not only need to find the mention of a phenotype but also need to determine the existence of attribute trigger terms in the context surrounding a phenotype. To reduce annotation costs, it is necessary to develop algorithms for the automatic annotation of PhenoSSU models.

The recognition task of PhenoSSU can be divided into 2 subtasks: phenotype concept recognition and attribute value prediction. The first subtask aims to recognize the text spans corresponding to phenotypes, and the second subtask aims to select appropriate values for 12 attributes based on a phenotype's context.

The 193 annotated clinical guides were randomly divided into a training set and a test set at a ratio of 6:4. For the subtask of phenotype concept recognition, we still used the MetaMap tool, which can recognize phenotype concepts based on the Metathesaurus in the Unified Medical Language System (2020AA release) [25]. We optimized the parameters of the MetaMap tool based on its performance on the task of recognizing phenotype concepts in the training set (Multimedia Appendix 1).

The subtask of attribute value prediction can be regarded as a classification problem, and two machine learning-based models were explored for this subtask. One model was based on a support vector machine (SVM), and the other model was based on a bidirectional long short-term memory (BiLSTM) neural network. For the value classification model of a specific attribute, the input was the encoded feature vectors of a phenotype's context and the output was one of the normalized values for this attribute.

We chose an SVM for developing attribute value prediction models because SVM-based models have proven their efficiency in the 2010 Informatics for Integrating Biology & the Bedside/Veterans Affairs challenge [26] and SemEval-2015 Task 14 [27]. In the SVM-based model (Multimedia Appendix 1), the context of a phenotype was encoded with the existence of trigger terms (terms that indicated a normalized value [eg, "sudden onset" was the trigger term of the normalized value "acute"]) and their distances to the target phenotype [26,27]. The SVM-based model was developed by using the scikit-learn package (version 0.23.1) [28]. The parameters of the SVM-based model were optimized by using a grid search strategy [29] on the training set.

Inspired by recent methodology developments for the assertion status prediction task [30,31], we chose BiLSTM for developing attribute value prediction models. The referenced studies [30,31] showed that BiLSTM and attention mechanisms could achieve better performances than other approaches when classifying assertions of medical concepts. Since assertion status prediction belonged to the task of attribute value prediction, we transferred the attention-enhanced BiLSTM model to our study. In a given BiLSTM-based model (Multimedia Appendix 1), the context of a phenotype was first split into 3 segments, including the left context, the phenotype itself, and the right context, which were then encoded into a 3×768 vector with a pretrained language model named BERT (bidirectional encoder representation from transformers) [32-34]. Each BiLSTM-based model was developed by using the Keras package (version 2.3.1) [35], and the BERT encoding process was performed by using the bert-as-service package (version 1.10.0) [36]. Considering the very imbalanced distributions of attribute values in our dataset (Multimedia Appendix 1), we used the synthetic minority oversampling technique [37] from the imbalanced-learn package (version 0.7.0) [38] to balance the sample distributions. The hyperparameters of the constructed BiLSTM-based models were optimized using an early stopping strategy [39] on the training set.

Evaluation of the Performance for Recognizing PhenoSSU

To evaluate the performance of the proposed algorithm in extracting PhenoSSU models from free text, we used the evaluation metrics from SemEval-2015 Task 14: Analysis of Clinical Text [27].

The evaluation metric for the subtask of phenotype concept recognition was the F1-score. A predicted phenotype concept was regarded as a true positive if its text span overlapped with a gold standard text span. The precision metric was calculated as the fraction of correctly predicted phenotypes among all phenotypes identified by MetaMap, and the recall metric was calculated as the fraction of correctly predicted phenotypes among all phenotypes identified by the annotators. The F1-score was calculated as the harmonic mean of precision and recall.

We chose the average weighted accuracy as the evaluation metric for the subtask of attribute value prediction because the distributions of different attribute values were very imbalanced. The average weighted accuracy metric considers the prevalence of an attribute value in the corpus, so it can measure how good an algorithm is at predicting the rare values of an attribute. The detailed calculating process of the average weighted accuracy can be found in Multimedia Appendix 1.

Evaluation of the Expressive Power of PhenoSSU

Since the aim of this work was to develop a semantic information model that was more suitable than current approaches for representing phenotype knowledge in clinical guidelines, it was necessary to evaluate whether the annotated PhenoSSU model could capture the full semantics underlying the original descriptions of phenotypes. For example, in Figure 2B, the description "common symptoms include sudden onset of fever" could be perfectly represented by the PhenoSSU model (phenotype: fever; assertion: possible; frequency: frequent; temporal pattern: acute). By comparison, the description "abscesses grow larger as disease progress, often over months" was only partially represented by the PhenoSSU model (phenotype: abscess; assertion: present), which missed the information regarding the course and duration of abscess associated with the description.

To evaluate the expressive power of PhenoSSU, we introduced a virtual attribute named "equal to the original description" into the PhenoSSU model. If the annotated PhenoSSU did not capture the full semantics of an original description, we set the value of this attribute to "partial." Two annotators (TY and SL) independently evaluated the expressive power of the annotated PhenoSSU model. The initial interannotator agreement as measured with Cohen kappa statistic was 0.903 (3631/4020).

We reached a consensus for those inconsistent judgments by an adjudication process (TJ).

Results

Overview of the PhenoSSU Model and PhenoSSU-Based Knowledge Graphs

To characterize the details of phenotypes for clinical guidelines, a semantic information model named PhenoSSU was proposed. With the introduction of 12 attributes associated with various phenotypes, the obtained knowledge graphs based on PhenoSSU were more fine-grained than those based on phenotype concepts. In this work, 193 PhenoSSU-based knowledge graphs for infectious diseases were constructed. At the concept level, we annotated 4020 phenotypic terms, 3962 of which could be normalized with 1508 concepts in SNOMED-CT. At the attribute level, we annotated 5278 nondefault attribute values ("present" was the default attribute value for the assertion attribute, and "none" was the default attribute value for other attributes), which indicated the widespread presence of contextual properties for phenotypes in clinical guides. The most commonly used attributes included assertion, frequency in a population, age specificity, phenotype severity, and temporal pattern (Figure 2A).

Since the knowledge graphs in WikiData were also extracted from Wikipedia, we compared our knowledge graphs with those in WikiData at the concept level. WikiData built knowledge graphs for 66 of the 193 diseases, and these graphs included 354 phenotype concepts. Our annotations covered 297 of the 354 (83.9%) phenotypes from WikiData. For the uncovered phenotypes, we could not confirm their existence on the corresponding webpages of Wikipedia (including current and historical webpages). Most of these uncovered phenotypes may come from the manual additions of volunteers, who made use of sources other than Wikipedia (Multimedia Appendix 1).

Expressive Power of PhenoSSU for Representing Phenotype Knowledge

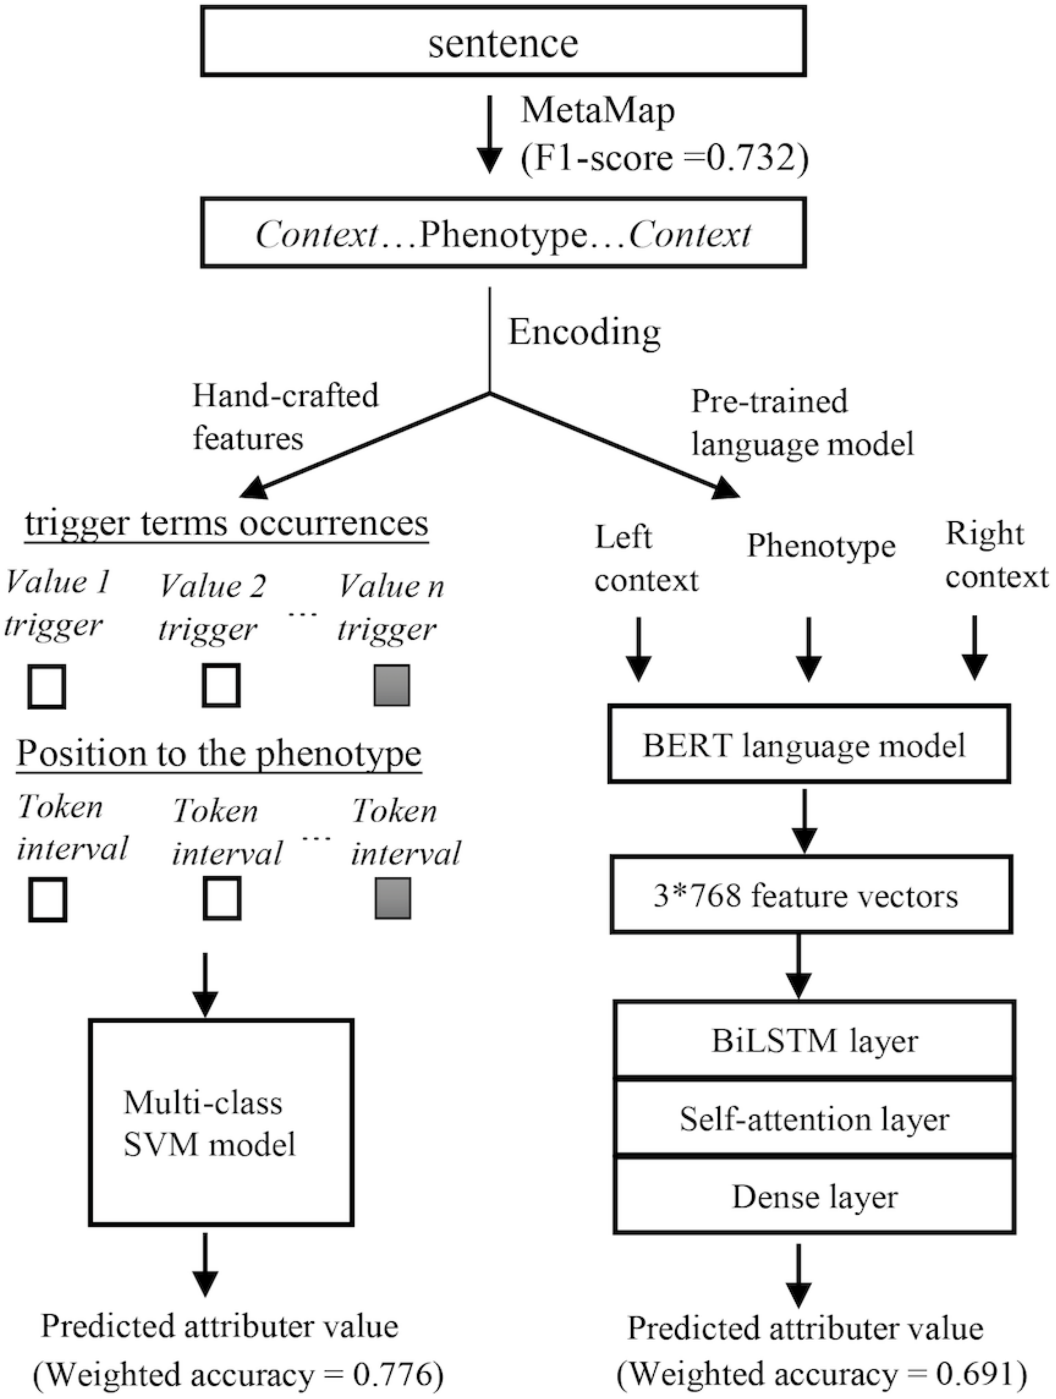
To evaluate the expressive power of the PhenoSSU model quantitatively, we manually analyzed whether a PhenoSSU instance could capture the full semantics underlying the corresponding descriptions of phenotypes (Figure 2B).

In this study, we annotated 4020 PhenoSSU instances, 3757 of which (89.5%) were determined to precisely represent the original phenotype knowledge described by natural language (Figure 2C). If we only considered the presence and absence of phenotype concepts (concept-based representation), the percentage of precise representations decreased to 20.3% (853/4200). This result further suggested the necessity of introducing the attributes associated with phenotypes into the developed model. We also analyzed the expressive power of the CEM and FHIR models for phenotypes and found that their percentages of precise representations were 48.4% (2034/4200) and 21.8% (914/4200), respectively. Most of the attributes defined in the CEM and FHIR models were not used in clinical guidelines except for the severity and laterality of phenotypes. The CEM model achieved a higher expression power than that of the FHIR model because it considered the uncertainty of phenotypes (assertion: possible), which is a frequently used attribute in clinical guidelines. Please see Multimedia Appendix 1 for detailed comparisons between the attributes used in the PhenoSSU, CEM, and FHIR models.

Potential for Increasing the Speed of PhenoSSU Model Annotation With Machine Learning

With the introduction of attributes, it would take more time to annotate a PhenoSSU model than to annotate phenotype concepts. To increase the efficiency of annotating PhenoSSU models, we developed a hybrid strategy that first recognized phenotype concepts with the MetaMap tool and then predicted the attribute values of phenotypes with SVM-based or BiLSTM-based classifiers (Figure 3). For the subtask of phenotype concept recognition, the MetaMap tool achieved an F1-score of 0.732 (precision 0.660; recall 0.824), which was comparable to its performance on other medical corpora [40]. For the subtask of attribute value prediction, the average weighted accuracy of the SVM-based method (0.776) was better than that of the BiLSTM-based model (0.691). This may be due to limited number of training data, which made it hard for the deep learning-based approach to learn useful features from contexts. However, the performance of the BiLSTM-based model was still higher than the performance of a reference model (0.542) that always selected default values for attributes (it selected "present" for the assertion attribute and "none" for other attributes). These results indicate that machine learning methods have the potential to speed up PhenoSSU annotations. The detailed performances of the compared models for predicting the values of different attributes are listed in Multimedia Appendix 1.

Figure 3. Automatic recognition of PhenoSSU.



Discussion

Principal Findings

In this work, we designed a fine-grained information model named PhenoSSU, which can precisely represent phenotype knowledge for clinical guidelines. We also developed an automatic strategy to extract PhenoSSU models from clinical guidelines and found that machine learning could be used to improve the efficiency of PhenoSSU annotation. Taken together, our work will provide a useful theoretical and technical guide for the construction of fine-grained phenotype knowledge graphs.

From the design of PhenoSSU, it can be seen that PhenoSSU was derived from SNOMED-CT because both the phenotype concepts and attribute values in PhenoSSU came from SNOMED-CT. PhenoSSU strengthened the expressive power of SNOMED-CT by combining 12 attributes with phenotype concepts. In SNOMED-CT, there was a technique named postcoordination expression [24] that could also capture the details of phenotypes by using combinations of existing concepts. For example, the out-of-vocabulary concept “severe headache, unilateral” can be expressed as a postcoordination of 3 concepts—headache (25064002): severity (272141005) = severe (24484000) and laterality (272741003) = unilateral (66459002). Compared with the postcoordination expression technique, PhenoSSU is a predefined information model that provides a general framework for knowledge representation. It is more convenient to configure the PhenoSSU model into the BRAT annotation tool to construct fine-grained phenotype knowledge graphs than to use the competing approach.

In recent years, machine learning, especially deep learning, has been widely used for processing medical information [41-44]. In this work, we also explored the potential of automatically constructing fine-grained phenotype knowledge graphs based on machine learning. The results in Figure 3 suggest that machine learning can assist with the human annotations of PhenoSSU to some extent. However, there are still great challenges to overcome to improve the performance of machine learning, especially the insufficiency and imbalanced distributions of training data. In future work, an active learning framework [45] that incorporates both human intelligence and machine intelligence may be a better strategy for constructing fine-grained knowledge graphs.

The improvement of knowledge granularity for disease phenotypes may potentially benefit knowledge-based diagnosis systems because the differential diagnostic capability of a PhenoSSU model is theoretically stronger than that of a single phenotype concept. From the perspective of coarse-grained knowledge graphs, some diseases (eg, the flu and common cold) have many similar symptoms (eg, fever and cough); however, these similar symptoms may have obvious differences from the perspectives of fine-grained knowledge graphs. For example, fever may be present in both flu and common cold. However, fever is more common in flu patients and usually appears suddenly with a body temperature of 38 degrees or above. By comparison, fever is rarely seen in common cold cases and usually appears gradually. Therefore, a diagnosis system cannot exclude the common cold if a patient has fever; however, it can safely exclude the common cold if a patient has such a PhenoSSU instance like “phenotype: fever; temporal pattern: acute; severity: severe.” PhenoSSU-based knowledge graphs should be very suitable for dialogue-based symptom checkers such as babylon [46] and symptoma [47], which collects the symptoms of a patient one by one. Considering the details of phenotypes in inquiry processing may potentially improve the efficiency and accuracy of dialogue-based symptom checkers.

Limitations

One limitation of this work is that we only considered the corpus of infectious diseases during the modeling process of PhenoSSU. In addition, we only considered attributes with categorical values and did not consider attributes with numeric values. Another limitation of this study is that we only tested the effectiveness of the PhenoSSU model for 193 infectious diseases, which is a small number considering that thousands of other diseases exist. In addition, attributes suitable for infectious diseases may not be suitable for other types of diseases. We will solve these limitations during the process of constructing PhenoSSU-based knowledge graphs for more diseases in future work.

The annotation guidelines for PhenoSSU and the PhenoSSU-based knowledge graphs for 193 infectious diseases can be found by visiting our website [48]. The scripts for modeling and extracting PhenoSSU can be found on GitHub [49].

Conclusions

PhenoSSU is a fine-grained semantic information model that can precisely represent phenotype knowledge in clinical guidelines, and machine learning can be used to improve the efficiency of constructing PhenoSSU-based knowledge graphs.

Abstract

Background: The Multidimensional Prognostic Index (MPI) is an aggregate, comprehensive, geriatric assessment scoring system derived from eight domains that predict adverse outcomes, including 12-month mortality. However, the prediction accuracy of using the three MPI categories (mild, moderate, and severe risk) was relatively poor in a study of older hospitalized Australian patients. Prediction modeling using the component domains of the MPI together with additional clinical features and machine learning (ML) algorithms might improve prediction accuracy.

Objective: This study aims to assess whether the accuracy of prediction for 12-month mortality using logistic regression with maximum likelihood estimation (LR-MLE) with the 3-category MPI together with age and gender (feature set 1) can be improved with the addition of 10 clinical features (sodium, hemoglobin, albumin, creatinine, urea, urea-to-creatinine ratio, estimated glomerular filtration rate, C-reactive protein, BMI, and anticholinergic risk score; feature set 2) and the replacement of the 3-category MPI in feature sets 1 and 2 with the eight separate MPI domains (feature sets 3 and 4, respectively), and to assess the prediction accuracy of the ML algorithms using the same feature sets.

Methods: MPI and clinical features were collected from patients aged 65 years and above who were admitted to either the general medical or acute care of the elderly wards of a South Australian hospital between September 2015 and February 2017. The diagnostic accuracy of LR-MLE was assessed together with nine ML algorithms: decision trees, random forests, extreme gradient boosting (XGBoost), support-vector machines, naïve Bayes, K-nearest neighbors, ridge regression, logistic regression without regularization, and neural networks. A 70:30 training set:test set split of the data and a grid search of hyper-parameters with 10-fold cross-validation—was used during model training. The area under the curve was used as the primary measure of accuracy.

Results: A total of 737 patients (female: 370/737, 50.2%; male: 367/737, 49.8%) with a median age of 80 (IQR 72-86) years had complete MPI data recorded on admission and had completed the 12-month follow-up. The area under the receiver operating curve for LR-MLE was 0.632, 0.688, 0.738, and 0.757 for feature sets 1 to 4, respectively. The best overall accuracy for the nine ML algorithms was obtained using the XGBoost algorithm (0.635, 0.706, 0.756, and 0.757 for feature sets 1 to 4, respectively).

Conclusions: The use of MPI domains with LR-MLE considerably improved the prediction accuracy compared with that obtained using the traditional 3-category MPI. The XGBoost ML algorithm slightly improved accuracy compared with LR-MLE, and adding clinical data improved accuracy. These results build on previous work on the MPI and suggest that implementing risk scores based on MPI domains and clinical data by using ML prediction models can support clinical decision-making with respect to risk stratification for the follow-up care of older hospitalized patients.

Introduction

Background

Previous studies have highlighted the importance of using functional measures to predict mortality among older hospitalized patients, a complex population characterized by different degrees of frailty, comorbidity burden, and polypharmacy [1,2]. In particular, the Multidimensional Prognostic Index (MPI), an objective and quantifiable comprehensive geriatric assessment (CGA)–based tool developed from 8 separate CGA domains, is an example of a cumulative deficit model of frailty [3]. The MPI is strongly associated with mortality [2], length of hospital stay [4], and hospital readmission [3] in subpopulations suffering from acute and chronic conditions, including general and geriatric hospital patients. The MPI patient score is created by aggregating the total scores from the 8 separate CGA tools and normalizing the resulting total score to provide a value in the range from 0 to 1. The latter is then categorized into three categories of risk: low (0.0-0.33), moderate (0.34-0.66), and severe (0.67-1.0), allowing clinicians to better tailor their care management.

Prediction accuracy for 12-month mortality (12MM) using the area under the receiver operating curve (AUC) of 0.751 was achieved with the three MPI categories when validated in an older Italian population [2]. However, despite it being a significant predictor of 12MM in a similar older hospital population within Australia [5], its diagnostic accuracy was not confirmed (AUC=0.64, with age and gender adjustment). The relatively poor performance for prediction compared with the prediction accuracy with the Italian cohort might be partly explained by the homogenization of scores from the separate MPI domains into a single aggregate-weighted scoring system. Although this simplifies risk classification, the use of an aggregate-weighted scoring system has been shown in general to remove important domain-specific information, resulting in poorer risk prediction [6]. Conversely, the use of individual MPI domains in place of an aggregate score has the potential to cause overfitting of the prediction model (ie, reduced bias), which results in lower accuracy when used on independent data sets (ie, increased variance) [7].

Machine learning (ML) is a branch of artificial intelligence in which various algorithms are used to make predictions [8]. The algorithms differ from standard statistical modeling approaches such as those using least squares or maximum likelihood, which focus on linear relationships and have no additional aspects to their respective error functions (such as the use of regularization) that help reduce the likelihood of model overfitting. The strengths of ML algorithms include their ability to handle feature selection in the presence of collinearity, and the ability to deal with a larger number of features including complex nonlinear patterns and interactions [9]. Furthermore, the validation of ML-based approaches is generally more rigorous than that of the standard statistical approaches, with special care taken to consider the aforementioned trade-off between bias and variance when developing the prediction model during the training process [10]. Finally, model development is more data driven; it does not rely solely on content knowledge, thereby increasing the opportunity to identify previously unconsidered features for enhanced prediction [8].

Objective

Given the relatively poor performance of the aggregate MPI score in predicting 12MM in an Australian cohort, we seek to improve the prediction accuracy in several ways. First, we use the separate components of the MPI as input features for a traditional logistic regression with maximum likelihood estimation (LR-MLE). Second, we assess nine different binary-classification ML algorithms that might perform better than LR-MLE. Third, we add 10 routinely collected clinical measures to the MPI domain-based feature data set.

Methods

Overview

Details of the data collection methods, including a description of the study design, study cohort, and collected data, have been previously published [5]. Briefly, the cohort consisted of patients aged 65 years and above admitted to the Flinders Medical Centre Acute Medical Unit and then transferred to either the general medical or acute care of the elderly wards between September 14, 2015, and February 17, 2017. Flinders Medical Center is a 593-bed metropolitan teaching and trauma hospital within the Southern Adelaide Local Health Network, which has a catchment area of approximately 350,000 people. Acute care of the elderly wards provides a comprehensive individualized approach for assessing older frail medical inpatients using a multidisciplinary team. The study was conducted in accordance with the Declaration of Helsinki and the guidelines for Good Clinical Practice. Approval for the study was obtained from the local ethics committee (reference number: 170.15).

Feature Sets

The 63-item MPI is a prognostic tool based on averaging the standardized scores obtained from the eight core domains of the CGA, which were obtained in all study participants within the first 3 days of hospital admission. We trained the prediction models using four different feature sets. The first feature set contained age, gender, and the 3-category MPI as three separate dummy variables (n=5 features in total). The second feature set contained the five features from the first feature set as well as 10 additional clinical features: BMI, anticholinergic risk score (ARS) [11], serum sodium, hemoglobin, serum albumin, creatinine, urea, urea-to-creatinine ratio, estimated glomerular filtration rate (eGFR), and C-reactive protein (CRP; n=15 features in total). The third and fourth feature sets included the eight separate MPI domains used in the calculation of the overall MPI score, in place of the 3-category MPI used in the first and second feature sets, resulting in n=10 and n=20 features, respectively. The eight MPI domains consist of cohabitation status (living alone, with family or friends, or in an institute), the total number of prescribed medications (taken at admission), functional status evaluated with activities of daily living (ADL) and instrumental ADL (IADL) scales; cognitive status evaluated by the Short Portable Mental Status Questionnaire; evaluation of pressure sores using the Exton Smith Scale (ESS); comorbidities assessed using the Cumulative Illness Rating Scale (CIRS); and nutritional status evaluated by the Mini Nutritional Assessment (MNA). The additional biochemical features are known to be associated with adverse outcomes in older patient populations [12-18]. The target variable for the prediction models was all-cause mortality within 12 months (12MM), defined as death from any cause and obtained using the Australian national death registry.

ML Algorithms

We implemented a systematic ML-based framework to construct the 12MM prediction models. The steps included data preprocessing, splitting of the data into training and validation data sets, model development using the training data set for each algorithm, and final assessment of the accuracy of each algorithm using the validation data set. The data preprocessing step included imputation of missing values and the scaling of continuous features, which included all features except for gender, the 3-category MPI, and cohabitation status. Any continuous features with missing values were imputed using the mean value of that feature before scaling the features and data splitting. Continuous features were scaled to have a zero mean and unit variance. Following preprocessing, the data were split into a training data set for the development of the prediction models and a test data set for accuracy validation. Data were split randomly into two sets in the ratio 70:30 with the 69.9% (515/737) sample defined as the training set and used for development of the prediction models, and the 30.1% (222/737) sample defined as the test (ie, validation) set and used to validate the accuracy of the algorithm. Once the training set was defined, an optimal model was developed for nine different ML algorithms: decision trees (DTs), random forests (RFs), eXtreme Gradient Boosting (XGBoost), support vector machines (SVM), naïve Bayes, K-nearest neighbors (KNN), ridge regression (logistic regression with *L2* regularization), logistic regression without regularization, and neural networks (NNs). A description of each algorithm is provided in Multimedia Appendix 1. Multimedia Appendix 2 provides the data set for the study and Multimedia Appendices 3-7 contain the Python code for all of the analysis performed for this study. All features were used without creating interactions or higher-order terms. However, as a sensitivity analysis, we also assessed each algorithm using all linear and second-order polynomial terms, that is, after squaring each feature and including all 2-way interactions.

For each algorithm, a grid search of hyper-parameters was performed to find the optimal set of hyper-parameters for training data accuracy. Each grid search was performed using 10-fold cross-validation, in which the training data set was split into 10 equally sized discrete folds. A model was then created using 90% (9/10 folds) of the data, and its accuracy was assessed using the remaining fold of data. The process was repeated 10 times, with each fold held out for one of the 10 training steps and used to assess the model accuracy for the training data. The AUC was used as the accuracy metric during the grid search. Once the optimal set of hyper-parameters was defined for each of the algorithms based on the training data, the performance of the optimal model for each ML algorithm was assessed on the test data set using the AUC as the primary accuracy metric. Although numerous accuracy measures are available for ML algorithms, the AUC is the most used in clinical settings and allows comparison with other studies, and we therefore used this as our primary accuracy measure. However, for completeness, we also report accuracy, precision, recall, and F1 score, given the imbalance in the number of positive and negative outcomes (dead and alive patients) that can, by itself, lead to higher AUC values [19].

Logistic Regression With Maximum Likelihood Estimation

For each feature set, the estimated logit coefficients obtained for the LR-MLE using the training data set were used to predict and assess the accuracy of the model on the test data set. The odds ratios (ORs), 95% CIs, and *P* values for the training data set with feature set 4 are reported.

Statistical Analysis

All analyses were performed using Python version 3.8.3. The normal distribution of the features was assessed using quantile-quantile plots and histograms, and descriptive statistics, including the mean, median, or frequency, were used for each feature as appropriate. Between-group comparisons for those alive and deceased at 12 months were performed using two-tailed independent *t* tests, Mann-Whitney tests, or chi-square tests. Each ML algorithm was implemented using Python's scikit-learn library [20], except for the XGBoost algorithm, which has its own Python package [21]. Relative importance feature plots and calibration plots were produced for the best algorithm, and violin plots were used to describe the distribution of the most important features. The calibration of the best-performing algorithm was shown by plotting the observed versus predicted deciles of risk. LR-MLE was performed using the logit function of Python's *statsmodels* module, and the LR-MLE models included all features within each feature set. Descriptive statistics were analyzed using the SciPy library (version 1.4.1) *stats* module, and plots were drawn using the *matplotlib* and *seaborn* libraries.

Data Sharing Statement

All data generated or analyzed during this study are included in Multimedia Appendix 2. The Python code used to analyze the data is also available in the Multimedia Appendices 3-7.

Results

Overview

The cohort included a total of 737 patients that were each assessed for MPI and followed up for 12 months. There were no missing values for age, sex, or each of the MPI domains. Among the additional five variables used in feature set 4, there were a total of 66 missing values, including sodium (n=1) albumin (n=3) hemoglobin (n=2), urea (n=1) creatinine (n=1), urea-to-creatinine ratio (n=1), eGFR (n=1), and CRP (n=56). Table 1 describes the characteristics of the patients according to their vital status at 12 months after mean imputation for missing values. There were significant differences between the two groups for all 20 features except for sex, the total number of medications used, the Short Portable Mental Status Questionnaire score, eGFR, creatinine, and the ARS.

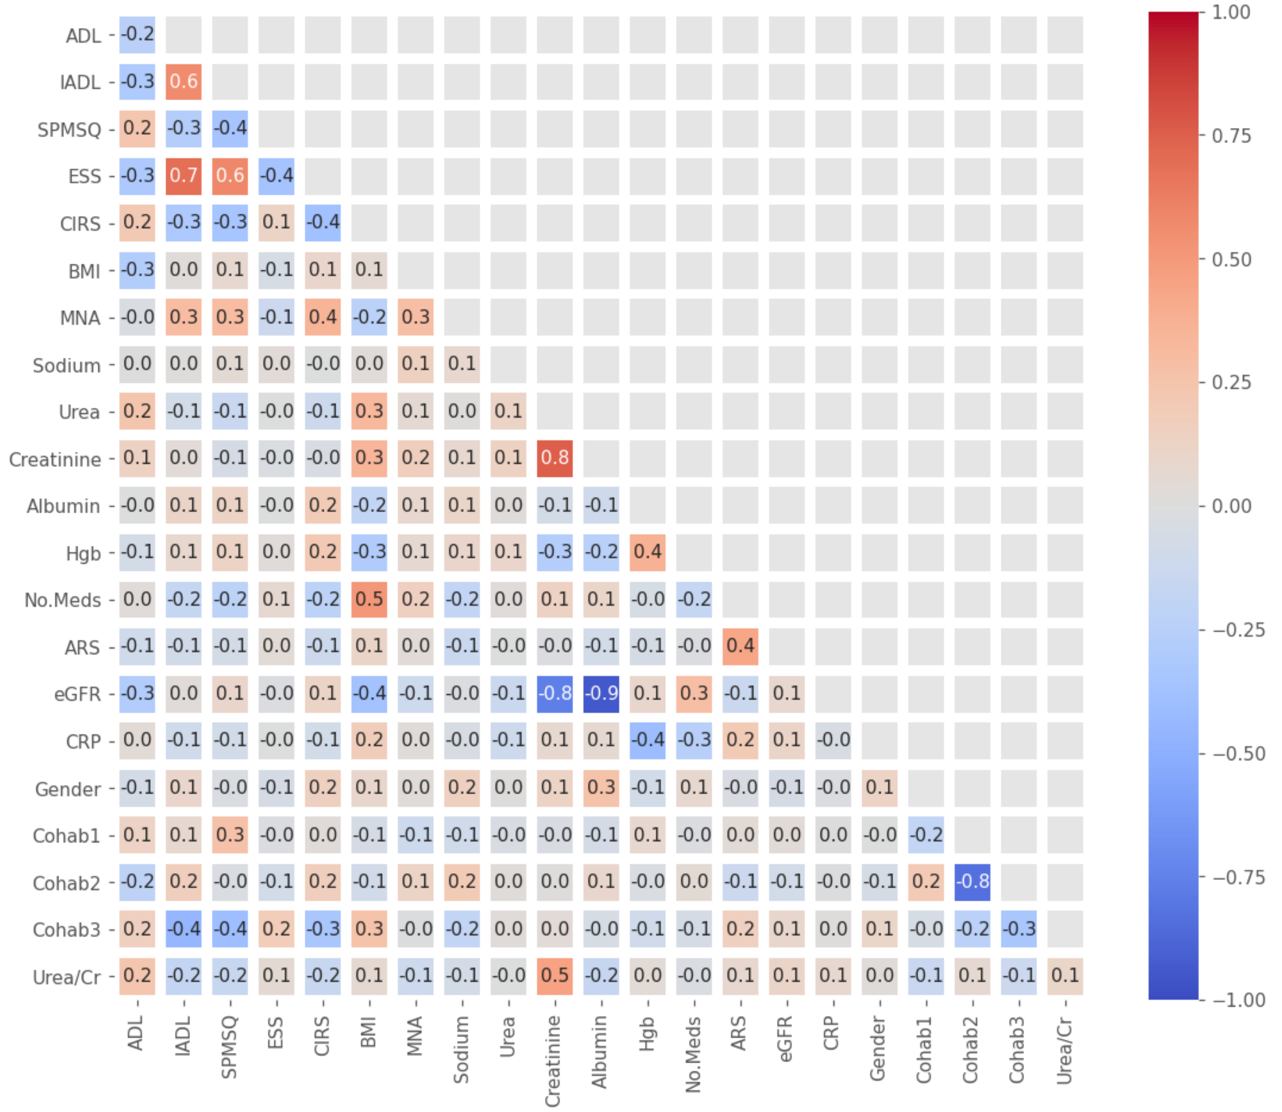
Correlation Matrix Heatmap

Figure 1 shows the Spearman ρ correlation matrix heatmap for features in feature set 4. Moderate to strong positive correlations were observed between creatinine and urea (ρ=0.75), ADL and ESS (ρ=0.69), IADL and ESS (ρ=0.58), ADL and IADL (ρ=0.57), and between CIRS and number of medications (ρ=0.51). There were also strong to moderate negative correlations between cohabitation status 1 and 2, that is, living alone and living with family or friends (ρ=−0.84), eGFR and creatinine (ρ=−0.94), eGFR and urea (ρ=−0.77), and CRP and albumin (ρ=−0.41). The absolute strengths of all other correlations were ｜ρ｜≤0.40. The lack of many highly correlated features suggested that the use of data reduction techniques such as principal component analysis before modeling was unnecessary.

Figure 1. Spearman ρ correlation matrix heatmap for feature set 4. ADL: activities of daily living; ARS: anticholinergic risk score; CIRS: Cumulative Illness Rating Scale; Cohab1: living alone; Cohab2: living with family or friends; Cohab3: living in an institute; CRP: C-reactive protein; eGFR: estimated glomerular filtration rate; ESS: Exton Smith Scale; Hgb: serum hemoglobin; IADL: instrumental activities of daily living; MNA: Mini Nutritional Assessment; No.Meds: number of medications; SPMSQ: Short Portable Mental Status Questionnaire; Urea/Cr: urea-to-creatinine ratio.



ML Algorithms

Test Data Accuracy

Table 2 and Figure 2 describe the test accuracy results for the four feature sets. The AUC for LR-MLE for feature sets 3 and 4 (0.738 and 0.757, respectively) that contained the eight MPI domains were considerably higher than those for feature sets 1 and 2 (0.632 and 0.688, respectively) that contained the three MPI categories. The AUC for LR-MLE was lower than those for at least one of the ML algorithms for each feature set 1 to 3 and was very similar to the best ML algorithms for feature set 4 (0.757 for LR-MLE vs 0.757 for XGBoost and 0.758 for NN). Overall, the best-performing ML algorithm was XGBoost, with an AUC ranging from 0.635 to 0.757 for feature sets 1 and 4, respectively, and a mean AUC of 0.714 for all four feature sets. The AUC for LR-MLE and all nine ML algorithms was improved with the addition of the clinical data (feature set 2 vs feature set 1 and feature set 4 vs feature set 3). The AUC was also improved for some, but not all, of the ML algorithms with the addition of clinical data. Multimedia Appendix 8 provides the results of accuracy, precision, recall, and F1 score for the LR-MLR model and the nine ML algorithms. As with the AUC, values for accuracy and precision were comparable across the various models with a range of 0.707 (KNN) to 0.752 (NN) for accuracy and a range of 0.474 (KNN) to 0.654 (SVM) for precision. However, there was a wider variability for recall and F1 scores with recall ranging from 0.031 (DT) to 0.531 (naïve Bayes) and the F1-score ranging from 0.059 (DT) to 0.751 (SVM).

Table 2. Diagnostic accuracy for logistic regression with maximum likelihood estimation and the 9 machine learning algorithms using feature sets 1 to 4 with the test data set.

Model	AUC[a]				
	Feature set 1[b]	Feature set 2[c,d]	Feature set 3[e]	Feature set 4[f,d]	Value, mean (SD)
LR-MLE[g]	0.632	0.688	0.738	0.757	0.704 (0.06)
Machine learning algorithms					
XGB[h]	0.635	0.706	0.756	0.757	0.714 (0.06)
Neural network	0.637	0.689	0.749	0.758	0.708 (0.06)

Training Data Accuracy

Multimedia Appendices 9 and 10 show the AUC values for LR-MLE and each ML algorithm for feature sets 1 to 4 using the training data set. The accuracy for LR-MLE was slightly higher for each feature set with the training data than for the test data values shown in Table 2. In comparison, the accuracy for each ML algorithm was considerably higher than that obtained using the test data, especially for the RF, XGB, and SVM, which obtained values of 0.956, 0.877, and 0.855, respectively, using feature set 4 and the training data.

Calibration

Multimedia Appendix 11 shows the distribution of predicted risk scores, the calibration plot, precision-recall curve, and receiver operating characteristic curve for the XGBoost algorithm using feature set 4. The calibration plot showed that overall, the predicted risks of mortality were in line with each observed risk decile. An AUC of 0.757 indicates fair to good accuracy in terms of overall sensitivity and specificity. The precision-recall curve indicates that the precision (ie, sensitivity or the ability to identify the patients that died) gradually decreased as the threshold for positivity decreased, and the recall, that is, the value of a positive classification, increased.

Feature Importance and Distributions

Figure 3 shows the feature importance plots for the XGBoost algorithm for the test data set using feature sets 1 to 4. In feature set 4, the MNA, IADL, and CIRS domains had the highest feature importance, indicating that they had the largest relative importance among the included features. Living alone (Cohab1) and urea were also highly ranked. The violin plots in Figure 4 show the distribution of MNA, IADL, and CIRS domains and urea—the four continuous features that accounted for the highest relative importance for the XGBoost algorithm in test feature set 4. The shape of the distributions was markedly different among patients who remained alive and those who died for the MNA score and the IADL score, which together accounted for 26.4% of the relative importance. The distributions were more similar for the CIRS score and urea, which accounted for 7.5% and 6.1% of the relative importance, respectively.

Figure 3. Feature importance plot for the eXtreme gradient boosting algorithm using test data with feature sets 1 to 4. ADL: activities of daily living; ARS: anticholinergic risk score; CIRS: Cumulative Illness Rating Scale; Cohab1: living alone; Cohab2: living with family or friends; Cohab3: living in an institute; Creat: creatinine; CRP: C-reactive protein; eGFR: estimated glomerular filtration rate; ESS: Exton Smith Scale; Hgb: serum hemoglobin; IADL: instrumental activities of daily living; MNA: Mini Nutritional Assessment; MPI: Multidimensional Prognostic Index; MNA: Mini Nutritional Assessment; ROC: receiver operating curve; SPMSQ: Short Portable Mental Status Questionnaire; Ur/Cr: urea-to-creatinine ratio.

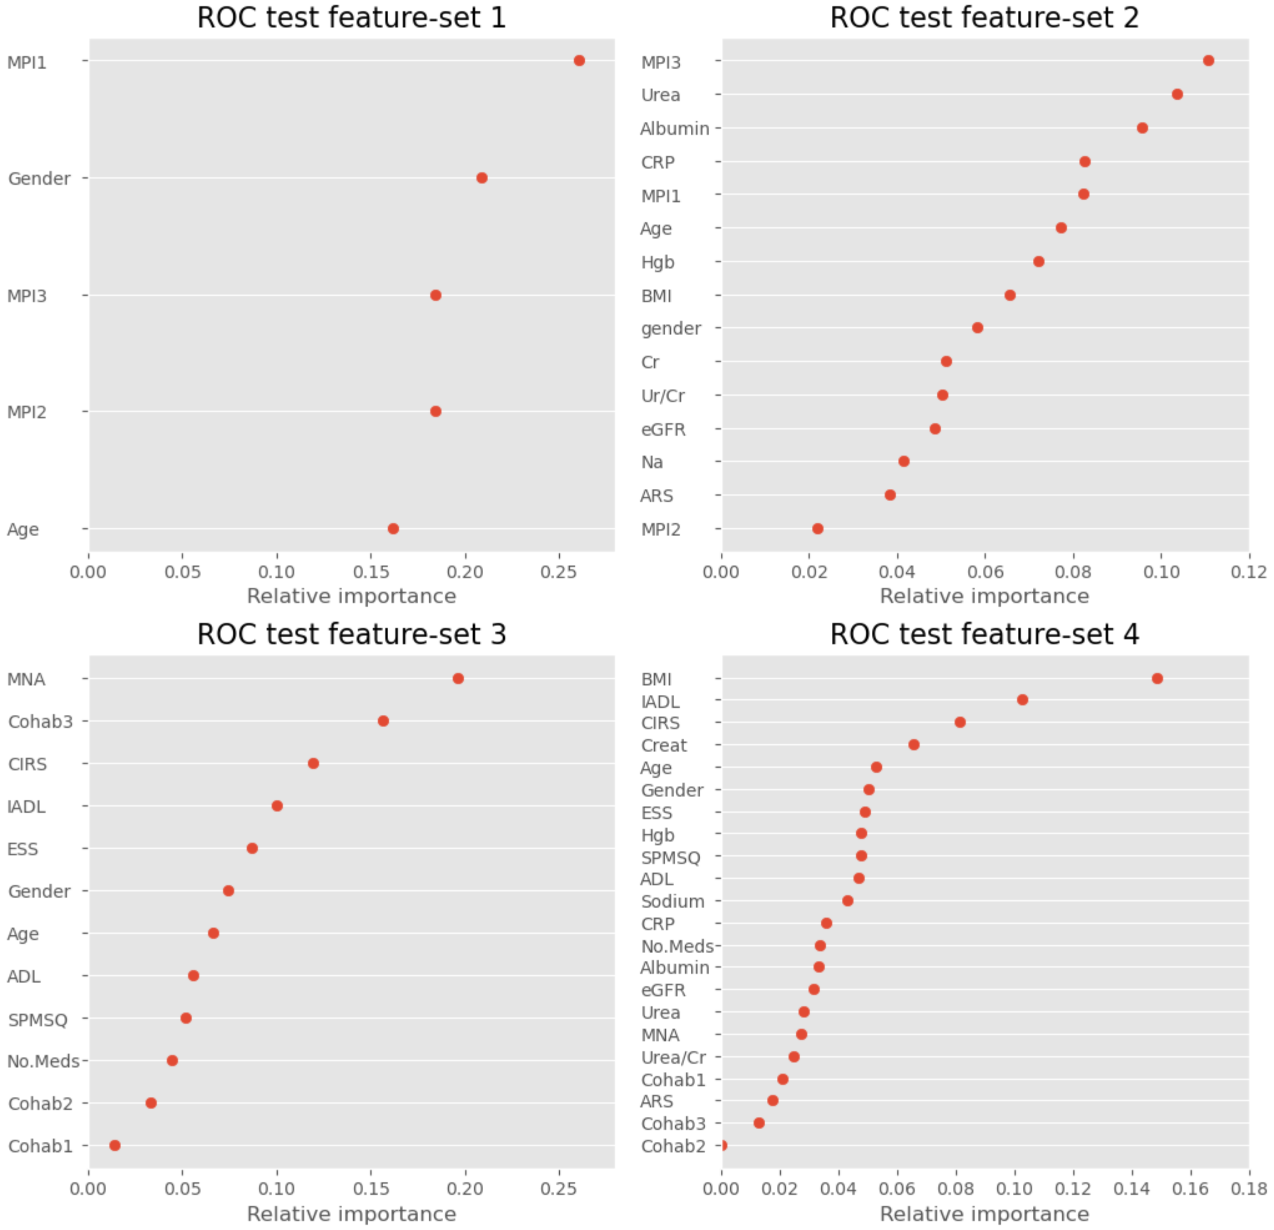

Figure 4. Violin plots showing distributions for the top 4 features for eXtreme gradient boosting in the second test feature set by patient vial status at 12 months after hospital discharge. CIRS: Cumulative Illness Rating Scale; IADL: instrumental activities of daily living; MNA: Mini Nutritional Assessment.

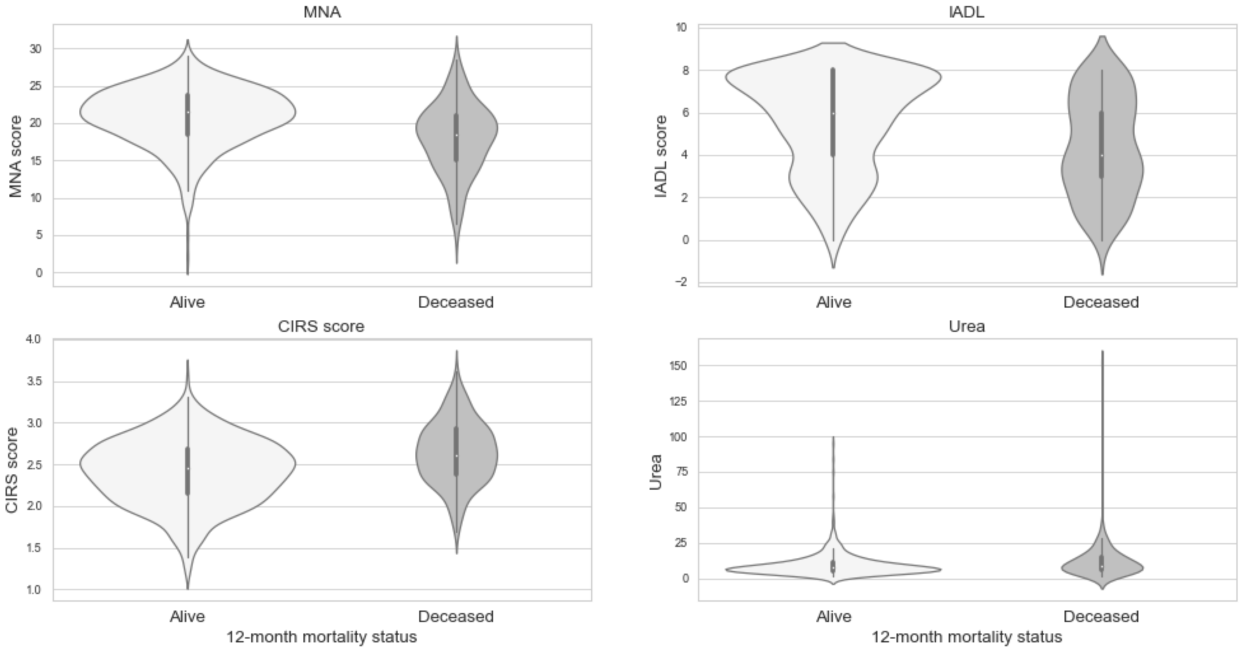

LR-MLE Accuracy

Table 3 shows the standardized odds ratios, 95% CIs, and *P* values for the LR-MLE model using test feature set 4. The variables that were statistically significant also had the largest standardized effect sizes: the MNA (OR 0.57, 95% CI 0.44-0.74; *P*<.001), CIRS domain (OR 1.81, 95% CI 1.32-2.49; *P*<.001), and the number of medications prescribed (OR 0.69, 95% CI 0.52-0.93; *P*=.02).

Table 3. Odds ratios (95% CIs) for the logistic regression with maximum likelihood estimation model using the test data with feature set 4[a].

Feature	Odds ratio (95% CI)	*P* value
Age	1.20 (0.90-1.61)	.21
ADL[b]	0.99 (0.71-1.39)	.96
IADL[c]	0.88 (0.63-1.22)	.44
SPMSQ[d]	0.99 (0.78-1.25)	.91
ESS[e]	0.89 (0.62-1.27)	.51
CIRS[f]	1.81 (1.32-2.49)	<.001
BMI	0.82 (0.63-1.07)	.14
MNA[g]	0.57 (0.44-0.74)	<.001
Sodium	0.96 (0.77-1.20)	.74
Urea	1.77 (0.89-3.51)	.10
Creatinine	0.85 (0.53-1.36)	.50
Albumin	0.83 (0.64-1.07)	.15
Hemoglobin	0.88 (0.68-1.14)	.35
Number of medications	0.69 (0.52-0.93)	.02
ARS[h]	1.06 (0.82-1.36)	.66
eGFR[i]	1.15 (0.74-1.80)	.53
CRP[j]	0.94 (0.73-1.20)	.61
Cohabitation		
Alone	1.00[k]	N/A[l]
Family or friends	0.96 (0.73-1.25)	.75
Institute	1.22 (0.95-1.57)	.12
Gender		
Female	1.00[k]	N/A
Male	0.69 (0.40-1.18)	.18
Urea-to-creatinine	1.13 (0.67-1.91)	.64

[a] All continuous variables were scaled before analysis to have a mean of zero and an SD of 1. Gender and cohabitation status were dummy coded for each category.

[b] ADL: activities of daily living.

[c] IADL: instrumental activities of daily living.

[d] SPMSQ: Short Portable Mental Status Questionnaire.

[e] ESS: Exton Smith Scale.

[f] CIRS: Cumulative Illness Rating Scale.

[g] MNA: Mini Nutritional Assessment.

[h] ARS: anticholinergic risk score.

[i] eGFR: estimated glomerular filtration rate.

[j] CRP: C-reactive protein.

[k] This is the reference group. Therefore, there is no CI.

[l] N/A: not applicable.

Sensitivity Analysis

In the sensitivity analysis that included all features as both first- and second-order terms, all results for the AUC for the nine ML algorithms were very similar to those obtained using only first order terms (data not shown).

Discussion

Principal Findings

In this study, we applied a range of ML binary-classification algorithms to data from 737 older inpatients in an Australian teaching hospital to develop and test a 12MM prediction model that can potentially be used in clinical settings to assist with risk management. The test data accuracy using the eight MPI domains and age and gender reached an AUC of 0.738 using LR-MLE, considerably higher than that obtained using the MPI categories plus age and gender (AUC=0.632). The addition of 10 clinical features improved the prediction accuracy further to AUC=0.757, which matched the accuracy obtained for the best overall ML-based algorithm (XGBoost), which outperformed most of the other algorithms except for the largest feature set in which the NN algorithm had similar accuracy (AUC=0.758).

The major strengths of our study include the use of both LR-MLE and a wide range of commonly used ML algorithms to compare the prediction accuracy for aggregate versus domain-based data. In the development of the ML algorithms, we also used a systematic ML framework, with a grid search of the hyperparameter space and 10-fold cross-validation for each algorithm. The much-improved accuracy warrants the calculation of individual patient risk scores, which, with appropriately developed technology platforms linked to the MPI domain and clinical information, can be used to better stratify patient risk and provide appropriate posthospital discharge surveillance and care [22,23].

Comparison With Prior Work

The prediction accuracy using the MPI categories and the test data set (AUC=0.632) was very similar to the poor accuracy obtained previously with follow-up on only 697 of the same patients (AUC=0.62), in which all records were used for assessing prediction accuracy rather than using separate training and testing data sets [5]. However, the higher accuracy obtained using the eight individual component features of the MPI combined with clinical data led to an accuracy similar to that originally reported for the three-category MPI within the original Italian MPI cohort [2]. In addition, the improvement in prediction accuracy with ML algorithms for some but not all feature sets provides general support for the use of ML in addition to LR-MLE when developing risk scores, at least for moderately sized data sets and feature numbers. The accuracy values obtained for precision, recall, and F1 score, which are less subject to variation than the AUC in imbalanced data sets, were of the same order for LR-MLE and the XGBoost algorithm and within the upper range of values obtained for these metrics.

The significantly higher accuracy obtained by using the separate domains of the MPI compared with using the 3-category aggregate MPI supports other studies in which the use of component domain data outperformed an aggregate score. In a meta-analysis of 6 studies comparing individual domain feature input to aggregate weighted scores for mortality and intensive care unit transfer, prediction using ML algorithms or multivariate regression with separate features considerably enhanced prediction compared with that obtained using the aggregate scoring systems (AUC=0.80 vs AUC=0.73) [6]. These findings suggest that caution should be used when employing aggregate risk scoring systems and the need to consider the underlying individual components. In addition, in our study, certain MPI domains, including the MNA, IADL, ESS, and CIRS, had either strong feature importance using the XGBoost algorithm or were strongly associated with 12MM using LR-MLE. Therefore, it may also be possible to obtain predictive accuracy similar to or better than that of the 3-category MPI feature sets in this study, by using data collected for only a subset of the eight MPI domains and by using the individual items for these specific domains. However, such an approach requires validation using data collected from additional retrospective and/or future prospective cohorts.

Unlike many ML algorithms that attempt to reduce the potential for overfitting and increased variance, the traditional LR-MLE approach to prediction modeling is not implicitly designed to deal with bias, multicollinearity, nonlinearity, or feature interactions. Thus, although the addition of features and model complexity generally improves a model's performance during training, a new and larger model does not guarantee similar improvements in model fit in the validation phase. Indeed, without some form of additional penalty term in the model's loss function to ensure that the training model is not being overfit, a decrease in testing accuracy is not uncommon [24]. When an additional *L2* penalty term was applied to the Logistic Regression classifier, the resulting ridge regression ML classification algorithm provided a slight increase in prediction accuracy for all four test feature sets (mean AUC of 0.698 for ridge regression vs AUC of 0.667 for nonregularized logistic regression). This reduction in strength (ie, regularization) of the estimated parameters for the ridge regression and the other ML algorithms during the training phase of model development may partly explain the higher test accuracy for LR-MLE in which there is no equivalent model training or an additional penalty term to help ensure that the LR-MLE coefficients are not inflated and that residual error is not overly reduced. Similarly, although many of the ML algorithms had better training performance than the LR-MLE, this did not translate into better test performance, suggesting that these ML algorithms often overfit the data during training, a problem that could potentially be solved with greater tuning of the algorithm's hyper-parameters.

A common criticism of ML approaches compared with standard statistical approaches is that they rely on blackbox algorithms in which the source of the improved performance is not readily transparent [25,26]. One method to overcome this lack of transparency is through the calculation of feature importance, which shows the relative importance of each feature in terms of reducing prediction error [26]. By using this method, we demonstrated the very high relative importance of the MNA and IADL domains of the MPI regarding risk for 12MM. Thus, although the ML algorithms do not generally provide a single specific effect estimate and CI for each variable or feature, our findings support other studies in which the MNA [27] and the IADL [28] have been shown to be independently and strongly associated with medium-term mortality in similar cohorts. These two features were also the strongest independent features in the LR-MLE model using feature set 4, emphasizing their importance in 12MM prediction.

The independent predictive ability of functional, cognitive, and psychological measures in predicting mortality in older hospitalized patients has been previously identified, with the IADL, mini mental state examination, and geriatric depression scale all shown to be independent predictors of mortality after risk adjustment for clinical characteristics [1]. However, the prediction accuracy in that study was modest (AUC=0.690), suggesting that complementary clinical data may have further improved prediction. The improvement in performance with the addition of blood biochemistry data, BMI, and ARS in our study highlights the independent predictive value of clinical data. Many of these features are known markers of malnutrition or frailty [29,30] and are associated with poorer outcomes in older patients [12,31,32]. Their independence with the MPI domains is demonstrated by weak univariate correlations, indicating their potential to add predictive power to that obtained from the domains. As each biochemical marker is routinely measured in hospital laboratories, it is highly feasible to incorporate them into hospital-based prediction algorithms.

Our results for the ML algorithms, based on a rigorous train-test validation approach with a grid search of hyper-parameters for each algorithm during training, demonstrate the potential of such methods in predicting mortality in clinical settings. In particular, the XGBoost algorithm, which is known as a superior and fast prediction ML algorithm, had the highest overall level of accuracy for the feature sets using the validation data set, and one of the highest levels of accuracy using the training data set, suggesting that the prediction accuracy observed for our cohort is likely to be repeatable in other cohorts with a similar patient profile. A distinguishing feature of the XGBoost algorithm is its approach of building a *strong learner* from an ensemble of *weak learners* (ie, separate DTs) by building successive trees, in which additional weight is placed on harder to predict subsets of the training data [33]. XGBoost uses a second-order Taylor series expansion to approximate the value of the loss function and incorporates regularization to avoid overfitting [21]. These features together ensure a fast solution as well as an unbiased estimate of prediction accuracy, both of which are important in building an automated risk prediction model at a system level within a clinical setting.

Limitations

Our study had several limitations. In using only routine geriatric assessment tools and basic biochemical, medication, and demographic data, it is likely that we were limited in our ability to obtain higher levels of predictive accuracy. The development of better prediction models should be possible using a richer set of features, such as additional information on demographics, comorbidities, laboratory test measurements, and medication type. Specifically, the Charlson Comorbidity Index, which determines the risk of medium-term mortality due to a specific set of 17 different comorbidities, is generally readily calculable using the secondary diagnosis codes captured in most administrative databases [34]. Similarly, routine hospital blood tests capture biomarker data associated with 12MM [35], and most hospitals capture medication data that can be used to assess the predictive capacity of medication type, dose, and polypharmacy. Other potentially predictive features include the number of hospitalizations and GP visits in the previous 12 months [36]. Our study data were also limited by its relatively small size, given that the test data set included only 222 patients and 64 deaths. ML methods have been found to generally require larger data sets, and particularly a higher number of events before stable measures of prediction performance are obtained in comparison with standard statistical models [37]. Despite this limitation, we still achieved moderate to good validation accuracy using data sets with a relatively limited number of events. In addition, although we were careful to use cross-validation throughout the model training process and to validate each model in a held-out test data set, we cannot be sure that our prediction accuracy will be the same in different cohorts of the same patient population or in different older populations such as persons living in aged care facilities. Further validation of the models in additional retrospective cohorts as well as prospective cohorts is required to ensure generalizability.

Conclusions

An MPI domain-based approach, together with clinical and demographic data, improved the prediction of mortality compared with a logistic regression model that used the aggregate MPI score. The ML algorithms in this study generally provided improved prediction accuracy compared with LR-MLE. These results build on previous work for the MPI and suggest that implementing risk scores based on MPI domains and clinical data with ML prediction models can be used to support clinical decision-making with respect to the medium-term follow-up care of older hospitalized patients.

Abstract

Background: Sepsis is the leading cause of death in US hospitals. Compliance with bundled care, specifically serial lactates, blood cultures, and antibiotics, improves outcomes but is often delayed or missed altogether in a busy practice environment.

Objective: This study aims to design, implement, and validate a novel monitoring and alerting platform that provides real-time feedback to frontline emergency department (ED) providers regarding adherence to bundled care.

Methods: This single-center, prospective, observational study was conducted in three phases: the design and technical development phase to build an initial version of the platform; the pilot phase to test and refine the platform in the clinical setting; and the postpilot rollout phase to fully implement the study intervention.

Results: During the design and technical development, study team members and stakeholders identified the criteria for patient inclusion, selected bundle measures from the Center for Medicare and Medicaid Sepsis Core Measure for alerting, and defined alert thresholds, message content, delivery mechanisms, and recipients. Additional refinements were made based on 70 provider survey results during the pilot phase, including removing alerts for vasopressor initiation and modifying text in the pages to facilitate patient identification. During the 48 days of the postpilot rollout phase, 15,770 ED encounters were tracked and 711 patient encounters were included in the active monitoring cohort. In total, 634 pages were sent at a rate of 0.98 per attending physician shift. Overall, 38.3% (272/711) patients had at least one page. The missing bundle elements that triggered alerts included: antibiotics 41.6% (136/327), repeat lactate 32.4% (106/327), blood cultures 20.8% (68/327), and initial lactate 5.2% (17/327). Of the missing Sepsis Core Measures elements for which a page was sent, 38.2% (125/327) were successfully completed on time.

Conclusions: A real-time sepsis care monitoring and alerting platform was created for the ED environment. The high proportion of patients with at least one alert suggested the significant potential for such a platform to improve care, whereas the overall number of alerts per clinician suggested a low risk of alarm fatigue. The study intervention warrants a more rigorous evaluation to ensure that the added alerts lead to better outcomes for patients with sepsis.

Introduction

Sepsis Background

Sepsis is the leading cause of death in US hospitals [1], accounting for 6% of all hospitalizations and 35% of all inpatient deaths [2]. Hospital performance in sepsis care has a significant impact on patient outcomes. A recent study demonstrated that every hour of delay in the completion of a sepsis bundle, including antibiotic administration, was associated with a 4% increase in risk-adjusted hospital mortality [3]. Thus, every failure to complete a sepsis bundle on time potentially represents a barrier to optimal patient care. There is a clear and urgent need for effective interventions to improve the performance of sepsis care and meet the expectations of patients and stakeholders.

International guidelines and the Centers for Medicare and Medicaid Services (CMS) Sepsis Core Measures (SEP-1) bundle emphasize the importance of adhering to specific steps in the diagnosis and management of sepsis [4]. Consistent adherence can be very challenging, especially in the setting of a busy emergency department (ED), ward, or intensive care unit, where there are multiple simultaneous demands on providers' attention. In this environment, SEP-1 bundle care can be delayed or missed, even when team members are knowledgeable about best practices in sepsis care [5].

The CMS SEP-1 severe sepsis bundle is an all-or-nothing measure that requires antibiotics, blood cultures, and a lactate measurement within 3 hours of sepsis onset and a repeat lactate measurement within 6 hours if the initial lactate level is elevated. In cases of septic shock, additional requirements include adequate fluid resuscitation, reassessment of volume status and perfusion, and possible addition of vasopressors. As an all-or-nothing measure, a deficiency in any element of the bundle counts as failing the entire measure. In the first 2 years after the measure was introduced in 2015, two-thirds of sepsis cases submitted to CMS by hospitals failed the measure [6], and recent Hospital Compare data from 2019 still show a failure rate of 61% [7]. There has been argument in the literature about the appropriateness of some components of the bundle [8-10]; however, the fact remains that early identification and treatment of patients with sepsis remains an important quality opportunity.

Strategies to Improve Sepsis Care

Institutions have attempted both nondigital and digital processes to improve sepsis care, including provider and nursing huddles and standardized electronic order sets. Most digital initiatives studied thus far have focused on identifying patients at risk for sepsis using the severity of illness scores in the electronic medical record (EMR). This has helped improve the early detection of sepsis [11,12] but has only modest effects on adherence to evidence-based bundle care elements and outcomes [13]. In concept, digital solutions offer the potential to close this gap by enabling real-time monitoring of adherence and providing just-in-time alerts to providers at the bedside. Electronically available data from the patient's medical record would make this possible, as it includes most of the key elements of the SEP-1 bundle, including venipuncture for laboratory studies and medication administration. Any solution that could increase adherence and decrease cognitive load must also ensure that it does not cause alarm fatigue.

To date, we have not found any studies in the literature describing electronic alerting based on the completion of bundle elements for sepsis. Therefore, we developed a digital software solution called the Sepsis Care Tracking Platform (SCTP), which continuously monitors patients at risk of sepsis for completion of SEP-1 bundle elements and delivers actionable reminders to medical providers at the bedside in time for them to correct these deficiencies.

Study Objectives

The objective of this paper is to describe the design, implementation, and validation of a novel electronic monitoring platform for optimal sepsis care in an ED at a large urban teaching hospital. By establishing feasibility, we hope to lay the groundwork for future randomized controlled studies that can determine the efficacy of the electronic monitoring platform in impacting process and outcome measures in sepsis care.

Methods

Initial Stakeholder Consultation

Multiple stakeholder groups were consulted to devise and implement the SCTP in the ED. For project approval and scope, the study team met with the chairperson and operational leaders of the Department of Emergency Medicine. The project was also presented to the quality and safety committees, both at the departmental and hospital levels. For feedback and iterative improvement, the ED Quality and Safety Committee was updated every 2 weeks regarding the project status and areas for improvement. ED providers who were paged by the SCTP received surveys regarding their experience and suggestions for improvement. This study was a quality improvement project based on institutional guidelines from the institutional review board and was thus exempted from the institutional review board review.

Project Overview

The timeline for this project was divided into three phases: design and technical development, pilot, and postpilot program rollout.

Design and Technical Development Phase

The design and technical development phase spanned from September 1 to November 30, 2019. During this phase, the study team aimed to develop components of the SCTP and alert workflow, including defining the patient cohort, selecting the bundle measures from CMS SEP-1 for alerting, and determining recipients of alerts, mode of alert delivery, and alert content. In addition, technical development was performed, including linking EMR data to the platform, validating that the correct patients and bundle elements were captured, and performing initial quality control on data and alerts via chart review.

Pilot Phase

The pilot phase spanned from December 9, 2019, to January 12, 2020. During this phase, the study team deployed the initial version of the platform in the ED, including monitoring actual patients and sending alerts to their providers. This phase aimed to ensure the technical stability of the platform through confirmed receipt of alerts, monitor for false-positive results, and obtain feedback from alert recipients via a survey to determine the usefulness of the platform, alarm fatigue, and potential improvements. Monitoring for false positives was performed by study team members who manually verified every page sent during the pilot phase by confirming through the patient record that alerts reflected the correct bundle element deficiencies. Providers who received a page would be emailed a two-question survey the next day asking for feedback regarding each page. The two questions in the survey were (1) *Was this page alert useful in providing sepsis care to the patient?* with a ranking from *not at all helpful* (1) to *extremely helpful* (5), and (2) *If not helpful, why?* An additional space allowed for additional feedback, and providers could receive the survey multiple times for different pages.

Postpilot Rollout Phase

After incorporating modifications and improvements identified during the pilot phase, the postpilot rollout was initiated, in which a prospective trial was performed between January 13, 2020, and March 1, 2020. This trial aimed to assess the function of the platform and describe alerting patterns and subsequent adherence to alerts during this period.

Platform Setup

The SCTP ED platform was coded in C#, using .NET Microsoft Development Platform and Microsoft SQL databases. It was linked to the institutional EMR (EPIC) through a web service that extracted data each minute. The SCTP checked for the completion of the sepsis bundle elements every 15 minutes. These elements included completion of blood culture orders; initial and repeat lactate results; and administration of antibiotics, vasopressors, and fluids (as described in the *Results* section, vasopressors and fluids were later eliminated from the SCTP). If one or more elements were incomplete, the ED providers would be paged with the deficiency. Each patient was added to the platform after the institutional sepsis best practice alert (BPA) was accepted and monitored until the end of the 6-hour window for optimal sepsis care. The platform tracked a patient within that window even if the patient was admitted or transferred to a different area of the hospital and continued to page the appropriate responding clinician.

Study Measures and Analysis

During both the pilot and postpilot program rollout phases, several study measures were tracked to assess the platform function and outcomes. Data were abstracted from the SCTP, an institutional clinical and administrative database, and surveys administered to paged providers. Subsequent data analyses were performed using Microsoft Excel.

We defined an *alert* as when the SCTP identified a sepsis bundle element deficiency within 1 hour of the bundle element becoming due. We defined a *page* as occurring when a clinical provider received a notification on their pager. As there were usually multiple providers caring for each patient, a single *alert* could trigger multiple *pages* at the same time. During the pilot phase, we assessed the total number of pages sent to providers; the number of alerts per provider shift, defined as the number of alerts divided by the number of shifts completed by the attending providers; and the etiology of alerts, defined as the bundle measure that triggered the alert. In addition, we administered an email survey to the providers after receiving an alert. The survey consisted of two questions regarding whether the pages were helpful and whether they had any further feedback regarding the SCTP.

During the postpilot program rollout, we measured the characteristics of patients who were monitored by the platform, including age and length of stay in the ED. Similar to the pilot phase, we also measured the number and etiology of the pages sent to the providers. In addition, we measured the *postalert successful adherence rate* of sepsis bundle measures, which was defined as the completion of the sepsis bundle element within the next hour after the relevant page was sent to the provider.

Results

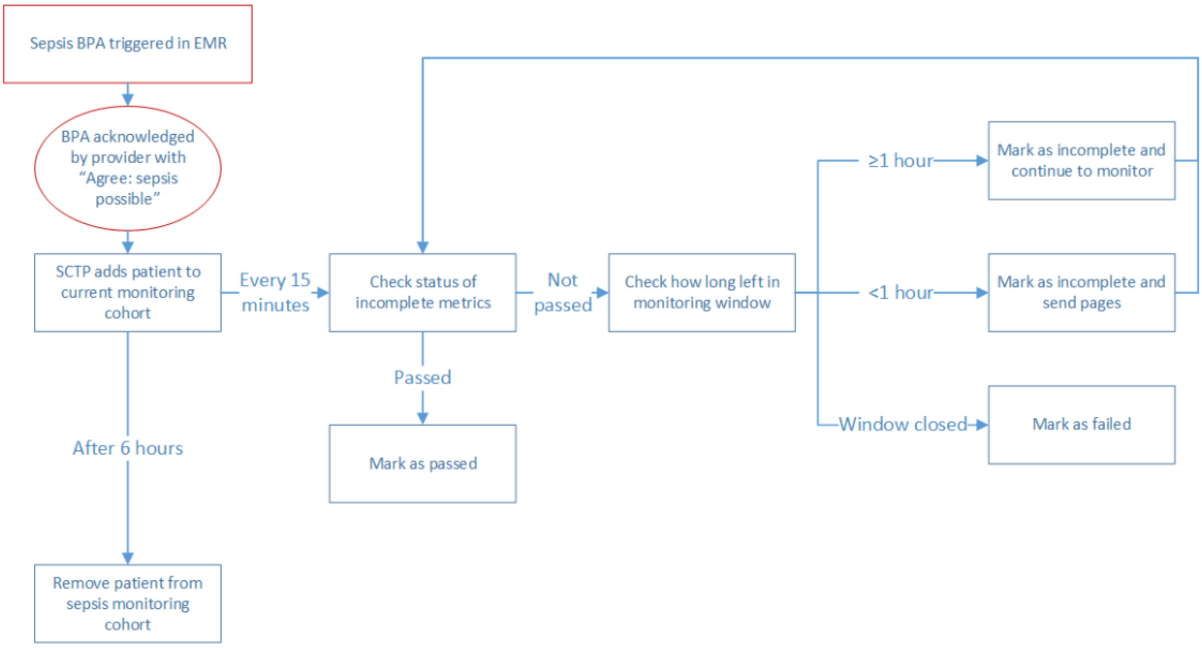
SCTP Design and Technical Development Phase

The SCTP was developed and validated in close cooperation with ED Quality and Safety leadership and intended to fit within the existing workflow of the institution to decrease barriers to adoption.

Inclusion Criteria for Active Monitoring

In consultation with ED Quality and Safety leadership, it was determined that patients should qualify for monitoring if they met the criteria for possible sepsis based on an electronic health record (EHR)–derived algorithm that existed before this study. This algorithm is based on the Sepsis-3 2016 European Society of Intensive Care Medicine and Society of Critical Care Medicine consensus definition of sepsis and incorporates both signs of infection such as fever, positive laboratory results, and patient risk factors, as well as signs of organ dysfunction as measured by the Sequential Organ Failure Assessment score [14]. Providers caring for patients identified as potentially septic receive a prompt in the EHR in which they could click that they agreed or disagreed that sepsis was likely. If accepted, the patient would qualify for SCTP monitoring. Stakeholders and study team members believed that the advantage of this approach was to include only those patients in the active monitoring cohort whom the team suspected of sepsis, thereby increasing the relevance of SCTP alerts they received (Figure 1).

Figure 1. Sepsis care tracking platform page generation logic. BPA: best practice alert; EMR: electronic medical record; SCTP: Sepsis Care Tracking Platform; SEP-1: sepsis core measure.



Measurement Selection for Alerting

From the commonly accepted SEP-1 bundle, stakeholders selected antibiotics, blood cultures, and lactate measurements as the bundle elements that would be monitored and excluded measures related to the volume of intravenous fluids administered. The decision to exclude fluids was made because of the belief that significant practice variation existed due to patient-specific conditions and comorbidities [15,16] and that alerts suggesting that additional fluids should be administered could be clinically inappropriate.

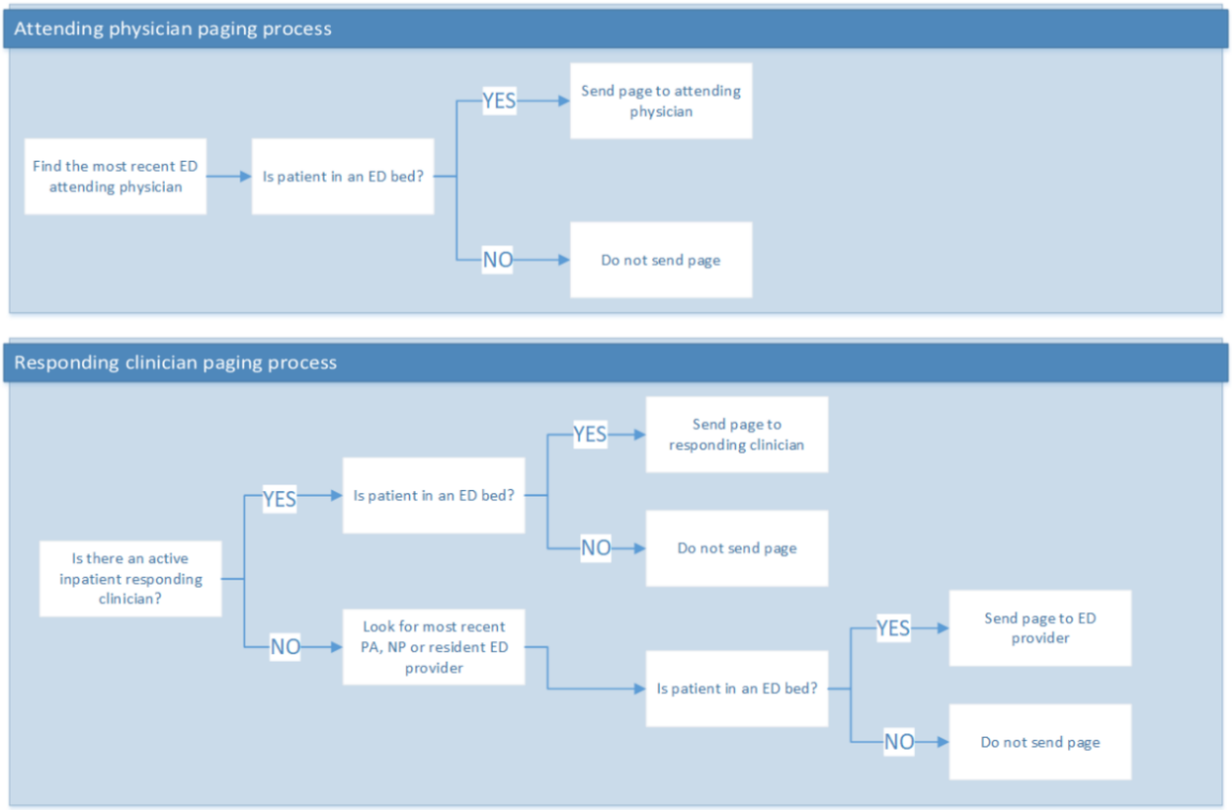
Alert Time Threshold

Stakeholders agreed that paging 1 hour before the deadline for bundle compliance gave providers sufficient time to address the deficiency (Figure 1). To minimize alert fatigue, stakeholders agreed that providers would receive a maximum of two pages per patient that would be sent 1 hour before the 3-hour and 6-hour SEP-1 time windows. Each page would list all the deficient bundle elements at that time.

Alert Recipients

Given that multiple providers were simultaneously responsible for a single patient, stakeholders designed the software to use the logic shown in Figure 2 to determine the appropriate clinicians to page. The decision was made to send alerts to both the responding clinician (resident or advanced practitioner) and the supervising attending because each played a unique role in the patient's sepsis care. The resident and advanced practitioner were responsible for placing orders and closing the loop of communication with bedside nurses about bundle measures, whereas the attending physician could supervise and monitor the overall care of the patient to ensure appropriate care was provided. Although the study team and ED stakeholders thought it valuable to alert bedside nurses, given their important role in sepsis care delivery, this was technically not feasible as they did not carry pager devices.

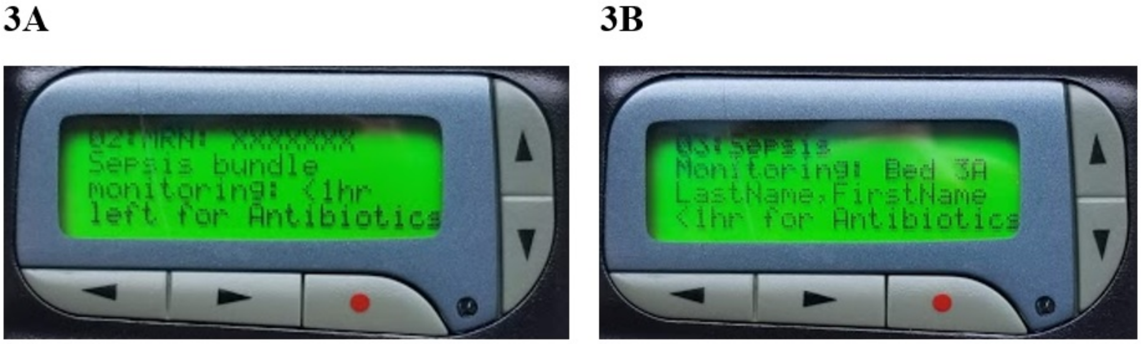
Figure 2. Sepsis care tracking platform page recipient logic. ED: emergency department; NP: nurse practitioner; PA: physician assistant.



Alert Message Contents

Stakeholders agreed that alert message contents should state the deficient element without providing prescriptive language recommending that the provider performs a particular action (Figure 3). The message contents would list which element was deficient, but otherwise the remainder of the message would remain the same for all pages. This decision was made on the rationale that in some cases providers would appropriately not administer bundle care to patients based on the evolving diagnostic and clinical course of the patient.

Figure 3. Pilot phase (3A) and rollout phase (3B) pager display.



Alert Delivery Mechanism

Stakeholders determined that the hospital's paging system was the most effective means of communicating time-sensitive alerts, given that providers always carry their pager and typically view messages immediately. This was preferred over EMR-based pop-up alerts because it required the provider to log on to the patient's medical record to see the alerts. It was felt that this mode would be burdensome to the provider and potentially delay the receipt of the message.

Pilot Phase

During the 35-day period, 453 patients met the inclusion criteria to be monitored by the SCTP. Overall, 371 pages were sent, resulting in 0.79 pages per attending shift. Of the alerts, 27.3% (50/183) were for blood cultures, 50.3% (92/183) were for antibiotics, and 22.4% (41/183) were for lactate measurements.

In total, 70 surveys were returned with responses. In total, 87% (61/70) of respondents found the alerts to be helpful (21/70, 30%), very helpful (17/70, 24%), or extremely helpful (23/70, 33%). Specific examples of positive feedback included "The page helped us realize blood cultures were not initially ordered and we ordered them after this page" and "It prompted us to reassess the patient for sepsis." Providers also suggested that pages "would be more useful if patient's name was also displayed on the page and not only the MRN." Providers also noted that their suspicion for sepsis can change over the course of an ED visit, with comments such as "Patient was later felt not to have sepsis so bundle was not completed." On the basis of this feedback, the alert message content was modified to allow providers to more easily identify the patient (Figure 3) and the alert routing algorithm was adjusted to identify the correct attending physician (Figure 2). We also removed reminders to initiate vasopressors for hypotensive patients because a reliable bedside monitoring alarm system already existed to alert clinicians to hypotension and clinicians consistently responded by initiating vasopressors when appropriate. Our survey responses helped to elucidate this frontline practice.

Postpilot Program Rollout Phase

After completion of the pilot program with subsequent adjustments to the SCTP, the postpilot program rollout phase was initiated. During this 48-day period, 711 patient encounters (mean 14.8, SD 4.4 encounters per day) for 648 unique patients met the inclusion criteria to be monitored by the SCTP (Table 1).

Of the 711 encounters monitored by the SCTP, 439 (61.7%) passed all measures without requiring a page, as all sepsis bundle elements were completed more than an hour before the deadline. In comparison, 38.3% (272/711) patients had one or more pages sent to the responding providers. In total, 634 pages were sent, averaging 0.89 pages per patient in the active monitoring cohort and 0.98 pages per attending shift (Table 2).

Of the 634 pages, the most frequent alert sent was for deficient antibiotics (136/327, 41.6%), followed by the second lactate measurement (106/327, 32.4%), blood cultures (68/327, 20.8%), and first lactate (17/327, 5.2%). This distribution was similar to the results from the pilot study, with pages related to antibiotics being the most common etiology.

Overall, there was a substantial proportion of sepsis bundle element deficiencies that triggered a page and were successfully adhered to within the SEP-1 time window. There was a 26% (18/68) postalert successful adherence rate for collecting blood cultures, 12.5% (17/136) for administering antibiotics, and 24% (4/17) for initial lactate measurement and an impressive 81.1% (86/106) for the second lactate measurement.

Table 1. Postpilot rollout phase patient demographics (N=648).

Characteristics	Values, n (%)
Age (years)	
18-65	271 (41.8)
>65	377 (58.2)

Total	125 (38.2)
Blood cultures	18 (26.5)
Antibiotics	17 (12.5)
Initial lactate	4 (23.5)
Repeat lactate	86 (81.1)

Discussion

Principal Findings

To improve adherence to sepsis guideline care at our tertiary care hospital, we designed and implemented a real-time sepsis care tracking and alerting platform in a busy ED environment. With feedback from frontline clinicians, quality and safety program representatives, and departmental leadership, we customized the SCTP to the needs of clinicians and the clinical environment. In our postpilot program rollout phase, the SCTP actively monitored 711 ED encounters where sepsis was thought to be likely, in 272 of these encounters, the platform sent text pages to ED providers due to a deficiency in sepsis bundle completion, with an overall postpage adherence rate of 38.2% (125/327).

During the development phase, it was important to select the sepsis bundle elements that were felt to be most clinically appropriate and could be identified by our monitoring platform. The SEP-1 framework served as a foundation for this study, as the framework was widely accepted and aligned the interests of multiple stakeholder groups, including providers, departmental and quality and safety leadership, and hospital administration. Engaging with provider stakeholders allowed us to make the application more effective. Through these discussions, we were able to understand the clinical workflow and target alerting to the frontline provider who places the orders.

Moreover, we note the importance of the provider feedback obtained during the pilot phase. The surveys emphasized the need to provide critical information concisely in the SCTP paging alerts, including what information can quickly and accurately identify the patient and the specific bundle element deficiency. In addition, given the complex structure of provider teams in our ED, which can change multiple times over a patient's ED visit, we had to consider different clinical scenarios and which provider would be the optimal recipient for paging alerts. Finally, given the learning curve that comes with new technologies, the pilot phase allowed providers to acclimate to this system before the full rollout.

During the postpilot rollout, we found that there was a substantial proportion of encounters (272/711, 38.3%) in which the clinician was at risk of missing the SEP-1 care measure and for which an alert was paged, indicating the potential impact of such a platform on adherence. Furthermore, we found that the postalert successful adherence rate ranged from 12.5% (17/136) to 81.1% (86/106), depending on the measure for which the alert was sent, further suggesting the potential for the platform to improve adherence. Finally, we found that the number of pages per clinician shift (0.98) was low enough to not be overly disruptive but high enough that we would expect the SCTP to meaningfully impact SEP-1 performance. On the basis of these findings, we believe that a real-time sepsis care tracking and alerting platform is feasible in a hectic ED environment and could have a significant impact on adherence to life-saving sepsis care without causing alarm fatigue.

In addition, we found it concerning that the most common deficiency triggering a paging alert was a delay in antibiotics, which is the SEP-1 element that is most closely linked to mortality in previous studies [17]. This suggests the possibility that the SCTP could be associated with mortality improvement if it is able to improve timely antibiotic administration. However, we found that the postalert adherence success rate for antibiotics was the lowest among all alerts. It may be that antibiotics were, in fact, administered just outside of the monitored 3-hour window or that patients were subsequently determined to likely not have sepsis. Regardless, this discrepancy requires further exploration to determine why antibiotics may have a lower rate of postalert adherence compared with other measures.

In comparison, we found that repeat lactate was the second most common etiology of pages (106/327, 32.4%) and had the highest postadherence rate (86/106, 81.1%). This suggests that the SCTP may be especially valuable over a prolonged time course in which providers may be distracted by the needs of other patients, and paging alerts in this situation can refocus provider attention with sufficient time to deliver optimal care.

We believe that the postalert adherence rate of 12.5% (17/136) to 81.1% (86/106) for bundle element deficiencies represents the completion of bundle elements that likely would have been missed otherwise and is a significant potential improvement in increasing adherence to sepsis bundle care. However, the majority of pages did not result in adherence, which deserves further study. On the basis of our survey data, we believe that an important driver of this trend may be that the clinician no longer believed sepsis was likely. The sepsis BPA, which the SCTP used as a trigger to begin monitoring, was designed to cast a wide net early in the patient's ED encounter to reduce the likelihood of missing any patient who could be septic given the high mortality of the disease. As more data are gathered and the patient's care evolves, clinical teams may have judged that sepsis was unlikely and thus appropriately withheld sepsis bundle care. We believe that this could have accounted for much of the nonadherence. A future iteration of the SCTP may enable frontline clinicians to *off ramp* from the page alerts if they judge that sepsis is highly unlikely later in the patient's ED course.

SCTP differs from previous EHR-related innovations in improving sepsis care. The majority of previous studies have focused on identifying sepsis through different clinical criteria [18] or through predictive algorithms and machine learning [19], usually followed by an EHR warning or paging alert. Other studies have used alerts to trigger sepsis workflows, including bedside assessment and order sets [11]. SCTP builds on these innovations by following patients suspected of having sepsis through the next several hours of care, which can be the most critical and prompts providers toward optimal care. Therefore, we expect it to influence provider action more directly for patients suspected of having sepsis and have a meaningful impact on clinical outcomes.

The focus of this study is on alert fatigue, as recent articles have shown that an increase in the number of alerts decreases the provider's acceptance rate [20] and many alerts in the EHR may not directly change clinical care [21]. The SCTP incorporated many design features to minimize alert fatigue, such as restricting enrollment to patients where the sepsis BPA was confirmed by an ED provider and condensing pages so no more than two pages are sent for any patient. Consultations with frontline providers and survey data were also used to optimize the message content to determine the appropriate page recipient. All of these factors likely contributed to the low number of pages sent per attending shift (0.98) and favorable survey responses. However, further work is needed to ensure that the clinical benefit of this system outweighs the alert fatigue it generates.

This study had several limitations. First, system implementation was conducted at a single academic site, which may not be generalizable across different health care settings. Second, the survey response rate was low for providers receiving alerts from the paging system. Subsequent iterations may consider text-based phone messaging or in-person surveys at the time of the provider receiving the page, which may encourage more detailed and complete responses. Third, the study was not designed to measure the effect size of SCTP paging alerts or review patient cases where providers understand sepsis to be unlikely despite the initial BPA. Our institution is currently initiating a randomized controlled trial to determine the efficacy of SCTP in improving compliance with SEP-1 bundle elements and patient outcomes. It will also further quantify any marginal increase in alert fatigue. Finally, there may be other simultaneous quality improvement initiatives and the Hawthorne effect that may confound our data.

Conclusions

In conclusion, we have demonstrated a feasible, technically sound, real-time provider alert system that has the potential to improve the SEP-1 compliance rate without significant amounts of alert fatigue. We anticipate that future work will involve a randomized controlled trial to measure potential increases in SEP-1 compliance rates and patient outcomes and further characterize alert fatigue. The expansion of this promising intervention could be considered in other inpatient settings.

Authors' Contributions

AHL, EA, KAH, and KCS designed the study, analyzed the data, and wrote the manuscript. MHF and HR adapted and implemented the electronic monitoring platform. EM and JDS assisted with carrying out the study in the hospital and editing the manuscript. All the authors provided critical feedback and contributed to the manuscript.

Abstract

Background: The *secondary use of clinical data in data-gathering, non-interventional research or learning activities* (*SeConts*) has great potential for scientific progress and health care improvement. At the same time, it poses relevant risks for the privacy and informational self-determination of patients whose data are used.

Objective: Since the current literature lacks a tailored framework for risk assessment in *SeConts* as well as a clarification of the concept and practical scope of *SeConts*, we aim to fill this gap.

Methods: In this study, we analyze each element of the concept of *SeConts* to provide a synthetic definition, investigate the practical relevance and scope of *SeConts* through a literature review, and operationalize the widespread definition of risk (as a harmful event of a certain magnitude that occurs with a certain probability) to conduct a tailored analysis of privacy risk factors typically implied in *SeConts*.

Results: We offer a conceptual clarification and definition of *SeConts* and provide a list of types of research and learning activities that can be subsumed under the definition of *SeConts*. We also offer a proposal for the classification of *SeConts* types into the categories *non-interventional (observational) clinical research*, *quality control and improvement*, or *public health research*. In addition, we provide a list of risk factors that determine the probability or magnitude of harm implied in *SeConts*. The risk factors provide a framework for assessing the privacy-related risks for patients implied in *SeConts*. We illustrate the use of risk assessment by applying it to a concrete example.

Conclusions: In the future, research ethics committees and data use and access committees will be able to rely on and apply the framework offered here when reviewing projects of secondary use of clinical data for learning and research purposes.

Introduction

The secondary use of clinical data for research purposes is increasingly recognized as a promising and crucial tool for improving health care and advancing medical research. Several initiatives strive to use data from medical care for secondary research and learning activities [1]. The US Institute of Medicine has called for a transformation toward a learning health care system (LHCS) to improve quality, expedite translation, and reduce costs [2]. The American Society of Clinical Oncology is pioneering the linkage of patient, provider, and research data with their quality improvement portal CancerLinQ [3]. In Germany, the national Medical Informatics Initiative aims to establish a national network of data integration centers to collect, aggregate, and analyze clinical data from all university hospitals in Germany.

There are numerous advantages of the secondary use of clinical data (ie, data derived from patient care) for research and learning activities. First, the clinical data are readily available. There is no need for any physical intervention or data collection through surveys. Costs for data aggregation, staff, and materials are considered to be low; data can be collected quickly [4]. Data have a high level of generalization due to the real-life setting in which they are collected, and this facilitates representative sampling while simultaneously increasing external validity [5,6]. Moreover, large sample sizes can be obtained by aggregating the data from different sites. For example, this benefits research on rare diseases [7]. Moreover, interventional studies that cannot be conducted prospectively due to ethical reasons may be performed retroactively [8], for instance, by systematically analyzing experimental therapies such as off-label use of drugs. Most importantly, patients can contribute their clinical data to research or learning activities without being exposed to immediate physical risks [5]. However, the secondary use of clinical data in research or learning activities entails data-associated risks that require further investigation.

This paper focuses on the most relevant aspects for patients in particular and for the trustworthiness and sustainability of secondary use of clinical data in general: risks concerning patients' privacy and informational self-determination. The European Union General Data Protection Regulation (GDPR) requires data processors to carry out an "assessment of the impact of the envisaged processing operations on the protection of personal data" where there is a high risk to the "rights and freedoms of natural persons" (Article 35, 1, GDPR). An appropriate framework for risk assessment of the secondary use of clinical data in research or learning activities is lacking, as is a conceptual basis for such secondary data use. We aim to fill this gap by developing a framework for risk assessment that supports decision makers in research ethics committees and data use and access committees, as well as scientists, bioethicists, and funders who deal with the ethics and governance of secondary use of clinical data in data-gathering, non-interventional research or learning activities (ie, research and learning activities that rely solely on the collection of existing data). We will develop the risk assessment framework on a strong conceptual and empirical basis of two preceding elementary steps: (1) an analytical clarification of the concept of secondary use of clinical data in data-gathering, non-interventional research or learning activities (*SeConts*); and (2) an illustration of the types of research and learning activities that can be subsumed under this concept.

Methods

In this study, we proceed in three main steps, each with a methodological approach. In *step one*, our methodological approach to clarify the concept of *SeConts* is to investigate the *intension*. In other words, what does the concept of *SeConts* mean? We first analyze each element of the concept (analysis) and then compile them for a comprehensive definition of the concept (synthesis). As the application of this methodological approach to clarify the concept cannot easily be separated from the result itself (the definitional clarification of the concept), we decided not to separate them and thus present both parts in the *Results* section.

Building on the clarification of the concept of *SeConts* (step 1), *step 2* examines its practical relevance. Regarding our methodological approach, we investigate the *extension* of the concept of *SeConts*, that is, the range of *objects* to which the concept can be applied. We examine concrete types of research or learning activities that can be subsumed under this concept. These types of research or learning activities were inferred from a scoping review (a), in which we searched PubMed and Google Scholar between October and November 2019 for bioethical literature that deals with the expected risks and benefits of secondary use of clinical data for biomedical research. The search terms used were *ethics*, *secondary use*, *re-use*, *clinical data*, *electronic health records*, *risks*, and *benefits* in different combinations. We limited our search to publications in English. We found numerous types of research or learning activities that, according to the authors, solely used clinical data. Next, we searched the biomedical literature for concrete studies (b) to find examples of previously identified types of research or learning activities. Relevant publications were identified after reading abstracts. After reading the full texts of the identified publications, we categorized them into the types of *SeConts* developed before (a).

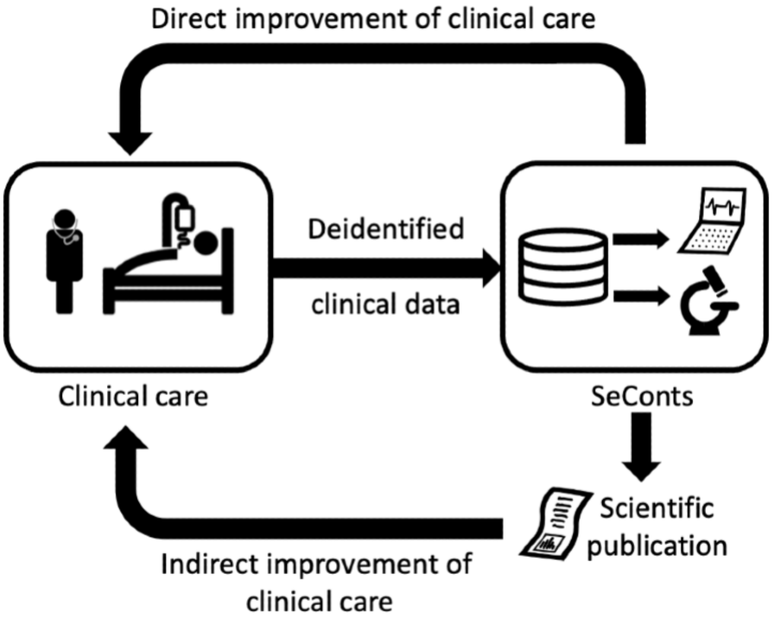
On the basis of step 1 (conceptual clarification of *SeConts*) and step 2 (examination of the practical relevance of *SeConts*), we develop a framework for the systematic assessment of risks implied in *SeConts* in *step 3*. Operationalizing the general concept of risk to tailor it to *SeConts* presents a key methodological challenge when developing a risk assessment framework. We apply a widespread definition of risk as a *harmful event of a certain magnitude* that occurs with a certain *probability* [9-11]. According to this definition, risk assessment ideally results in a number. If we bet US $10 on a single number out of 37 in the roulette, the probability of losing is $1-(1/37)$ and the magnitude of harm is US $10. The resulting risk could therefore be quantified by the number of 9.7, which is $10\times[1-(1/37)]$. Although this quantitative understanding of risk is intuitively plausible, it is fraught with several difficulties in the context of *SeConts* concerning the quantification of *the probability* and *magnitude of harm*.

In terms of quantifying the *probability* of a harming event in the context of *SeConts*, there is neither a stochastic rule (as in the roulette example) nor empirical data that would allow an estimate of the probability of these events. Reports indicate that there have been data breaches (defined here as: *all types of events in which the confidentiality and planned protection of data is violated, whether through technical failure, human error, or deliberate unethical or criminal acts*) in the health care system in the past [12-14] that may suggest that such events could also occur in the context of *SeConts*. However, they do not allow for an assessment of their likelihood. Similarly, there is little information about the probability of further misuse of data stolen in the course of a breach. The *magnitude of harm* caused by the misuse of data is equally difficult to quantify. This is due to the fact that possible harm is predominantly of an immaterial social and psychological nature.

In the field of data science and in bioethics, various approaches have been developed to address the problem of operationalizing risks without recourse to quantification [15-20]. However, these approaches are neither designed nor transferable to *SeConts*. In this paper, we therefore propose a nonquantitative approach to operationalize both the *probability* and *magnitude of harm* for the assessment of risks within *SeConts*. We (1) identify risk factors in relation to data and their use within *SeConts* that increase or decrease the probability and magnitude of harm, (2) assess their individual severity, and (3) subsequently estimate the overall risk of a specific form of *SeConts*.

Similar to existing initiatives for secondary use of clinical data, such as the Medical Informatics Initiative [21] or CancerLinQ [3], we assume the following data flow from patients to *SeConts* (Figure 1): (1) Clinical data from electronic health records (EHRs) are deidentified, that is, identifying attributes (eg, names, addresses) are removed or replaced with a code. (2) Deidentified data are transferred to a central data warehouse and stored. (3) Deidentified data stored in the central data warehouse can be made available to researchers upon request to enable *SeConts*. Regarding risks to the confidentiality of EHRs that contain directly identifying data, there is evidence of leaks and attacks on EHRs. However, these risks affect every care unit that works with EHRs and are not specific to *SeConts*. Therefore, the risks to the confidentiality of EHRs are not the focus of our study.

Figure 1. Flowchart of the secondary use of clinical data in data-gathering, non-interventional research or learning activities.



Regarding the operationalization of *probability*, we assume that the most negative consequences for the individual patient are only expected if the patient can be identified from the data. Therefore, we assume unauthorized reidentification as a prerequisite for possible harm in connection with *SeConts*. According to our understanding, factors that increase the *probability of unauthorized reidentification* also increase the probability of misuse. We identify two categories of factors that directly or indirectly determine the *probability of unauthorized reidentification*: data-specific and contextual factors.

In terms of operationalizing the *magnitudeof harm*, we distinguish different types of data according to their harm potential (see studies by Dyke at al [20] and Rumbold and Pierscionek [22]). To do this, we identify risk factors in the data that determine the extent of harm that may result from the misuse of the data. In other words, we provide an analytical answer to the question of what data aspects determine the degree of harm in the event of misuse. This approach is in line with the risk-based distinction between different categories of data in the GDPR (Article 9 GDPR).

How did we arrive at the factors that determine the *probability of unauthorized reidentification* and *magnitude of harm*? In the *first step*, we built on existing literature. As a basis for the factors determining the *probability of unauthorized reidentification*, we focused on the literature from different areas: literature on ethical, legal, and social implications of *SeConts*; literature on data security, data protection, and the assessment of reidentification risks; and national German and European data protection laws and regulations. For factors that determine the *magnitude of harm*, we analyzed the literature on genetic data that are generally classified as very sensitive, to learn what makes these data sensitive and transfer this knowledge, mutatis mutandis, on other types of data. In the *second step*, we extracted the individual factors—for both the *probability of unauthorized reidentification* and the *magnitude of harm*—from the literature and categorized them inductively. In the *third step*, we cross-referenced the factors with qualitative interviews conducted with experts from research, care, medical informatics, patient advocacy, and politics on the topic of perceived risk potentials of *SeConts*, part of which are to be published elsewhere [23]. In the presentation of the individual factors below, we refer to the literature on which they are based. Factors without a literature reference are taken from expert interviews that have not yet been published.

Results

Conceptual Clarifications and Definition of Secondary Use of Clinical Data in Data-Gathering, Non-Interventional Research or Learning Activities

Secondary use of health data is defined by the American Medical Informatics Association as "non-direct care use of PHI [personal health information] including but not limited to analysis, research, quality/safety measurement, public health, payment, provider certification or accreditation, and marketing and other business including strictly commercial activities" [24]. On the basis of a systematic scoping review, Robertson and colleagues categorized secondary use by distinguishing between four types of secondary use of clinical data: research, improving quality and safety of care, informing financial management, and education [25]. These and other similar classifications [26-28] help in understanding the broad spectrum of secondary uses of clinical data and illustrate that it is not limited to research. However, as pertains to the focus of this paper, that is, *the secondary use of clinical data in data-gathering, non-interventional research or learning activities*, the generic classifications lack further specifications and detail.

The term *secondary use* (or reuse) implies that there is also a primary use. Primary use encompasses the generation and use of data within the context of individual health care in hospitals and doctors' offices to serve direct care needs. Secondary use refers to the use of these data for purposes other than individual care. Two points of criticism could be made against the distinction between primary and secondary use and the implied distinction between care and research. First, the distinction between care and research is notoriously difficult and widely discussed. Second, if secondary use of clinical data was to be implemented in the future as a standard in the health care system (ie, all health care data would be made available for possible research), this could lead to a tendency to collect data more systematically or collect more data than necessary in the care context, thereby blurring the distinction between data generation for care (primary use) and data generation for research (secondary use). In arguing against these two criticisms, however, we find that (1) ethical and legal codes are still fundamentally based on the distinction between care and research, which is unlikely to be abandoned in the coming years as blurred boundaries in governance and regulation are difficult to manage. Furthermore, we argue (2) that even if data are collected with the additional motivation of secondary use, the generation and collection of data would be driven by the primary goal of individual care.

Clinical data refers to data generated and collected in clinical contexts for patient care (diagnoses, anamnesis, treatment, medication, and so on) as well as data for accounting purposes or patient management, such as age, employment status, and other sociodemographic information. Clinical data also include data generated in the course of nonroutine treatment (off-label or experimental therapies) as long as it is collected for the primary objective of individual care. In terms of clinical data, we also include data reported from health care services and units to health insurance. In contrast to the widely used term health data, clinical data includes neither data gathered by (common, ie, nonclinical) smart devices and smartphone apps or research data understood as data generated for research purposes.

In contrast to research that generates data, *SeConts* only *gathers existing clinical data*. The gathering of data in *SeConts* can be done either by collecting clinical data of different patients from one institution or several institutions or by collecting only the results of analyses of clinical data carried out in the institution of primary use (decentralized analysis).

SeConts is *non-interventional* as it does not use data from interventions carried out with the aim or priority of data generation for research. *SeConts* solely uses existing data from medical care. The data used in *SeConts* may originate from interventions, but only from interventions carried out for the sake of individual diagnosis and treatment.

Both the terms *research* and *learning activities* refer to investigations in which the acquisition of generalizable knowledge beyond the needs and logic of individual care is the sole or primary intension. Research and learning activities cannot be clearly separated, but a rough distinction can be made in terms of their respective objectives. Research primarily aims at acquiring scientifically generalizable knowledge to be shared within the scientific community through scientific publications. Research usually indirectly improves health care and is realized through publications and by implementing practical conclusions based on research results. Learning activities, on the other hand, are designed to acquire knowledge about current care practices (eg, in a defined care unit) to derive appropriate and immediate measures to directly improve a specific health care unit or service. When talking about improving health care, the question arises whether *SeConts* has the potential to directly benefit the individual patient whose clinical data are reused. A direct (therapeutic) benefit is only possible under certain circumstances, for example, infection control of a clinical unit or research on a chronic disease. Younger patients with such a chronic disease could possibly benefit in several years from research that improves treatment of that very disease. However, as such benefits seem rather unlikely and exceptional, we understand *SeConts* as activities that are neither intended nor expected to directly benefit the individual patient whose data are used. In addition, there are ethical reasons for this narrow definition of *SeConts*, namely, to avoid any possibility of therapeutic misunderstanding.

In summary, the central concept of this paper, that is, *SeConts* can be defined as activities that:

1. exclusively use data produced for the purposes of and in the context of health care.
2. exclusively collect and do not generate data, that is, they are not based on data generated by interventions carried out primarily for the sake of research.

3. aim to acquire generalizable knowledge that goes beyond the needs and logic of individual care.
4. aim to directly improve health care units or services or publish their results for the promotion of biomedical science.

In a nutshell, *SeConts* describes *activities that solely use data produced for the sake of health care and in the context of health care to improve biomedical science or services.*

Overview of Different Types of Secondary Use of Clinical Data in Data-Gathering, Non-Interventional Research or Learning Activities

Having clarified the concept of *SeConts* in the previous section, we now examine the scope and practical relevance of the concept of *SeConts* as previously defined. Which studies fall under the concept of *SeConts* (scope)? What is their practical relevance to medical research and improving medical care? We explore these questions in the next section. The literature review carried out to investigate the scope and practical relevance of research or learning activities that fall within our definition of *SeConts* (step 1) led to the following results: many types of research or learning activities common in the field of quality control and quality improvement can be subsumed under the concept of *SeConts* (in particular, under the term *learning activities*). Examples include *improvement of infection control*, which can be done by monitoring clinical data in hospitals to identify patients at high risk of infection [29]. Clinical data can also be used to create computerized algorithms for the *early detection of possible hazards from germs* [30]. These activities can be considered a component of the comprehensive ideal for transforming a particular health care institution into an LHCS.

At the national level, clinical data are used for *public health surveillance*. For instance, data from EHRs are searched for indicators of influenza in primary care to detect a pandemic in its early phase [31]. *Epidemiological studies* focus on the distribution of diseases as well as their causes and effects in populations, such as studies on the epidemiology of a certain infection to inform and improve vaccination initiatives [32]. In *outcomes research*, the effects (outcome) of certain interventions are investigated, such as the effects of a nationwide antismoking law on childbirth in the area of public health [33] or, on a clinical care level, evaluating the quality of care [34]. In *health services research*, investigators can use clinical data to explore the mean costs associated with (treatment of) a certain disease [35]. A well-established form of secondary use of clinical data is *registry studies* analyzing collections of data on all patients affected by a particular disease (registries) such as cancer registries [36].

Clinical data are also reused in clinical research in the form of *in-silico hypothesis testing*, where clinical trials are modeled with the help of data from EHRs [37]. Moreover, clinical data can be used for *comparative effectiveness research* [38] to compare “the benefits and harms of alternative methods to prevent, diagnose, treat, and monitor a clinical condition or to improve the delivery of care” [39]. *Evaluation of experimental therapies* can be conducted in terms of *SeConts*, for instance, by sharing data from single off-label (or compassionate) use from different hospitals. The secondary use of data from these therapies can help inform other physicians with similar patients about the course and outcome of different experimental therapeutic approaches [40]. Other studies that reuse clinical data in the sense of *SeConts* are *drug safety and efficacy studies* [41]. In addition, some basic research is conceivable using existing clinical data, such as *studies on risk factors* for certain diseases that can be linked to single influencing or moderating factors [42,43]. Another form of secondary use of clinical data lies in the area of *informatics research*, which uses clinical data to develop new software tools that have the potential to improve patient care or analyze and improve data security within a health system [44].

In addition to the different studies mentioned above, clinical data can be used in an *explorative* manner, which can be understood as encompassing three (potentially subsequent) steps. First, data can be analyzed (possibly using artificial intelligence) to *generate hypotheses* for future studies; second, in the case of new research ideas resulting from this, the data can be used to *check feasibility*; and third, to *identify potential participants* for recruitment of upcoming studies [45].

To further clarify the scope and concept of *SeConts* (by means of definitio ex negativo), we also want to mention two areas beyond the concept of *SeConts*: prospective clinical trials (eg, randomized controlled trials) and all other forms of studies that include interventions carried out for the sake of generating data; genome wide association studies in so far as they combine clinical data (phenotypes) with sequencing data generated for research purposes (genotypes).

Thus far, we have illustrated that there are many types of research or learning activities that can be conducted in the sense of *SeConts*. These types of research or learning activities display huge heterogeneity with respect to study designs, research questions, and contexts. Even the names of the types show this heterogeneity, as they refer to very different attributes describing the respective type of *SeConts*: some names refer to a specific method or study design (eg, in-silico hypothesis testing), whereas others refer to a subject area (eg, epidemiology). Given this heterogeneity, the question arises as to whether the different types of *SeConts* can be categorized in a way that allows for a better overview. The literature that attempts to capture the potential applications of secondary use of clinical data does not systematically distinguish between different types of research and learning activities [25,26]. Therefore, we searched for criteria or a particular logic that would provide some kind of categorization of the different types of *SeConts*. Some criteria that provide useful approaches to classification in other biomedical contexts are inappropriate. For example, although categorization by medical specialty seems conceivable at first glance, we determined it to be unhelpful on closer inspection. With all the different specialties that exist in medicine, such a categorization does not provide any reduction of heterogeneity. Categorization into common typologies of biomedicine, such as *basic research*, *clinical research*, and *translational research*, is also not useful, because learning activities, as described above, cannot be clearly assigned here. Ultimately, we found a categorization in terms of the *object of investigation* (ie, the entity about which *SeConts* seeks to produce knowledge) using three levels most appropriate. These three levels are familiar from the social sciences: micro level, meso level, and macro level. The object of investigation can be either patients (micro level), clinical care units such as clinical departments or single hospitals—a specific delimited patient population (meso level), or the general public (macro level). Taking the *object of investigation* as a criterion, we can attribute each type of research or learning activities to a general area of application: *non-interventional (observational) clinical research* focusing on individuals, *quality control and improvement* (and similar uses contributing to the creation of an LHCS) focusing on clinical units, and *public health research* focusing on the general public. Table 1 sums up all types of the aforementioned research or learning activities, including the object of investigation and area of application. It also shows that some types of research or learning activities are not limited to a single object of investigation or area of application.

Table 1. Possible types of research or learning activities within secondary use of clinical data in data-gathering, non-interventional research or learning activities.

Type of research or learning activities	Object of investigation	Area of application
Improvement of infection control	Clinical unit	Quality control and improvement
Early detection of possible hazards from germs	Clinical unit	Quality control and improvement
Public health surveillance	General public	Public health research
Epidemiology	General public	Public health research
Outcomes research	Patients or clinical unit	Public health research or quality control and improvement
Health services research	General public	Public health research
Register studies	General public	Public health research
In-silico hypothesis testing	Patients	Non-interventional (observational) clinical research
Comparative effectiveness research	Patients	Non-interventional (observational) clinical research
Experimental therapy evaluation	Patients	Non-interventional (observational) clinical research
Drug safety and efficacy studies	Patients	Non-interventional (observational) clinical research
Studies on risk factors	Patients	Non-interventional (observational) clinical research
Medical informatics research	Patients, clinical unit, or general public	Possible in all three areas of application
Explorative use	Patients, clinical unit, or general public	Possible in all three areas of application

Tailored Framework for Risk Assessment of Secondary Use of Clinical Data in Data-Gathering, Non-Interventional Research or Learning Activities

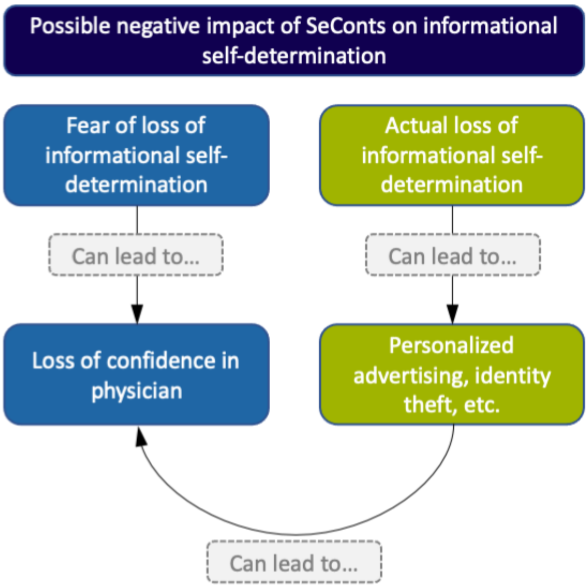
Risks for Informational Self-determination and Confidentiality

In the previous section, we addressed two desiderata of the current literature on *SeConts* by defining our understanding of *SeConts* and clarifying its scope and practical relevance. These steps allow us to offer what we consider to be the third desideratum: a detailed analysis of risks for patients implied in *SeConts* as well as a framework to assess these risks. The risks to patients associated with the data are critical to *SeConts* because if they were to materialize, they could also have a major impact on the role, trustworthiness, and reputation of doctors, hospitals, and the public health system. *SeConts* implies potential risks for patients because of their (potentially reidentifiable and sensitive) clinical data being used. We assume that *SeConts* will usually rely on clinical data that cannot be classified as anonymous data. Even if direct identifiers are removed from data or replaced by a code (deidentification), the possibility of reidentifying a specific person in the data can rarely be excluded (see the list of potential risk factors below). In most cases, *SeConts* will use deidentified personal (or person-related) data; they imply risks for patients' right to *informational self-determination*.

The term informational self-determination refers to "a person's ability to freely decide whether and how personal data and information about her are collected, stored, multiplied, processed, and transferred by third parties" [46]. We regard informational self-determination as an instrumental value, that is, a means of protecting liberal individual and social rights and values such as equality or personal autonomy [47-49]. The protection of informational self-determination is particularly important in the health care sector: clinical data are highly sensitive as they contain information about the health status of a person and can therefore be highly susceptible to possible misuse. The confidentiality of the data is crucial for the patient-physician relationship and communication.

SeConts can have a negative impact on the patient's ability to exercise informational self-determination in two ways (Figure 2): (1) the fear of a loss of informational self-determination and (2) its actual loss in case of data breaches in the meaning defined above (which, in turn, will most likely reinforce the fear of a loss of informational self-determination among patients).

Figure 2. Possible negative impact of the secondary use of clinical data in data-gathering, non-interventional research or learning activities on the patient's ability to exercise informational self-determination.



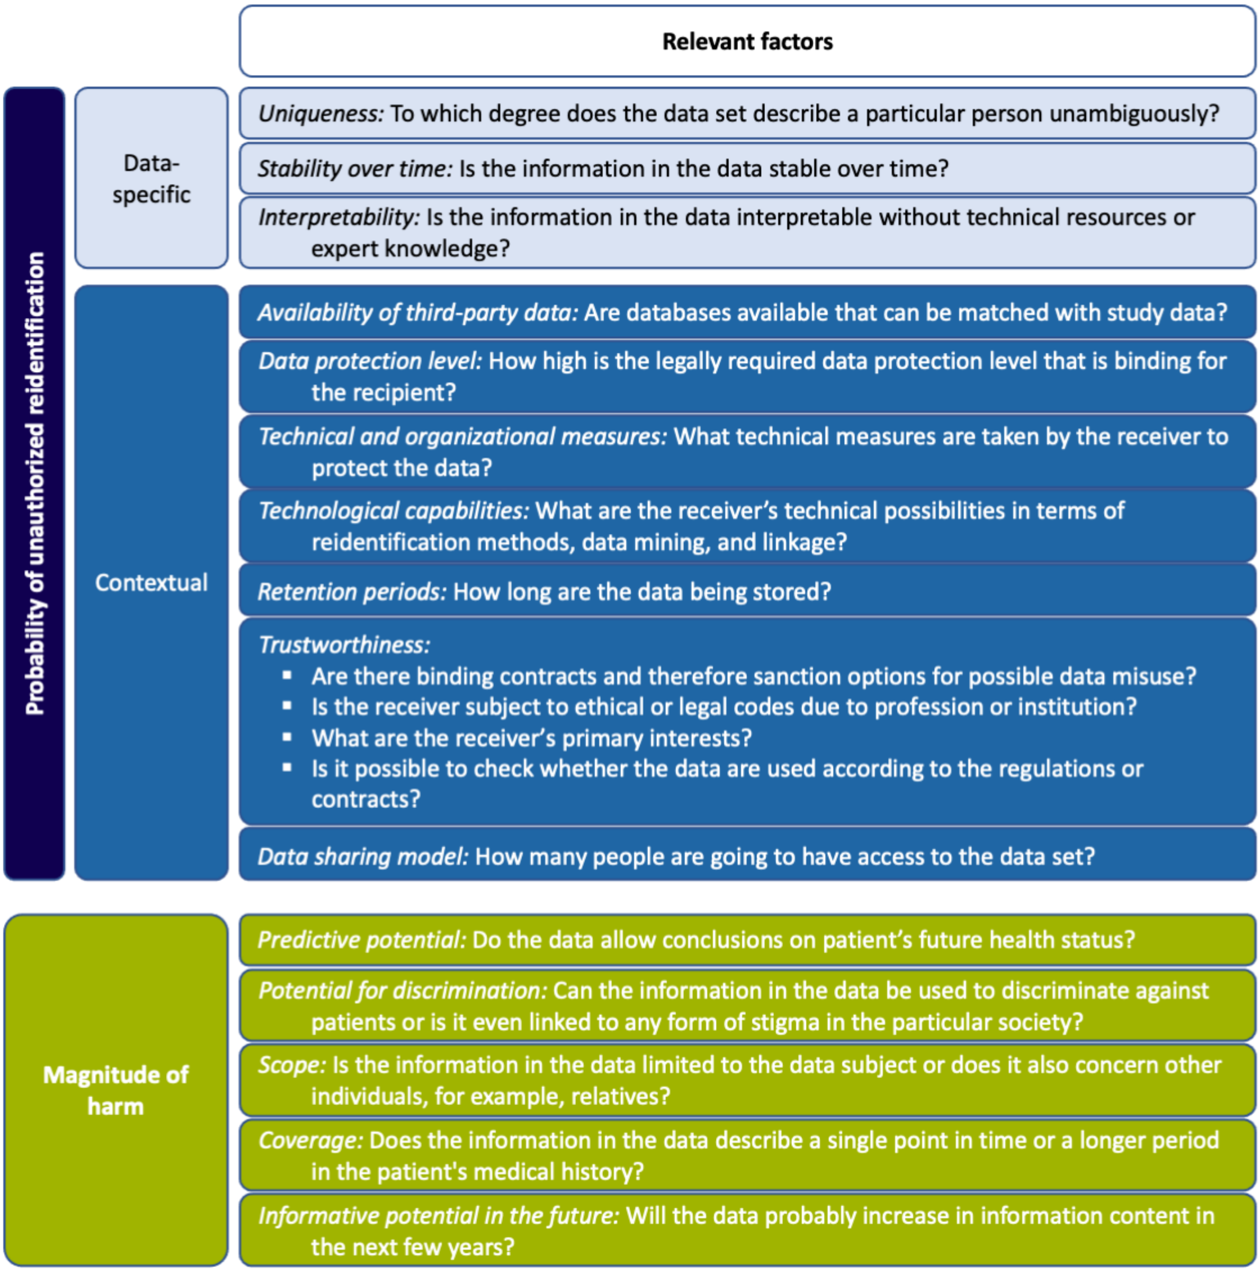
With regard to fear (1), it is important to stress that informational self-determination is not only impaired if there are indications that third parties have accessed the data without authorization (and might or do use them against the data subject). Informational self-determination is already undermined if data subjects have reasons to develop a sense of vague uncertainty about the confidentiality of personal data [50] (chilling effect [51]). The fear of loss of informational self-determination alone can already have negative consequences. For instance, the fear that their data are not protected from unauthorized access can lead to patients not disclosing all the information that could be important for their personal care [52,53] due to a lack of confidence in their physician.

Concerning actual losses of informational self-determination (2), data breaches are a serious threat. A study carried out between 2010 and 2013 revealed a total of 949 data breaches in American hospitals involving almost 30 million patient records [14]. Even if the reported data breaches occurred in the context of patient care, and not in the context of *SeConts*, they uncover general problems with the protection of clinical data. As assumed by several authors [52,54,55], the negative consequences of data breaches, including unauthorized reidentification, could range from minor annoyances through personalized advertising to serious harms such as identity theft, stigmatization, blackmail, or discrimination, as well as other forms of data use without patient consent, such as the sale of data or use in studies in which patients have not consented.

Criteria to Assess Risk: Probability of Unauthorized Reidentification and Magnitude of Harm

In the previous chapter, we outlined the potential risks to patients' informational self-determination associated with *SeConts*. On the basis of our approach to assessing these risks (probability and magnitude of harm, see *Methods* section), we present a list of relevant factors that determine the *probability of unauthorized reidentification* and the *magnitude of harm*. These factors are partly interrelated and cannot always be clearly distinguished. Figure 3 provides an overview of the relevant factors, which we discuss in more detail below.

Figure 3. Factors of risk assessment for the secondary use of clinical data in data-gathering, non-interventional research or learning activities.



Relevant factors

Probability of unauthorized reidentification

Data-specific

Uniqueness: To which degree does the data set describe a particular person unambiguously?

Stability over time: Is the information in the data stable over time?

Interpretability: Is the information in the data interpretable without technical resources or expert knowledge?

Contextual

Availability of third-party data: Are databases available that can be matched with study data?

Data protection level: How high is the legally required data protection level that is binding for the recipient?

Technical and organizational measures: What technical measures are taken by the receiver to protect the data?

Technological capabilities: What are the receiver's technical possibilities in terms of reidentification methods, data mining, and linkage?

Retention periods: How long are the data being stored?

Trustworthiness:

- Are there binding contracts and therefore sanction options for possible data misuse?
- Is the receiver subject to ethical or legal codes due to profession or institution?
- What are the receiver's primary interests?
- Is it possible to check whether the data are used according to the regulations or contracts?

Data sharing model: How many people are going to have access to the data set?

Magnitude of harm

Predictive potential: Do the data allow conclusions on patient's future health status?

Potential for discrimination: Can the information in the data be used to discriminate against patients or is it even linked to any form of stigma in the particular society?

Scope: Is the information in the data limited to the data subject or does it also concern other individuals, for example, relatives?

Coverage: Does the information in the data describe a single point in time or a longer period in the patient's medical history?

Informative potential in the future: Will the data probably increase in information content in the next few years?

There are three data-specific factors that determine the probability of unauthorized reidentification:

1. *Uniqueness* of a data set [56,57]: Even after removing identifying attributes (name, date of birth, etc), unauthorized reidentification is possible, as the combination of attributes of a person's medical record can be identifying. Therefore, the more unambiguously a person is represented in a data set by the combination of individual attributes, the higher the probability of unauthorized reidentification. Statistically, the smaller the number of cases in a data set, the more likely it is to correctly assign one data set to a specific individual. In addition, a larger number of variables (attributes of patients) in a data set allows for a more unique combination of attributes that again increases the probability of unauthorized reidentification [56,58,59]. Concepts such as *k*-anonymity [60], *l*-diversity [61], and*t*-closeness [62] aim to mitigate these risks by defining standards for data sets to reduce the probability of unauthorized reidentification.
2. *Stability over time* [63]: The more stable the attributes described in the data, the more likely it is to link the data set to a specific person. If an attribute described in the data is not permanent and is likely to change between each measurement (eg, blood pressure or blood glucose levels), it is impossible to use the associated data to uniquely assign it to an individual patient.
3. *Interpretability:* Certain types of data require special skills or technical tools to understand them. Thus, the degree to which data is easier or more difficult to interpret determines the number of people who are able to misuse the data. For example, anyone can interpret data relating to obesity, but laypersons are currently unable to interpret data from genetic sequencing or magnetic resonance imaging.

However, the interpretability of data is a dynamic factor. Modern software development suggests that the interpretation of certain data might soon be supported by self-learning algorithms that may allow laypersons to interpret complex data such as genomic data or magnetic resonance imaging. *Interpretability* is directly related to the possible contexts in which data are used.

In addition to the data-specific factors regarding the probability of unauthorized reidentification in the context of *SeConts*, seven contextual factors must be considered.

1. *Third-party data:* Personal data of patients stored by third parties, such as voting registers or records from residents' registration offices, can be used for reidentification when linked to clinical data [64-66]. Therefore, the availability of third-party data makes unauthorized reidentification easier [63], especially when the factor of uniqueness of the data set is high.
2. *Data protection level:* Every act of data exchange with other institutions or countries or jurisdictions brings with it the possibility of weaker data protection standards. The legally required data protection level that is binding to the recipient must therefore be taken into account [67].
3. *Technical and organizational measures:* Adequate measures need to be taken by the data recipient to protect the data. Here, the data protection level of the recipient, for example, according to approved codes of conduct (Article 40, EU-GDPR) or a data protection certification (Article 42, EU-GDPR), can be used as a benchmark.
4. *Technological capabilities:* The factor *technological capabilities* describes the technical means available to the respective data recipient to perform unauthorized reidentification. These include self-learning algorithms or other forms of artificial intelligence [68].
5. *Retention periods*: The longer the data are stored, the higher the risk of a data breach that can lead to unauthorized reidentification. Therefore, the retention (and deletion) periods specified by the data recipient are relevant factors in estimating the probability of unauthorized reidentification.
6. *Trustworthiness:* The factor *trustworthiness* is determined by several aspects [67]: the existence of binding (sanctionable) contracts that determine the terms of data use and access; the existence of ethical or legal codes on the part of the data recipient [22]; the primary interest of the receiver, for example, monetary or public interests; the verifiability of the use of the data in accordance with the applicable regulations or contracts.
7. *Data sharing model:* Depending on the data sharing model, data are disclosed to a different number of people; for example, data can be disclosed only to a small work group, a consortium, or can be uploaded to a public database. Every person with access to the data increases the probability of unauthorized reidentification.

Together with the aforementioned factors determining the probability of unauthorized reidentification, the following five factors must be considered to determine the magnitude of possible harm.

1. *Predictive potential:* The predictive potential of data refers to the extent to which a data set contains information that allows insights regarding future health status [69-71]. If a data set has a time-limited relevance, it can be considered less problematic than a data set that allows conclusions to be drawn about a person's expected state of health for the next 30 years. Information with predictive potential could be, for example, the diagnosis of a chronic disease, but also the documentation of traumatic events that make a posttraumatic stress disorder diagnosis very likely within the next few years. In contrast, information about a fracture, for instance, does not necessarily provide information about future health status.
2. *Potential for discrimination:* Some data have obvious potential for discrimination because they contain information that can be used against individuals and groups. For example, it is conceivable that some employers discriminate against employees (eg, by not renewing contracts) if they know that the employee is affected by an illness (or has a disposition to illness) that is likely to lead to a longer absence of the employee in the future. Furthermore, stigmatization is possible [20]. For example, the disclosure of an HIV diagnosis can lead to stigmatization (through prejudice or social rejection).
3. *Scope:* The factor *scope* describes whether the information, and thus the possible risk in the data is limited to the data subject or whether it allows inferences about family members (eg, in the case of genomic information [69]) or colleagues (eg, information on diseases related to certain working conditions) [70].
4. *Coverage:* The factor *coverage* describes the data in terms of the period in which they were collected. Data from a single hospital visit cover a less extensive period than data documenting the entire medical history, for example, as collected by insurance companies. A complete medical history is likely to provide a more multifaceted picture of a person's life than data collected on a single point in time and can therefore potentially cause greater harm in the event of misuse.
5. *Informative potential in the future:* Some data types can be expected to contain more information than can currently be made available. For example, we currently assume that the information content of genomic data is still largely unknown [70]. However, the constant progress in the field of genomic research suggests that in the future, we will be able to retrieve significantly more information from genomic data than is the case today, which can potentially cause greater harm in case of misuse.

Discussion

Application and Use of the Risk Assessment

After introducing the individual factors that determine the *probability of unauthorized reidentification* and the *magnitude of harm* implied by *SeConts*, questions arise concerning their application and use. How do these factors form a comprehensive framework for risk assessment in the context of *SeConts*? How can the framework be applied? How can the assessment results be used? Who may apply and use this framework?

With our risk assessment, we intend to support the analysis, evaluation, and potential decision-making process of research ethics committees and data use and access committees, as well as scientists, bioethicists, and funders investigating the ethical acceptability of requests for concrete types of *SeConts*. We recommend the following procedure with five consecutive steps to apply and use the risk assessment framework.

Application of the Risk Assessment (Steps 1 and 2)

The first two steps concern the application of the risk assessment framework:

- Step 1—*identification and evaluation of single risk factors:* A concrete projected study is examined in light of all factors determining the probability of unauthorized reidentification and magnitude of harm listed in Figure 3. The individual severity of each factor is evaluated, that is, whether and to what extent the factor is present and relevant in the specific study (plans) by classifying it as low, midrange, or high. We advise *against* converting these levels into numbers (eg, low=1, medium=2, and high=3), as this would falsely suggest a mathematical accuracy and cardinal order and could lead to a misinterpretation.
- Step 2—*comprehensive evaluation of risks for patients:* An overview of the evaluation of the single factors leads to a comprehensive picture of the risk profile of the concrete study. At this point, the methodological question of the relationship between the individual factors arises: Is the same importance attached to each factor, or are some factors considered more important than others and therefore given greater weight when moving from the estimates of the individual factors to a more comprehensive picture? We do not consider it plausible to state a priori that some factors are more important or should count more than other factors. As a default approach to a comprehensive evaluation of risks for patients in practice, we recommend that all factors be weighted equally. In particular circumstances, practical reasoning might suggest that the estimation of a single factor as *high* still does not adequately reflect the importance of that factor in the assessment of the comprehensive evaluation of risks for patients. In this case, more weight could be given to this factor, or it could even be treated as a decisive or exclusionary criterion. This might be appropriate, for instance, if a study plans to store very large and detailed sets of personal data in an open access data repository (factor *data sharing model*).

The fact that we advise against using numbers to evaluate the individual factors (step 1) already excludes the possibility of summing up numerical values as part of a comprehensive evaluation of risks for patients and presenting the risk (step 2) in a single number. Such a numerical approach would unreasonably suggest a mathematical or empirical reliability or precision that is not justified by the framework. Instead, a comprehensive evaluation of risks for patients is based on a rough summary of the evaluations of the single factors, considering their individual weight within the evaluated study. The results of the comprehensive evaluation of risks for patients can again be presented as low, midrange, or high, depending on the distribution of the individual factors.

Use of the Tailored Risk Assessment (Steps 3-5)

Steps 3-5 concern the use of the risk assessment framework:

- Step 3—*complete risk assessment:* It is important to be aware of the fact that the risk assessment addresses data-related risks for patients, which we deem to be the central and most important kind of risk from *SeConts*, but which are potentially still not the only kind of risk. Therefore, to gain a complete and comprehensive understanding, risks for other stakeholders (such as physicians and institutions) need to be taken into consideration.
- Step 4—*comprehensive ethical evaluation:* The complete risk assessment of a study is only one part of the comprehensive ethical evaluation. Typically, comprehensive ethical evaluation needs to include other aspects, in particular, the potential benefits of the envisaged study (to analyze and assess the risk-benefit ratio).
- Step 5—*reducing the risk profile by mitigating single factors:* The comprehensive ethical evaluation (step 4) can lead to three evaluation results of a planned study: (1) unethical and thus to be rejected, (2) ethically problematic but approvable under certain conditions, and (3) ethically sound and thus to be approved. In the case of (2), the applicant may be required to take specific measures to mitigate data-related risk to the data subjects. Tailored risk reduction measures should be chosen in light of the identification and evaluation of single risk factors (step 1) and against the backdrop of the comprehensive evaluation of risks for patients (step 2). Possible risk reduction measures may, for example, include modifying the data set to reduce the factor *uniqueness*, for example, by aggregating information (eg, age groups instead of age). In addition, special data sharing contracts can be applied to reduce the number of people who have access to the data (factor *data sharing model*).

A Practical Example of the Application of the Risk Assessment

After presenting the application and use, in the following section, we illustrate our risk assessment (steps 1 and 2) by applying it to a concrete study. Our example is a study on the epidemiology of Streptococcus pneumoniae infections [32] that we mentioned above in our list of examples for *SeConts*. According to the different areas of application (*non-interventional [observational] clinical research*, *quality control and improvement*, *public health research*) of *SeConts* we introduced above, the study can be classified as public health research. It gathers data from medical charts on “demographic characteristics, clinical syndromes, underlying conditions [eg, chronic diseases], and outcomes of illness” [32]. Figure 4 illustrates the application of the risk assessment framework for each factor (step 1) to a concrete example (For the sake of complete illustration of the risk assessment framework, we have added certain features to the study context where the study does not provide detailed information.).

Figure 4. Practical example of a study on the epidemiology of Streptococcus pneumoniae infections.

		Relevant factors in the practical example	Risk evaluation
Probability of unauthorized reidentification	Data-specific	*Uniqueness:* As it is an epidemiological study, data are gathered for secondary use from several hospitals or laboratories in one country. Therefore, although the number of variables increases the probability of unique combinations of attributed, the sample size is large enough to be associated with a relatively low uniqueness.	Low
		Stability over time: As the data contain information on chronic diseases, the information in the data set can be considered very stable.	High
		Interpretability: The information in the data are easy to be interpreted; additional knowledge or technical resources are not necessary to understand the data.	High
	Contextual	*Availability of third-party data:* In our example, we assume that there are no freely available data that could be linked to the patients' health data for reidentification.	Low
		Data protection level: The legally required data protection level that is binding for the recipient is the same as for the institution of data origin.	Low
		Technical and organizational measures: Data security measures are considered adequate in the medical research institute that analyzes the data.	Low
		Technological capabilities: Technological possibilities are limited as in our example we assume that the medical research institute has only limited public funding, without the possibility to use sophisticated and expensive new reidentification methods.	Low
		Retention periods: According to good scientific practice, the data are kept for a documentation period of 10 years.	Mid-range
		Trustworthiness: The recipient is considered trustworthy, some reasons being: ▪ Binding contracts of data usage ▪ Professional code of conduct ▪ Research is done by a public research institution without monetary interests ▪ Transparency of data usage according to the regulations and contracts?	Low
		Data Sharing Model: Data use is limited to a small research team. No publication of raw data.	Low
Magnitude of harm		*Predictive Potential:* The data contain information on chronic diseases that allows predictions on future health status.	High
		Potential for discrimination: Information on chronic diseases has (limited) potential for discrimination by employers.	Mid-range
		Scope: The information in the data is limited to the person concerned, although some diseases may be associated with an increased risk for the next of kin to get the same disease.	Mid-range
		Coverage: Data from a single hospital stay are used.	Low
		Informative potential in the future: New analytical methods are not expected to be able to extract more concrete information from the data in the future.	Low

In accordance with the application of our risk assessment approach, the results are as follows: (1) The probability of unauthorized reidentification can be considered relatively low because the majority of the relevant factors were assessed as low and (2) the magnitude of harm is in the midrange because most factors relevant to harm magnitude were assessed to be low or midrange. The comprehensive evaluation (step 2) shows that the overall risk for patients can be considered relatively low to midrange. After taking into account risks for other stakeholders (step 3), as well as the potential benefits of the study and other ethically relevant points (step 4), reviewers could request further mitigation of single risk factors (step 5). In our example, however, this is only possible to a limited extent because not all risk factors can be addressed without rendering the study itself impossible.

Limitations

Having presented our risk assessment, its application and use, and illustrating its applicability by means of a concrete example, we will address the limitations and possible criticisms of our framework. Two objections can be raised against the risk assessment approach. First, we classify a priori certain data types according to their harm potential as a basis for operationalizing the *magnitude of harm*. However, it can be argued that such an a priori classification does not take into account the information that can be inferred from the data beyond the apparent information content [72,73]: Information that is considered potentially harmful (eg, sexual orientation, religious beliefs) can be derived from information that would probably be considered harmless a priori (eg, Facebook likes) [74]. We are aware that our a priori classification of data does not consider possible inferences that can be drawn from data in the future. However, there is an important difference in whether data contain information about a certain diagnosis or whether this diagnosis can only be assumed with a certain probability. Likewise, possible inferences that can be drawn from the data can rarely be predicted a priori. Therefore, our approach is limited to identifying the types of data that have a clear potential to cause harm themselves.

A second possible criticism of the proposed approach is conceivable. Regardless of whether information is inferred indirectly from data or whether the information is contained directly in it, the same data can entail different levels of individual risk for different people. Risk assessment, such as the one we present here, cannot reflect these different levels of individual risk. Both the probability of unauthorized reidentification and the possible magnitude of harm can be very different for the same data types in different people. The x-ray of a patellar luxation may be considered as nonsensitive information for most people, especially as it does not contain any identifying information. Nevertheless, a professional soccer player might disagree, as the information in the data contains the risk of unauthorized reidentification (due to possible analog and comparable x-rays of his club) and could be potentially harmful to his career (eg, through discrimination in relation to a possible contract extension). Our approach cannot depict these individually possible risks and can only provide guidelines for the assessment of generally expected risks. The risks of individual persons with special risk profiles must be addressed using individual measures. Among other things, this calls for the establishment of a suitable information and consent procedure or an opt-out option that allows persons with an individually high risk to decide for themselves whether this risk is too high or not. Which model of informed consent may be appropriate is not the subject of this study.

Conclusions

In this paper, we addressed three desiderata of the current literature on *SeConts*. In the first step, we clarified the concept of *SeConts*. To this end, we analyzed each element of the concept and then provided a comprehensive definition of *SeConts* as *activities that solely use data produced for the sake of health care and in the context of health care to improve biomedical science or services*.

In the second step, we illustrated the scope and practical relevance of *SeConts* by providing a list of concrete types of research or learning activities that can be subsumed under the concept. These types of research or learning activities were roughly classified as either *non-interventional (observational) clinical research*, *quality control and improvement*, or *public health research*.

In the third step, we provided a framework for risk assessment for *SeConts*, focusing on the risks for patients related to informational self-determination. By operationalizing the concept of risk for application to *SeConts*, we identified factors that determine the *probability of unauthorized reidentification* as well as the *magnitude of harm* of a potential harming event implied in *SeConts*. We then discussed the application and use of our risk assessment framework and presented a practical example of a concrete study to illustrate its application.

Through our conceptual clarification of *SeConts*, we created a basis for understanding what *SeConts* means. The analysis of its scope shows that *SeConts* can realize its potential in a broad field of medical research. This illustrates the high practical relevance of *SeConts*. The risk assessment presented can be applied as an essential building block for an ethical evaluation of concrete *SeConts* conducted by research ethics committees and data use and access committees, as well as scientists, bioethicists, and funders. It can thus benefit the safe secondary use of clinical data in data-gathering, non-interventional research or learning activities.

Acknowledgments

This paper was developed within the framework of the project *Learning from Clinical Data (LinCDat)* funded by the Deutsche Forschungsgemeinschaft (DFG; German Research Foundation)—406103282. Project funding was awarded to ECW. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. No additional external funding was received for this study. We would like to thank our project partners Kai Cornelius and Markus Spitz (University of Heidelberg, Germany). We also thank Nikolaus Kleindienst (Central Institute of Mental Health, Mannheim, Germany) and Adrian Thorogood (University of Luxemburg) for conceptual counseling and Vincent Lotz (National Center for Tumor Diseases, Heidelberg University Hospital, Germany) for his assistance in researching the literature and linguistic correction of the manuscript.

Authors' Contributions

MJ, CS, and ECW conceptualized the manuscript. MJ drafted the manuscript, and CS supervised the preparation. AK and KM have revised the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: In 2020, the number of internet users surpassed 4.6 billion. Individuals who create and share digital data can leave a trail of information about their habits and preferences that collectively generate a digital footprint. Studies have shown that digital footprints can reveal important information regarding an individual's health status, ranging from diet and exercise to depression. Uses of digital applications have accelerated during the COVID-19 pandemic where public health organizations have utilized technology to reduce the burden of transmission, ultimately leading to policy discussions about digital health privacy. Though US consumers report feeling concerned about the way their personal data is used, they continue to use digital technologies.

Objective: This study aimed to understand the extent to which consumers recognize possible health applications of their digital data and identify their most salient concerns around digital health privacy.

Methods: We conducted semistructured interviews with a diverse national sample of US adults from November 2018 to January 2019. Participants were recruited from the Ipsos KnowledgePanel, a nationally representative panel. Participants were asked to reflect on their own use of digital technology, rate various sources of digital information, and consider several hypothetical scenarios with varying sources and health-related applications of personal digital information.

Results: The final cohort included a diverse national sample of 45 US consumers. Participants were generally unaware what consumer digital data might reveal about their health. They also revealed limited knowledge of current data collection and aggregation practices. When responding to specific scenarios with health-related applications of data, they had difficulty weighing the benefits and harms but expressed a desire for privacy protection. They saw benefits in using digital data to improve health, but wanted limits to health programs' use of consumer digital data.

Conclusions: Current privacy restrictions on health-related data are premised on the notion that these data are derived only from medical encounters. Given that an increasing amount of health-related data is derived from digital footprints in consumer settings, our findings suggest the need for greater transparency of data collection and uses, and broader health privacy protections.

health privacy; digital health privacy; privacy law; health law; digital epidemiology

Introduction

In 2020, internet users spent 1.25 billion years online. The average internet user spends 6 hours and 43 minutes online each day [1], leaving a trail of information about his/her habits and preferences that collectively generates a digital footprint.

A consumer's digital footprint can reveal health-related behaviors, such as diet and physical activity, that can predict health [2]. For example, data from social media sites, including Twitter and Facebook, can be used to screen for signs of depression, suicidal ideation, and sleep disorders based on user activity and language patterns [3-6]. These applications of data toward health purposes erase past distinctions between health and nonhealth data [7,8].

The COVID-19 pandemic has accelerated these applications. Smartphone location services and cashless transactions have been used to identify and track COVID-19–positive individuals [9]. Social media posts have been used to track reports of physical symptoms of COVID-19 and mental health sequelae of the pandemic [10,11]. Apple and Google have updated their smartphone operating systems to enable tracking of human-to-human interactions to enable digital contact tracing [12]. These public health applications of consumer digital data have triggered global debates and urgent policy discussions about digital health privacy [13].

A majority of Americans simultaneously reported feeling concerned about how their personal data are being used and yet continue to use digital technologies. Many believe it is impossible to go through daily life without having personal data collected by companies or the government, with 80% feeling they lack control over what data are collected and 63% admitting having little to no understanding about data privacy laws and regulations [14].

We interviewed a diverse sample of American consumers to evaluate their awareness of the health applications of their digital data and identify their privacy views and concerns.

Methods

Participants

Interviews were conducted between November 1, 2018, and January 31, 2019. Participants were identified from the web-enabled Ipsos KnowledgePanel, a probability-based panel designed to be representative of the US population [15]. For this study, Ipsos provided the contact information of 200 participants drawn from the nationally representative panel with even distribution for various demographic variables (gender, race, age, household income, and geographic region) to ensure diversity in the study sample. From these, team members (XLM and AL) completed 45 interviews, ensuring equal proportions of participants were included from each category so that the sample of 45 reflected the larger sample of 200. Participants who completed the interview were paid US $50.

This study protocol was reviewed by the Institutional Review Board of the University of Pennsylvania and declared exempt. Verbal consent was obtained from participants prior to their interview. All results are reported following the Standards for Reporting Qualitative Research (SRQR) reporting guidelines.

Design

Telephone interviews were conducted using a semistructured qualitative interview guide (Multimedia Appendix 1). This guide was informed by a consequential ethics framework, in which the presence or absence of a substantial risk of harm from a loss of privacy determines the need for protections [16]. The guide asked consumers to reflect on their own use of digital technology, evaluate sources of digital information, and consider several hypothetical scenarios with varying uses of digital information (scenarios shown in Table 1). While the scenarios were hypothetical, they were developed based on plausible use cases in today's landscape of consumer digital data. The interviews lasted 30 to 45 minutes, and were conducted by research coordinators (AL and XLM) trained in qualitative interviewing methods. The audio recordings were sent to a professional transcription service (ADA Transcription) where they were deidentified. Transcripts were uploaded to NVivo Version 12 for data analysis [17].

Table 1. Scenarios.

No.	Text	Source	User	Use
1	*Your health insurance company is trying to find ways to keep people healthier and save money. They have found that consumers that buy certain kinds of food are more likely to develop diabetes. The insurance company is planning a program where they will access the grocery shopping records of their patients from grocery stores. The health insurance company will use this information to find out who is at high risk of developing diabetes, then send those people tips and advice on how they can prevent diabetes by making changes to the food they buy.*	Grocery shopping records	Health insurance company	Prevent diabetes
2	*Your doctor's office is trying to find ways to prevent people from getting sick and needing to go to the hospital. They have found that patients that search on the internet for certain symptoms are more likely to get sick and need to go to an emergency room. Your doctor's office is planning a new program where they will access internet searches of their patients and contact patients that search for certain symptoms to try to start treatment sooner.*	Internet search history	Doctor's office	Diagnose disease earlier
3	*University researchers are trying to find ways to prevent cancer. Researchers at a nearby university hospital are starting a research study where they will track patients over time to try to determine causes of cancer. In addition to using medical records, the research team will use location information from patient's smartphones so they can study how the places where people spend most of their time impact their risk of getting cancer. The researchers want to use this knowledge to help develop public health strategies in the future that could reduce the number of people with cancer.*	Electronic health record and location data from a smartphone	University researchers	Research to identify risk factors for cancer
4	*DigiHealth is a company selling a new smartphone app that can automatically collect and store information on places users visit and the food they eat so that it can give advice on ways to lower their risk of obesity. The app tracks where users go using location services on their smartphone and tracks what they eat by having them upload a picture of their meals. DigiHealth is able to offer the app for free because it shares user information with advertisers so they can send out grocery coupons.*	Location data and photos from a smartphone	Technology company	Send grocery coupons for healthier foods to prevent obesity

Analysis

The study team developed a codebook through line-by-line iterative reading and notation of transcripts, which produced 12 key codes [18]. Some codes were used a priori in order to compare data from consumers to the data from similar interviews conducted with experts [7]. Two research coordinators used the codebook to complete coding (AL and XLM). In order to establish agreement, five interview transcripts were double coded. Interrater reliability was high, with overall agreement (97.5%) and Cohen kappa of 0.7. After agreement was established, the remaining transcripts were coded individually. Interviews were coded sequentially in the order they were conducted. A memo was written, and it thematically summarized the content of each code. These memos were reviewed collectively by the study team in order to identify salient findings. The study team found that they were no longer learning new information in the process of coding new transcripts. Therefore, through coding and analysis meetings, key study personnel reached a consensus that thematic saturation was reached. The results from these interviews are reported along with supporting quotes to highlight relevant findings.

Results

Participants

The sampling methods produced a final cohort of 45 consumers with diversity in gender, race, age, household income, and geographical distribution (Table 2).

Table 2. Demographics of the participants (N=45).

Characteristic	Value, n (%)
Gender	
Male	24 (53%)
Female	21 (47%)
Race	
Minority (non-White)	22 (49%)
White/Caucasian	23 (51%)
Age (years)	
18-30	14 (31%)
31-45	10 (22%)
46-60	11 (24%)
>60	10 (22%)
Household income (US$)

Part 1: Views on Digital Privacy and Health

The first portion of participant interviews focused on consumers’ understanding of current data use as well as their views on digital health privacy. Key themes are described below, and illustrative quotes are presented in Table 3.

Table 3. Key themes from consumer interviews.

Theme	Illustrative quote
Lack of consumer understanding	*I don't really have a great knowledge of what they gather from me. I know when I signed up and you gotta go through the cursory that says do you agree to all this, there's just pages of stuff and you just say, like everything else, you just say yeah, I agree.* *I don't think Google collects any information about me when I use it.* *My health? I mean, they wouldn't think I have any health issue...I don't make any payments in regards to my health .* *I don't think they could learn nothing. You don't put your health information on there. Like what would they know from Instagram?* *I don't necessarily know what they would gain about my health overall other than sometimes when I'm sick, I'll research my symptoms online or something like that.*
Benefits	*Well, I think the biggest benefit that I can think of –the reason that I use Reddit is because it's beneficial to feel like I belong to a handful of communities. And so, I think I deepen my interest –the things that I'm interested in feel more meaningful when I read what other people are talking about.* *I think it would help them –if they were gathering that information, they would use it for marketing and potential sales, how they go about structuring better ways to advertise to persons in organizations.* *Well, benefits –I get to find out things that my friends are doing that they want me to know, because otherwise they wouldn't post it. But it's also a double-edged sword in that –basically, that –that those –whatever they're talking about –whatever –however I'm reacting to it, is more information for advertisers to target me with.*
Harms	*Well, I think that information should just be between me and my doctor. I wouldn't want any advertisers to be able to learn that information, and I wouldn't want anything that I wouldn't share with my family or friends to come out in the public regarding anything that was physically going on with me.* *Well, I think the –some of the worry is that the Fitbit–I don't have one or use one, but –so the worry is that it might provide inaccurate data that might be used against me. For example, if I applied for life insurance, I would worry that if the insurance company got a hold of Fitbit records out of context that they could –I could wind up with a higher premium or something like that.* *That's just sensitive private information. Whether I have a cold or whether I have a more serious ailment disease, I think that's private. Unless I wanna share it with people, that shouldn't be disclosed to anyone without my expressed consent.*
Consumer attitudes	*I really don't have nothing to hide, but that's pretty personal to a lot of people, and I really wouldn't like it. So I would just –I mean, you've got to have a little bit of freedom here. That's what this country's about.* *I think the worst ones would be my health bills. If that was not kept private, that would be really problematic. If you think about cell phone bills, electricity bills, internet bills, I don't think I would have as much as an issue.*

Lack of Consumer Understanding of Digital Data Practices

Few participants could express a basic understanding of digital data collection practices, including how information is routinely tracked, stored, and subsequently used by third parties. Some were unaware that by downloading and using an app (eg, Facebook), they had consented to data collection. Participants who were aware that their data were being collected generally assumed the data were being used only by the entity collecting it and were not shared with third parties. Almost none of the participants named ways in which data are aggregated across sources and over time, a common practice by marketers to build profiles of individual consumers.

Participants generally did not recognize the connections between their digital data and inferences about their health. They were not able to conceptualize health information outside of a traditional definition of health care data. They were unaware that predictions or inferences about their health status could be drawn from sources like internet browsing information or social media posts.

Perceived Benefits and Harms of Digital Data Practices

Participants noted benefits of digital data collection to consumers and companies. They described the benefits of advertising highly tailored to their interests. They discussed convenience derived from data tracking. They discussed health benefits when prompted by specific health-related scenarios, but rarely mentioned them during other parts of the interview despite the interviewers introducing the study focus as related to health.

Indeed, most privacy concerns were broad rather than specific to health. Participants worried that their information could affect their finances, particularly that insurance coverage could be lost or premiums raised because of health information being made available to their insurer. Some participants feared losing employment opportunities if their information, especially health information, was available to an employer.

For some participants, the main harm was the intrusiveness of the digital data collection practices of the government, commercial companies like health insurers, and even health care providers, with access to information that some felt should remain private.

Participants split into two points of view when weighing tradeoffs between the benefits and risks of digital data collection and use. Some felt that it was a choice to give up privacy for convenience or other benefits. Several of these participants discussed tradeoffs in transactional terms. The use of discount cards, apps, and other programs naturally involves relinquishing some privacy, which is sometimes a worthwhile choice. Others described data tracking and sharing as inescapable. These participants did not consider these privacy risks acceptable but struggled to articulate how to avoid them.

Attitudes Regarding Digital Privacy

Despite a lack of knowledge on data privacy issues, participants strongly endorsed the significance of data privacy, based partly on a right to privacy and on concerns about harms.

When asked about privacy preferences for different types of data (health information, internet searches, and financial information), participants consistently expressed the greatest concern if their health information was not kept private. However, participants did not understand that data generated outside of health care could also be used to make inferences about their health.

Part 2: Health-Related Applications of Consumer Digital Data

To make health applications of digital data more salient to participants, we prompted them with a series of hypothetical scenarios (Table 1) representing various sources, uses, and users of digital information for health purposes. For each scenario, participants were asked to provide their overall impression, describe what they liked and disliked about it, identify limits or protections they desired, and share whether they would want to participate.

Although participants' responses to each scenario varied, certain themes were consistent. Participants appreciated the health benefits that could be achieved through the programs, including interventions to improve individual or population health, research to make advances in health care, and efforts to reduce health care costs. However, participants often expressed concern that many uses seemed too invasive and that their data might be used for other purposes beyond what was intended. They often desired protections so that data could be used only for the originally intended purpose, data could be kept private and secure, and participation could be voluntary and require consent. Table 4 provides illustrative quotes for the benefits, risks, and protections discussed by participants for each scenario.

Table 4. Consumer perspectives on digital data use scenarios (illustrative quotes).

Scenario[a] (% favorable)	Rated favorable (N=45), n (%)	Benefit quotes	Risk quotes	Desired protection quotes
A health insurance company accesses data on consumers' grocery store purchases to identify individuals at high risk for developing diabetes and sends them healthy eating tips.	20 (44%)	*I think it could give some valuable information. And especially if someone is unaware that their purchases are causing problems.* *The idea that someone is going to help me because I might not have that information that this product might not be good for my health, that is wonderful.*	*How much do you want them to stick their nose into what you're doing? … Now they want to tell you what to eat? They could easily raise the premium on it. I know they would.* *That's just my personal choice if that's what I wanna purchase and I don't need my health insurance charging me...*	*It's just I don't want them using it for different purposes, other than what … they were gonna use it for.* *I don't think they should be able to use your –that information against you as far as, again, raising premiums or copays or deciding what's a covered cost and what's not a covered cost based on my lifestyle as far as what I eat.*
A doctor's office monitors internet search data of their patients and contacts individuals who search for symptoms of illness in order to provide an early diagnosis.	12 (27%)	*…The doctor can be like hey, I seen you looked this up about measles and now all of a sudden you think you have measles –it's all in your head.* *They can say, oh, I see that you're looking for information on a child that's throwing up chronically. Let's get him in here and check him out...*	*They shouldn't have access to what I'm searching for online because I am a Web M.D. queen…I will Google the symptoms and see if it's something else or what I can do before I go to the doctor.* *It's just an invasion of privacy. Again, if you are volunteering that information, then you can volunteer whatever information you want.*	*It would have to be on an opt-in basis so that people are made aware of what's gonna happen and they're choosing to let that happen* *That should definitely be protected, because that's sensitive.*
University researchers access the smartphone location and medical records of patients to study risk factors for cancer.	35 (78%)	*I mean, that idea is something worth being monitored for because it's for a good cause. I mean, it can potentially save hundreds of lives, and it can also save insurance companies.*	*Just I don't like anyone knowing my whereabouts all hours of the day and all night, especially – and it's not even just anyone. It's – a stranger…* *Personally, no, because I don't want them thinking because of where I work at that I'm buying tobacco all the time because I work at a store that sells tobacco and alcohol.*	*If there was a situation where I thought that someplace I went would give the wrong idea out of context, then just turn off GPS.* *Just knowing that they are not allowed to sell my information for anything else other than using it specifically for this research.*
A technology company creates an app that tracks users' locations and asks them to upload photos of their meals with the intention of encouraging healthy eating and sharing this information with advertisers who can provide users with coupons.	27 (60%)	*I like that idea of if somebody wanted to do it so they don't get diabetes. Upload any pictures of the food you eat and get tips about what to do.* *People have to actively want to use it and those individuals may want to receive grocery store coupons that are in line with the goals of losing weight, right? So I don't have a negative reaction to that.*	*I would worry that in the future or – I think it's already possible to – for them to sell the data to another company that could reverse engineer the data and result in higher insurance premiums for individuals and that sort of thing.* *…Nothing would prevent me from taking a picture of the salad that my wife is eating and post that as my dinner, while I'm – in reality, I'm eating a big, thick juicy steak and baked potato…It seems like a lot of effort to go through, and I'm not sure what the benefit's going to be.*	*They have to disclose exactly who they're sharing that information with outside of their company and the advertisers and what specific information they're sharing with those advertisers and the other third parties that may be involved.* *I would think there would have to be a government mandate for a lot of transparency, including specific fines for misusing or not protecting the data.*

[a]Responses by participants to each scenario were coded as favorable, unfavorable, or neutral.

Scenario 1

Scenario 1 was a follows: *A health insurance company accesses data on consumers' grocery store purchases to identify individuals at high risk for developing diabetes and sends them healthy eating tips.*

Overall, 20 out of 45 participants (44%) rated this program favorably. Participants liked the idea they could receive recommendations to improve their diet or management of their health conditions. Others thought the program could address population-level health problems in the United States or reduce insurance costs for those making healthy food choices. Participants were concerned by the motive of health insurers running such a program. They worried about losing insurance coverage or paying higher premiums based on their grocery purchases. Participants described protections they desired, including limits on other uses of data collected for this program, destruction of data after the program was complete, and opt-in and consent procedures for interested participants.

Scenario 2

Scenario 2 was as follows: *A doctor's office monitors internet search data of their patients and contacts individuals who search for symptoms of illness in order to provide an early diagnosis.*

Overall, 12 out of 45 participants (27%) rated this program favorably. Participants identified several beneficial elements of this program, including the prevention of illness, possible savings on health care costs, convenience of care that could be provided remotely particularly for those with barriers to face-to-face care, and additional support from clinical providers for overall health. Additionally, participants liked that this scenario could provide patients with better quality information, preventing inaccurate self-diagnoses using web searches. Some participants felt that having a doctor access their searches would be too invasive, and they would rather conduct personal research and contact their provider if they had concerns. Some felt uncomfortable with the idea that their data could potentially be used for targeted drug or treatment advertising.

Participants emphasized the negative aspects of this scenario. Many were concerned about inadequate protections for their internet search data. They asked for full transparency and limits around the uses of their data, as well as personal data access. Participants also generally preferred that this program be opt-in and wanted assurances that there would be adequate data security safeguards in place.

Scenario 3

Scenario 3 was as follows: *University researchers access the smartphone location and medical records of patients to study risk factors for cancer.*

Overall, 35 out of 45 participants (78%) rated this program favorably. Participants saw benefit in participating in any program that could lead to cancer prevention, often citing personal or family history as motivators for participation. Some viewed this scenario more favorably because consent is required for research participation. Some participants who did not approve felt that the data sharing required was an invasion of their privacy. In particular, some participants indicated that they were not comfortable with researchers having access to their medical records.

Participants suggested that researchers obtain additional consent to have their location tracked and that they have the ability to turn off their location sharing at will. Participants also indicated the importance of transparency, specifically that the location information was secure, was not sold to other companies, and was used solely for research purposes. Finally, participants desired data to be deidentified.

Scenario 4

Scenario 4 was as follows: *A technology company creates an app that tracks users' locations and asks them to upload photos of their meals with the intention of encouraging healthy eating and sharing this information with advertisers who can provide users with coupons.*

Overall, 27 out of 45 participants (60%) rated this program favorably. Those who responded favorably to this program thought it would help them to eat healthier and prevent diabetes, and many wanted to receive coupons for using the app. A few appreciated the voluntary or opt-in nature of the app. Others were mistrustful of the motives and felt that only the company or insurers would benefit.

Many participants did not want their information to be sold to advertising companies. Some would not participate because of the inconvenience of having to use the app consistently or the nuisance of receiving advertisements. Others had privacy concerns and worried about downstream use of their information for other purposes. For many, the only desired protection was the ability to either opt-in or opt-out of the app. Finally, participants discussed the importance of anonymity and the ability to use the app without advertisers or third parties identifying them.

Discussion

Principal Findings

In a broadly representative sample of US consumers, we examined attitudes and knowledge about digital health privacy. We identified several key findings. First, participants generally did not draw connections between the data they leave behind when they use digital technology and what it may reveal about their health. Second, participants struggled to weigh harms and benefits of data collection and use. Third, while preferences varied, participants generally wanted some protections in place for health-relevant consumer digital data.

Prior work has demonstrated that consumers value privacy but nonetheless continue to use digital technologies that routinely compromise that privacy [19]. Turow et al argued that this behavior should not be interpreted as consumers being unconcerned with privacy, but rather a sense of resignation that threats to privacy are unavoidable [20]. Our findings suggest that consumers often recognize that information is shared when they use digital technology but are often unaware of the extent of use or what can be learned about them from their data. Obar et al demonstrated that simply presenting consumers with more information will not necessarily lead to more informed consumers or yield higher quality decision making. In an experiment simulating registration with a social networking program, they found that consumers viewed lengthy privacy policies as a nuisance, felt overburdened by privacy statements, and missed "gotcha" provisions that were extreme (eg, many consented to give up their first-born child) [21].

Given that many consumers rank health privacy above other areas [22], it is concerning that most participants in our study could not draw connections between consumer digital data and inferences about their health. Broadly available analytic tools allow for the health status to be inferred from a wide range of data sources including smart devices in the home, language analysis from social media, financial spending habits, and internet search patterns [7,8,23]. Even when health applications were made explicit in the study scenarios, the tradeoffs between threats to privacy and benefits of use remained difficult for our study participants to reconcile. The difficulty assessing tradeoffs is likely compounded by the absence of limits on data use and the uncertain risks posed. Conger et al have argued that the relationships between consumers and businesses have become too complex for the individual consumer to assess given the involvement of third-party data brokers and open-ended uses of data [24].

Facing vignettes about commercial users, participants often raised concerns about economic harms (eg, higher insurance premiums and threats to employment) as well as unbridled secondary uses of their data. When considering vignettes with researchers and doctors as the data users, participants were often concerned with reputational harms (eg, sharing of embarrassing or unflattering information) [25]. Overall, participants responded much more favorably to some scenarios over others suggesting that consumers apply a nuanced evaluation of the use, including whether it is beneficial to themselves, the type of data that is being used, who is using their data, and the overall benefit of the use.

Participants sought privacy safeguards to reconcile the tradeoffs between health benefits and privacy. Many of the safeguards raised mirror those that have been part of the EU General Data Protection Regulation, including consent for data collection and use (opt-in), explicit statements of what data would be used for and by whom, limits on data transfer and selling, and data security requirements [26]. Participants were overwhelmingly in favor of protections for their digital health data. However, prior work points to practical limitations on the effectiveness of some of these approaches. For example, consumers often click through overly complex privacy agreements, suggesting a vastly simplified approach would be needed [20]. Policymakers might consider varying privacy protections based on the associated risks and benefits of different uses or curtail downstream transfers and aggregation of data that are far removed from the original point of collection.

Limitations

This study has several limitations. Digital privacy is a topic with growing relevance and has been increasingly highlighted in popular media, which could shape consumers' attitudes. Events just prior to interviews may have heavily influenced participants' knowledge and perceptions. Therefore, the interviews reflect the time period (2018-2019) in which they were conducted. Despite efforts to recruit consumers with a wide range of characteristics, consumers who were willing to respond to and complete a request for an interview may have characteristics or attitudes not shared by those who chose not to participate. Social desirability bias may limit the credibility of participants' expressed views. Despite these limitations, the interviews show a diverse array of attitudes regarding digital privacy.

Conclusions

This study reveals how individual consumers wish to protect their own health information privacy and how little they are aware of the threats to that privacy from their conventional behaviors. Digital personal health information is now derived from consumer engagements as well as medical engagements. To the extent we need protections for personal health privacy, those protections need to extend beyond their current reach. Our study reinforces the finding that a purely market-based approach to privacy that depends on rational consumers making decisions with full information relies on faulty assumptions [27]. Future debates in the United States may need to focus on whether more robust privacy standards (similar to the European Union's General Data Protection Regulation) are needed to protect consumer digital data from entities beyond health care systems [28,29].

Acknowledgments

This research was supported by the National Human Genome Research Institute/National Institutes of Health (NIH) (5R01HG009655-04). The funder had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication. We thank Ashley Lewson for her role in conducting and coding interviews.

Abstract

Background: The use of social big data is an important emerging concern in public health. Internet search volumes are useful data that can sensitively detect trends of the public's attention during a pandemic outbreak situation.

Objective: Our study aimed to analyze the public's interest in COVID-19 proliferation, identify the correlation between the proliferation of COVID-19 and interest in immunity and products that have been reported to confer an enhancement of immunity, and suggest measures for interventions that should be implemented from a health and medical point of view.

Methods: To assess the level of public interest in infectious diseases during the initial days of the COVID-19 outbreak, we extracted Google search data from January 20, 2020, onward and compared them to data from March 15, 2020, which was approximately 2 months after the COVID-19 outbreak began. In order to determine whether the public became interested in the immune system, we selected *coronavirus*, *immune*, and *vitamin* as our final search terms.

Results: The increase in the cumulative number of confirmed COVID-19 cases that occurred after January 20, 2020, had a strong positive correlation with the search volumes for the terms *coronavirus* (R=0.786; P<.001), *immune* (R=0.745; P<.001), and *vitamin* (R=0.778; P<.001), and the correlations between variables were all mutually statistically significant. Moreover, these correlations were confirmed on a country basis when we restricted our analyses to the United States, the United Kingdom, Italy, and Korea. Our findings revealed that increases in search volumes for the terms *coronavirus* and *immune* preceded the actual occurrences of confirmed cases.

Conclusions: Our study shows that during the initial phase of the COVID-19 crisis, the public's desire and actions of strengthening their own immune systems were enhanced. Further, in the early stage of a pandemic, social media platforms have a high potential for informing the public about potentially helpful measures to prevent the spread of an infectious disease and provide relevant information about immunity, thereby increasing the public's knowledge.

(J Med Internet Res 2021;23(6):e26368) doi:10.2196/26368

Introduction

Following the onset of an infectious pneumonia that could be traced to Wuhan, China, in 2019, the World Health Organization (WHO) announced that the cause of the pneumonia was a new type of coronavirus. The International Committee on Taxonomy of Viruses named it SARS-CoV-2 on on January 11, 2020, and the infectious pneumonia was referred to as COVID-19. As of December 2020, the virus has spread globally; the cumulative number of people infected with SARS-CoV-2 has reached approximately 67 million, and approximately 1,530,000 have died from the virus [1].

Since the year 2000, there have been attempts to use big data to better understand and solve challenges related to public health. Indeed, in the context of health care, the use of big data is an important emerging trend that is only likely to increase in importance over time. The Pillbox project of the National Laboratory of Medicine is one of the most representative examples of health care that uses big data to predict real-world situations. The Pillbox project is a service that provides information such as how to take various pills that are not well known by the public and their potential side effects. The use of such information not only improves consumer convenience but also saves health care expenditures with regard to economics through the gathering of information to estimate statistics, such as the causes of disease outbreaks, rates of spread, and distribution and regional growth [2,3]. Social big data refers to large volumes of data that relate to people or describe people's behaviors and technology-mediated social interactions in the digital realm [4]. Internet search volume is a valid and effective tool for detecting public attention [5]. One of the most representative examples of using social big data for disease prediction is Google's flu forecast. In 2009, Google predicted the spread of the flu 7 to 10 days earlier than the Centers for Disease Control and Prevention (CDC) based on users' search records for the flu [6]. This prediction was confirmed in countries around the world, including South Korea, India, and China [7-9]. Predictive analyses that use social big data, which are not easily accessible in reality, help with making relatively accurate predictions of real-world events. In recent times, attempts have been made to further increase the precision of disease predictions [10,11]. Furthermore, predictive analyses were also used for the real-time monitoring of SARS (severe acute respiratory syndrome) and its transmissibility and for the identification of the natural history of emerging pathogens, such as the Ebola virus [12,13].

The spread of infectious diseases has led to increased interest in the human immune system among the public. During a pandemic, the public often becomes interested in how to strengthen their immune systems. Furthermore, the act of purchasing products that may strengthen one's immune system is popular, even without clear evidence that shows whether these supplements are effective. However, there is almost no scientific proof for confirming this trend, and there is a need to confirm that such interest results in people actually searching more areas of the internet for products related to strengthening their immune system. Eventually, people are likely to respond to this lack of evidence by relying on existing common sense when it comes to maintaining health and hygiene. In this regard, a health literacy approach is needed during a crisis such as the COVID-19 pandemic. At the beginning of a pandemic, the public's response to an infectious disease is the most sensitive, and people have a burgeoning interest in infectious diseases during this period. After the passage of a certain period of time, exhaustion and the adjustment to the social situation results in a relative decline in this interest [14].

Our study aims to analyze the public's interest in the global pandemic and correlate internet search volumes for COVID-19–related terms with the public's interest in the immune system and vitamins.

Methods

Data Extraction

To assess the public's interest in infectious diseases during the initial days of the COVID-19 outbreak, we extracted Google Trends search data from January 20, 2020, onward and compared them to data from March 15, 2020, which was approximately 2 months after the COVID-19 outbreak began. Apart from in a few countries such as China and Japan, the Google search engine has an overwhelming dominance of market shares [15]. Google provides data on search word volumes through Google Trends, which provides usable data for specific countries and time periods. In this study, our unit of data was extracted from data on total worldwide numbers. In addition, to account for trends by country, we selected the United States and the United Kingdom for analysis, as these countries are the most representative countries of the English-speaking world that use the Google search engine. Moreover, we also studied Italy, which was the first European country to experience an explosion in the number of COVID-19 cases. The market share of Google in Italy in January 2020 was 98.9% [16]. Finally, we studied South Korea, which had the second highest COVID-19 spread rate in Asia and the fourth highest spread rate in the world at the time the Google Trends search was performed. On the date that the data were gathered, South Korea was ranked fourth in the world for COVID-19 case numbers, with 8000 cases. In South Korea, the domestic portal site Naver (Naver Corporation) has a much higher market share than Google. Therefore, additional data supplied by Naver Data Lab were used for cross-verification.

Primary Keywords

We used the terms *covid*, *corona*, and *coronavirus* as search terms. In order to determine which of these words were the most commonly used, the search volume of each word was ascertained. According to our preliminary analysis of the data provided by Google Trends, the term *coronavirus* was searched twice more often than *corona* and 5 times more often than *covid*. Therefore, we selected *coronavirus* as our final search term.

Searches Regarding Immunity and Products That Might Strengthen Immunity

In order to determine whether the public became interested in the immune system, we selected *immune* as a keyword. The term *immune* was strongly related to the term *immunity* and had an almost 2-fold higher search volume. Therefore, for the United States, United Kingdom, and Italy, the search term *immune* was studied, and in the case of South Korea, the term *myeonyeok*, which means “immunity” in Korean, was studied.

Following the outbreak of COVID-19, the public’s interest in products that can enhance one’s immune system increased dramatically. The Guardian in the United Kingdom and the Washington Post in the United States have both reported on the rising demand for vitamins and other products [17]. Vitamins are the most familiar to the public, are usually available over the counter, and are the most representative product that enhances the immune system. Therefore, in order to analyze the public’s actual interest in immune system strength, we selected the term *vitamin* as a keyword. For the United States and the United Kingdom, the term *vitamin* was used. For Italy, the term *vitamina* was used. Finally, for South Korea, the Korean-language spelling of the term *vitamin* was used.

Data and Statistical Analysis

Search volumes were calculated for each period (1 week), and the search volume of the period with the highest search volume was 100, which normalized every other search volume value from 0 to 100. The unit of extraction was 1 week. In order to account for the spread of COVID-19, we used the cumulative number of confirmed cases. The official announcements made by the WHO and announcements from each country’s respective government were the most accurate indices for tracking the spread of SARS-CoV-2. The number of cumulative, confirmed cases was verified with data downloaded from Our World in Data [18] and additional data from COVID-19 situation reports issued by the WHO [1]. We conducted an analysis of the correlation between the number cumulative, confirmed COVID-19 cases and search terms. Up until the middle of January 2020, before COVID-19 had begun to spread on a large scale, the figure for confirmed cases and search volume was close to 0. In other words, the actual figure was 0 or 1; therefore, a correlation analysis of the entire year could lead to errors. As such, we selected countries that experienced some of the earliest COVID-19 outbreaks as our target countries. Moreover, we analyzed approximately 2 months’ worth of data, beginning from when COVID-19 cases first began to emerge globally during the week of January 20, 2020, up until March 15, 2020.

Data Availability

Data can be downloaded from the Google Trends website. If the processed data are needed, the authors can be contacted to request the data.

Results

Up until the middle of January 2020, the number of confirmed COVID-19 cases remained extremely low worldwide. Afterward, beginning in the week of January 26, the number of confirmed cases began to increase rapidly, especially in China. The search volume for the term *coronavirus* began to increase earlier—beginning in the week of January 12—and the search volume increased rapidly during the week of February 16. For the past year, the search volume for the term *immune* has consistently been between 10 and 20. After January 12, the search volume increased steadily, and from February 16 onward, the search volume increased rapidly. Throughout 2020, the search volume for the term *vitamin* was at a level that slightly exceeded 50. However, this began to increase after February. The increase in the number of cumulative, confirmed cases of COVID-19 after January 20 had a strong positive correlation with the search volumes for the terms *coronavirus* (R=0.786; P<.001), *immune* (R=0.745; P<.001), and *vitamin* (R=0.778; P<.001), and the correlations between variables were all mutually statistically significant (Figure 1, Table 1).

Figure 1. Worldwide trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases over the past year (from March 18, 2019, to March 15, 2020).

With respect to the United States, up until February 2020, the number of cumulative, confirmed cases remained low (10 people). This number began increasing in the latter half of February and began increasing rapidly in March. The search volume for the term *coronavirus* began increasing earlier—beginning in the week of January 12—and it began to increase rapidly in the week of February 16. The search volume for the term *immune* began to rapidly increase on February 16. Over the past year, the search volume for the term *vitamin* was at a level that slightly exceeded 50. This number increased slightly after December 2019 and increased more rapidly in March 2020. The increase in the number of cumulative, confirmed cases after January 20 had a strong positive correlation with the search volumes for the terms *coronavirus* (R=0.921; P<.001), *immune* (R=0.890; P<.001), and *vitamin* (R=0.913; P<.001), and the correlations between variables were all mutually statistically significant (Figure 2, Table 2).

Figure 2. Trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases in the United States over the past year (March 18, 2019, to March 15, 2020).

In the United Kingdom, the number of confirmed cases increased rapidly after March 2020. Increases in search volumes for the terms *coronavirus*, *immune*, and *vitamin* followed a trend that was similar to those observed for the United States and the rest of the world. The number of cumulative, confirmed cases had a strong positive correlation with the search volumes for the terms *coronavirus* (R=0.931; P<.001), *immune* (R=0.962; P<.001), and *vitamin* (R=0.801; P<.001), and the correlations between variables were mutually statistically significant (Figure 3, Table 3).

Figure 3. Trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases in the United Kingdom over the past year (March 18, 2019, to March 15, 2020).

In Italy, the number of confirmed cases started to rise in the second half of February 2020, with case numbers increasing dramatically in March. The search volumes for the terms *coronavirus* and *immune* began to increase slightly in the week of January 26, and they began to increase dramatically in the middle of February. The search volume for the term *vitamin* first began to increase rapidly in the middle of February, but afterward, it repeatedly decreased and increased. The number of cumulative, confirmed cases had a positive correlation with the search terms *coronavirus* (*R*=0.600; *P*<.001), *immune* (*R*=0.763; *P*<.001), and *vitamin* (*R*=0.474; *P*<.001), and the correlations between variables were all mutually statistically significant (Figure 4, Table 4).

Figure 4. Trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases in Italy over the past year (March 18, 2019, to March 15, 2020).

In South Korea, the number of cumulative, confirmed cases increased rapidly in the middle of February. The search volume for the term *coronavirus* increased earlier—beginning in the week of January 19. After decreasing for a brief period, this search volume again increased rapidly in the week of February 9 and again decreased in March. The search volume for the term *immune* was highest during the first week of March, whereas the search volume for the term *vitamin* was highest during the week of March 15. However, unlike in other countries, the search volumes for these terms did not rapidly increase. The increase in the number of cumulative, confirmed cases had a statistically significant positive correlation with the search volumes for the terms *coronavirus* (*R*=0.359; *P*=.007) and *vitamin* (*R*=0.637; *P*<.001); however, its correlation with the search volume for the term *immune* (*R*=0.254; *P*=.06) was not statistically significant. When analyzing data from Naver, the search volume for the term *coronavirus* increased from the middle of February onward, and the search volumes for the terms *immune* and *vitamin* increased slightly in the beginning of January and increased again in the second half of January and from February 16 onward. All three search terms reached their peak search volumes in the beginning of March, and thereafter, these search volumes began trending downward. When compared with data from Google Trends, the results were similar, and the increasing trend in search volumes for the terms *immune* and *vitamin* that appeared after the occurrence of confirmed cases was slightly clearer (Figure 5, Table 5).

Figure 5. Trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases in South Korea over the past year (March 18, 2019, to March 15, 2020).

Discussion

During the COVID-19 pandemic and other pandemics, educational approaches to health and health care are an important problem from the perspective of public health. This study analyzed the increase in the public's interest in COVID-19 by using social media big data and attempted to gain knowledge concerning what interventions must be implemented from a health and health care perspective. Our findings revealed that increases in search volumes for the terms *coronavirus* and *immune* preceded the actual occurrences of confirmed COVID-19 cases. Moreover, search volumes increased gradually before increasing rapidly at the same time as when a rapid increase in the number of confirmed cases was reported. Search volumes for the term *vitamin* also increased concomitantly. This occurred at the same time as the increase in the number of confirmed COVID-19 cases. Although there were slight differences in the increasing trends among countries, worldwide trends coincided with each other in general. With respect to South Korea, although Google search results did correspond with worldwide trends in a characteristic manner, the data from the domestic portal Naver corresponded more closely with worldwide trends (Figure 6, Table 6).

Figure 6. Trends in search volumes for the terms *coronavirus*, *immune*, and *vitamin*, and the number of cumulative, confirmed COVID-19 cases in South Korea over the past year (March 18, 2019, to March 15, 2020) based on data from the Naver portal.

By using search records from its search engine, Google was able to predict the 2009 flu pandemic before the CDC. Similarly, this study also found that the increase in the volume of related search terms preceded an increase in the number of confirmed COVID-19 cases, thereby confirming the validity of using social big data for predicting real-world events. However, there are several possible interpretations for the increased volume of certain search terms. First, this may reflect a rising concern about infectious diseases, such as worries about the outbreak of a disease and demands for knowledge. Second, the results of this study confirmed that in addition to the search volume for the term *coronavirus* increasing, the search volume for the terms *immune* and *vitamin* also similarly increased. This can also be interpreted as an act of disease prevention, which reflects a desire to control situations and prevent disease. During the period of the SARS pandemic, as an act of disease prevention, the number of searches for information on the internet and consultations with experts by people in the United States and Canada who were highly concerned about the disease increased [19]. It is known that increased interest and concern about a disease has a very close relationship with disease prevention measures, and it appears that during a pandemic, increased concern about disease is intimately related to handwashing, personal hygiene and related activities, mask wearing, and the avoidance of public places [19].

In particular, the fact that an increase in search volume preceded the spread of COVID-19 implies that before the complete outbreak of a pandemic, the public has a tendency to be concerned about a disease and engage in corresponding prevention activities. COVID-19 symptoms do not present until 5 to 6 days after SARS-CoV-2 infection, and the incubation period can be as long as 14 days [20]. Taking this into account, the results of this study—those showing that an increase in search volumes directly precedes a rapid increase in cases—reflects the coping mechanisms of a public that has already been exposed to COVID-19 and has been experiencing early warning symptoms. Regardless, before the onset of a full-blown pandemic, supplying prior education and information on health care and health should be the central task of public health departments during these situations.

It cannot be ruled out that an increase in search volumes related to COVID-19 reflects an increase in simple interest. Even if this is the case, it is important to place importance on the dissemination of proper knowledge. The control of a disease's outbreak cannot rely solely on the efforts of public health specialists. Coping behaviors and prevention measures that are achieved through an increase in knowledge among the public are critically needed [21,22]. In particular, behavioral measures such as social distancing are an effective strategy for coping with an epidemic. However, it is only possible to achieve this through the cooperation of a well-informed public [22]. It is certain that Wuhan residents who moved to other cities without knowing whether they were infected with SARS-CoV-2 contributed to the early spread of COVID-19 [23]. In addition, homeless people and those of similar social classes that have little access to medical information have been identified as potentially dangerous groups that might be transmitters of the disease [24]. Therefore, the propagation of health care information through mass communication methods is emerging as an issue that is more important than ever before. Therefore, in an epidemic or pandemic situation, a variety of strategies are needed to use social media and the internet to alleviate people's fears and discomfort and increase the public's awareness of proper health measures.

Alongside the COVID-19 pandemic, not only did the search volumes of the terms *immune* and *vitamin* increase, the number of news reports related to COVID-19 that contained these keywords increased as well (Multimedia Appendix 1). Moreover, in addition to an increase in interest in food products such as elderberry, which are known to be beneficial in enhancing the immune system, because these news reports were related to SARS-CoV-2 (Multimedia Appendix 1), they add to the proof for the public's increasing interest in immunity following the spread of COVID-19.

The interests of the public are always inextricably tied to the media [25]. As such, rather than supplying sufficient information on the subjects that the public are interested in, news outlets have a tendency to instead provide distracting and shocking content [26]. During a pandemic, web-based media outlets focus on reporting related news, which causes worry about the disease spreading rapidly among the public [27]. Such an anxious and worried public has a tendency to search for health information that cannot be trusted [28]. In particular, it has already been reported that incorrect health information, rather than accurate health information, tends to spread on social networks [29], and this can also cause people to adopt improper health measures [30]. Moreover, despite there being information that is important to understand, during pandemics and similar emergency situations, it is likely that the public will miss certain important information about disease prevention amid the flood of information, and the likelihood of people adopting false beliefs or actions will also rise. The public's interests and fears concerning COVID-19 can lead to various negative actions such as the panic buying of health products and the aggressive exclusion of certain racial groups, which, in the end, has a negative effect on preventing the spread of SARS-CoV-2 [31,32]. In contrast, during the SARS pandemic, it was known that a certain amount of worry and panic had a positive effect on preventative actions [33], which suggested that because of knowledge deficiencies and areas of irrational risk perception, mediation was needed [33]. Moreover, research on a section of the United States showed that in 2009, newspaper reports on the H1N1 flu had a positive effect on people's desire to seek prevention measures.

The internet can be used to disseminate information across the globe, and it supplies individually tailored and interactive information. As such, it is an extremely appropriate platform for promoting public health interventions [34,35]. In fact, it is known that information searches conducted through social networks such as Google, YouTube, and Facebook have a positive effect on gaining knowledge about how to prevent infectious diseases, which results in people taking preventative measures [36]. However, as mentioned earlier, the chances are very high that current internet culture will be applied negatively to the COVID-19 pandemic. Within this context, interventions that can assist people in finding information through search word matching and help with actually preventing and coping with the spread of the disease are a key issue with regard to the expansion of proper health literacy. Although such measures can be considered beyond the scope of public health science, during a disaster situation, health authorities must make active interventions to prevent the spread of a disease and do so from a public health science and health information perspective. It is clear that doctors and health care workers must strive to provide accurate information to the public.

It is a known fact that products such as vitamins are helpful for strengthening one's immune system, and they may have a positive effect on decreasing the rates of infections and deaths caused by SARS-CoV-2 [37,38]. However, although a lack of vitamins can become a medical problem, there is no evidence that an overconsumption of vitamins prevents the transmission of COVID-19. It is known that in seriously ill patients, high doses of vitamin C can be helpful for treatment [39]. However, although it has medical uses, this does not mean that the public should be taking vitamin C to prevent the contraction of COVID-19. The interests of the public, including those of the media, are not necessarily based on accurate medical science. When SARS-CoV-2 emerged, the media disseminated a high volume of reports on immunity and vitamins. Since articles on immunity and vitamins were written mainly about SARS-CoV-2, the public might have believed that vitamin C could prevent SARS-CoV-2 infection. However, although these articles may increase people's knowledge about self-care related to COVID-19, they can also increase incorrect health literacy. There is also a possibility that such articles will be used for commercial purposes. In the initial stages of the COVID-19 outbreak, the public's interest in how to protect themselves from infectious diseases, such as by strengthening one's immune system, grew rapidly. Moreover, an infodemic [40] of misinformation, which spread through various media, became an obstacle to managing public health [41].

During the COVID-19 pandemic, delivering accurate information to the public and correcting false information is the responsibility of experts. Our study confirmed that during the initial phase of the COVID-19 crisis, the public's desire and actions of strengthening their own immune systems were enhanced. Therefore, when considering our results in conjunction with earlier findings, it is clear that the initial stage of the spread of an infectious disease is the period in which methods for strengthening accurate knowledge about a disease become the most effective. Moreover, these results also verify the importance of intervention strategies that are meant to prevent the spread of an infectious disease during the early stages.

Acknowledgments

This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF), which is funded by the Ministry of Education (NRF-2020R1I1A1A01070465).

Authors' Contributions

JL and MBP designed the study, conducted the literature review and statistical analysis, and wrote the manuscript. YK and JYL reviewed related articles and references and wrote the manuscript. JIS and KHL checked the statistical analysis and collected the data. A Kronbichler, LS, A Koyanagi, LJ, SWC, and RAG checked the manuscript as a whole. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Low adherence to real-world online weight loss interventions reduces long-term efficacy. Baseline characteristics and use patterns are determinants of long-term adherence, but we lack cohesive models to guide how to adapt interventions to users' needs. We also lack information whether very early use patterns (24 hours) help describe users and predict interventions they would benefit from.

Objective: We aim to understand the impact of users' baseline characteristics and early (initial 24 hours) use patterns of a web platform for weight loss on user adherence and weight loss in the long term (24 weeks).

Methods: We analyzed data from the POEmaS randomized controlled trial, a study that compared the effectiveness of a weight loss platform with or without coaching and a control approach. Data included baseline behavior and use logs from the initial 24 hours after platform access. Latent profile analysis (LPA) was used to identify classes, and Kruskal-Wallis was used to test whether class membership was associated with long-term (24 weeks) adherence and weight loss.

Results: Among 828 participants assigned to intervention arms, 3 classes were identified through LPA: class 1 (better baseline health habits and high 24-hour platform use); class 2 (better than average health habits, but low 24-hour platform use); class 3 (worse baseline health habits and low 24-hour platform use). Class membership was associated with long-term adherence ($P<.001$), and class 3 members had the lowest adherence. Weight loss was not associated with class membership ($P=.49$), regardless of the intervention arm (platform only or platform + coach). However, class 2 users assigned to platform + coach lost more weight than those assigned to platform only ($P=.02$).

Conclusions: Baseline questionnaires and use data from the first 24 hours after log-in allowed distinguishing classes, which were associated with long-term adherence. This suggests that this classification might be a useful guide to improve adherence and assign interventions to individual users.

KEYWORDS

obesity; overweight; web platform; digital health; engagement; latent profile analysis; online interventions; use data; weight loss; weight loss platform

Introduction

More than a third (36%) of adults worldwide are overweight (BMI >25 kg/m^2) or obese (BMI >30 kg/m^2) [1], which increases the risk for metabolic, cardiovascular, and neoplastic diseases. Daily behaviors such as excessive energy intake and lack of physical exercise are major determinants of excess weight. The advent of the internet and the ubiquity of digital technologies, such as smartphones, has created an opportunity for behavior change at scale.

Interventions delivered using digital technology (digital health interventions) and, in particular, web-based platforms, are promising tools to behavior change and weight management promotion [2]. However, as demonstrated in systematic reviews, their effect is typically short term [3,4]. Technology adherence, defined as the percentage of users who follow an intervention's intended use pattern, affects the implementation of large-scale digital health interventions [5]. In many ways, adherence has been the Achilles heel of any health intervention aimed at behavior change. The law of attrition, which states that a considerable proportion of users will stop using eHealth interventions, is one of the few laws that has remained consistent throughout the years of digital health intervention development [6]. There seems to be some agreement as to how we can design for adherence, using concepts such as tailoring and fit and combining personal support with digital functionalities [7]. However, developers face several challenges to formulating personalized digital health interventions, given the individual variation of patient characteristics and motivation to use digital health technology.

Adherence to technology can be explained by environmental, technological, and support variables, as well as individual user demographics and psychological characteristics [8]. User characteristics present intervention designers with two challenges. The first is that different user segments may require different products [9]. By understanding user needs, digital literacy, and habits, interventions can be tailored to users' needs. Tailoring and personalization [10], which also inherently considers individual characteristics, goals, and previous motivation, have been shown to be more effective than static nonadaptive interventions [2]. The second challenge is the high variability on the adoption, response, and outcomes of digital behavior change interventions across users [11]. With some users benefiting more than others, it appears that preintervention individual characteristics are important determinants of adopting a new behavior [12,13]. Given health apps' low retention rates after the first few days [14], the capacity to adequately adapt apps based on data available on day 1 (baseline and initial use data) could improve user experiences and potentially improve follow-up.

To meet these challenges and improve understanding about user adherence in weight loss interventions delivered through web platforms, we will perform subanalysis of the POEmaS randomized controlled trial (RCT). This provides an opportunity to study users' baseline characteristics and the impact of these characteristics on adherence and behavior change. Our main goals are to understand the impact of users' characteristics and the first 24-hour use patterns of a web platform on user adherence within 24 weeks and evaluate whether preintervention characteristics affect the intervention effect within 24 weeks.

Methods

Study Design

The Online Platform for Healthy Weight Loss (POEmaS, from the abbreviation in Portuguese) study was a 3-arm (1:1:1), parallel, RCT evaluating the efficacy of a coach-supported online platform for promoting weight loss [15]. The protocol [16] and main results [15] are described in detail elsewhere. The RCT was registered at ClinicalTrials.gov (NCT03435445). This is a substudy of the POEmaS RCT that includes data from the two intervention arms only.

Setting

The setting was the university community (all campuses) of the Universidade Federal de Minas Gerais, Brazil.

Recruitment

University students and staff were recruited online using mailing lists and notice boards and through banners and posters across the university campuses reaching current and previous staff, students, and alumni from September to October 2017. They were directed to a website where they received further information about the study, eligibility criteria, and enrollment information.

Eligibility Criteria

Inclusion criteria for the RCT included age 18 to 60 years, BMI ≥25 kg/m^2, intention to lose weight through a behavior change program, and internet access. Exclusion criteria included pregnancy, presence of conditions that demand specific dietary or physical activity recommendations (diabetes, heart failure, coronary artery disease, kidney disease, hepatic disease, cancer, phenylketonuria, celiac disease, food allergies, bariatric surgery history), and participation in any other weight loss program at baseline. For this substudy, participants of the comparison (control group) were excluded since their adherence to the intervention was not measured.

Randomization and Allocation

Those who were eligible were allocated to 1 of 3 study groups using a stratified randomized block design by sex and category of BMI (25 to <30 or ≥30 kg/m^2) using blocks of variable length (either 3 or 6). Participants then received an email with information about the activities available to the group they were allocated to. The random allocation sequence and algorithm for randomization were developed by a team of information technology specialists who did not participate in the recruitment or assessment processes. Those who did not complete the questionnaires about dietary and physical activity habits during the onboarding process could not proceed to the use of the platform.

Intervention

The platform-only group was given access to a weight loss program delivered by a web-based platform. The program was based on diet and physical activity guidelines and on the behavior change wheel [17] model comprising a total of 24 weekly sessions (12 weeks of intensive and 12 weeks of maintenance program). Knowledge/empowerment, goal setting, outcomes expectations, self-monitoring, modeling, social support, personalization, and problem solving were the behavior change techniques applied [18]. They were delivered by a range of software functionalities such as short educational readings and videos, graphical and interactive tools, qualitative and quantitative (food diary) dietary monitoring, physical activity self-monitoring tasks, interactive games that created opportunities to invite friends and adopt healthy habits in daily life, and an online social network moderated by physicians and dietitians (Table 1). Personalized feedback on achievements and suggestions of strategies to improve their success in accordance to their individual goals were provided to participants from the fourth week of the intervention. This personalized feedback was generated by a computational algorithm that took into account the goals set by each individual participant, data on habits reported by them in initial questionnaires and through the self-monitoring tools, and patterns of use of the platform (types of functionalities most and least used by each participant) during the first 4 weeks. This platform was adapted from commercial software that had been used for multiple workforce behavior change/wellness interventions in Brazil and is described at length in Beleigoli et al [16].

The platform + coach group followed the same 24-week weight loss program delivered by the platform enhanced by a 12-week initial course of online personalized education and feedback by a dietitian. In addition to the interactions with the platform depicted in Table 1, participants in this group could interact with a dietitian through a private chat forum embedded in the platform. The interactions could be initiated by either side. There was not a limit around the number of interactions that could occur.

Table 1. Interactions participants could have with the platform in the two intervention groups.

Category	Interaction
Social	Open the online social network; create or interact with a personal or public post or comment
Self-reporting	Report of a behavior or outcome or entries in the food diary
Content	Read a text or watch a video
Profile	Interaction with profile for personal data visualization

First 24 Hours of the Intervention

The first 24 hours of the intervention were dedicated to onboarding, including introduction and basic tutorial. Users were informed about which group they were assigned to during onboarding and by email. Both intervention groups (platform and platform + coaching) had access to the same platform and content. Additionally, the platform + coaching group had access to a prerecorded video of the coach welcoming participants to the group. No additional messages were exchanged during the initial 24 hours.

Data Collection

Baseline data were collected during enrollment and included self-reported anthropometry (weight, height), physical activity and sedentary behavior (short form of the International Physical Activity Questionnaire [19]), health perception (single question derived from the Short Form 36), overall health status (modified from the Short Form Six-Dimension [20]) and exercise stage of change (adapted from Sutton et al [21]); all questionnaires in the validated Brazilian version. We also collected information about health goals, education, and marital status.

To evaluate food content, questions were asked about the total number of daily servings of fruit and vegetables, whole carbohydrates sources, and weekly servings of sweetened beverages and snack foods. This questionnaire was adapted from Molina et al [22]. Eating behaviors were evaluated by including number of days having breakfast, number of daily meals, frequency of take-away food consumption, and eating while watching television. These questions were derived from a dietary guideline tailored to the Brazilian population [23].

For both the food content and eating behavior questionnaires, each question was scored ranging from 1 to 5, with higher scores reflecting higher frequency of recommended habits (eg, consumption of fruits and vegetables and number of days having breakfast) and lower frequency of eating habits that should be avoided (eg, daily consumption of sweetened beverages or eating while watching television). Scores were then averaged to find the final result for each questionnaire.

Additionally, user interactions (clicks and page transitions) were recorded and stored in access logs. Access data were time stamped, categorized according to type of interaction (see Table 1), and filtered to only include data from 24 hours after initial log-in.

Due to intervention design, the initial interaction of control group with the platform was very limited. Additionally, continuous adherence was also limited and, therefore, we excluded this group from the current analysis.

Outcomes

For this substudy, adherence and weight loss within 24 weeks of the beginning of the intervention were the outcomes of interest. Adherence was defined as the number of distinct days each user logged in to the platform during the first 24 weeks of the intervention. Weight was self-reported by participants at baseline and 24 weeks after the beginning of the intervention. Weight loss was defined as the difference in weight between these two points in time.

Statistical Analysis

To find the main categories of weight loss intervention users, we analyzed data using latent profile analysis (LPA), a mixture model suited for recovering hidden groups from data [24]. This method is a commonly used cluster method that categorizes individuals into 1 of n groups (or classes), making the findings easier to interpret while losing the least amount of information.

To select the variables used, we initially included all variables describing baseline characteristics (age, eating, and exercise behaviors) and user interactions with the system in 24 hours. Variables that prevented the model from converging or reduced accuracy were removed. The period considered to collect user interactions (24 hours) was selected due to a high number of users (27%) who didn’t return to the app after the first session.

To prevent disproportionate influence from variables with different magnitudes, continuous data were normalized (mean = 0 and standard deviation = 1). Subsequently, we ran the LPA algorithm. To find the best fit, we compared models using different parameters such as the number of possible classes and which variables should be included in the model. We progressively removed variables from the model and ran the algorithm with a growing number of classes, starting at 1 and moving up to 6 classes. The best model was selected using two criteria: Bayesian information criterion (BIC) and highest entropy. The BIC has been shown as a good indicator to select the correct number of classes in mixture models [25]. A lower BIC means a better fit. Entropy is a measure of accuracy (ie, how much each individual belongs to the class it was assigned by the algorithm). High entropy means the individuals were well classified in the groups. Models with similar BIC and entropy were selected based on theoretical plausibility and parsimony.

Finally, we analyzed how classification into the newfound groups predicted future adherence to the intervention and weight loss at 24 weeks (6 months). To test whether the groups are related to long-term adherence and weight loss, we performed the Kruskal-Wallis nonparametric test with a .05 significance level.

Missing weight data at 24 weeks was imputed by fitting logistic and linear regression models with both the predictors and outcome as well as with other variables regarded as important to explain the missing values. This procedure generated 5 complete data sets, which were used to estimate the association between group allocation and primary and secondary outcomes.

We used Python packages Pandas [26] and Scipy [27] for data preprocessing and statistical analysis, respectively. For the LPA, we used the R package tidyLPA [28]. Multiple imputation was performed using SPSS (version 18, IBM Corp).

Ethics

The study was approved by the ethics committee of the Universidade Federal de Minas Gerais (CAAE: 73545717.5.0000.5149). All participants signed an online informed consent form prior to recruitment.

Results

Of the 1298 patients enrolled in the POEmaS trial, 828 were randomly assigned to the intervention arms (420 in the platform only group and 408 in the platform + coach group) and included in this analysis. Baseline characteristics can be found in Table 2.

The model with best fit was found using the number of self-report interactions during first 24 hours and scores for 4 questionnaires: the Modified Short Form Six-Dimension, Self-health evaluation (extracted from a single question derived from the Short Form 36), Eating behavior (higher scores means higher frequency of recommended eating habits), and food content (higher scores means frequent consumption of recommended foods such as fruits and vegetables). The optimal number of classes according to the BIC measure was 3, with a BIC 14,833 (see Figure 1).

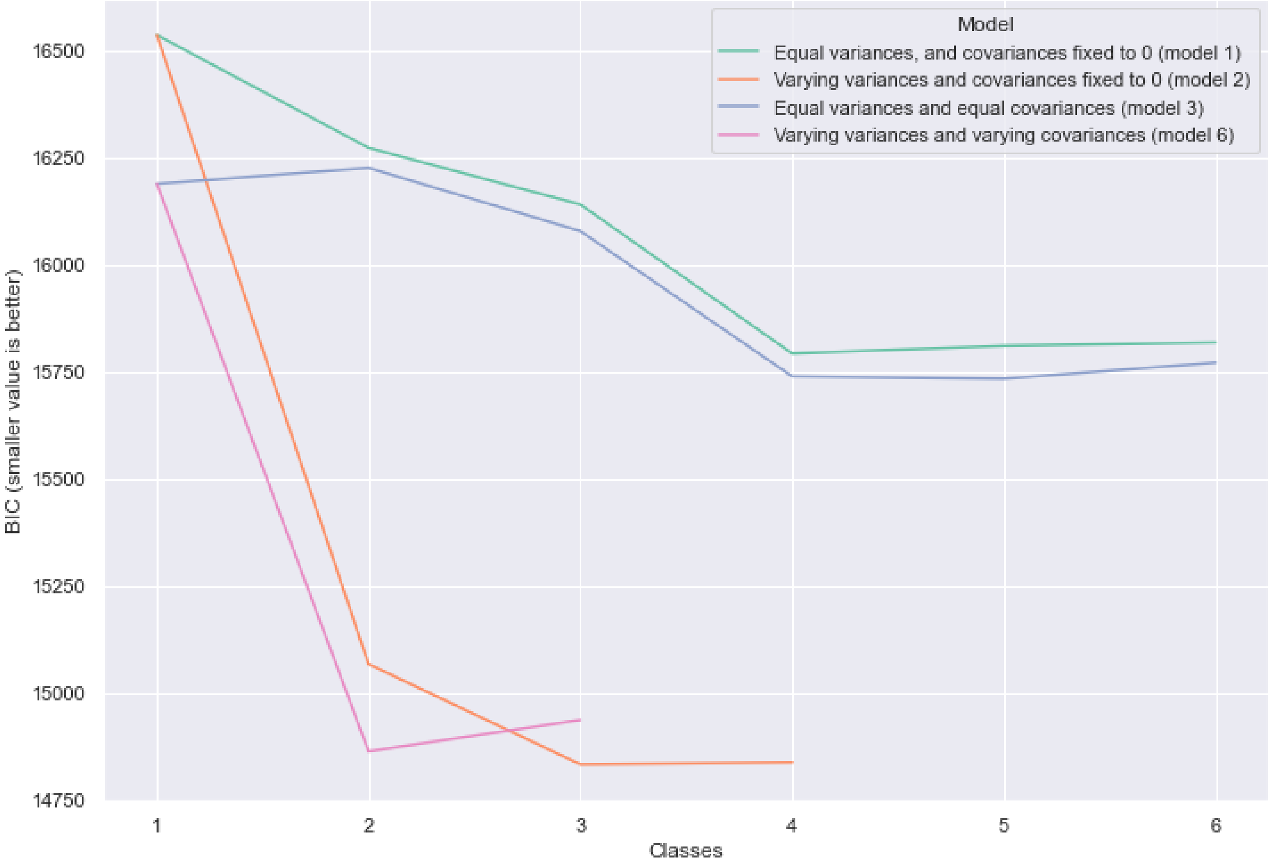
Table 2. Baseline characteristics of the groups included in the analysis[a].

Characteristic	Platform only group (n=420)	Platform + coach group (n=408)
Weight (kg), mean (95% CI)	83.4 (81.7, 85.0)	82.3 (80.8, 83.7)
Age (years), mean (95% CI)	34.4 (33.4, 35.6)	33.0 (31.9, 34.0)
BMI (kg/m^2), mean (95% CI)	30.12 (29.67, 30.58)	29.85 (29.44, 30.26)
Female, n (%)	315 (75.0)	319 (78.2)
Stages of change for physical activity[b], n (%)		
Precontemplation	12 (2.9)	15 (3.7)
Contemplation	163 (38.8)	126 (30.9)
Preparation	96 (22.9)	94 (23.0)
Action	79 (18.8)	91 (22.3)
Maintenance	45 (10.7)	43 (10.5)
Did not respond	25 (6.0)	39 (9.6)

[a] Control group participants were excluded from this analysis since they had limited interaction with the platform.

[b] Precontemplation: not intending to engage in physical activity within 6 months; contemplation: intending to engage in physical activity within 6 months; preparation: intending to engage in physical activity within 30 days; action: physically active for less than 6 months; maintenance: physically active for more than 6 months.

Figure 1. Comparison of different numbers of classes and models as measured by the Bayesian information criterion indicator.



The 3 distinct groups identified presented significant differences between them (see Figure 2), and the accuracy of the model in correctly classifying individuals was 0.89 as measured by the entropy indicator (entropy for the 2-class model was 0.82 and for the 4-class model was 0.79). Their characteristics are described in Table 3.

There were no significant differences in terms of marital status. Individuals in class 1 had more education years than classes 2 and 3, with 50% graduate students or alumni compared to 40% and 20% in classes 2 and 3, respectively (*P*<.001).

Individuals in class 1 were more likely to select a goal than those in classes 2 and 3, but the choice of goal (lose weight or improve habits or health) was similar in all classes.

At baseline, the classes were significantly different in terms of BMI (*P*=.04), although the difference was small and not clinically important. Users classified as class 1 had a lower BMI, while users in class 3 had a higher BMI than the other classes. Classes also differed according to the number of users assigned to different interventions, with 56% (107/190) of users in class 3 assigned to coaching as compared to 41% (107/260) in class 1.

Figure 2. Classes identified in the latent profile analysis as described by the normalized variables.

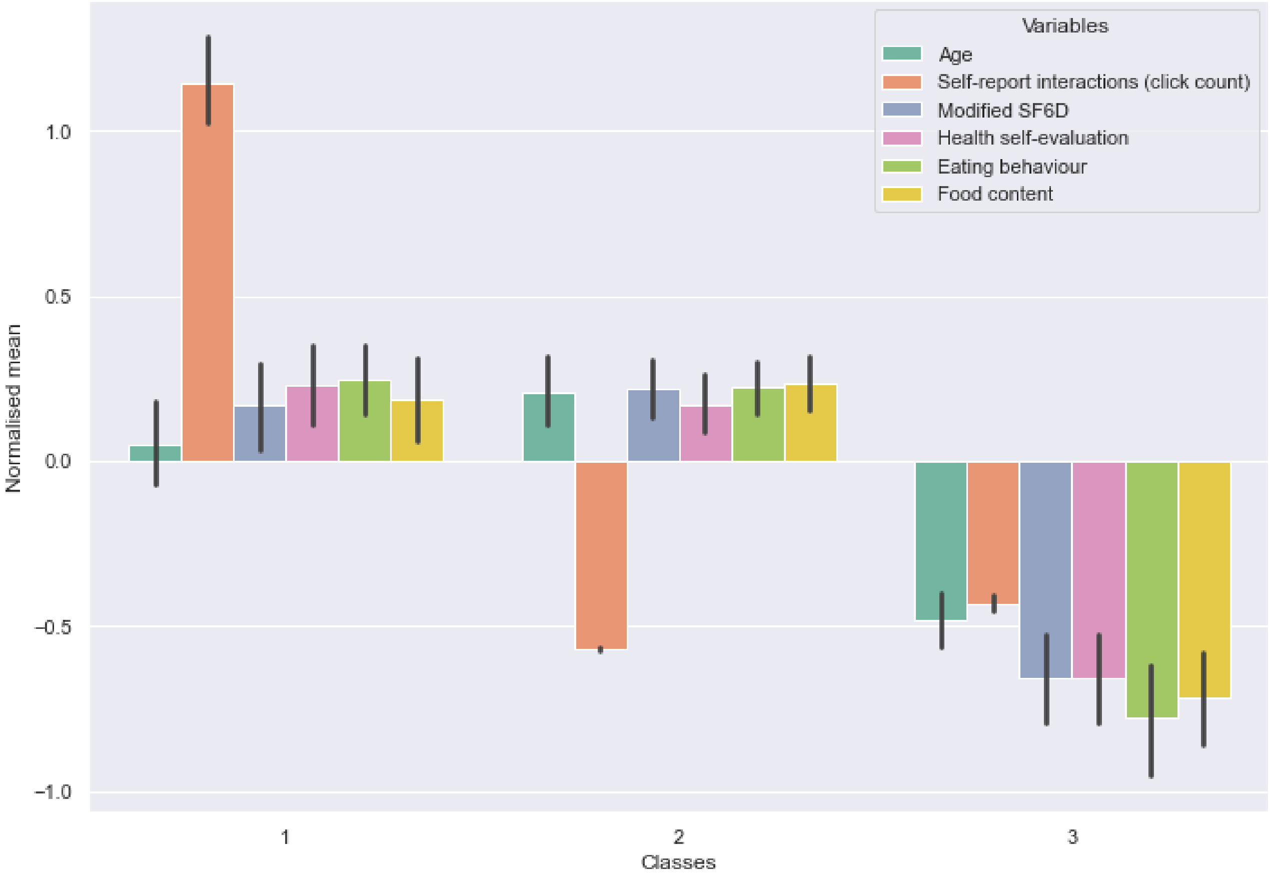


Table 3. Characteristics of users according to latent profile groupings.

Covariates	Class 1 (n=260)	Class 2 (n=378)	Class 3 (n=190)	*P* value

Associations With Weight Loss and Program Adherence at 24 Weeks

There was a significant difference ($P<.001$) among the classes regarding adherence. Class 1 users were more adherent to the intervention than other users, followed by users in class 2. There was no statistically significant difference in weight loss at 24 weeks (Table 4).

To control for the potential influence of intervention assignment at baseline, we stratified the classes by intervention. The stratification did not change the results. The number of sessions was still significantly different within the platform only group and platform + coach group. Weight loss was not significantly different among users in different classes.

Finally, to investigate whether any particular class of individuals would benefit from different interventions, we stratified participants by class and analyzed their weight change at 24 weeks (see Table 5). Individuals in class 2 who were assigned to the platform + coach intervention had a significantly larger weight loss than those assigned to platform only. The other classes showed no significant difference.

Table 4. Number of sessions and weight change at 24 weeks by class.

Outcome	Class 1	Class 2	Class 3	*P* value
Sessions completed in 24 weeks, mean (SD)	9 (19)	6 (12)	4 (6)	<.001
Weight change at 24 weeks (kg), change (SD)	–1.3 (3.6)	–1.2 (3.7)	–1.5 (3.2)	.49
Platform only				
Sessions completed in 24 weeks, mean (SD)	7 (17)	5 (7)	4 (6)	.001
Weight change at 24 weeks (kg), change (SD)	–1.2 (3.5)	–0.8 (3.4)	–1.4 (3.3)	.27
Platform + coach				
Sessions completed in 24 weeks, mean (SD)	12 (22)	7 (15)	4 (5)	<.001
Weight change at 24 weeks (kg), change (SD)	–1.3 (3.7)	–1.7 (3.8)	–1.6 (3.2)	.12

Table 5. Differences in weight change at 24 weeks by class.

Outcome	Platform only	Platform + coach	*P* value
Class 1			
Number (%)	153 (59)	107 (41)	—[a]
Mean weight loss in 24 weeks (kg), mean (SD)	–1.24 (3.48)	–1.34 (3.70)	.93
Class 2			
Number (%)	184 (49)	194 (51)	—
Mean weight loss in 24 weeks (kg), mean (SD)	–0.80 (3.43)	–1.67 (3.82)	.02
Class 3

Discussion

Principal Findings

Our data suggest that 3 class groups of users that differ by preintervention characteristics and use within the first 24 hours of the intervention are related to adherence and weight loss outcomes in an RCT testing a web-based platform with and without online coaching for adults with overweight or obesity. The first group (class 1) was composed of users with better eating habits and higher use in the first 24 hours with a lower baseline BMI. The second and largest group (class 2) was balanced in terms of both healthy/unhealthy habits and low/high first 24-hour use. This group was slightly older and had an average BMI similar to that of the whole population. The third and smallest group (class 3) was formed by users with the worst habits and lowest use in 24 hours. This class had higher baseline BMI and younger age than the other groups.

Analyzing the groups' characteristics at baseline and their longitudinal behavior reveals some insights to help plan future interventions. The first insight is that clustering using 24-hour and baseline data was predictive of higher adherence to the platform 24 weekly sessions. Early identification of the class 2 individuals can help intervention developers adopt different strategies to promote adherence, such as active communication or change in platform content/value proposition. This suggestion is further reinforced by the differences in weight loss between class 2 individuals assigned to platform and platform + coach. The coaching introduces an active component to the intervention that seems better suited to these individuals and resulted in improved weight loss in this study. Enhancing motivation is a key coaching role, so it probably removes some of the effect of preintervention motivation [29].

The second and most important finding, but perhaps least surprising, was that adherence was highest among the class 1 individuals and smallest in class 3. This suggests that this digital health intervention was used by individuals who needed it the least and was dropped by those who would benefit most from it. The path to changing behaviors associated with weight loss depends on a combination of emotional factors, motivation, knowledge, and external factors. Behavior change theories and frameworks, such as the transtheoretical model [13] and the behavior change wheel [17], posit we should consider current individual needs and stages of change to design successful strategies. This is reflected by the higher proportion of users in the action or maintenance phase (physical exercise) in class 1 compared to class 3 individuals. It is also reflected in the larger proportion of individuals choosing health goals, a characteristic of individuals in later phases of change.

This finding reinforces the opportunity for tailoring apps to user current needs. Commonly offered functionalities, such as calorie counters, are better suited to individuals in preparation and action phase. This may explain why studies show a higher baseline BMI and poorer health status in noncompleters [30]. Results also suggest goal setting as a desired functionality for class 1 individuals. This is recommended, given the evidence that goal setting promotes behavior change [31,32]. The 3 groups identified in this study provide an empirical starting point to guide development of different products for different segments.

An innovation in this study was to use the initial 24 hours of user interactions as a latent profile determinant. These interactions may carry information on digital literacy, prior motivation, and whether users immediately perceive the interventions' value. Early intervention use patterns will vary according to onboarding process and interaction flow. Therefore, it is envisaged that any system collecting interaction data to group users into the 3 classes will require identifying which interaction is most reflective of the initial variable engagement. Finally, in real-world interventions, early interaction may be influenced by factors unrelated to motivation, such as device (mobile vs desktop) or environment where enrollment occurs (work vs home). When known, these factor should be considered to calibrate interaction information.

In this study, the type of intervention had a small but significant influence on the latent profile classification, evidenced by the higher proportion of platform only users in class 1. This was unforeseen, given that data used to discriminate the classes were limited to that collected during the initial 24 hours of the intervention. Additionally, users assigned to different interventions (platform only and platform + coaching) received remarkably similar interventions, with two differences: users in the second group were informed they were assigned to coaching, and they saw a prerecorded video with a welcoming message by the coach. However, our analysis showed that intervention assignment was not the main driver of adherence predicted by the latent profile. Segmented analysis of the platform only and platform + coaching users revealed similar results of differences in adherence between classes.

Strengths and Limitations

Our understanding about users of digital health interventions aimed at promoting weight loss was facilitated by the very inclusive and pragmatic strategy for recruiting participants. The strategy used for recruiting and the low barrier for joining the intervention mimicked real-life interventions, allowing us to measure how users react outside of controlled trial settings. The use of LPA as a cluster method allowed an improved understanding of users of weight loss interventions. Furthermore, due to the longitudinal nature and multiple repeated measures of outcomes collected, we could analyze the power of the identified classes at baseline in predicting weight loss and adherence at 24 weeks.

Limitations of this study include the self-report nature of questionnaire data, which can carry misclassification biases. Given recruitment happened at a university, the study population may not reflect the general population. This can affect the number of classes identified. Finally, enrollment was an active process that may have selected individuals more likely to benefit from it.

Implications to Future Research

The intervention planned for the POEmaS project was designed with an active user in mind. In other words, it required users to log in to the platform, report their activities, and interact in the social network. Such interaction was not suitable for the class 3 individuals, evidenced by the large number of users who didn't return to the intervention. Being able to predict nonadherence allows developers to explore tailoring the intervention, possibly improving intervention effect. The question of how it could be tailored requires further investigation. This study suggests human intervention (coaching) can have a positive effect for class 2 individuals. Additional avenues of investigation include changing the number of active interventions (notifications, emails, or text messages), the content of the messages (focused on contemplation), and understanding the use of gamification techniques aimed at different groups.

This study also highlights the importance of considering the heterogeneity of users when creating and reporting digital health interventions. Any given intervention will affect individuals in different ways based on their baseline habits and motivation. Enrollment strategies may bias the sample (eg, by requiring more active effort before enrollment vs paying participants to complete a study). Setting (clinic, community), barriers to join the intervention (upfront costs, long registration forms, and commitment mechanics), and recruitment method (mailing, targeted communication) all have an impact on selecting the population and, therefore, can influence results. While an additional challenge for creating quality evidence for digital health interventions, careful description of the baseline characteristics and prior motivation of the population groups will create deeper understanding about which intervention is useful for each user.

Conclusions

Three major groups of weight loss intervention users were identified in a large RCT. Baseline questionnaires and use data from the first 24 hours after log in allowed distinguishing classes, which were highly related to long-term adherence. Individuals classified as class 2 lost more weight when assigned to platform + coach than platform only, suggesting this early classification may be a useful guide to intervention selection. These results encourage efforts for early identification of effect predictors to trigger more effective interventions.

Acknowledgments

We acknowledge the priceless contributions of Dr Roberta Alvares, Leonardo Andrade, and Tiago Sizenando to this study. This study was supported with grants from the National Institute of Science and Technology for Health Technology Assessment (CNPq) of Brazil. AB was supported by Prêmio Coordenação de Aperfeiçoamento de Pessoal de Nível Superior de Teses. Abstract

Background: Missing data are common in mobile health (mHealth) research. There has been little systematic investigation of how missingness is handled statistically in mHealth randomized controlled trials (RCTs). Although some missing data patterns (ie, missing at random [MAR]) may be adequately addressed using modern missing data methods such as multiple imputation and maximum likelihood techniques, these methods do not address bias when data are missing not at random (MNAR). It is typically not possible to determine whether the missing data are MAR. However, higher attrition in active (ie, intervention) versus passive (ie, waitlist or no treatment) conditions in mHealth RCTs raise a strong likelihood of MNAR, such as if active participants who benefit less from the intervention are more likely to drop out.

Objective: This study aims to systematically evaluate differential attrition and methods used for handling missingness in a sample of mHealth RCTs comparing active and passive control conditions. We also aim to illustrate a modern model-based sensitivity analysis and a simpler fixed-value replacement approach that can be used to evaluate the influence of MNAR.

Methods: We reanalyzed attrition rates and predictors of differential attrition in a sample of 36 mHealth RCTs drawn from a recent meta-analysis of smartphone-based mental health interventions. We systematically evaluated the design features related to missingness and its handling. Data from a recent mHealth RCT were used to illustrate 2 sensitivity analysis approaches (pattern-mixture model and fixed-value replacement approach).

Results: Attrition in active conditions was, on average, roughly twice that of passive controls. Differential attrition was higher in larger studies and was associated with the use of MAR-based multiple imputation or maximum likelihood methods. Half of the studies (18/36, 50%) used these modern missing data techniques. None of the 36 mHealth RCTs reviewed conducted a sensitivity analysis to evaluate the possible consequences of data MNAR. A pattern-mixture model and fixed-value replacement sensitivity analysis approaches were introduced. Results from a recent mHealth RCT were shown to be robust to missing data, reflecting worse outcomes in missing versus nonmissing scores in some but not all scenarios. A review of such scenarios helps to qualify the observations of significant treatment effects.

Conclusions: MNAR data because of differential attrition are likely in mHealth RCTs using passive controls. Sensitivity analyses are recommended to allow researchers to assess the potential impact of MNAR on trial results.

Introduction

Background

In the world of mobile health (mHealth), high and rapid attrition is the rule rather than the exception [1]. This *law of attrition* [1] applies both to the use of mHealth interventions in naturalistic settings (eg, internet-based interventions for anxiety and depression [2]) as well as to studies designed to test the efficacy of mHealth interventions (eg, randomized controlled trials [RCTs] of smartphone-based interventions for mental health problems [3]). Attrition in naturalistic settings involves nonusage or discontinuation of usage, whereas attrition in research settings can involve these usage patterns along with dropouts from the study itself [4]. Nonusage and discontinuation of usage can limit the therapeutic potential of mHealth, and the development of methods to increase the sustained uptake of mHealth interventions is an area of active research [5,6]. In research contexts, attrition can not only attenuate therapeutic effects but can also produce additional problems such as reduced statistical power and the introduction of bias. This bias can skew results and limit the generalizability of the study findings (eg, only able to generalize to those who continue use). Various methods have been proposed to prevent attrition in mHealth research (eg, making interventions more engaging, implementing a *run-in* period before randomization, and including remainders and financial incentives [3,7]). However, to date, high attrition appears to be the rule rather than the exception of mHealth research [3].

Attrition in research contexts typically results in missing data. Some exceptions to this may include measures that continue to be assessed regardless of ongoing study participation (eg, smartphone app usage). Nonetheless, decades of methodological work have focused on characterizing the various types of missing data and developing statistical approaches for handling missingness [8,9] (for a more thorough discussion of the various types of missing data and methods for handling them, interested readers are directed to Enders [8] and Graham [9]; for a tutorial specifically geared to nonstatistician mHealth researchers, refer to Blankers et al [10]). There are three basic types of missing data that can be distinguished by their presumed cause as well as their impact on statistical tests [9]. The first and most benign type is data that are missing completely at random (MCAR). For example, an RCT testing a smartphone-based intervention for depression compared with a waitlist control group. In this context, it is common for posttreatment depression scores to be missing for a subset of participants [11]. If the missing data are MCAR, the cases with missing values can be viewed as a random sample of all cases. As such, the missing values did not systematically differ from the observed values. Statistical tests that ignore missing cases (eg, listwise deletion) provide unbiased estimates of parameter values, albeit with reduced statistical power. The second missing data type is data that are missing at random (MAR). For MAR data, the missing value (eg, posttest depression scores) does not depend on the missing value itself (ie, whether the missing score, if observed, would have been high or low) but depends on the observed data. For example, missingness may be more likely for those who had higher depression scores at baseline or were younger, but conditional upon such variables, the outcomes for missing cases resemble those of the observed cases (MCAR is actually a special case of MAR, specifically one in which the missing values are neither associated with observed values or missing values). Similar to MCAR, MAR data can also be analyzed in ways that produce unbiased parameter estimates, provided observed variables on which the missing value depends are included in the imputation and analysis model. Most recent advances in missing data analysis operate under the assumption of MAR. Multiple imputation (MI) and maximum likelihood (ML) are two widely used modern statistical methods that effectively use observed data for unbiased and statistically efficient (ie, not underpowered) analysis of MAR data and can also be applied to MCAR data.

Missing data that are MCAR and MAR are relatively straightforward to handle (so-called *ignorable* missing data [9]). In contrast, data that are missing not at random (MNAR) are a larger problem (ie, not ignorable), particularly when there is a substantial amount of missing data (eg, >5% [9]). For MNAR data, missingness depends on the value of unobserved data. For example, those who would have reported higher depression symptoms posttreatment may be more likely to drop out. The consequences of MNAR in RCTs can be substantial. In our depression RCT example, we found that participants in the active condition (ie, the intervention arm) were more likely to have missing posttest depression scores than the waitlist control (ie, passive control). It is generally impossible to demonstrate that data are MNAR, and simply having differential attrition does not necessarily indicate MNAR data or lead to biased results [12]. Although MNAR cannot be assessed directly, we might speculate that participants in the active condition who did not benefit as much from the smartphone-based intervention may be more likely to drop out of the study (refer to Crutzen et al [13] for similar possibilities offered to explain higher attrition in treatment vs control conditions in health behavior change interventions). This could be because of, for example, the greater effort required to participate in the treatment arm, especially if experiencing higher levels of depression. Such a relationship may well supersede what can be explained by the other measured variables for such subjects. In this case, the likelihood of having an unobserved posttest depression score is dependent on the value of the score itself, had it been observed. Thus, we are under the condition of MNAR. Further, the consequences of the MNAR on the estimation of treatment effects may be substantial, leading to an overestimation of the effect of the treatment because of missing observations. It is theoretically possible that the influence of MNAR data is reversed, with those dropping out experiencing better rather than worse outcomes (eg, dropping out of the study because one's symptoms have already improved). This possibility is viewed as unlikely in related disciplines (eg, addiction research [14]). Lacking data or a strong rationale suggesting that missingness because of improved outcomes is likely in mHealth research, we focus on the more plausible MNAR mechanism of individuals who fail to respond to be those most likely to discontinue study participation.

Unlike MCAR and MAR missingness patterns, MNAR cannot be easily handled in a confident manner. Moreover, MNAR can have multiple causes, making it difficult to develop a single method that can universally address it, even in a single study. As a result, some form of sensitivity analysis is recommended to understand the possible effects of MNAR [12,15]. Advanced tools for evaluating the consequences of MNAR data have been developed, most notably selection models [16] and pattern-mixture models [17]. These models accommodate the joint distribution between the probability of missingness and the observed data and can be powerful techniques for evaluating the impact of MNAR. At once, understanding and implementing selection models or pattern-mixture models is a high bar for many applied researchers who may be faced with MNAR data. These models also involve untestable assumptions whose violations can produce biased results [8,18]. Thus, the application of MNAR procedures is undertaken more in the spirit of understanding the possible implications of missingness rather than explicitly correcting it. This approach is consistent with viewing missing data on a continuum from MAR to MNAR and focuses on evaluating whether the results are robust to MAR assumptions implicit in MI and ML analytic approaches [9].

Other methods have been proposed to assess the influence of MNAR data. The combination of high attrition and data that are potentially MNAR is not unique to mHealth research, and several approaches have come from the addiction field [19,20]. A classic example of MNAR data occurs in smoking cessation research, where individuals who drop out of the study are more likely to have returned to smoking. Historically, a widely used approach to handling missing smoking cessation data is simply to assume that missingness equals smoking [14]. This approach is considered conservative and is arguably preferred over treating the missing values as MAR or MCAR. However, assuming missing equals smoking can also introduce bias [21]; for example, if missingness is strongly related to group assignment in the context of an RCT and not all participants who drop out, in fact, return to smoking (eg, higher attrition in the waitlist vs nicotine patch condition).

Hedeker et al [14] offered a sensitivity analysis approach for evaluating the impact of MNAR on study results within the context of smoking cessation that could be adapted for use in mHealth research. Specifically, Hedeker et al [14] recommend evaluating the sensitivity of results to varying assumptions about the smoking status for those with missing data [14]. Models range, for example, from assuming a perfect association between missingness and smoking (ie, missing=smoking) to assuming that the odds of smoking for an individual with missing data are between 2 and 5 times higher than those with nonmissing data [14,22]. If the results are robust to variations in the assumed value of missing data, one can be more confident that the potential MNAR does not undermine the findings. If the results change, one can also characterize the point at which this occurs (eg, shifting from statistical significance to nonsignificance). Similar approaches have been proposed in other fields as well (eg, cost-effectiveness analyses) and incorporated into a broader MAR framework (eg, MI [23]).

Despite a longstanding acknowledgment that missing data are common in mHealth research [1], to our knowledge, there has not been a systematic investigation of the nature of missing data (ie, MAR vs MNAR) and no recent evaluation of the ways in which study authors are handling missing data (for an older review of missing data analysis techniques in internet-based interventions for anxiety and depression, refer to Christensen et al [2]). As noted, it is unfortunately not possible to definitively determine whether missing data are MAR or MNAR [8]; by definition, one cannot establish an association between the likelihood of a missing value and the unobserved value itself. Some readers may be familiar with Little [24] MCAR test, which is designed to evaluate the likelihood of MCAR across a data set. Although it is tempting to consider this as a reliable option for establishing missingness as MCAR, it has a number of substantial drawbacks, including low power (which can lead to failure to reject the null hypothesis that data are MCAR), unlikely and untestable assumptions (eg, shared covariance matrix among miss data patterns), and failing to identify specific variables that violate MCAR (ie, providing only an omnibus test [8]). In the absence of a method for determining whether data are MNAR, one could argue that it is incumbent upon researchers to consider whether their handling of potentially MNAR data yields biased results.

As noted above, a pattern of missingness that may be suggestive of MNAR in mHealth research is when missingness is higher in an active condition relative to a passive (eg, waitlist) control group. The context of an RCT is important for making this claim. Random assignment should produce groups balanced on all relevant covariates at baseline, including those that would predict drop out [25]. As attrition would be caused, at least in part, by group assignment (ie, active vs waitlist), it is, therefore, important to speculate on the primary mechanism by which treatment creates missingness. In the context of mHealth, one could easily imagine that active participants are more likely to drop out because of the increased burden associated with their intervention. Presumably, participants who find the burden of remaining engaged to exceed the benefits (or lack of benefits) they are experiencing may be most likely to drop out. Likewise, participants who experienced adverse reactions to the intervention itself would be more likely to drop out. In both instances—participants failing to realize benefits or experiencing adverse reactions—missing posttreatment data are likely MNAR, with unobserved scores on average reflecting less improvement than observed scores. Regardless of the specific cause, the meaning of missingness in the active condition will almost certainly not be equivalent to the missingness in waitlist control. This makes it problematic to treat missing data as reflecting the same outcomes as others in their respective groups, which is precisely what MAR methods do.

A recent meta-analysis of attrition in RCTs testing smartphone-based mental health interventions [3] found evidence consistent with this potential source of MNAR data. Linardon and Fuller-Tyszkiewicz [3] noted that active participants were significantly more likely to drop out of the RCTs than the passive control group participants (odds ratio [OR] 1.87, 95% CI 1.45-2.41, across all follow-up time points). In contrast, this differential attrition was not observed when an active control condition was used (OR 1.13, 95% CI 0.91-1.42). As Linardon and Fuller-Tyszkiewicz's [3] study was not primarily focused on differential attrition, they did not further explore the possibility of MNAR or its implications, nor did they conduct standard meta-analytic sensitivity analyses for this specific effect (eg, trim-and-fill adjustment [26]). It would be valuable to extend this finding by systematically evaluating how differential attrition is handled statistically in these mHealth RCTs and examining study design features associated with higher rates of differential attrition (ie, meta-analytic moderators).

In addition to further clarifying how differential attrition and potential MNAR are handled within the mHealth literature, there is a need to understand the potential implications of MNAR for study outcomes. Selection models and pattern-mixture models are two promising approaches. Sensitivity analyses such as those recommended by Hedeker et al [14] for smoking cessation could also be readily adapted for mHealth research.

This Study

This study has 2 primary aims. The first is to systematically review the analytic methods used to address missingness in a portion of the mHealth literature that has previously shown indications of potential MNAR. We examined 36 RCTs drawn from Linardon and Fuller-Tyszkiewicz's [3] recent meta-analysis of smartphone-based mental health interventions that compared active interventions and passive controls. To examine statistical moderators of differential attrition, we coded attrition and study design features. We then cataloged how missing data were handled within these trials, focusing on whether the statistical approaches could handle MAR or MNAR data.

Our second aim is to present methods for evaluating the effects of MNAR that may be relevant to mHealth research. We illustrate the value of sensitivity analyses by applying an MI-based pattern-mixture model along the lines of Hedeker et al [14], as well as a simpler fixed-value replacement sensitivity analysis as examples of informative methods for evaluating the impact of MNAR. To illustrate these approaches, we use data drawn from a recent RCT of a smartphone-based mental health intervention comparing 2 active conditions with a waitlist control group [27].

Methods

Assessment of MNAR and Systematic Review of Missing Data Analytic Approaches

To evaluate study design features associated with differential attrition and the methods used to handle missing data, we reanalyzed and systematically reviewed RCTs included in the meta-analysis of attrition in smartphone-based mental health interventions by Linardon and Fuller-Tyszkiewicz [3]. This meta-analysis is recent and includes a reasonably large sample of RCTs (n=36 studies) that compared active treatment with a passive control condition (ie, waitlist or no treatment). We coded the completer and drop out sample sizes for both active and passive conditions at posttreatment to characterize differential attrition. These values were then converted to ORs using standard meta-analytic methods [26]. Log ORs and their variance were then aggregated using a random effects meta-analysis, weighted as typical using inverse variance [26] in the metafor R package (R Core Team). As ORs and the variance of ORs cannot be computed for cells with zeros, we conducted analyses using the Peto method [28], as recommended in the Cochrane handbook [29]. We also conducted analyses by adding a continuity correction for instances of empty cells (ie, 0.5 added to all cells in a study with an empty cell [30]). Heterogeneity of effect sizes was characterized using I^2 (ie, proportion of effect size variance that occurs between studies) and interpreted based on Higgins et al [31]. We assessed the potential influence of outliers by conducting a *leave-one-out* analysis in the metafor package [32] and using the *find.outliers* function in R [33] that excludes effect sizes whose CI do not overlap with the omnibus effect size CI.

We systematically reviewed several features of the included studies. These included the overall sample size, overall dropout rate, whether potential differential attrition was statistically evaluated (ie, comparing dropout rates for active vs passive conditions), whether differential attrition was detected, the approach used for handling missing data, whether a modern MAR data analytic approach was used (ie, MI or ML), and whether a sensitivity analysis was conducted to evaluate the potential impact of MNAR data. To evaluate whether these study characteristics were linked with differential attrition, we tested them as moderators [26]. All analyses were conducted using R [34].

MNAR Sensitivity Analysis

We used data from a recently conducted RCT testing a smartphone-based mental health intervention [27] to illustrate 2 sensitivity analysis approaches for MNAR data. As many mHealth RCTs include pre- and posttreatment assessments on a continuous variable, we apply these sensitivity analyses using data of this kind. In this study, 2 versions of an active smartphone-based meditation intervention were compared with a waitlist control on changes in psychological distress for 8 weeks (n=343). The original RCT included 3 time points (pretest, midtreatment, and posttreatment), and the primary models used multilevel modeling with ML estimation. However, in keeping with the possibility of MNAR data, attrition was higher in the active intervention than the waitlist (OR 2.10, 95% CI 1.34-3.33).

The first approach is a variant of the pattern-mixture model [23]. First, one conducts MI, imputing missing values based on available data (eg, pretest scores and demographics). Code in Multimedia Appendix 1 implements this in R using the jomo [35], mitools [36], and mice [37] packages with 100 multiply imputed data sets. It is worth noting that a limitation of MI in this context is the likely simulation of a positive treatment effect in the missing outcomes (assuming a positive treatment effect is seen in the observed outcomes), which may not be correct in the presence of MNAR. Thus, we next modify the imputed (ie, previously missing) posttest values using an *offset* parameter representing varying MNAR conditions. In our example, we assume progressively worse outcomes for those with missing posttest values. As a lower distress score is better, we add positive constants defined in relation to the residual SD from a model predicting posttest scores controlling for pretest scores and group status. As the added positive constant increases, the assumed outcome for missing observations becomes progressively worse. To aid in interpretability, we followed Cohen [38] effect size convention and added this value multiplied by 0.20, 0.50, 0.80, 1.10, and 1.40 to the multiply imputed values for cases with missingness. For example, the deviation applied for the 0.20 condition is as follows:

$$\text{Missing} = \text{Multiply imputed value} + 0.20 \times \text{SD}_{\text{Model}} \quad \textbf{(1)}$$

A possible limitation of this approach is that, in the possible absence of useful covariates in predicting missing outcomes, all missing observations will be generated with large SDs, implying a high degree of uncertainty in the missing outcomes. Thus, even when introducing the offset parameter following the pattern-mixture strategy, the observed variability in the missing observations will still be large. To the extent that we should not confuse lack of knowledge about missing outcomes with actual variability in the missing outcomes, a sensitivity analysis that also considers a fixed-value replacement for missing observations can be useful. Therefore, we also applied a second sensitivity analysis approach outside the context of MI. Consistent with our strategy, this second approach focuses on estimating residualized change scores, although simple change scores could also be used. Once residualized change scores are imputed for missing cases, nonparametric tests (eg, Wilcoxon signed-rank test) can then be conducted using these values to compare changes in the active and passive conditions while avoiding statistical drawbacks associated with conducting parametric tests using single imputed data (eg, artificially deflating SE by treating imputed values as if they were observed values [8]). Similar to the approach described above, to evaluate the influence of potential MNAR data, we tested varying assumptions about the meaning of missing posttest data from complete case analysis to a worst-case scenario. The first analysis assumes that the missing data are MCAR and uses complete cases.

$$\text{Complete case analysis: Missing=NA} \quad \textbf{(2)}$$

For the worst-case scenario, the missing data were assumed to reflect the worst possible observed outcome. Residualized change is operationalized as the observed posttreatment score minus the predicted posttreatment score based on pretreatment. For an outcome such as distress, in which lower values are preferred (ie, lower distress), a larger (ie, more positive) residual indicates a smaller decline in distress (for negative values), or even an increase in distress over time (for positive values). For an outcome in which higher scores were better (eg, well-being), one would simply reverse this approach (ie, replace missing values with the minimum observed residual). In our example, the worst-case scenario replaces the missing values with the maximum value of the observed residualized change scores:

$$\text{Worst-case scenario: Missing=Maximum}_{\text{Residual}} \quad \textbf{(3)}$$

We then evaluated possibilities between the complete and worst-case scenarios, with missing values imputed to be 0.20, 0.50, and 0.80 SD from the mean residualized change score. These specific values were chosen to reflect small, medium, and large deviations based on Cohen [38] guidelines. Again, as a lower score is better for distress, these deviations were added to the mean residualized change score (the mean residual is expected to be zero but is included here for the sake of completeness):

$$\text{Small MNAR deviation: Missing} = \text{Mean}_{\text{Residual}} + 0.20 \times \text{SD}_{\text{Residual}} \quad \textbf{(4)}$$

$$\text{Medium MNAR deviation: Missing} = \text{Mean}_{\text{Residual}} + 0.50 \times \text{SD}_{\text{Residual}} \quad \textbf{(5)}$$

$$\text{Large MNAR deviation: Missing} = \text{Mean}_{\text{Residual}} + 0.80 \times \text{SD}_{\text{Residual}} \quad \textbf{(6)}$$

For example, psychological distress in the RCT by Goldberg et al [27] was a composite of 3 measures assessing depression, anxiety, and stress, which were combined into a single measure and scaled to z units (ie, mean 0, SD 1). The mean residualized change in psychological distress was 0 (SD 0.65), and the maximum residualized change in psychological distress was 2.3. Therefore, the worst-case scenario replaced all the missing residualized change scores of 2.3. In the midrange scenarios, missingness was replaced with a small deviation from the mean (0 + 0.2 × 0.65 = 0.13), a medium-sized deviation from the mean (0 + 0.50 × 0.65 = 0.33), and a large deviation from the mean (0 + 0.80 × 0.65 = 0.52). Wilcoxon signed-rank tests compared the rank sum for the active and passive conditions based on the complete case analysis and the 4 scenarios. All analyses were conducted using R [34]. Deidentified data [39] and the R code necessary for conducting the sensitivity analyses are included in Multimedia Appendix 1.

Results

Assessment of MNAR and Systematic Review of Missing Data Analytic Approaches

Linardon and Fuller-Tyszkiewicz’s [3] review included 36 RCTs that compared one or more active conditions with a waitlist control condition. Intention-to-treat and completer sample sizes, along with study characteristics related to missing data analysis, are included in Table 1. The average sample size per study, combined across active and passive conditions, was 143.53 (SD 118.66). Average attrition rates were numerically higher in the active condition (23.32%, SD 19.88%) than in the passive condition (15.36%, SD 15.51%), and 2 studies reported no attrition [40,41]. Among the 34 studies with attrition, a minority (11/34, 32%) statistically compared attrition rates between active and passive conditions. A total of 6 studies detected differential attrition, in all cases reporting higher attrition in the active conditions relative to the passive conditions.

Table 1. Attrition rates and study design characteristics.

[a] Tx: active treatment conditions.

[b] ITT: intention-to-treat sample size; drop=attrition at posttreatment assessment.

[c] WL: waitlist (or no treatment control condition).

[d] Whether differential attrition was tested and, if so, whether a between-group difference was detected.

[e] Primary data analysis method.

[f] N/A: not applicable (because of lack of missing data or differential attrition test not conducted).

[g] ANOVA: analysis of variance or related method (eg, analysis of covariance).

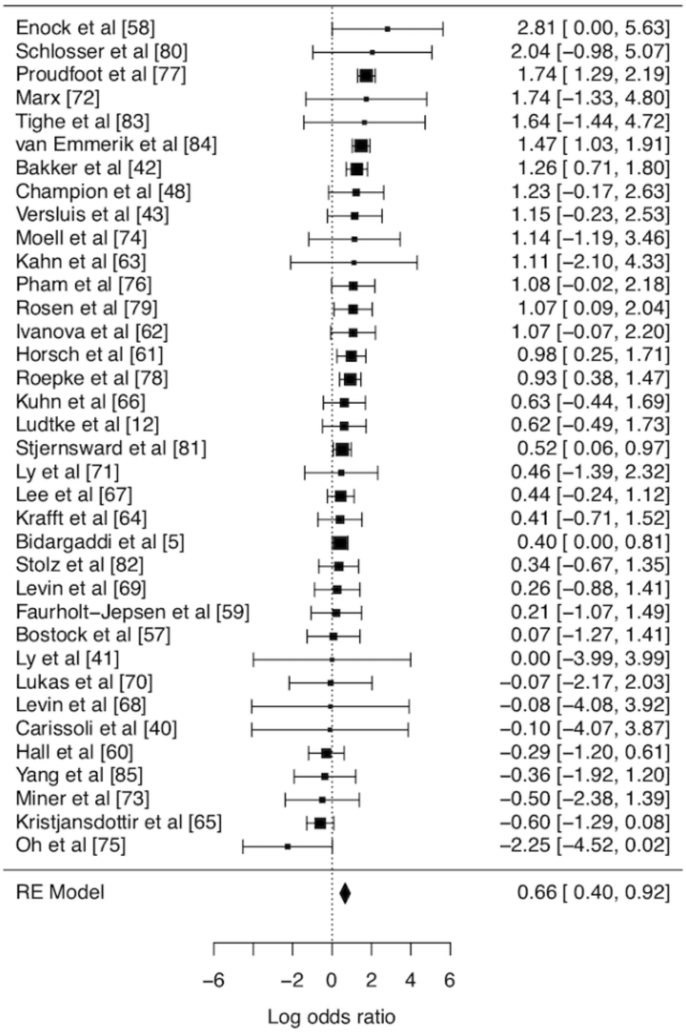
[h] MLM: multilevel model.

[i] Unclear whether multiple imputation estimator was used.

Most studies used multilevel modeling (17/36, 47%) or a variant of analysis of variance (eg, analysis of covariance, multivariate analysis of variance; 16/36, 44%) as the primary analytic approach, with 8% (3/36) of studies using a *t* test. Half (18/36, 50%) of the studies used ML or MI to handle missing data. MI was used in 31% (11/36) of studies, with multiple imputed data sets then analyzed using analysis of variance or *t* tests [5,42]. ML was used in combination with multilevel modeling in 28% (10/36) of the studies. An additional 19% (7/36) of studies used multilevel modeling but did not specify the estimator [72]. No study conducted a sensitivity analysis to evaluate the potential impact of MNAR data.

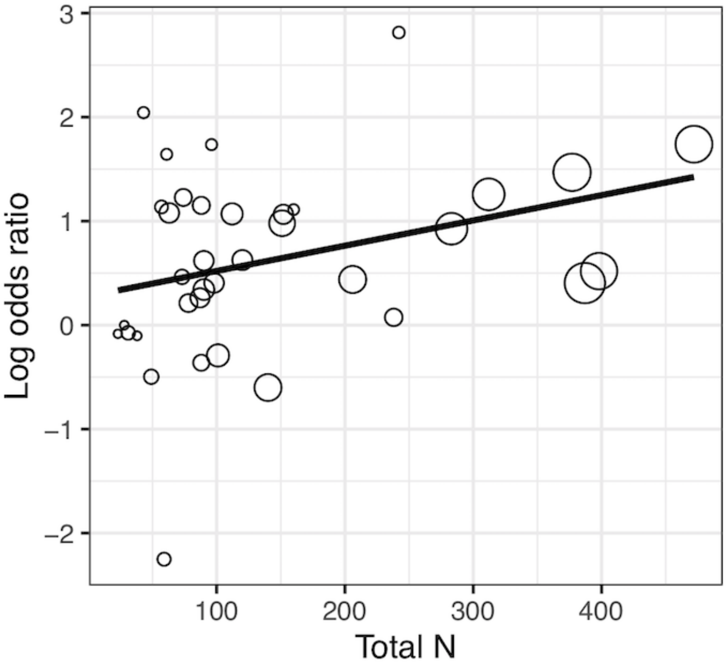
Consistent with Linardon and Fuller-Tyszkiewicz [3], the results of our reanalysis provided a clear indication of differential attrition, with participants randomized to the active conditions approximately twice as likely to drop out relative to those in passive conditions (OR 1.94, 95% CI 1.50-2.51, using the Peto method; OR 2.22, 95% CI 1.93-2.54 using a continuity correction; both *P* values are <.001; Figure 1). The heterogeneity was moderate (I^2=53.85%, 95% CI 19.46-71.09). The results were robust to *leave-one-out* analyses (OR range 1.82-2.10; all values of *P*<.001). The *find.outlier* function detected 4 outliers. Results were similar with these studies removed (OR 1.91, 95% CI 1.58-2.32; *P*<.001).

Figure 1. Forest plot displaying results of the meta-analysis. Effects sizes are in log-odds units, with larger values indicating higher attrition in active conditions relative to passive conditions. The size of points indicates relative weight in the meta-analysis (ie, inverse variance). RE: random effects.



Several potential moderators were assessed using a meta-regression analysis. Active conditions were more likely to show higher attrition than passive conditions as the overall sample size increased (B=0.0022, 95% CI 0.0005-0.0039; note that all meta-regression coefficients are in log OR units; *P*=.01; Figure 2). Higher overall attrition was not associated with differential attrition (B=0.57, 95% CI −0.89 to 2.03; *P*=.45). Studies with higher differential attrition were marginally more likely to test for differences in attrition rates between active and passive conditions (B=0.49, 95% CI −0.002 to 0.99; *P*=.05, where testing=1 and not testing=0). There was no association between differential attrition rate and the likelihood of detecting differential attrition (B=0.55, 95% CI −0.19 to 1.29; *P*=.15, where detecting a difference=1 and not detecting a difference=0). The use of a modern missing data analysis method (ie, ML or MI) was associated with higher rates of differential attrition (B=0.73, 95% CI 0.25-1.2; *P*=.003, where use of ML or MI=1, no use of ML or MI=0).

Figure 2. Results of meta-regression indicating that larger studies are associated with higher rates of differential attrition (ie, higher attrition in active vs passive conditions). Points are displayed relative to their weight in the meta-regression model (ie, inverse variance).



MNAR Sensitivity Analysis

Selection and pattern-mixture models are 2 valuable modeling strategies for handling MNAR (see Multimedia Appendix 2 [8,74,75] for a brief discussion of these methods and their limitations). New strategies and extensions of these approaches are continually being developed (eg, the index of local sensitivity to nonignorability [76]). However, many mHealth researchers may not be familiar with these methods. Selection models, in particular, require the missing data mechanism to be specified, which can be difficult to do. Moreover, a pattern-mixture approach of the kind described above often reflects a larger degree of uncertainty in the missing observations, an uncertainty that should not be confused with the presence of known variability in the missing outcome. Therefore, rather than abandon attempts to assess the potential impact of MNAR, mHealth researchers could consider approaches that simply make specific assumptions regarding anticipated outcomes for missing observations (ie, fixed-value replacement). By examining the estimated treatment effects in the presence of specific assumed outcomes for missing observations, we can similarly provide some insight into the degree to which varying missingness assumptions impact study results [14]. We illustrate both the pattern-mixture model and fixed-value replacement approaches using data drawn from the RCT by Goldberg et al [27].

Of the 343 participants randomized, 228 (66.5%) were assigned to 1 of the 2 active conditions, and 115 (33.5%) were assigned to the waitlist control. Consistent with the possibility of MNAR, noncompletion of posttreatment assessments was higher in the active condition (137/228, 60.1%) than in the waitlist condition (48/115, 41.7%; OR 2.10, 95% CI 1.34-3.33; *P*=.001). Goldberg et al [27] primary analyses used all 3 time points in multilevel models with ML estimation. The results indicated a steeper decline in psychological distress for the active conditions relative to the waitlist (time × group interaction; *P*<.001). Here, we examine how this result changes based on varying MNAR scenarios using either an MI-based pattern-mixture model approach [23] or a fixed-value replacement sensitivity analysis approach.

Table 2 shows the estimates of the effect of group status on posttest distress, controlling for pretest distress across varying MNAR conditions within the pattern-mixture model framework. As the positive constant added (ie, offset parameter) increases, increasingly worse outcomes are assumed for the missing observations. Those in the active group continued to show larger declines in distress until imputed posttest distress scores were offset by a value of 1.10 or greater residual SD. Figure 3 depicts the impact of these varying MNAR conditions. The first panel displays the MAR-based estimates provided by MI, with imputed values closely following the trajectory of the respective groups. As MNAR conditions vary, the trajectories for imputed values become increasingly divergent from the observed scores, including the point that they reflect worsening scores with time.

Table 2. Results of pattern-mixture model sensitivity analysis based on multiple imputation[a].

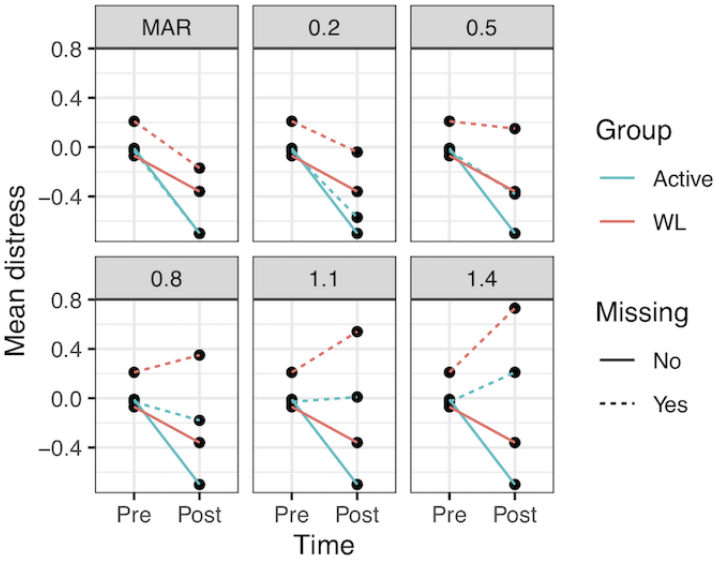
Model	Estimate[b]	*P* value
MAR[c]	−0.34	.002
0.20	−0.31	.004
0.50	−0.28	.01
0.80	−0.24	.03
1.10	−0.20	.08
1.40	−0.17	.16

[a] Models are based on varying assumptions regarding the meaning of missingness. Multiply imputed posttest values based on 100 imputations are offset [23] by varying amounts (ie, 0.20, 0.50, and residual SD).

[b] Coefficient for active group status (vs waitlist) predicting posttest distress scores controlling for pretest distress scores pooled across imputed data sets.

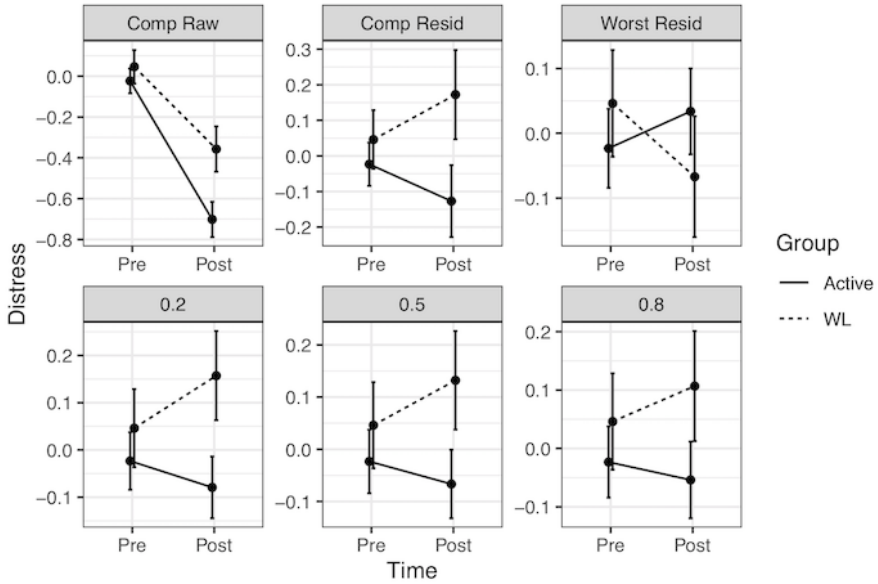
[c] MAR: missing at random (with no offset applied to posttest values).

Figure 3. Pre- and posttreatment scores for active and passive conditions with varying constant offset parameters added to multiply imputed values for missing outcomes under conditions of missing not at random (ie, Missing). Values are in z-score units, scaled by distress at baseline (mean 0, SD 1). Panels illustrate trajectories with offsets ranging from 0.2 to 1.4 residual SD. The missing at random panel represents values derived using multiple imputation with no offset applied. MAR: missing at random; WL: waitlist.



We now turn to the results of the fixed-value replacement sensitivity analysis. Figure 4 visually depicts the impact of MNAR conditions on the trajectories of pre-post change for the active and passive groups using this approach. The first 2 panels (Comp Raw and Comp Resid) display changes for completers only (in raw units and residualized change units, respectively). However, if MAR is violated in the way hypothesized above, one would expect the trajectory for unobserved active group participants to be worse than the observed active group scores (ie, following a trajectory more similar to the passive condition). If the missing data are consistent with MAR, this adjusted trajectory can be adequately recaptured with observed data (eg, baseline variables), allowing unbiased estimation using ML and MI. However, in the case of MNAR, the likelihood of missingness depends upon the unobserved value itself, making it impossible to recapture from available data alone. The subsequent panels (Worst Resid, 0.20, 0.50, and 0.80) display the impact of varying assumptions about the meaning of missing values. As can be seen in the Worst Resid panel, assuming the worst observed outcome for those with missing data reverses the direction of effect, with control group participants now showing more improvement than active participants. One can see how the gap in outcomes between active and passive condition participants narrows as increasingly strong assumptions are made regarding the degree to which missing values deviate from observed values. As missingness was more prevalent in the active conditions, these modifications exerted a stronger influence on the change in the active group.

Figure 4. Pre- and posttreatment scores for active and passive conditions under varying missing not at random conditions using fixed-value replacement of missings. Pretreatment values represent z-scaled distress at baseline (mean 0, SD 1). Posttreatment values vary across plots. For Comp Raw, posttreatment values are posttreatment distress scaled based on baseline distress. Subsequent plots display residualized change scores z-transformed at posttreatment to aid in visual interpretation of relative, between-group pre-post change. Comp Resid computed posttreatment as baseline plus residualized change scores for completers only. Worst Resid replaced missing posttreatment Comp Resid values with the lowest improvement in distress. Subsequent figures (0.2, 0.5, 0.8) replaced missing posttreatment Comp Resid values with values 0.2, 0.5, and 0.8 SD worse than the mean residual. Comp: completer; Resid: residualized change; WL: waitlist.



For null hypothesis testing purposes, we used nonparametric tests of mean residualized change scores. Consistent with the multilevel modeling results [27], the Wilcoxon signed-rank test favored the active conditions in the completer sample (mean ranks 69.11, 93.61, SD 43.01 and 45.90, for active and passive conditions, respectively, *P*<.001, where a lower rank indicates a larger decline in distress; Table 3). In the worst-case scenario, the direction of the mean rank difference flipped, now favoring the passive condition, although only marginally significantly (*P*=.08). Mirroring Figure 4, the influence of the varying missingness assumptions is apparent in Figure 5. The gap between active and passive conditions narrows, as missing data are assumed to reflect poorer and poorer outcomes. The pattern specifically indicates that statistical significance persists when missing values are assumed to be 0.20 above the mean residual but not 0.50 or higher. This result differs slightly from Goldberg et al [27], who detected statistical significance at an offset of 0.50. The discrepancy is because of Goldberg et al [27] calculating the SD for the residual without the group variable in the model. We recommend the inclusion of the group variable in the model, as the resultant SD is presumably more conservative, based on the assumption that an intervention increases the SD. Therefore, these results can be interpreted as robust to MNAR missing, in which the unobserved values deviate from the observed values only to a small degree, but not when showing moderate or larger deviations.

Table 3. Results of fixed-value replacement sensitivity analysis.

Group and model	Sample size, n (%)	Mean rank (SD)	SE	*P* value[a]
Active				
Comp[b]	91 (39.9)	69.11 (43.01)	4.51	<.001
Worst[c]	228 (100)	178.1 (93.05)	6.16	.08
0.20[d]	228 (100)	161.89 (83.25)	5.51	.004
0.50[d]	228 (100)	165.19 (84.25)	5.58	.05
0.80[d]	228 (100)	168.52 (86.01)	5.70	.32
Waitlist				
Comp	67 (58.3)	93.61 (45.9)	5.61	N/A[e]
Worst	115 (100)	159.9 (85.62)	7.98	N/A
0.20[d]	115 (100)	192.05 (102.27)	9.54	N/A
0.50[d]	115 (100)	185.5 (102.26)	9.54	N/A
0.80[d]	115 (100)	178.9 (100.34)	9.36	N/A

[a] *P* value from Wilcoxon signed-rank test comparing active and passive conditions across varying missingness assumptions.

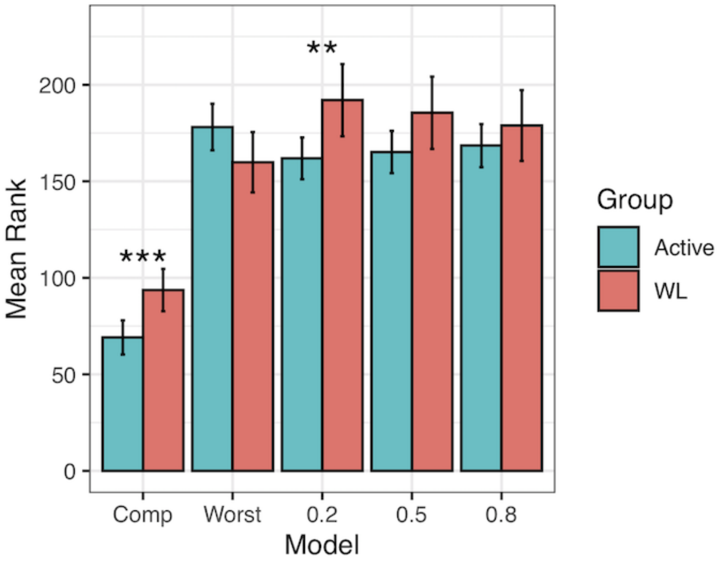
[b] Comp: completer sample.

[c] Worst: worst-case scenario, which assumed missing values are equivalent to the worst outcome (ie, smallest change in distress).

[d] 0.20, 0.50, 0.80: missing values assumed to be 0.20, 0.50, or 0.80 SDs worse than the mean residualized change score.

[e] N/A: not applicable.

Figure 5. Results of Wilcoxon signed-rank test using a fixed-value replacement sensitivity analysis across varying missing not at random conditions. A lower mean rank indicates larger relative decreases in distress. Comp: completer sample; Worst: worst-case scenario which assumed missing values are equivalent to the worst outcome (ie, the smallest change in distress); 0.2, 0.5, 0.8: missing values assumed to be 0.2, 0.5, or 0.8 SD worse than the mean residualized change score; error bars: 1.96×SE; WL: waitlist. **P*<.05, ***P*<.01, ****P*<.001.



Discussion

Principal Findings

This study had two primary aims: to systematically evaluate the handling of a potential source of MNAR data in mHealth research—differential attrition—and advocate for sensitivity analyses as a family of strategies that might be used to assess the impact of MNAR data. At the broadest level, results suggest that MNAR data are likely to be a problem in mHealth research and one that, to date, has not been adequately addressed. As reported by Linardon and Fuller-Tyszkiewicz [3], the substantially higher attrition in active relative to passive conditions in RCTs testing smartphone-based mental health interventions is marked; active participants were approximately twice as likely to drop out of the study. Although it is impossible to say what the missing posttreatment data would have shown had it been collected, it is plausible that those dropping out from the active conditions were less likely to have benefited from the mHealth intervention (or at least that the benefits they were experiencing did not outweigh the costs of remaining in the study). Thus, the observed values may overestimate treatment effects for those under active conditions. Given that the likelihood of missingness is related to the unobserved values themselves, these data would be MNAR.

Although patterns of attrition consistent with potential MNAR data were detected in the literature as a whole, only a minority of the included studies tested for differential attrition. However, in keeping with the literature-wide pattern of differential attrition, 6 of the 11 studies comparing attrition rates between active and passive conditions detected higher attrition in the active conditions, whereas the remaining 5 studies failed to detect a difference. Despite the possibility of MNAR data, none of the 36 studies directly assessed the potential influence of MNAR data on the study results. Half of the studies employed other modern missing data methods, such as MI or ML. These approaches have many strengths and are certainly preferred over historical approaches for handling missingness (eg, last observation carried forward and complete case analysis [9]). Encouragingly, it appears that less sophisticated missing data analysis techniques (eg, last observation carried forward [2]) are being replaced by modern methods. However, both MI and ML rely on the assumption that data are MAR; therefore, missing values can be reliably determined based on measured variables. Importantly, they are not robust to MNAR [8].

Moderator analyses further characterized the correlates of differential attrition. The results indicated that differential attrition was more likely to occur in larger studies. Unfortunately, this association could produce a pernicious source of bias within the literature, as larger studies are presumably the ones most looked to when evaluating evidence of efficacy and are likely to carry more weight in meta-analyses examining efficacy. Interestingly, studies with higher differential attrition were only marginally more likely to assess differential attrition. It may be that differential attrition is simply not recognized or acknowledged as a potential concern worth assessing, even when dropout rates differ. Somewhat counterintuitively, studies with higher differential attrition were not more likely to detect differential attrition when assessed. This lack of association could be because of the limited statistical power for the moderator test itself [77], as only 11 studies tested for differential attrition. Statistical power may also be low in primary studies themselves. For example, Champion et al [44] did not detect differential attrition in their sample of 74 participants, although active participants were 3.42 times more likely to drop out of the active condition relative to the passive condition. It appears that researchers are more likely to use modern missing data analysis techniques (ML/MI) when differential attrition is higher, which is preferred to techniques that are not robust to even MAR data (eg, complete case analysis and last observation carried forward). Nonetheless, these techniques are not capable of eliminating the bias associated with MNAR data.

Perhaps the most notable finding of our review is that none of the included studies conducted a sensitivity analysis to evaluate the potential influence of MNAR data on study findings. Although several meta-analyses suggest that smartphone-based mental health interventions produce benefits relative to waitlist control conditions [78-80], the lack of sensitivity analyses coupled with literature-wide differential attrition makes the apparent efficacy more tenuous.

The primary aim of this study is to encourage mHealth researchers to consider sensitivity analyses to assess the potential impact of MNAR missingness, particularly when differential attrition is present. Several modern techniques exist for evaluating the potential impact of MNAR missingness, including selection models and pattern-mixture models that have been discussed. As most of these methods have limitations (eg, they are heavily influenced by untestable assumptions) and may not be within the current analytic repertoire of many mHealth clinical trialists, we presented an MI-based pattern-mixture model sensitivity analysis approach adapted from smoking cessation research [14,22] as well as a fixed-value replacement sensitivity analysis approach as examples of more user-friendly strategies for evaluating the impact of MNAR data. These methods are fairly straightforward to implement using a continuous outcome variable assessed at pre- and posttreatment—a typical situation for mHealth research [80,81]—and move beyond the traditional MAR methods currently emphasized in mHealth research. An attractive feature of these sensitivity analyses is that one can visually and statistically evaluate the impact of varying missingness assumptions on the pattern of findings. As these assumptions would only apply in cases of missing data, they would have a minimal impact on the results when missingness is low (eg, <5% [9]). As expected, the actual impact of varying MNAR assumptions will be sensitive to other patterns in the data (eg, trajectories of change for waitlist control participants because of regression to the mean or natural history). Thus, they do not imply a particular direction of influence but rather evaluate a range of possible impacts based on deviations from the observed data.

It is worth noting that the 2 sensitivity analysis approaches illustrated in this study provided somewhat discrepant conclusions regarding the degree to which data from Goldberg et al [27] were robust to MNAR conditions. This fact highlights the value of sensitivity analyses and the importance of authors using various approaches and assumptions to evaluate the strength of their findings. These differences are also illuminating. In particular, the MI-based pattern-mixture model approach suggested that the results were robust to MNAR deviations that were large (ie, 0.80) but not larger, whereas the simpler sensitivity analysis approach indicated that the results were not robust above small deviations (ie, 0.20). Figure 3 illustrates a plausible explanation for this: the MI-based approach makes the initial assumption that missing values are similar to observed values unique to each group. Thus, the fact that the active group improved overall produced improvement in the imputed change for missing active participants. In contrast, the fixed-value replacement approach did not adjust the expected residualized change scores based on the group status. We contend that both approaches may provide a valuable perspective on MNAR sensitivity and should simply be interpreted in light of their underlying assumptions.

Limitations and Future Directions

This study had several important limitations. The first and broadest limitation is that we cannot definitively conclude that the observed differential attrition necessarily results in MNAR data. It is possible that remaining in the study was because of factors unrelated to changes in study endpoints (ie, distress). Likewise, drop outs in the active group could have been because of participants not using the smartphone app and losing interest in the study because their psychological symptoms had already improved (as can be the case in psychotherapy [82]), which could produce an MNAR bias in the opposite direction (ie, missing values are better, not worse). As is typical for research on missing data, the data necessary to test for MNAR are by definition missing. The methods proposed here could certainly be extended to evaluate potential *best-case scenarios*, in which missing observations reflect better rather than worse outcomes or when missingness has different meanings depending on group assignment (eg, worse outcomes for active conditions but better outcomes for passive condition). Second, we only evaluated the degree and correlates of differential attrition in a small subset of the large and rapidly growing mHealth literature. It is possible that researchers are improving their ability to retain study participants and adherence strategies being investigated [6,83] may be decreasing attrition in the active conditions. Future reviews may see less evidence of this potential source of MNAR data. Similarly, there are mHealth RCTs that conducted sensitivity analyses to evaluate MNAR (eg, pattern-mixture models [84]), even though none of the 36 RCTs with passive controls we evaluated did so. Third, we focused only on differential attrition in smartphone-based RCTs. It is conceivable that higher attrition in active than passive conditions is somehow idiosyncratic to this delivery platform. An important future direction would be to evaluate differential attrition in other mHealth delivery formats (eg, internet-based interventions). Fourth, we explored only a few examples of possible methods for addressing sensitivity to MNAR data. Nonetheless, we hope our introduction of these approaches with corresponding R syntax encourages mHealth researchers to begin implementing and perhaps even testing and developing strategies for addressing the missing data realities of mHealth.

Several future directions follow naturally from this study. MNAR sensitivity analyses could be integrated into future mHealth RCTs. For instances with longitudinal data, more complex pattern-mixture models may be especially attractive [84]. For studies with fewer time points, approaches such as those introduced here may be worthwhile. If a specific sensitivity analysis approach were to become widely used, it could provide researchers with a common metric for evaluating the potential influence of differential attrition as a source of MNAR on study results. An approach based on readily interpretable metrics (eg, Cohen d) could be helpful, although there are certainly many viable possibilities, many of which may have advantages over the strategy introduced here. This is an area of active research, and new and much more sophisticated methods are regularly becoming available [76].

Short of incorporating sensitivity analyses into mHealth RCTs, researchers could, at a minimum, test for differential attrition, especially when comparing active and passive conditions. Acknowledging the potential influence of MNAR, when differential attrition is present, can allow readers to more accurately evaluate study findings in light of this limitation. A way to assess the potential impact of MNAR because of differential attrition would be through reanalysis of published mHealth RCTs, especially large trials that were seen to have higher rates of differential attrition. Reanalyses of this kind could help determine the degree to which findings are sensitive to varying MNAR assumptions, and by extension, the degree to which conclusions drawn from the broader literature may be similarly influenced. Another future direction is intentionally adopting methods that decrease attrition generally [85], given that differential attrition and associated MNAR data are less concerning when the amount of missing data is small. Finally, it could be valuable to investigate differential attrition for in-person interventions as well. To our knowledge, no such meta-analysis exists, although the same potential risk of bias because of MNAR may be applied.

Conclusions

Attrition is a persistent thorn in the side of mHealth clinical trialists [1]. Modern missing data methods such as MI and ML successfully minimize the negative impact of some types of missing data (MCAR and MAR), restoring statistical power and reducing bias in parameter estimates. However, these methods cannot remove the bias associated with MNAR data.

Evidence of differential attrition supports the possibility that MNAR may be a common problem in mHealth RCTs with passive controls and one that is largely unacknowledged to date. Sensitivity analyses offer an approach for establishing the impact of differential attrition on the study results.

Abstract

Background: Self-focused augmented reality (AR) technologies are growing in popularity and present an opportunity to address health communication and behavior change challenges.

Objective: We aimed to examine the impact of self-focused AR and vicarious reinforcement on psychological predictors of behavior change during the COVID-19 pandemic. In addition, our study included measures of fear and message minimization to assess potential adverse reactions to the design interventions.

Methods: A between-subjects web-based experiment was conducted to compare the health perceptions of participants in self-focused AR and vicarious reinforcement design conditions to those in a control condition. Participants were randomly assigned to the control group or to an intervention condition (ie, self-focused AR, reinforcement, self-focus AR × reinforcement, and avatar).

Results: A total of 335 participants were included in the analysis. We found that participants who experienced self-focused AR and vicarious reinforcement scored higher in perceived threat severity (*P*=.03) and susceptibility (*P*=.01) when compared to the control. A significant indirect effect of self-focused AR and vicarious reinforcement on intention was found with perceived threat severity as a mediator (b=.06, 95% CI 0.02-0.12, SE .02). Self-focused AR and vicarious reinforcement did not result in higher levels of fear (*P*=.32) or message minimization (*P*=.42) when compared to the control.

Conclusions: Augmenting one's reflection with vicarious reinforcement may be an effective strategy for health communication designers. While our study's results did not show adverse effects in regard to fear and message minimization, utilization of self-focused AR as a health communication strategy should be done with care due to the possible adverse effects of heightened levels of fear.

Introduction

Overview

With self-focused augmented reality (AR) usage increasing in recent years [1], the utilization of this technology has a potential in addressing health communication and behavior interventions challenges. Whereas AR technology layers digital content onto the real world [2], self-focused AR visually augments the self, layering digital content onto the self. One technology enabling self-focused AR is video filters, which superimpose computer-generated content onto a user using their web or smartphone camera (eg, Snapchat Lenses [3] and AR effects on Instagram [4]). For example, Snapchat's Time Machine AR lens morphs a user's reflection to display what the user might look like at different ages. Smart mirrors, another self-focused AR technology, combine digital screens (eg, an LCD [liquid-crystal display] monitor) with semitransparent glass. A smart mirror looks and functions similarly to a traditional mirror but with digital content displayed in the foreground [5]. Real-world applications of smart mirrors are on display in vehicles [6], dressing rooms [7], and home gyms [8]. For example, the MIRROR home gym [8] displays fitness instruction layered on top of the user's reflection. Both AR video filters and smart mirrors provide new opportunities for displaying health behavior communication to the public.

In response to the recent increase in self-focused AR usage [1,6-8], we investigated the potential impact of self-focused AR within the health domain. For behavior change researchers, the effect of layering health threats along with mitigative behaviors and their results on top of a user may be of particular interest. For example, would using AR to layer a set of very healthy teeth due to good oral hygiene on dental patients impact their behavior? Could using AR in rearview mirrors to overlay scratches and bruises on top of drivers and riders encourage seat belt usage? We now have self-focused AR technologies in the hands of millions, presenting the opportunity to visually show individuals the impact of their decisions before they make them.

Research in psychology suggests that heightening self-focused attention (manipulated by using a mirror or video camera) has implications for perception, affective experiences (emotions, feelings, and moods), and behavior [9]. Objective self-awareness occurs when an individual places attention on themself, viewing themself as a social object. Objective self-awareness theory [10] posits that self-focused attention heightens the awareness of the gap between one's perceived "real self" and "ideal self," resulting in negative affect. For example, if one desires good health and believes that exercise is vital to maintain one's health and yet does not exercise, heightening objective self-awareness will likely result in negative emotions. The increased negative affect resulting from the awareness of discrepancies leads to either (1) the avoidance of self-focused attention and the discrepancy or (2) actions to reduce the discrepancy [10]. This theory suggests that self-focused AR might impact behavior. We investigated which perceptions could be involved when individuals experience self-focused AR within a health context. Research prototypes have explored self-focus [11] and self-focused AR [5,12-14] technologies for health behavior change. However, few have investigated how the design of interventions that aim to increase self-focused attention might impact health perceptions and emotions. Similarly, prior studies did not consider the potential of combining self-focused AR with vicarious reinforcement, that is, reinforcement from observing others' behavior and the results of those actions. This paper draws upon insights from objective self-awareness theory [2] and social cognitive theory [15] to inform hypotheses about the relationships between predictors of health behavior change and self-focused AR.

We present findings from an online experiment on the impact of combining self-focused AR with vicarious reinforcement, visualizing the cause and effect of risk-mitigating behavior layered onto one's reflection. Our study took place during the COVID-19 pandemic, focusing on hand hygiene behavior as an effective measure against pathogen transmission [16,17]. We discuss the implications of the results in light of the public health emergency, addressing the following research question: how does reinforcement in self-focused AR impact health perceptions during a pandemic?

Background

Various health behavior change models [18,19] highlight the roles of predictors of intentions such as risk perceptions (perceived threat severity and threat susceptibility) and outcome expectancy. Drawing on objective self-awareness theory and social cognitive theory, we postulated that health behavior change–themed self-focused AR could impact these predictors of intention.

Research suggests that self-focused attention can result in action consistency with behavioral standards [9]. Objective self-awareness theory posits that self-focused attention will result in negative affect through the increased awareness of contradicting beliefs about one's self or discrepancies between belief and behavior [10]. If negative affect is experienced, and one does not avoid the self-focused attention, they will attempt to reduce the discrepancy to reduce the negative affect, such as by changing their behavior. To further illustrate this, recall the individual from the example earlier who values their health and believes that exercise is vital for their health but does not exercise. According to objective self-awareness theory, an increase in self-focused attention would result in an attempt to reduce the discrepancy, which may result in exercise behavior. We propose that when increasing self-focused attention in the context of a health threat, especially during a pandemic, that the negative affect experienced will include fear and will increase to levels higher than if self-focused attention was not activated.

Research suggests that fear may play a large role in health behavior, especially during public health emergencies such as the current pandemic. Harper et al [20] found COVID-19 fear scores to be a positive predictor of behavior change. Fear may also impact behavior as it relates to risk perception. Risk perception, an individual's perceived susceptibility to or severity of a threat, is included in many health behavior change theories [21]. Li [22] found perceived threat (measured by averaging threat susceptibility and severity) to be a positive predictor of fear. Affective factors are believed to play a role in the formation of risk perception [23]. While risk perceptions can increase fear, fear has also been found to induce higher risk perceptions [24]. Self-focused AR content layering onto the body increases the sense of spatial presence (ie, the object "being there"), potentially heightening fear if the object is threatening. Due to the combination of self-focus and spatial presence, we suggest that health threat–related self-focused AR may impact levels of fear, perceived threat severity, and perceived threat susceptibility.

It is important to consider the potential negative impact of heightening fear and risk perceptions. While Harper et al [20] found increased fear to be associated with higher behavioral adherence, they also found fear to be correlated with decreased physical and environmental quality of life and warned about mental health implications. Fear can also have an adverse effect on behavior. The Extended Parallel Process Model (EPPM) [25] outlines the importance of a balance of fear and efficacy for health communication campaigns to be effective. While fear can be a motivator for behavior, where the fear/efficacy balance is disrupted, individuals may use cognitive defense mechanisms instead of behavior as a means of fear control. In this case, not only would the behavior change method be ineffective, but it could result in the adverse effect of prompting the development of these defense mechanisms. Based on the EPPM, Li [22] tested a model for protective behaviors during a public health emergency with a study during the Ebola outbreak of 2014. Fear controls measured included negative reactance to messages, message minimizing, and defensive avoidance. Li [22] found perceived threat to have a significant effect on fear and fear controls but did not find self-efficacy to be a successful moderator of that relationship. This suggests that although fear may be an effective strategy to encourage health behavior adherence, certain levels of fear may lead individuals to minimize health behavior messaging to control their fear instead of engaging in behavior change. We take these findings and the EPPM into consideration, as our study directly layers a health threat onto participants, which could result in excessive levels of fear triggering adverse fear control mechanisms. We expected self-focused AR, in the form of AR video filters, to heighten both fear and fear control mechanisms when displaying a health threat.

Our study investigated the impact of vicarious reinforcement outcome expectancy when combined with self-focused AR. Research suggests that outcome expectancy mediates the impact of self-focused attention on behavior. For someone who has been made aware of a discrepancy between "actual state" and "desired state," if they don't believe a suggested behavior change will result in the "desire state," they are more likely to change the "desired state" [9]. When the "desired state" is health related, this can have adverse implications. Outcome expectancy can be impacted by experiencing vicarious reinforcement. Vicarious reinforcement occurs when a reinforcing effect for an individual takes place by observing others' behavior and the results of their actions [26]. Bandura et al [27] found that children who were exposed to media displaying aggressive behavior that was rewarded showed more imitative aggressive behavior than those who saw aggressive behavior that was punished. Bandura's [15] social cognitive theory details how behaviors can be formed by observing a model engage in a behavior. Bandura suggests that due to limited contact with physical and social environments, people rely largely on vicarious experiences to form their idea of reality. In our study, vicarious reinforcement consists of visual representations of pathogens (ie, germs), which are made visible on avatar hands. As a hand hygiene animation plays, covering all the steps of proper handwashing, these pathogens disappear from the avatar's hands. We predicted that this experience would heighten one's perception of outcome expectancy. Given that health behavior models, such as The Health Action Process Approach [18] attribute outcome expectancies to the formation of intention, we found this valuable to investigate in our study. We proposed that the vicarious experience described above would directly affect outcome expectancy.

Related Work

While studies combining self-focused attention and vicarious reinforcement have yet to see much direct utilization in human-computer interaction research, a few studies on health smart mirrors [5,12,13], self-representation [28], and spatial presence [14] suggest an impact of self-focused attention on perceptions and behavior.

While applications of smart mirrors for health care are limited, exploratory research prototypes have shown their potential to detect emotional states, monitor physiological parameters, and encourage behavior change. The Wize Mirror [12] encouraged users to improve their lifestyle to mitigate cardiometabolic risk assessed by tracking physical face signs)eg, skin color, subcutaneous fat, facial expressions). Medical Mirror [5] utilized computer vision and advanced signal processing within a smart mirror design to encourage people to keep track of their vital signs regularly. Fit Mirror [13] increased user's motivation, happiness, and fitness for the day by integrating exercising and challenging others into their morning routine. Although the rise of smart mirrors has resulted in studies exploring the use of these devices in health care, there is a lack of research investigating how self-focus specifically plays a role in influencing health behavior change. The studies mentioned above lack a control condition in which all design features are present except the mirror to study the direct impact of seeing one's self-reflection.

A recent study by Jung et al [14] used a projector and a mirror to show participants their bodies with x-ray visualization of smoking lungs. A separate condition displayed the same content but on a mannequin. Both conditions were compared to a control, which displayed the information on a screen in 2D. The researchers found that spatial augmented reality increases spatial presence, the perceptual illusion that the real world and the mediated world are "equally present." In addition, they found that higher levels of spatial presence were associated with a negative emotional change toward cigarettes and cigarette cessation campaign engagement intention. These findings support the idea that displaying the consequences of health behaviors on top of the user's own body can impact behavior change constructs regarding emotions and intention. Our study aimed to contribute to this line of research by exploring additional behavior change constructs.

One notable finding from Jung et al [14] was that the mannequin condition also resulted in higher levels of spatial presence. However, an analysis comparing emotions and intentions reported for those in the mannequin condition compared to the control was not reported. Gaining a better understanding of how objects that can serve as external self-representations, such as avatars and mannequins, could help develop more feasible design interventions when mapping AR elements directly on the body would be complex.

Yee and Bailenson [28] found that self-representations can help form our behaviors, even when this representation is digital, such as in the case of avatars. Yee and Bailenson [28] call this the Proteus effect and provided support from two experiments. In study one, participants were provided with an avatar that was previously rated as high, medium, or low on an attractiveness scale. They were asked to interact with another character (in a virtual reality environment) after looking at themselves in a mirror. Those in the high attractiveness condition disclosed more information and moved closer to the other character. The second experiment, testing avatar height in an ultimatum game, found that those in the tall condition were more likely to offer an unfair split. Those in the short condition were more likely to accept an unfair split. These findings suggest that augmentations to self-representation, as an avatar, may impact one's behavior. Fox and Bailenson [29] studied whether vicarious reinforcement with a user's avatar had an effect on physical exercise. Seeing one's avatar benefit from exercise behavior and experience consequences from not engaging in the behavior encouraged the observer to engage in the behavior. These results suggest that vicarious reinforcement using avatars may be effective. Based on the studies mentioned above, we expected that the display of health threats on an avatar representation of the self in an AR environment will impact levels of threat severity, susceptibility, fear, and message minimization.

Our study expands on existing research by investigating how health behavior self-focused AR may impact specific predictors of behavioral intentions and what negative implications may exist in regard to fear control responses.

This Study

In our research, we examined the impact of self-focused AR and vicarious reinforcement on perception and emotion as it relates to hand washing health beliefs and behavioral intentions. Below, we present our hypotheses:

> *H1: The combination of self-focused AR and vicarious reinforcement will result in higher levels of perceived positive outcome expectancy, perceived threat severity and susceptibility, fear, and message minimization when compared to a control.*
>
> *H2: Using avatar representations in self-focused AR with vicarious reinforcement will result in higher levels of threat severity, susceptibility, fear, and message minimization compared to a control.*

Methods

To study the effects of self-focused AR on behavioral intention and perception, we conducted an online experiment. Participants interacted (Figure 1) with a web application (Figure 2) that displayed health information regarding the coronavirus and a hand hygiene animation (Figure 3). Five conditions differed in their inclusion of self-focused attention and vicarious reinforcement.

Figure 1. A participant in one of the self-focused augmented reality design groups viewing a reflection of themselves using a video feed from their camera.

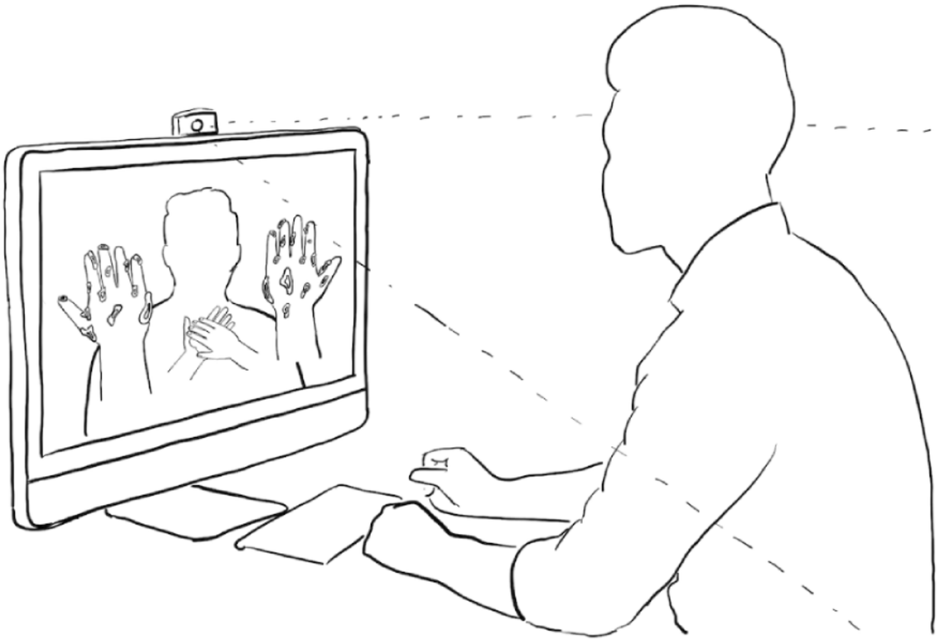

Figure 2. A screenshot from the web application.

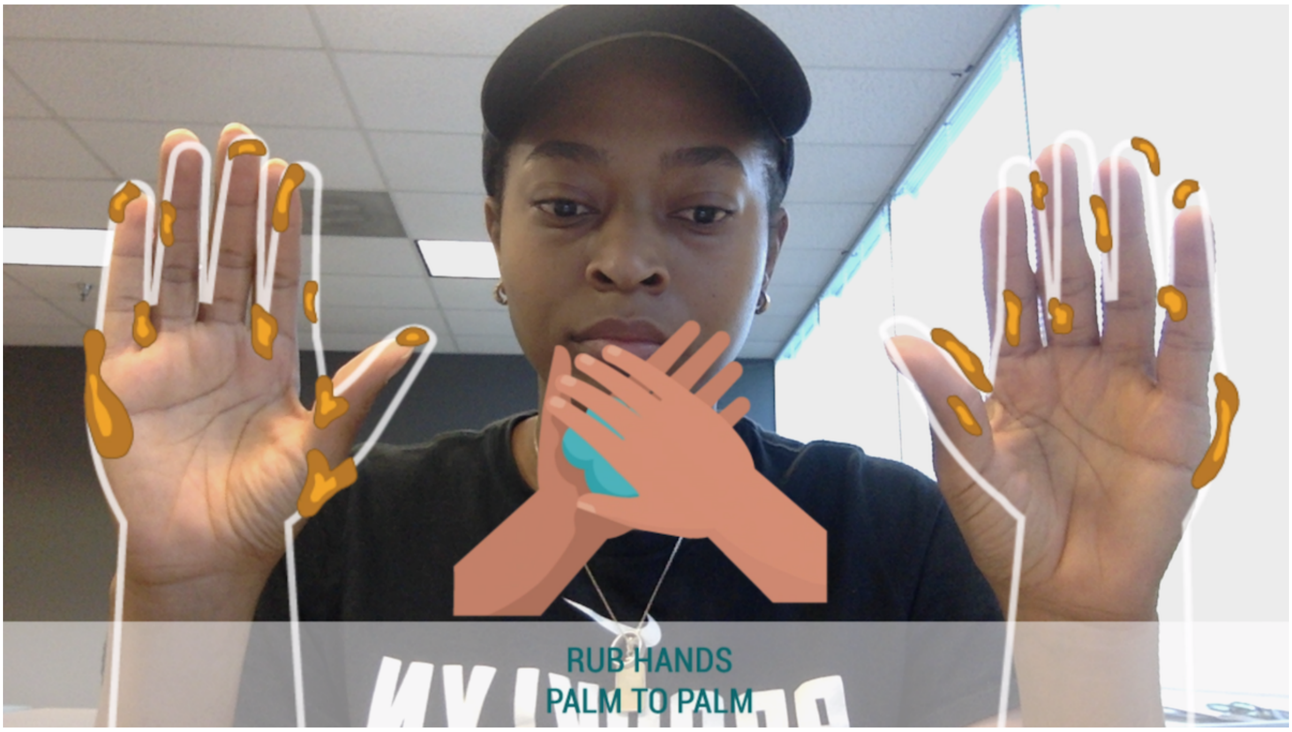

Figure 3. An example of the progression of vectors used in the handwashing animation.

Experimental Conditions

We conducted a between-subjects experiment where users interacted with a web application and then responded to an online questionnaire. The study followed a posttest-only control group design to avoid a testing threat to internal validity. The design of the web application differed depending on the intervention condition each participant was randomly allocated to. All five conditions displayed the same information about COVID-19, including how it is spread and preventative measures as described by the US Centers for Disease Control and Prevention (CDC) [17] and the World Health Organization (WHO) [30]. This information was followed by a hand hygiene animation, the display of which differed based on the participant's assigned condition.

Control Condition: No Self-focused AR or Vicarious Reinforcement

In the control condition (Figure 4), we displayed an animation of a 12-step handwashing technique following standards outlined by the WHO [30], accompanied by captions to describe each movement ("Rub hands palm to palm").

Figure 4. Control condition.

Reinforcement

In the reinforcement condition (Figure 5), the handwashing animation described in the control condition was accompanied by an additional animation showing germs disappearing from a pair of illustrated hands as the handwashing animation progressed. These animations were synced so that the appropriate areas of the hands displayed were affected based on the specific stage of the handwashing animation a viewer was watching. For example, the thumb cleaning animation segment was paired with germs disappearing from the thumbs.

Figure 5. Reinforcement condition.

Self-focused AR

The self-focus condition (Figure 6) utilized the participant's web camera to display their self-reflection, serving as the stimulus for self-focused attention. The handwashing animation was layered on top of the viewer's reflection. This reflection was shown in real time and was created using the participant's web camera.

Figure 6. Self-focused augmented reality condition.

Self-focus AR × Reinforcement

The self-focus AR × reinforcement condition (Figure 7) visualized germs directly on the participant's hands. Instructions at the beginning of the animation directed participants on where to place their hands. The handwashing animation was displayed in between their hands. As the animation progresses, the user saw the germs disappear from the reflection of their own hands.

Figure 7. Self-focus augmented reality × reinforcement condition.

Avatar

In the avatar condition (Figure 8), participants viewed an animation showing germs disappearing from a pair of illustrated hands layered on top of the user's reflection. These are referred to as avatar hands, as they are meant to represent the user's hands. The perspective displayed was that which is seen if the individual were to hold up their hands and look at them.

Figure 8. Avatar condition.

Participants

Participants were recruited via Prolific (a crowdsourcing platform [31]) and were compensated $2.50 for their time. Participation was limited to those residing in the United States, who spoke fluent English, and were ≥18 years of age. Pilot testing revealed technical challenges that could interfere with the study, mainly involving web camera use verification. To address this, prior to being recruited for the study, Prolific members were invited to a prescreener that verified (1) their access to an acceptable browser for the study (Safari, Chrome, and Firefox) and (2) that camera permissions worked with their technical setup. Prolific IDs for those who passed the screener were collected, and access to the main study was restricted to those IDs.

Procedure

The experiment took place between August 6-21, 2020. In all five conditions, after receiving consent, we described the experiment as a study on health information presentation and provided instructions to review the information given carefully. In the three self-focused-AR–based conditions, we displayed information on how to set up the web camera for the study.

All conditions provided information about COVID-19. Details focused on how the virus is spread and preventative measures as described by the CDC [17]. Participants next viewed an animation detailing the steps of proper hand hygiene as described by the WHO [30]. This was followed by a questionnaire to collect demographic information and measure health knowledge and perception, which concluded the study.

The questionnaire included questions to check whether the participant is paying attention. Three multiple-choice questions asked the user about the information displayed in the study (eg, What is a recommended preventative measure to reduce the spread of the coronavirus?). To validate that self-focused AR interventions were delivered correctly using the camera, participants in these conditions were informed, prior to the study, that screenshots would be collected randomly throughout the animation. The screenshots were reviewed to ensure that participant’s reflections were displayed to them and that those in the self-focus AR × reinforcement condition had their hands within the view as instructed. Only those who followed the instructions, verified by screenshots, were included in the final data set.

Variables and Measures

We collected measures of self-reported health beliefs, behavioral intention, and self-reported perceptions of COVID-19 (Table 1), along with demographic data. These measures were adapted from Schwarzer [18] and Li [22]. Items in this study were all measured on a 7-point Likert-type scale ranging from 1 (strongly disagree) to 7 (strongly agree).

Although adapted from previous research, cross loading was a concern due to the rewording of items and the difference in factors present compared to the adapted questionnaires. For example, we added items to measure opinions about perceived threat severity and susceptibility of family and friends. To examine the validity and reliability of our measures, we conducted exploratory and confirmatory factor analysis using a split-sample approach, with one half to develop a model and the other half to validate. Factors loaded as expected (Multimedia Appendix 1).

Data on demographics and the COVID-19 risk of a severe illness of loved ones were collected. Participants were asked to report their age, gender, and the state in which they currently reside. In addition, they were asked to report if they have a family member or friend who is at high risk of severe illness if they are infected with COVID-19. It was noted that one is considered high risk if they are ≥65 years and/or have underlying medical conditions.

Table 1. Questionnaire items.

Variable and code	Questionnaire item
Intention	
inte	I intend to wash my hands, as instructed in this study, *on a regular basis.*
Perceived outcome expectancy	
expe1	I believe proper handwashing, as instructed in this study, will help make me *less likely* to get the coronavirus disease (COVID-19).
expe2	I believe proper handwashing, as instructed in this study, will help *reduce the spread* of the coronavirus disease (COVID-19).
Fear	
fear1	The emotion that I am feeling about the coronavirus (COVID-19) pandemic is: …Frightened
fear2	…Scared
fear3	…Anxious
Message minimization	
reac1	To what extent do you feel that *preventative measures messaging*, in your state, regarding the coronavirus disease (COVID-19) is: …Manipulative
reac2	…Misleading
reac3	…Distorted
Perceived threat-severity	
seve1	I believe that the coronavirus disease (COVID-19) is a serious threat to my personal health.
seve2	I believe that the coronavirus disease (COVID-19) is a serious threat to my family members (immediate or extended).
seve3	I believe that the coronavirus disease (COVID-19) is a serious threat to my friends.
seve4	I believe that the coronavirus disease (COVID-19) is a serious threat to the general public.
Perceived threat-susceptibility	
susc1	I am at risk of catching the coronavirus disease (COVID-19).
susc2	My family (immediate or extended) members are at risk of catching the coronavirus disease (COVID-19).
susc3	My friends are at risk of catching the coronavirus disease (COVID-19).

Statistical Analysis

Analysis of our data using histograms and the Shapiro-Wilk test showed that the data were not normally distributed. Shapiro-Wilk *P* values ranged from 6.35e-08 (efficacy) to 1.927e-25 (intention). Therefore, hypothesis testing was conducted using the nonparametric Wilcoxon-Mann-Whitney test, comparing perceived threat severity, susceptibility, outcome expectancy, fear, and message minimization scores between intervention conditions. If condition pairs had the same distribution shape, medians were compared. If the shapes were different, the mean ranks were compared. Additionally, mediation models for dependent variables and design conditions with significant findings were tested. A bootstrapping method using PROCESS macro models 4 and 6 [32], 5000 bootstrap samples, and percentile bootstrap CIs were used. Significance was established at *P*<.05. Statistical analysis was performed using Python (Python Software Foundation) [33], and the pandas (Community) [34] and SciPy (Enthought) libraries [35] were used to conduct the Wilcoxon-Mann-Whitney test. SPSS software (IBM Corp) [36] was resourced, in which the PROCESS macro [32] was implemented to test mediation.

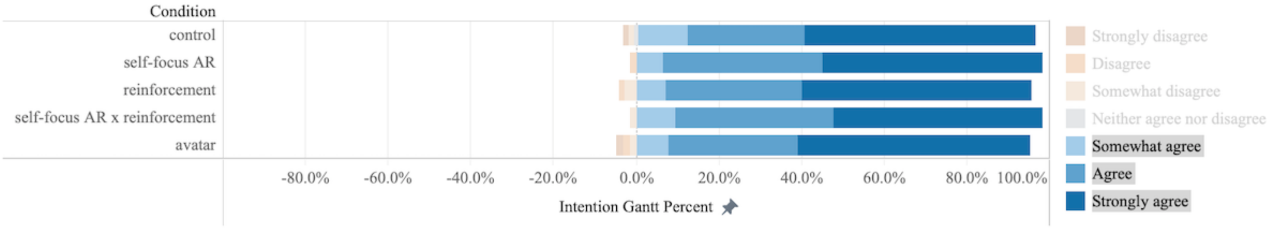
Results

Overview

A total of 502 individuals participated in the study. Of this, 335 participants met the attention and screenshot verification checks (see *Procedure* section) and were included in the analysis. Of the 335 participants, 77 were randomly assigned to the control condition, 61 to the self-focused AR condition, 70 to the reinforcement condition, 63 to the self-focus AR × reinforcement condition, and 64 to the avatar condition.

Although our study focused on predictors of behavioral intentions, we began with results pertaining to intention (Figure 9) to provide context for further discussion. A significant difference between design conditions and the control was not found (self-focused AR: *P*=.42; reinforcement: *P*=.43; self-focus AR × reinforcement: *P*=.41; avatar: *P*=.43).

Figure 9. Responses for behavioral intention. Responses are strongly skewed toward higher levels of agreement for all conditions, indicating a ceiling effect. AR: augmented reality.



Effects of Self-focused AR With Vicarious Reinforcement in Regards to Perceived Fear, Threat Severity, Threat Susceptibility, Outcome Expectancy, and Message Minimization (Hypothesis 1)

Hypothesis 1 proposed that a combination of vicarious reinforcement and self-focused AR would result in higher levels of fear, perceived threat severity, susceptibility, outcome expectancy, and message minimization compared to the control group. Compared with participants in the control (P=.43), message minimization scores of those in the self-focus AR × reinforcement condition were not significantly different. This was also the case for outcome expectancy (P=.41) and fear (P=.23) (Figure 10). However, perceived threat severity and susceptibility had significant findings.

For perceived threat severity, median scores for the self-focus AR × reinforcement and control groups were 6.25 and 6.00, respectively (Figure 11); the two groups' distributions differed significantly (Mann-Whitney U=1983, P=.03). Regarding perceived threat susceptibility, median scores for the self-focus AR × reinforcement and control groups were 6.00 and 5.33 (Figure 12); the two groups' distributions differed significantly (Mann-Whitney U=1897.0, P=.01). Our results partially supported H1 regarding perceived threat severity and susceptibility; however, we did not find support for outcome expectancy, fear, and message minimization.

Figure 10. Responses for outcome expectancy. Responses are strongly skewed toward higher levels of agreement for all conditions, indicating a ceiling effect. AR: augmented reality.

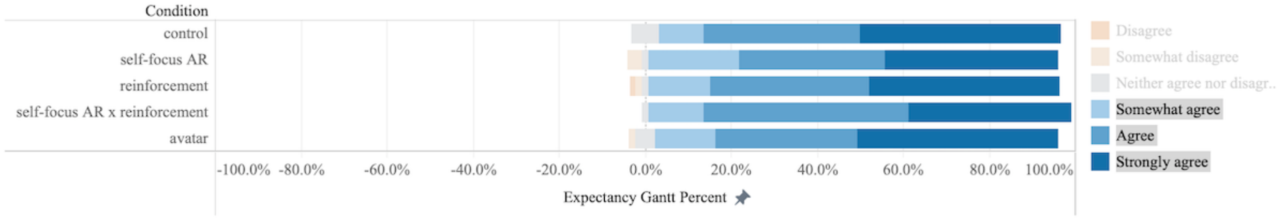


Figure 11. Significantly higher levels of perceived threat severity among participants in the self-focus augmented reality (AR) × reinforcement condition compared to the control condition. No significant differences were found between the control group and the other conditions.

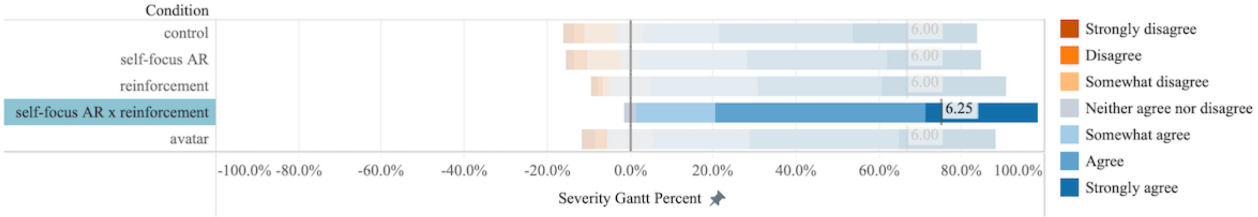

Figure 12. Significantly higher levels of perceived threat susceptibility among participants in the self-focus augmented reality (AR) × reinforcement condition compared to the control condition. No significant differences were found between the control group and the other conditions.

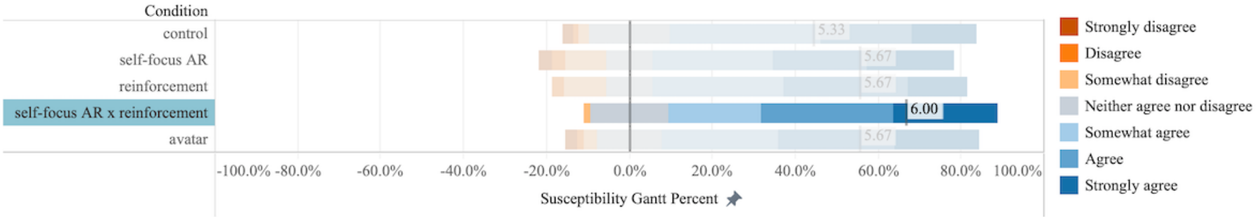

Additional analysis revealed that the use of self-focused AR and vicarious reinforcement individually did not impact measured predictors of intention, except for in the case of fear. When compared with participants in the control condition, those in the reinforcement condition (without self-focused AR) did not have a significant difference in medians for outcome expectancy (P=.48), threat severity (P=.39), susceptibility (P=.40), fear (P=.10), and message minimization (P=.47). Conversely, when compared to the control, those in the self-focused AR condition (without vicarious reinforcement) did not have a significant difference in medians for outcome expectancy (*P*=.26), threat severity (*P*=.21), susceptibility (*P*=.45), and message minimization (*P*=.39). Median scores for the self-focused AR and control groups were 5.0 and 5.3 (*U*=1950.5, *P*=.04).

A mediation model was used to test whether self-focus AR × reinforcement affects behavioral intention through perceived threat susceptibility and perceived threat severity (Figure 13). We found a significant indirect effect of self-focus AR × reinforcement on intention with perceived threat severity as the only mediator (b=.06, 95% CI 0.02-0.12, SE 0.02), but not with perceived threat susceptibility as the only mediator. In addition, a significant indirect effect of self-focus AR × reinforcement on intention was found when both perceived threat susceptibility and threat severity were included as serial mediators (b=.06, 95% CI 0.02-0.12, SE 0.03). These results indicate that although the self-focus AR × reinforcement condition does not directly affect intention in this study, its effect on threat susceptibility and threat severity results in an indirect effect on intention. A separate mediation model was used to investigate whether self-focus AR × reinforcement affects perceived threat severity through perceived threat susceptibility. A significant indirect effect of self-focus AR × reinforcement on perceived threat severity through perceived threat susceptibility was found (b=.26, 95% CI 0.08-0.45, SE 0.09).

Although fear was not significantly different from the control, we investigated whether fear or message minimization impacted intentions for those in the self-focus AR × reinforcement condition. First, a mediation model was used to test whether self-focus AR × reinforcement affects perceived fear through perceived threat susceptibility and perceived threat severity (Figure 14). A significant indirect effect of self-focus AR × reinforcement on fear was found with perceived threat severity as the only mediator (b=.16, 95% CI 0.05-0.29, SE 0.06) and with perceived threat susceptibility as the only mediator (b=.13, 95% CI 0.04-0.22, SE 0.05). In addition, a significant indirect effect of self-focus AR × reinforcement on fear was found when both perceived threat susceptibility and threat severity were included as serial mediators (b=.15, 95% CI 0.05-0.28, SE 0.06).

Next, a mediation model was used to test whether the self-focus AR × reinforcement condition affects behavioral intention through fear. A significant indirect effect of the self-focus AR × reinforcement condition on intention was found with fear as the mediator (b=.07, 95% CI 0.01-0.16, SE 0.04). An additional model tested whether the self-focus AR × reinforcement condition affects message minimization through fear, threat severity, or threat severity. A significant negative indirect effect of the self-focus AR × reinforcement condition on message minimization was found with severity as the mediator (b=–.07, 95% CI –0.16 to –0.008, SE 0.04. A negative serial mediation effect with susceptibility and severity was also found (b=–.07, 95% CI –0.16 to –0.008, SE 0.04).

Figure 13. The self-focus augmented reality (AR) × reinforcement, susceptibility, severity, and intention mediation model. The self-focus AR × reinforcement condition resulted in an indirect effect on intention through threat susceptibility and threat severity. This condition also had an indirect effect on perceived threat severity through perceived threat susceptibility.

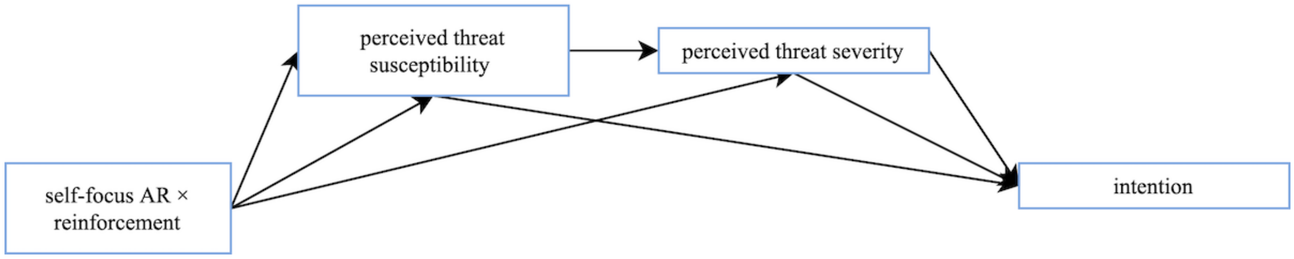

Figure 14. The self-focus augmented reality (AR) × reinforcement, susceptibility, severity, and fear mediation model. The self-focus AR × reinforcement condition resulted in an indirect effect on fear through threat susceptibility and threat severity.

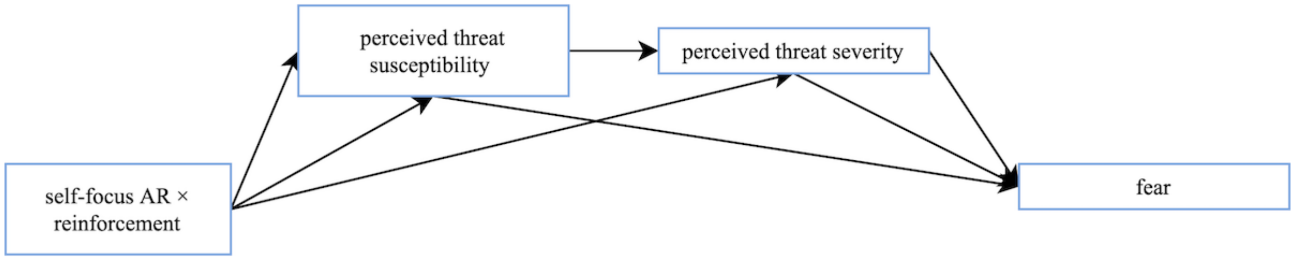

Effects of Using an Avatar on Outcome Expectancy, Fear, Threat Severity, Threat Susceptibility, and Message Minimization (Hypothesis 2)

Hypothesis 2 proposed that combining vicarious reinforcement and self-focused AR while using an avatar would result in higher levels of positive outcome expectancies, fear, perceived threat severity, perceived threat susceptibility, and message minimization when compared to a control. Compared to the control, those in the avatar condition did not have significantly different levels of outcome expectancy (*P*=.42), severity (*P*=.49), susceptibility (*P*=.15), fear (*P*=.23), or message minimization (*P*=.17).

User Feedback

At the end of the questionnaire, we asked participants to enter optional free-form text about the study. Themes among the responses included impact on knowledge, risk perception formation, and challenges with the self-focus AR × reinforcement condition. Several participants in the reinforcement condition provided generalized statements that the study was educational and helpful. The following comments from the self-focused AR group provided more details.

> *I thought the handwashing animation together with the illustration of where dirt is cleaned from the hands was very informative.* [P1]

Some participants learned a new technique or strategy:

> *I learned some new handwashing techniques! (Particularly, locking your hands together by curling your fingers into each other to get the backs of the fingers).* [P2]
>
> *I hadn't thought about separately lathering and washing my thumbs.* [P3]

Comments on personal concerns about risk indicate that future work measuring these variables may consider the time spent around others vs alone and personal risk:

> *I answered questions knowing that my husband's and my job allow us to work from home, which decreases our risk significantly, and that most of my family lives in a rural area, also less susceptible to infection.* [P4]
>
> *I know that I take it way more seriously due to the cancer treatment drug I take than most of my friends and peers because if I get it, I am not strong enough to fight it off. I think that factors in way more than friends and family risk, at least for me personally.* [P5]

Lastly, a few participants in the self-focus AR × reinforcement group expressed confusion about the design. P7, for example, expressed difficulty in positioning themselves on the screen.

> *It was an interesting survey, but the instruction given for the hand part was kind of hard to complete because the outline of the hands and the picture did not match. However, I tried my best to make it work.* [P7]
>
> *Found the movements in the video hard to follow along with, but I tried my best!* [P8]
>
> *The handwashing directions confused me. At first, I didn't understand that I wasn't supposed to mimic the exact instructions.* [P9]

The responses of P8 and P9 suggest that participants may have practiced along with the video animation. Practicing was not a requirement of participation but appeared to be a trend among those in this condition.

Discussion

This study explored the impact of self-focus and vicarious reinforcement design interventions on psychological predictors of behavior change during the COVID-19 pandemic. Our results showed that combining self-focused AR with vicarious reinforcement increases perceived threat severity and threat susceptibility and could potentially impact behavioral intentions.

Behavior Intention and Outcome Expectancy

Our results did not show any direct effects on behavioral intention (Figure 9). Given the severity of COVID-19, we expected these findings to result from a ceiling effect, as similar studies on behavior messaging strategies have found during COVID-19 [37,38]. A surprising finding was the lack of impact of the design interventions on outcome expectancy; however, this also appears to result from a ceiling effect (Figure 10), possibly resulting from the surge of news messaging surrounding hand hygiene's role in mitigating risk during COVID-19. News segments showed the impact of hand hygiene using blacklights [39] to simulate how hand washing reduces viruses' presence, which may have helped combat any disbelief. Due to the ceiling effect, our findings require replication studies post–COVID-19 or studies that include intention and outcome expectancy measures less susceptible to the ceiling effect to investigate the impact of self-focused AR and vicarious reinforcement.

Perceived Threat Severity, Threat Susceptibility, Fear, and Intention

Our findings also revealed interesting relationships between the self-focus AR × reinforcement condition, perceived threat severity, threat susceptibility, fear, and intention. Mediation models showed the self-focus AR × reinforcement condition to positively affect intention and fear through increased perceived threat susceptibility and threat severity. We found self-focus AR × reinforcement to increase perceived threat severity through increased perceived susceptibility. Lastly, we found self-focus AR × reinforcement to indirectly affect intention with fear as the mediator. These results suggest that design strategies that layer a health threat directly on an individual's reflection may increase one's perceived threat susceptibility, threat, severity, fear, and indirectly behavioral intention. While such strategies might help meet behavior change design objectives, it is essential to note the potential consequences of designs that increase fear, especially in the context of a public health emergency.

Based on the EPPM, Li [22] tested a model for protective behaviors during a public health emergency with a study during the Ebola outbreak of 2014. The study found perceived threat to have a significant effect on fear and fear controls. Our study partially supports these findings, indicating an impact of threat severity on fear but not a significant positive effect of fear on message minimization (a fear control mechanism). The danger/fear control responses and the impact of self-focused AR likely varies for each health behavior context, as levels of fear will be different for each health threat. While our study did not show adverse effects, researchers and designers should still use caution if utilizing similar design techniques to effect behavior change. More research is needed on the adverse effects of fear concerning triggering fear control mechanisms through design interventions. In addition, increased fear could have mental health implications. Harper et al [20] found fear of COVID-19 to be a positive predictor of behavior change and fear to be correlated with decreased physical and environmental quality of life. Given our findings, designers must investigate the extent to which a design strategy that involves self-focused AR with a health threat increases fear.

Independent Use of Self-focused Attention and Vicarious Reinforcement

Self-focused AR and vicarious reinforcement embedded as features independently (versus combined) did not show a significant result on any of the tested predictors of behavior change except fear. We provide a few possible explanations for these results. First, regarding mirror self-focus, threat severity, and susceptibility, there may have been too large of a time gap between when participants reviewed the health information provided and when they looked at their self-reflection. In the conditions combining the features, there was content on the screen, reminding participants of the threat at hand. Future work may account for this difference by providing text-based information over one's reflection. Second, regarding vicarious reinforcement and outcome expectancy, Figure 10 indicates the presence of a ceiling effect. This study may need to be replicated for a different health threat or mitigating behavior that wouldn't have as many positive, strong outcome expectancy beliefs.

Limitations and Future Work

It is important to note that this research took place during a long-term global public health emergency with restrictions on lifestyles that can take a while to get adjusted to. Health perceptions related to current circumstances are subject to change throughout the lifecycle of a pandemic. Our findings warrant replication studies that consider changes in severity, government mandates, social perceptions, and the availability and range of tools for risk mitigation (vaccines/medication, personal protective equipment, etc).

The data used in this study are self-reported and susceptible to response biases, specifically social desirability bias. Due to the severity of the pandemic, government mandates, news coverage, and social discussions may have increased the pressure to respond in ways that align with social norms. Future work should aim to use methods to decrease the impact of this limitation.

It is important to note that focusing on individual constructs may create an ineffective design system if the construct only works in combination with other constructs [40]. This should be taken into consideration as self-focused AR is explored in the future, possibly adding measures for other behavior change constructs such as normative beliefs and social facilitation.

While our study indicates that combining self-focused AR with vicarious reinforcement may affect health behavior change by influencing threat severity and susceptibility, we lack a data-driven explanation of why. Future work may benefit from the inclusion of quantitative measures for self-focused attention to compare with severity and susceptibility scores.

Future work may lend itself to developing experimental methods to explore the extent to which self-monitoring, reflective thinking, self-evaluation, and emotion management naturally occur (or do not occur) when using self-focused AR. Conducting these experiments will provide deeper insights into how self-focused AR impacts the psychological mechanism related to behavior change and possibly inspire experiments on how the combination of self-focused attention and other design features could enhance this effect.

According to user feedback, future work should also consider accounting for time spent around others vs alone and personal health when measuring perceived threat severity. Responses also indicate that when measuring perceptions about new messaging, participants should be instructed to respond based on their preferred news source to limit confusion related to the different opinions they hold for individual new sources.

Two comments from the user feedback indicated that participants might have been actually practicing handwashing movements while viewing the animation. During the screenshot verification process, it was noted whether a participant was observed practicing along with the handwashing video. Practicing was not a requirement of participation and was not mentioned in any instructions provided to them. A total of 32 out of 63 participants were observed practicing along with the video in the self-focus AR × reinforcement condition. The self-focused AR and avatar conditions had 7 and 6 individuals observed practicing, respectively. These results cannot be used to make any claims due to the study's technical setup. Those in the self-focus AR × reinforcement group were instructed to have their hands in view of the camera. Those in other conditions may have practiced off-camera. However, as practicing may affect behavior, this is another potential area for future research.

Conclusion

As self-focused AR technologies grow in popularity, it is important to understand how such experiences could impact perceptions, emotions, and behavioral intentions. Previous research [5,12-14,28] has explored self-focused AR to varying degrees revealing a potential impact on health behavior. Our study expands upon this work by combining self-focused AR and vicarious reinforcement. Doing so helped to reveal insights about the impact of each feature on perceptions and emotions as they relate to behavior change.

We found that displaying germs disappearing directly from the user's self-reflection during a handwashing animation will result in higher scores for perceived threat severity and susceptibility when compared to the control or conditions that implemented self-reflection and a display of germs disappearing separately. Increased perceived severity and susceptibility were found to increase behavioral intention. These findings indicate that combining self-focused AR with vicarious reinforcement may be an effective strategy for health communication designers. However, we also voice concern about the possible adverse effects of heightening levels of fear as a design strategy. While our study did not show concerning results, prior research indicates that heightening fear as a health communication strategy can lead to defensive reactions (versus changing behavior) [22,25] and can lower quality of life [20]. We recommend that this be taken into consideration by designers whenever augmenting self-focused attention with a health threat, especially during a public health emergency, as fear may already be at concerningly high levels. Future research should further investigate the role of fear, perceived threat severity, and threat susceptibility when using self-focused AR in health contexts and design strategies for maintaining the well-being of the user while inspiring behavior change.

Acknowledgments

We thank our Wellesley College HCI Lab colleagues, family, and friends for participating in the pilot testing for the study. We thank Angela Qian and Karl Ivan M San Luis for their feedback on the study, as well as Shaun Digan for proofreading. Abstract

Background: Health care professionals (HCPs) routinely have questions concerning the medications they are recommending. There are numerous resources available; however, each has its own advantages and disadvantages.

Objective: The purpose of this survey was to gain knowledge of the preferred methods and sources HCPs use to obtain information concerning medications.

Methods: A total of 511 HCPs (202 physicians, 105 pharmacists, 100 advance practice nurses, 53 registered nurses, and 51 physician assistants) were surveyed through a third-party market research firm. All participants were practicing in the United States. Individuals working for a pharmaceutical company were excluded. The survey collected demographics, frequency of searching medical information, types of questions searched, sources of medical information, and rationale for preferred and nonpreferred sources of medical information. Use of medical information resources were rated on a 5-point ordinal scale. Data were analyzed with descriptive statistics.

Results: Of the 511 respondents, 88.5% (452/511) searched for medical information either daily or several times per week. The most common questions involved dosing and administration, drug-drug interactions, adverse events and safety, clinical practice guidelines, and disease state information. The main rationale for using specific medical websites or apps and general online search engines frequently or very frequently was ease of use (medical websites or apps: 269/356, 75.6%; general online search engines: 248/284, 87.3%). Accuracy was the main rationale for frequent or very frequent use of medical literature search databases (163/245, 66.5%), prescribing labels or information (122/213, 57.3%), and professional literature (120/195, 61.5%). The main reason for rarely or never using specific medical websites or apps and medical literature search databases was unfamiliarity (medical websites or apps: 16/48, 33%; medical literature search databases: 35/78, 45%); for general online search engines, inaccuracy (34/54, 63%); and for prescribing labels or information and professional literature, excessive time (prescribing labels or information : 54/102, 52.9%; professional literature: 66/106, 62.3%). The pharmaceutical company was sometimes used as a resource for medical information. When the medical information department was used, the call center and the website were considered thorough and complete (call center: 14/25, 56%; website: 33/55, 60%). However, the rationale for not using the call center was the time required (199/346, 57.5%) and the website being unfamiliar (129/267, 48.3%).

Conclusions: The driving forces in the selection of resources are accuracy and ease of use. There is an opportunity to increase awareness of all the appropriate resources for HCPs which may aid in their daily clinical decisions. Specifically, pharmaceutical company medical information departments can help fulfill this need by addressing two major challenges with use of the pharmaceutical company: lack of awareness of medical information services and the speed at which responses are disseminated. Overall, there is lack of understanding or appreciation of the range of pathways to obtain published information and knowledge from pharmaceutical company medical information services. Among the many challenges resource champions will face are the ability to effectively make resources and their platforms accessible, known, and useful to the scientific community.

information-seeking behavior; access to information; internet; physicians; nurses; pharmacists; medical literature; databases; search tools; medical information

Introduction

Health care professionals (HCPs) routinely seek medical information concerning the therapies recommended or used to manage and treat their patients. The US Food and Drug Administration (FDA) approved over 100 novel medications between 2019 and 2020 with a trend for increasing annual approvals over the last decade [1]. Meanwhile, medical information resources that HCPs use to address questions and issues in caring for their patients are growing and expanding [2].

HCPs have a wide variety of options for seeking answers to their questions. The number of resources has expanded and now includes drug aggregate platforms (Epocrates, MicroMedex, Up-to-Date, Medscape), medical information departments, professional journals, prescribing labels, electronic health record systems, textbooks, search engine websites, and academic drug information centers [2]. Although the drug aggregate platforms provide a wealth of information, these databases may contain misinformation [3]. In a 2020 study of neurologists, online resources were preferred (96%) compared to offline resources (47%) [4]. According to the 2013 study by Kritz [5], physicians used online resources for medical information; however, access to quality information was a barrier of note.

Medical information services offered by pharmaceutical companies can provide evidence-based, scientifically balanced, accurate, truthful, nonmisleading responses to unsolicited inquiries from HCPs. These unsolicited inquires can be questions concerning the FDA-approved product labels or questions beyond the labeled information. The responses to these inquiries conform with internal procedures and policies as well as with the FDA draft guidance document [6].

Previous literature has suggested that ease of access and quality are important factors when physicians or medical students search for medical information [7]. For example, in a 2009 survey, 92% of physicians reported clicking results toward the top of a page when searching for medical information online [8]. Search engine algorithms are continually updating and adapting in an effort to improve the search results, identify high quality content, and devalue lower-quality content [9]. However, online access alone may not be enough, as barriers such as time constraints confounded by password or account creation requirements on some medical information department websites may impede use of these resources. Another key component noted in past surveys is that HCPs consider current information from a trusted source as high-quality information [7]. Overall awareness, access, and trust have been discussed as important factors HCPs consider when deciding on medical information resources [2]. In a comprehensive literature review of more than 30 studies, Davies et al [10] found that the majority of research focused predominantly on physicians and the type of information they sought. A key barrier to physicians' search for information was the time needed to perform the search effectively. The studies on this topic [2,7-10], most of which are outdated, highlight the lack of published literature on this subject, particularly evaluations on the search preferences of HCPs apart from those of physicians.

Given the numerous resources HCPs can use today for searching or requesting medical information, there is a need to better understand their search preferences, processes, and barriers to using these resources. Therefore, the purpose of this study was to gain knowledge about the frequency, preferred methods, and most common sources HCPs use to obtain medical information. An additional goal was to evaluate and categorize the rationale of HCP choices with the aim of enhancing medical information services within pharmaceutical companies.

Methods

A deidentified, web-based, qualitative survey was designed by members of phactMI to collect the opinions of HCPs concerning their search preferences for medical information. Surveys were distributed through a third party platform (Dynata market research organization). Recruitment and participation were communicated via email through Dynata. Participants received a unique identifier that did not reveal their identity to the study team. The survey was administered once and was open for 1 week in March 2019.

HCPs (physicians, pharmacists, nurse practitioners or advance practice nurses, registered nurses, and physician assistants) received an email inviting them to participate in the survey. These HCPs were registered with the third-party surveying platform, Dynata. The survey was distributed to a panel of verified HCPs and was available until the prespecified convenience sample was obtained. A sample size of 202 physicians, 105 pharmacists, 100 advance practice nurses, 53 registered nurses, and 51 physician assistants was chosen and felt to be representative of those HCPs who contact the typical mid- and large-size pharmaceutical companies' medical information departments. Registered HCPs responded to qualifying questions based on the inclusion and exclusion criteria. Participants were included based on their profession (practicing physician, pharmacist, nurse practitioner or advanced practice nurse, registered nurse, and physician assistant) and their country of practice (the United States). Participants who were not currently practicing or who were employed by a pharmaceutical or biopharmaceutical company were excluded. Once 511 qualified respondents completed the survey, the recruitment period ended. Participants were asked for their consent to participate in the survey prior to survey administration. Dynata follows the International Chamber of Commerce/European Society for Opinion and Marketing Research (ICC/ESOMAR) International Code on Market, Opinion, and Social Research and Data Analytics.

The survey collected information regarding HCPs' demographics (HCP type, years of practice, specialty, and practice setting) and their search preferences and processes. The survey took about 10 minutes and consisted of 13 questions. Questions in the survey included frequency of searching for medical information, inquiry categories, sources of medical information used, and rationale for preferred and nonpreferred sources of medical information. The survey consisted of multiple choice questions, ranking, and, to a lesser extent, a free-text field. Based on responses given throughout the survey, additional information was ascertained regarding reasons why or why not certain sources of medical information were preferred or not preferred. See Multimedia Appendix 1 for the full list of survey questions and available responses.

Descriptive analysis of data was conducted. Data were analyzed based on the entire cohort as well as on profession, specialty, and years in practice. Chi-square and Fisher exact tests were used for categorical data.

Results

Demographics

Based on the convenience sample set, a total of 511 health care professionals in the United States were included in the survey, comprising physicians (202/511, 39.5%), pharmacists (105/511, 20.5%), nurse practitioners or advanced practice nurses (100/511, 19.6%), registered nurses (53/511, 10.4%), and physician assistants (51/511, 10.0%). The most common practice settings represented included private practice (211/511, 41.3%), community hospitals (127/511, 24.9%), and academic or teaching hospitals (102/511, 20.0%). Consistent with the dominant practice settings in this survey, almost half (249/511, 48.7%) of all respondents worked in primary care. Moreover, 80.2% (410/511) of those surveyed had been in practice for ≥ 11 years. See Table 1 for additional details.

Table 1. Demographics.

[a] More than one practice setting could be selected.

[b] HCPs: health care professionals.

[c] NP/APN: nurse practitioner/advanced practice nurse.

[d] RN: registered nurse.

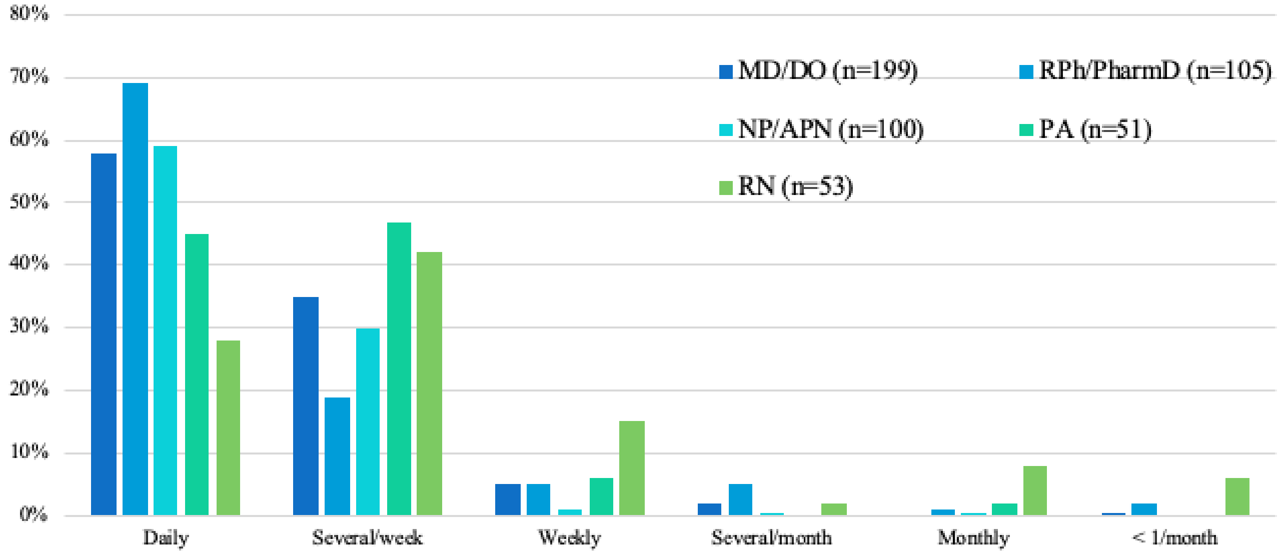
[e] PA: physician assistant.

[f] Other practice settings included health maintenance organization (n=73), pharmacy hospital (n=23), pharmacy retail (n=64), managed care (n=6), research (n=4), long-term care (n=22), and other (n=12).

Frequency of Search

Of the 511 respondents, 452 (88.5%) searched for medical information either daily or several times per week (Figure 1). In particular, 92.6% (187/202) of physicians surveyed search for medical information either daily or several times per week, compared to 87.6% (92/105) of pharmacists, 89.0% (89/100) of advance practice nurses, 70% (37/53) of registered nurses, and 92% (47/51) of physician assistants (X^2_4=49.51; P<.001). Overall, 90.1% (91/101) of respondents with 10 years of practice or less and 88.0% (361/410) of respondents with 11 or more years of practice searched for medical information daily or several times per week.

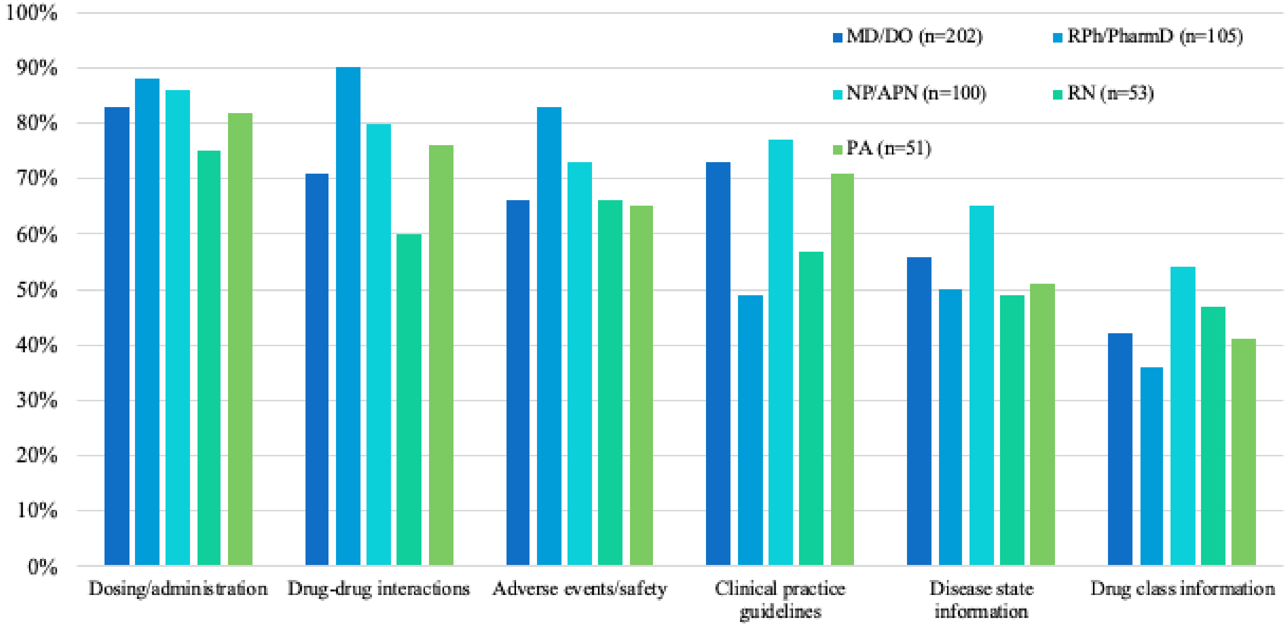
Figure 1. Frequency of medical information searches. APN: advanced practice nurse; DO: Doctor of Osteopathic Medicine; MD: medical doctor; NP: nurse practitioner; PA: physician assistant; PharmD: Doctor of Pharmacy; RN: registered nurse; RPh: registered pharmacist.



Inquiry Type

The most common questions across all HCP types concerned dosing or administration (428/511, 83.8%), drug-drug interactions (389/511, 76.1%), adverse events and safety (361/511, 70.6%), clinical practice guidelines (342/511, 66.9%), and disease state information (283/511, 55.4%; Figure 2). Overall, there were no significant differences between the professions and the type of information they were looking for.

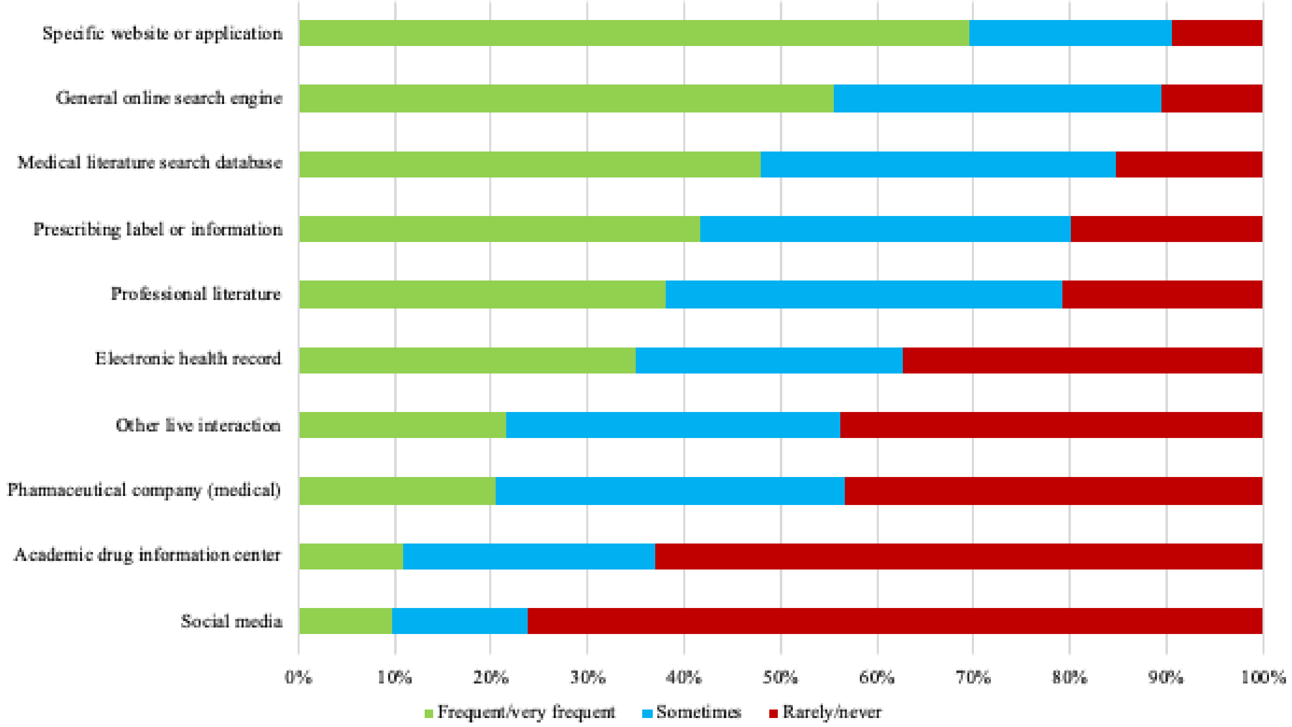
Figure 2. Information typically sought by healthcare professionals. APN: advanced practice nurse; DO: Doctor of Osteopathic Medicine; MD: medical doctor; NP: nurse practitioner; PA: physician assistant; PharmD: Doctor of Pharmacy; RN: registered nurse; RPh: registered pharmacist.



Search Tools

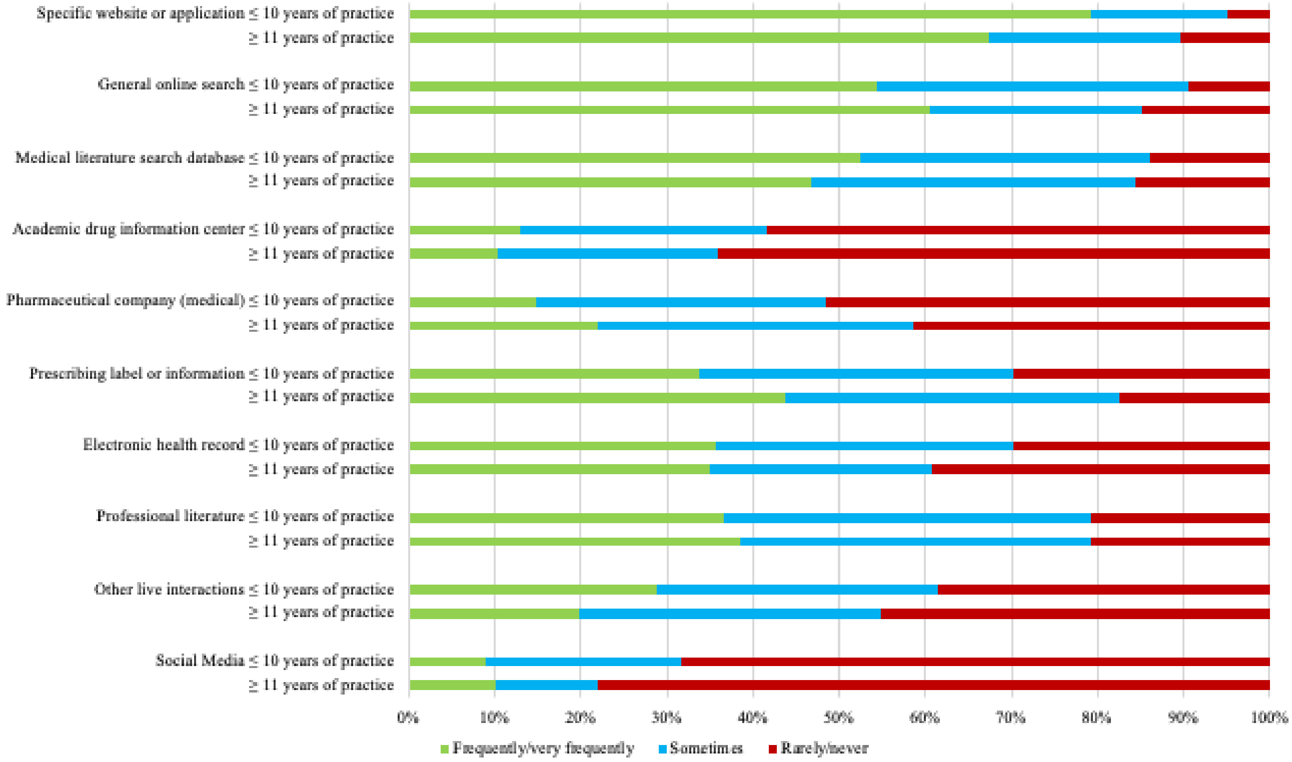
More than half (58.7%, 300/511) of respondents indicated searching for medical information from a desktop, laptop, or workstation a majority (ie, >50%) of the time as opposed to the 25.6% (131/511) of respondents who used a mobile device the majority of the time. Specific medication websites or apps were frequently or very frequently searched by 69.7% (356/511) of the respondents. Furthermore, 55.6% (284/511) of HCPs surveyed use general online search engines such as Google or Yahoo frequently or very frequently. Medical literature search databases, prescribing labels or information, professional literature, and company resources were accessed less frequently (Figure 3).

Figure 3. Frequency of use of major information sources.



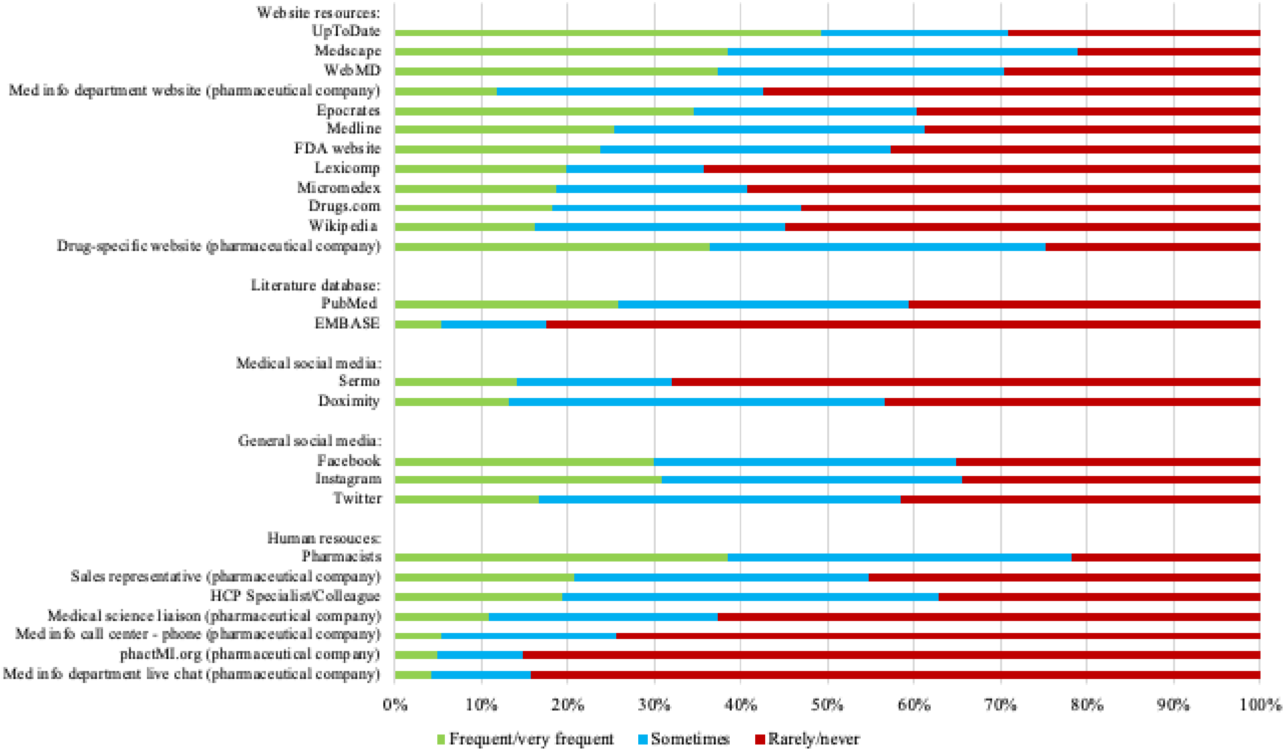
Differences in the search option used were observed based on the number of years in practice. Overall, 24.8% (25/101) of the less experienced respondents (10 years of practice or less) versus 36.8% (151/410) of the respondents with 11 years or more of practice reported sometimes using general online search engines; 79.2% (80/101) of the less experienced respondents versus 67.3% (276/410) of the more experienced respondents reported frequent or very frequent use of specific websites or app for their searching needs; 29.7% (30/101) of the less experienced respondents versus 39.3% (161/410) of the more experienced respondents reported rarely or never using electronic health record information; and 67.3% percent (69/101) of the less experienced respondents reported rarely or never using social media versus 78.0% (320/410) of the more experienced group (Figure 4). Differences in the search option used stratified by the number of years in practice did not reach statistical significance.

Figure 4. Search option preference based on years of practice.



In the analysis regarding the frequency of use of search options, UpToDate ranked highest among all individual sources of medical information (excluding general online search engines). The drug-specific website was the most frequently used resource by those contacting the pharmaceutical company directly. PubMed and MEDLINE were the most popular literature search databases used. Facebook, Sermo, and Instagram were the most popular social media platforms used (Figure 5).

Figure 5. Frequency of use of source information. FDA: Food and Drug Administration; HCP: health care professional.



Reasons for Frequent or Infrequent Use of Search Options

Ease of use was the rationale for the frequent or very frequent use of specific medication websites or apps (269/356, 75.6%) and general online search engines (248/284, 87.3%; Table 2). Accuracy was the major rationale for frequent or very frequent use of medical literature search databases (163/245, 66.5%), prescribing labels or information (122/213, 57.2%), and professional literature (120/195, 61.5%). The main reason for infrequent (rarely or never) use of specific medication websites or apps (16/48, 33%) and medical literature search databases (35/78, 44.9%) was unfamiliarity; for general online search engines, inaccuracy (34/54, 63%); and for prescribing labels or information (54/102, 52.9%) and professional literature, time (66/106, 62.2%; Table 2).

In general, there was low usage of the pharmaceutical company (medical information website, medical science liaison, or sales representative). HCPs in the setting of a hospital pharmacy (6/23, 26%) and retail pharmacy (16/64, 25%) were more likely than those in an academic hospital (16/102, 15.6%) to use the services of the pharmaceutical company frequently or very frequently. When the medical information department was used, the medical information department call center and the website were considered thorough or complete (14/25, 56% and 33/55, 60%); however, the barriers included excessive time (199/346, 57.5%; 79/267, 29.6%) or unfamiliarity with the service (118/346, 34.1%; 129/267, 48.3%; Table 2). Similar findings were reported regarding the pharmaceutical company field medical teams. For HCPs who frequently or very frequently contact a sales representative when searching for medical information, accessibility of the sales representative was the most stated rationale provided.

There was generally low usage of the medical information department live chat service, with only 3.7% (19/511) of HCPs reporting that they use this service frequently or very frequently. When used, accessibility was the main driver (13/19, 68%). For the majority of respondents who indicated having rarely or never contacted the pharmaceutical company via live chat, 33.8% (133/393) were unfamiliar with the service and 51.9% (204/393) noted it took too long.

Free-text entries were reviewed. Additional information regarding practice settings have been included under demographics (see Table 1); however, data obtained from other text fields did not provide any useful information and have not been summarized due to the limited range and number of entries.

Table 2. Rationale for frequent or very frequent or rarely/never use (N=511).

Rationale by use frequency	General online search, n (%)	Medical literature database, n (%)	Specific web app, n (%)	Med info[a] call center, n (%)	Med info[a] website, n (%)	Medical science liaison, n (%)	Drug website, n (%)

Discussion

Principal Findings

With the lack of recently published information on search preferences for HCPs, this study provides insights into frequency, preferred methods, and commonly used sources that a broad range of HCPs used to obtain medical information. Overall, 88.5% (452/511) of all HCPs, including almost 95% of physicians, search for medical information either daily or several times per week. Data from this study show that HCPs are using only a few of the aforementioned resources, and many valuable assets are being underused. Medical literature search databases, prescribing labels or information, professional literature, and pharmaceutical company resources were used less frequently compared to other resources, such as general online search engines or specific websites and apps. It is important to note here that general search engines may be used by HCPs to access specific web-based resources such as Medscape and WebMD. Potential reasons for low usage can vary from access issues with literature databases, inability to find a specific answer to a question from the label, or a lack of awareness of pharmaceutical resources such as medical information services or access to company representatives. With the rapidly expanding bank of scientific data, it is becoming increasingly important to have access to information from credible sources.

Taking a closer look at the use of the pharmaceutical company as a resource, less frequent use was due in part to perceived barriers which include the length of time it takes to produce data in response to a specific unsolicited question and the unfamiliarity of the HCPs with the medical information service provided. Previous research has documented that HCPs who use medical information services identify the information as trustworthy [11,12]. However, among the HCPs who had not used medical information services, the top 3 reasons were bias (55%), lack of awareness (41%), and lack of transparency (30%) [12]. The technological advancement and rise in new tools in the pharmaceutical and biotech industry have the potential to better address HCPs' needs, provided that some work is done to resolve the existing barriers.

Limitations

One limitation to this study is the inclusion of only US HCPs. In addition, the demographics of the various HCPs, including physicians (202/511, 39.5%), pharmacists (105/511, 20.5%), nurse practitioners or advanced practice nurses (100/511, 19.6%), registered nurses (53/511, 10.4%), and physician assistants (51/511, 10.0%), was not equally distributed and might have skewed the data towards physician preferences. Another limitation is that the survey was qualitative in nature; therefore, some of the terminology used within the questions could have been subject to personal interpretation. For example, the definition of "ease of use" might have been influenced by an individual's subjective perception. Another point to consider is that no information on the current level of digital tool usage was gathered from the respondents, so it is not clear if the results might have been influenced by a low level of familiarity with digital tools in general. Additional insights from a larger-scale study with HCPs worldwide would be of interest for comparison.

It is also important to realize the survey was conducted in March 2019, prior to the current global COVID-19 pandemic. Current remote workflow and reliance on technology could alter the responses of HCPs if the survey were repeated today, and it is unclear what the long-term consequences and duration of these changes will be.

Conclusions

Research has shown that accuracy and ease of use are the driving forces for HCPs in choosing resources for daily use. Data from this study show an opportunity to increase awareness of all the appropriate resources tailored to HCPs which may aid in their daily clinical decisions. In addition, there is an opportunity for medical information departments from pharmaceutical and biotech companies to help fulfill this need by addressing two major challenges in the use of pharmaceutical companies as a resource: lack of awareness of these medical information services and the speed at which responses are disseminated to HCPs. There is a potential opportunity for medical information departments and field medical teams (ie, medical science liaisons) to work together to overcome these perceived barriers through bringing awareness to the service and increasing accessibility to HCPs by emphasizing the point that medical teams are to only provide tailored scientific data in a nonpromotional manner that most suits their work style and demand [6].

With a significant push towards evidence-based medicine, there remains a need for a unified source for medical information that meets the shifting workstyle needs of practitioners. Optimal treatment decisions are incumbent on current, high-quality, nonpromotional data. The results of this research identified gaps in understanding the numerous ways HCPs obtain published data and the limited knowledge of medical information services provided by pharmaceutical and biotech companies. Among the many challenges resource champions will face are the ability to effectively make resources and their platforms accessible, known, and useful for the scientific community. This will further shape and impact the future of patient outcomes.

Conflicts of Interest

ERHD is employed by phactMI (a nonprofit collaboration of medical information leaders from the pharmaceutical industry). RTH and MAN are employed by EMD Serono, and RTH owns EMD Serono stock. DB is employed by Bristol Myers Squibb. JW and RB are employed by and own Biogen stock. RTH, DB, RB, JW, and MAN are members of phactMI.

Abstract

Background: The internet is used for information related to health conditions, including low back pain (LBP), but most LBP websites provide inaccurate information. Few studies have investigated the effectiveness of internet resources in changing health literacy or treatment choices.

Objective: This study aims to evaluate the effectiveness of the MyBackPain website compared with unguided internet use on health literacy, choice of treatments, and clinical outcomes in people with LBP.

Methods: This was a pragmatic, web-based, participant- and assessor-blinded randomized trial of individuals with LBP stratified by duration. Participants were randomly allocated to have access to the evidence-based MyBackPain website, which was designed with input from consumers and expert consensus or unguided internet use. The coprimary outcomes were two dimensions of the Health Literacy Questionnaire (dimension 2: "having sufficient information to manage my health;" dimension 3: "actively managing my health;" converted to scores 1-100) at 3 months. Secondary outcomes included additional Health Literacy Questionnaire dimensions, quality of treatment choices, and clinical outcomes.

Results: A total of 453 participants were recruited, and 321 (70.9%) completed the primary outcomes. Access to MyBackPain was not superior to unguided internet use on primary outcomes (dimension 2: mean difference −0.87 units, 95% CI −3.56 to 1.82; dimension 3: mean difference −0.41 units, 95% CI −2.78 to 1.96). Between-group differences in other secondary outcomes had inconsistent directions and were unlikely to be clinically important, although a small improvement of unclear importance in the quality of stated treatment choices at 1 month was found (mean difference 0.93 units, 95% CI 0.03 to 1.84).

Conclusions: MyBackPain was not superior to unguided internet use for health literacy, but data suggest some short-term improvement in treatment choices. Future research should investigate if greater interactivity and engagement with the website may enhance its impact.

Introduction

Background

Low back pain (LBP) is the leading cause of disability globally [1]. Unnecessary and ineffective management inflates its burden [2], and its impact is worsened by negative messages and beliefs [3,4]. Access to an evidence-based, consumer-focused tool to enhance health literacy and empower active participation in self-management and treatment selection could reduce the burden. Although tools are available, the evaluation of their effectiveness is limited.

The internet is a primary source of health-related information [5-7]. Up to 68% of individuals search for health-related information on the web [7,8]. Information is sought on the internet for treatment decision support [7,9,10], self-management advice [7,9], guidance regarding health care providers [10], increased knowledge [10,11], and preparation for consultations [10]. The advantages of the internet are accessibility, high reach, low cost, and scalability [12]. Unfortunately, most LBP websites are rated poorly [13-15], do not meet consumers' needs [16], provide inaccurate information and treatment recommendations [17], and use inappropriate language [14]. Although systematic reviews provide modest evidence of the efficacy of internet-delivered *interventions* (eg, cognitive behavioral therapy [18,19]), whether *information* resources improve outcomes and behaviors is unknown.

Objectives

This study aims to evaluate access to an LBP website [20] that integrates evidence-based LBP information developed through consumer consultation and expert consensus [21]. We hypothesize that the MyBackPain website more effectively improves health literacy (primary outcome), choice of evidence-based treatments, and clinical outcomes in people with LBP than unguided use of internet resources.

Methods

Trial Design

We conducted a two-arm pragmatic, web-based, superiority randomized controlled trial. It was prospectively registered (Australian New Zealand Clinical Trials Registry ACTRN12617001292369), and the protocol has been published [22]. Ethical approval was obtained from the University of Queensland Ethics Committee (#2017000995). Written informed consent was obtained from all participants.

Participants

We recruited community participants with current LBP using newsletters, email lists, consumer groups, websites, social media, and newsletters to members of a health insurer (Medibank Private). Inclusion criteria were current LBP of any duration, aged 18 years and above (no upper age limit), current residence in Australia, adequate English to use the MyBackPain website, and internet access. Participants were excluded if they reported a previous or existing serious spinal pathology (fracture, cancer, or infection) or specific diagnosis including sciatica (participants with leg pain but no diagnosis of sciatica were not excluded), lumbar spinal stenosis, or nerve root compromise.

Procedure

This trial was conducted on the web. Potential participants were provided with a web link to the participant information sheet and consent form. Those who consented completed an eligibility screening form and, if eligible, were invited to complete the baseline questionnaires. They were given contact details of the trial coordinator at baseline and at each follow-up assessment to ask any questions. Data were recorded in REDCap (Research Electronic Data Capture; hosted at the University of Queensland) [23,24]. In addition to primary and secondary outcomes, baseline data included duration of the current pain episode, demographics (age, gender, height, mass, education, job, and job status), and details about their low back symptoms (including location, intensity, duration, frequency, and past treatments; see Table 1 for specific questions and response options).

The participants were sent two reminders to complete the baseline data. Primary and secondary outcomes were collected at baseline and at 1, 3, 6, and 12 months after randomization. Pain intensity (pain visual analogue scale; see *Secondary Outcomes*), websites visited, and treatments used were recorded weekly until 3 months (primary endpoint) and then monthly until 12 months. Outcome data at each time point were collected using REDCap (automated email reminders), and up to three reminders were sent. To encourage retention, participants were entered into a draw for an iPad mini on completion of all data collection.

Table 1. Baseline characteristics of participants by group.

Characteristics	Group 1 (n=226)	Group 2 (n=214)
Acute[a], n (%)	59 (26.1)	53 (24.8)
Chronic[b], n (%)	167 (73.9)	161 (75.2)
Age at consent (years), mean (SD)	47.8 (14.1)	48.1 (14.0)
Gender, n (%)		
Female	174 (77)	161 (75.2)
Male	49 (21.7)	53 (24.8)
Other	3 (1.3)	0 (0)
Height (cm), mean (SD)	168.8 (10.1)	169.6 (9.3)
Mass (kg), mean (SD)	83.7 (20.1)	83.7 (20.7)
BMI (kg/m^2), median (IQR)	28.9 (24.5-33.6)	27.7 (24.1-32.6)
Level of education, n (%)		
High school certificate	38 (16.8)	30 (14)
Trade certificate	25 (11.1)	22 (10.3)
Diploma	37 (16.4)	29 (13.6)
Advanced diploma	12 (5.3)	13 (6.1)
Bachelor degree	59 (26.1)	57 (26.6)
Postgraduate degree	36 (15.9)	52 (24.3)
Other	19 (8.4)	11 (5.1)
Employment status, n (%)		
Full time/full duties	77 (34.1)	81 (37.9)
Full time/selected duties	8 (3.5)	2 (0.9)
Part time/full duties	33 (14.6)	43 (20.1)
Part time/selected duties	22 (9.7)	9 (4.2)
Not working/unemployed	4 (1.8)	6 (2.8)
Not working/employed/retraining	2 (0.9)	1 (0.5)
Not working/unemployed/retraining	4 (1.8)	7 (3.3)
Not working/unemployed	13 (5.8)	12 (5.6)
Not seeking employment	63 (27.9)	53 (24.8)
Aboriginal/Torres Strait Islander, n (%)	3 (1.3)	3 (1.4)
Born in Australia, n (%)	159 (70.4)	161 (75.2)
First experience of LBP[c], n (%)	14 (6.2)	12 (5.6)
Number of episodes of LBP, n (%)		
1-5	24 (11.3)	16 (8)
5-10	16 (7.5)	23 (11.4)
10-15	11 (5.2)	10 (5)
15-20	7 (3.3)	14 (7)
More than 20	63 (29.7)	54 (26.9)
I am never without LBP	91 (42.9)	84 (41.8)
Ever been given a diagnosis of LBP, n (%)	128 (56.6)	125 (58.4)
Have pain or altered sensation in buttocks/legs, n (%)	166 (73.5)	155 (72.4)
Had problems with your bowel or bladder function since your back pain started, n (%)		

Characteristics	Group 1 (n=226)	Group 2 (n=214)
Bladder	21 (9.3)	17 (7.9)
Bowel	22 (9.7)	15 (7)
Bladder and bowel	30 (13.3)	22 (10.3)
No	153 (67.7)	160 (74.8)
Had treatment for current episode of LBP, n (%)	142 (62.8)	116 (54.2)
Had treatments for previous episodes of LBP, n (%)	174 (82.5)	166 (82.6)
Have other medical conditions, n (%)	141 (62.4)	134 (62.6)
Have pain in other part of spine, n (%)	134 (59.3)	132 (61.7)
Feel pain in other areas of body, n (%)	143 (63.3)	130 (60.7)

[a] <6 weeks duration following period of no pain for at least 4 weeks.

[b] ≥6 weeks duration.

[c] LBP: low back pain.

Randomization and Allocation Concealment

The study biostatistician prepared the randomization schedule using stratification permuted block randomization, with block sizes of 6 to 12 stratified by symptom duration (acute LBP: <6 weeks duration with at least 4 weeks interval from a preceding episode; chronic LBP: all other presentations). After completion of baseline data, participants were randomized sequentially according to the schedule and provided with information regarding their mode of internet access.

Blinding

Participants and investigators (except the project manager) were blinded to treatment allocation. All participants were advised in the participant information sheet that the study aimed to investigate the impact of internet use on their LBP. To maintain blinding, all participants recorded the address of any website visited for information regarding LBP over 12 months. The intervention group had access to the password-protected MyBackPain website. The control group was not aware of this website and was unable to access it until the website was launched to the public on July 30, 2019, after the primary endpoint had passed for all participants. Given that all outcome measures were self-reported, outcome assessments were also blinded. A blinded biostatistician conducted the data analysis.

Study Treatments

Treatment

Participants randomized to the intervention group were given access to the MyBackPain website and encouraged to use it. The evidence-based content and framework of the MyBackPain website were developed according to consultation and collaboration with individuals with LBP, clinicians, and an international expert team [21].

Website development involved distillation of the highest quality information for acute and chronic LBP into easily understood resources in multiple formats. Textbox 1 lists the overarching principles.

Website access required a unique username and password provided to the intervention group participants. As we intended to study the natural use of the website, participants were free to determine how and when they accessed it and the content they used. Participants could use the website in multiple ways: self-directed browsing; automated, guided content tailored to the features of their presentation (evidence-based algorithms based on a pick-up tool for acute LBP [25] or STarT Back for chronic LBP [26]); and to *opt-in* for emails of key messages about LBP.

Textbox 1. Four overarching principles of the MyBackPain website.

Principles

- To enhance consumer confidence to manage their condition and make evidence-based treatment choices and avoid ineffective, unnecessary or harmful investigations and treatments
- To demedicalize and normalize low back pain (LBP) with messages that reinforce that back pain is a natural part of life for many and in most cases can be managed with early return to activity
- To provide tools for individuals to identify the necessity for further investigation, management, or both
- To engage users in healthy behaviors and attitudes to reduce the burden of LBP

Control

Participants randomized to the control group were asked to use the internet to obtain information about LBP in a self-directed manner and record the address of any relevant websites weekly (weeks 1-12) and monthly (months 3-12) web-based diaries. They did not have access to or knowledge of the MyBackPain website, at least until after the primary endpoint. We cannot exclude the possibility that some control participants might have become aware of and used the site after its launch. At launch, 89 control participants were yet to complete a long-term follow-up.

Outcome Measures

Primary Outcome

We used dimensions 2 and 3 of the Health Literacy Questionnaire (HLQ) [27] as coprimary outcomes to determine the extent to which participants considered "having sufficient information to manage my health" and "actively managing my health," respectively, at 3 months after randomization. The validated HLQ includes 44 items in nine dimensions, with each dimension considered individually [27]. Dimensions 2 and 3 included four items assessed using a 4-point Likert scale (1=strongly disagree; 4=strongly agree), converted to a score of 0 to 100 for analysis. The survey's preamble asked participants to consider their LBP when answering.

Secondary Outcomes

Secondary outcomes were (1) other HLQ dimensions, (2) quality of treatment choices, and (3) clinical outcomes. Secondary measures from the HLQ were dimensions: 1 ("feeling understood and supported by healthcare providers") and 4-9 ("social support for health;" "appraisal of health information;" "ability to actively engage with healthcare providers;" "navigating the healthcare system;" "ability to find good health information" and "understand health information well enough to know what to do"), assessed using 4-point (dimensions 1 and 4-5) or 5-point (dimensions 6-9) Likert scales.

The stated and observed quality of treatment choices was assessed in three ways:

1. Quality of treatment preference (stated): participants indicated on a 5-item scale (effective, somewhat effective, unsure, not very effective, and not effective) the degree to which they considered a subset of 10 treatments discussed in the MyBackPain website to be effective for LBP in response to the question "Do you think these treatments are effective for people's back pain? Note: think broadly about back pain, not just about your own." Treatment choices were scored against the recommendations provided in the MyBackPain website according to the classifications of "good evidence," "may work," "not enough evidence," "unlikely to work," and "may be harmful" (Multimedia Appendix 1 shows the scoring matrix; scores from −20 to +22; a 1-point change would relate to a shift from being *unsure* of the efficacy of one treatment that is *unlikely to work* to considering it to be *not very effective*).
2. Quality of treatment preference (observed-scored): treatments used by participants (diary recording) were evaluated against the recommendations provided on the MyBackPain website. Each reported treatment was scored according to Multimedia Appendix 1 and summed (no upper and lower limits).
3. Quality of treatment preference (observed-proportion): the proportion of participants who chose treatments that are, according to MyBackPain, either recommended ("good evidence" and "may work") or considered to have no effect or be harmful ("not enough evidence," "unlikely to work," and "may be harmful") were assessed separately. Using diary data, participants were allocated a score of 1 if they used at least one recommended treatment and separately if they used a treatment that was harmful or had no effect. Proportions with scores of 1 were calculated.

LBP clinical outcomes were measured with the following validated tools: pain—visual analogue scale of average LBP in the last week ("no pain" at 0 and "worst pain imaginable" at 100); disability—Roland Morris Disability Questionnaire [28] (scores from 0 to 24; higher scores indicate more disability); and quality of life—Assessment of Quality of Life–8 dimension (utility scores from 0.0 to 1.0, with higher scores indicating better quality of life).

Adherence to Intervention

We were unable to track the individual use of MyBackPain because of privacy concerns of the host sites (Arthritis Australia). We tracked the overall use of the site (number of sessions; new or returning users) using the Opentracker software.

Sample Size

Sample size calculation was based on an effect size of 0.30 for the coprimary outcomes. A sample size of 440 participants (a minimum of 110/440, 25% with acute LBP) was required to achieve 80% power to detect the desired effect size, type 1 error of 0.05, and allowing for a 20% loss to follow-up at 3 months.

Statistical Analysis

Data were analyzed using Stata version 16.0 (StataCorp) and included all participants in their randomized groups (intention-to-treat). The baseline characteristics of participants who did and did not provide primary outcomes were compared using two-tailed *t* tests or chi-square tests. Missing continuous outcomes were imputed using chained equations with predictive mean matching and five nearest neighbors, and missing binary outcomes were imputed using logistic regression imputation models with chained equations. The data were imputed separately for each randomized group. Imputation models for continuous outcomes included all baseline variables and all outcome variables, where possible. Imputation models for binary variables omitted binary baseline variables and outcome variables because of the potential for perfect prediction, including only continuous baseline variables. Estimates from 40 imputed data sets were combined using the Rubin rules [29].

For the primary outcomes and continuous secondary outcomes, mean differences between groups were estimated at each time point using longitudinal linear mixed-effects models. These models included all data from 1, 3 (primary endpoint), 6, and 12 months as outcomes for each participant. The models included an interaction between month and randomized group as a fixed effect and random intercepts for participants. Models were adjusted for baseline values of the outcome and stratification variables (symptom duration). Similar longitudinal logistic regression models were used for secondary binary outcomes, with results presented as odds ratios and risk ratios at each time point. Model assumptions and the validity of the imputed data sets were assessed using standard diagnostic plots. No statistical adjustments were made for multiple testing. Complete case analyses were also performed.

Results

Recruitment was conducted from December 6, 2017, to January 16, 2019, with follow-up completed on January 16, 2020. We enrolled 453 participants who completed the baseline assessment (Figure 1). In total, 13 withdrew (different time points), and their data were excluded from the analysis. The groups were similar at baseline (Multimedia Appendix 2). Loss to follow-up at the primary endpoint (3 months) was 26.1% (59/226) in the control group and 28% (60/214) in the MyBackPain group. Those lost to follow-up were younger and had fewer previous episodes of LBP (Multimedia Appendix 2).

For the primary outcomes at 3 months, between-group differences in dimensions 2 (mean difference −0.87 units, 95% CI −3.56 to 1.82) and 3 (mean difference −0.41 units, 95% CI −2.78 to 1.96) of the HLQ were small with wide CIs (Multimedia Appendix 3).

For secondary outcomes, the MyBackPain group scored greater for treatment choice (stated) than the control group at 1 month (−0.91 units, 95% CI 0.16 to 1.67), but differences beyond that time point were of inconsistent direction and unlikely to be clinically significant (Multimedia Appendix 3), as was the observed proportion of participants selecting a recommended treatment at all time points (Table 2). Between-group differences in other secondary outcomes (other HLQ dimensions and clinical outcomes) at any time point were of inconsistent direction.

The results for the complete case analysis were similar (Multimedia Appendices 4 and 5), except that more participants (observed-proportion) in the treatment group were likely to select a recommended treatment (odds ratio 5.76, 95% CI 1.01 to 32.71; risk ratio 1.29, 95% CI 1.01 to 1.58) at 3 months (Table 2).

Up to the launch date (after the primary endpoint for all participants), the MyBackPain website was accessed an average of 3.4 times, each by 183 unique users. This represented 85.5% (183/214) of the patients allocated to the MyBackPain group.

Figure 1. CONSORT (Consolidated Standards of Reporting Trails) flow diagram. LBP: low back pain.

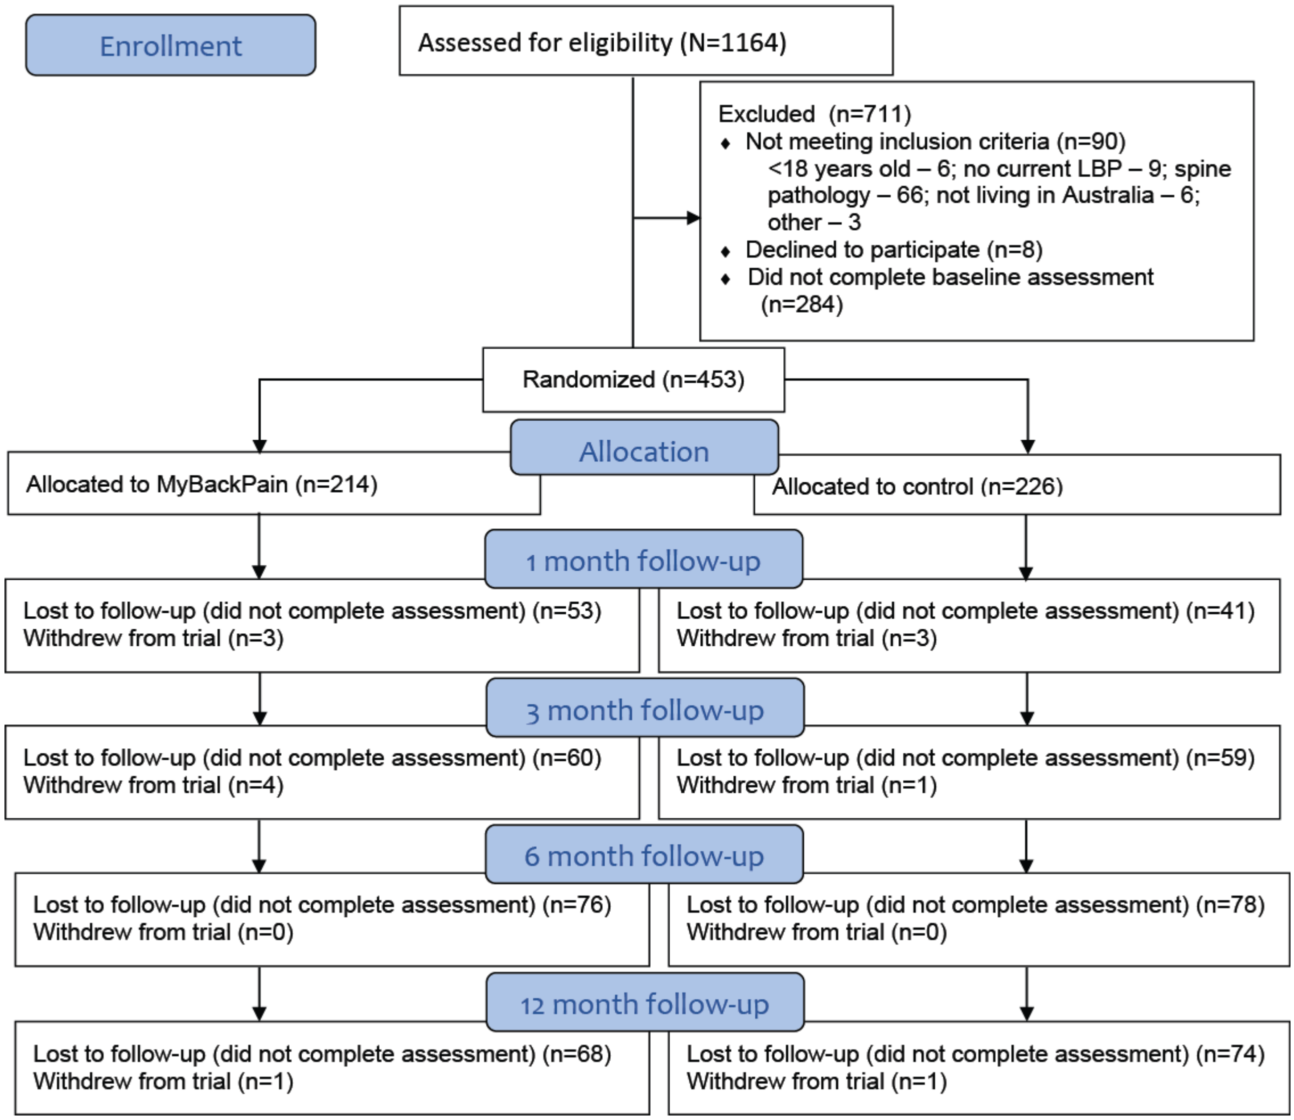

Table 2. Participants choosing treatment types (the binary outcomes)[a].

Treatment type and month	Control			MyBackPain			Risk ratio (95% CI)	*P* value
	Total, participant, n	Participant, n (%)	Number missing (n=226), n (%)	Total, participant, n	Participant, n (%)	Number missing (n=214), n (%)		
Observed treatment choice harmful or no effect								
1	83	20 (24.1)	143 (63.2)	63	17 (26.9)	151 (70.6)	1.07 (0.55-1.59)	.79
3	73	12 (16.4)	153 (67.7)	52	13 (25)	162 (75.7)	1.39 (0.56-2.23)	.35
6	67	11 (16.4)	159 (70.3)	67	11 (16.4)	147 (68.7)	0.76 (0.30-1.22)	.30
12	89	18 (20.2)	137 (60.6)	72	10 (13.8)	142 (66.3)	0.94 (0.40-1.48)	.83
Observed treatment choice recommended								
1	83	55 (66.2)	143 (63.2)	63	40 (63.5)	151 (70.6)	0.89 (0.69-1.08)	.26
3	73	49 (67.1)	153 (67.7)	52	37 (71.1)	162 (75.7)	0.99 (0.78-1.20)	.94
6	67	54 (80.6)	159 (70.3)	67	47 (70.1)	147 (68.7)	0.84 (0.64-1.05)	.13
12	89	65 (73)	137 (60.6)	72	54 (75)	142 (66.3)	0.99 (0.78-1.20)	.91

[a] Odds and risk ratios are calculated using multiply imputed data. Counts and percentages calculated using the observed data only.

Discussion

Principal Findings

The results of this study showed that the natural use of a web-based information-only resource (MyBackPain [20]) did not improve the two dimensions of health literacy more than self-guided access to web-based LBP information. Use of the website did not achieve better outcomes for other secondary measures of clinical features of pain, disability, quality of life, or other aspects of health literacy, except for the stated and observed selection of recommended treatments at one follow-up time point.

Interpretation of Findings

MyBackPain is a website for individuals with LBP that was developed with extensive consumer input to ensure that content and design are aligned with patient needs and preferences [21]. The website's intention is to enhance an individual's capacity or confidence to manage their condition, including decision support for the selection of effective treatments. The primary outcomes for this randomized controlled trial were selected to reflect this goal with respect to "having sufficient information to manage my health" or "actively managing my health." Contrary to our hypothesis, the use of the MyBackPain website did not achieve greater improvement in these domains than the unguided use of the internet. However, the finding that access to MyBackPain achieved greater improvement in stated treatment choices at 1 month provides preliminary evidence for the improvement of active management of their condition.

Health literacy is defined as "the cognitive and social skills which determine the motivation and ability of individuals to gain access to, understand and use information in ways which promote and maintain good health" [30]. Health literacy extends beyond the provision of information to the empowerment of individuals to use information [27]. The use of MyBackPain did not more effectively modify an individual's *perception* of their ability to manage their own health than unguided use of the internet, but the data suggest some short-term improvement in treatment choices. One interpretation is that improvement in these elements of health literacy may be satisfied by the general use of information on the internet but that the quality of the resulting actions (ie, treatment selection) depends on the quality of the information provided. The control group's lower treatment choice scores concur with a recent review that identified only 43.3% of treatment recommendations provided by freely accessible websites were accurate [17]. The treatment recommendations provided in MyBackPain are based on expert panel consensus.

On the basis of population data for the HLQ domains from the Australian Bureau of Statistics, our sample had similar health literacy at baseline (dimension 2: our data=mean 3.12, SD 0.6, vs Australian Bureau of Statistics data for individuals who report a *back problem*=mean 3.13, relative SE 0.5; dimension 3: 3.23, SD 0.6, vs 3.03, SE 0.6). However, our sample had low quality of life utility scores compared with Australian norms (our data: mean 0.55, SD 0.22, vs mean 0.799, 95% CI 0.792-0.806 [31]). Despite the co-design of MyBackPain in individuals with LBP, the presentation of information might not be optimal for those with low quality of life [32].

MyBackPain was designed as an information resource. The information is provided in multiple formats but with limited interactivity. Benefits might be enhanced by greater interactivity, such as inclusion of a web-based discussion group [33], regular action plans [34], or provision of active intervention. Refinement of MyBackPain would require assessment because recent evidence highlights inconsistent evidence for the efficacy of web-based cognitive behavioral therapies for LBP [18,19,35,36], interactivity [12], and personalization [36,37].

Treatment Selection

This study provides preliminary evidence that access to MyBackPain might achieve short-term improvement in treatment choices. The largest component of the website, as requested by consumers [10], is a treatment comparison tool. This tool provides summaries of the treatment, the quality of evidence for efficacy, and pros and cons for its use with an evidence icon that provides a quick reference of the level of evidence and effectiveness [21]. Summaries were developed with input from an international expert team and consumers [21]. Although no other studies have tested the effectiveness of web-based information to improve treatment choices, studies that are not specific to LBP have reported reduced health care usage (improved self-management and decreased use of ineffective treatments) related to high-quality, evidence-based, web-based information [38].

We did not include treatment selection as a primary outcome because of the novelty of our measures. The measures were tested for comprehension in individuals with LBP but had unknown psychometric properties. The *observed* and *stated* measures of treatment choice were based on expert consensus recommendations in the website. Alignment of stated and observed choices with the recommended treatments resulted in a higher score. Better stated treatment choices by the MyBackPain group at 1 month provide stimulus for further work. No group difference at 3 months implies that sustained improvement might require sustained engagement with the website.

Web Resource Evaluation

It is recommended that information resources be tested for the credibility and accuracy of content [39]. According to these criteria, the MyBackPain website has a strong foundation supported by research with consumers [32] and expert consultation for content accuracy [21,40]. Multimedia Appendix 6 [10,21,25,32,41-43] considers MyBackPain against evidence standards for digital health technologies [41].

Limitations

There are several limitations that need to be considered. First, there was a large loss to follow-up, which is common in web-based trials [35,44]. Although multiple imputations were implemented, if participants were lost to follow-up due to worsening of their condition, this analysis may not be appropriate. Second, the individual use of MyBackPain could not be tracked. That 14.5% (31/214) of the treatment group did not access MyBackPain is disappointing, but it is important to note that the trial was pragmatic and designed to evaluate natural use.

Conclusions

This is the first randomized controlled trial of an information resource for LBP to test its impact on health literacy, quality of treatment choices, and clinical outcomes. Unlike most websites for LBP, MyBackPain was specifically designed to meet the needs of individuals with LBP and included a focus on treatment choices. The results provided no evidence of differences between groups for the primary outcomes related to health literacy. There is limited preliminary evidence of the impact of empowerment on making informed choices for the management of their condition, which is the intention of improved health literacy. Loss to follow-up should be considered when interpreting these results. Future work should consider the potential to enhance impact through the addition of interactivity and interventions and greater support provided to users to engage with the resource.

Acknowledgments

This work was supported by grants from the National Health and Medical Research Council (NHMRC, Australia; APP1079078 and APP1091302) and the Medibank Health Research Fund. Abstract

Background: In China, significant emphasis and investment in health care reform since 2009 has brought with it increasing scrutiny of its public hospitals. Calls for greater accountability in the quality of hospital care have led to increasing attention toward performance measurement and the development of hospital ratings. Despite such interest, there has yet to be a comprehensive analysis of what performance information is publicly available to understand the performance of hospitals in China.

Objective: This study aims to review the publicly available performance information about hospitals in China to assess options for ranking hospital performance.

Methods: A review was undertaken to identify performance measures based on publicly available data. Following several rounds of expert consultation regarding the utility of these measures, we clustered the available options into three key areas: research and development, academic reputation, and quality and safety. Following the identification and clustering of the available performance measures, we set out to translate these into a practical performance ranking system to assess variation in hospital performance.

Results: A new hospital ranking system termed the China Hospital Development Index (CHDI) is thus presented. Furthermore, we used CHDI for ranking well-known tertiary hospitals in China.

Conclusions: Despite notable limitations, our assessment of available measures and the development of a new ranking system break new ground in understanding hospital performance in China. In doing so, CHDI has the potential to contribute to wider discussions and debates about assessing hospital performance across global health care systems.

KEYWORDS

hospital ranking; performance measurement; health care quality; China health care reform

Introduction

Hospital rating systems have the potential to play an important role in patient decision-making as well as offer policy makers and practitioners valuable opportunities to monitor and improve the quality of hospital services [1-4]. In China, significant emphasis and investment into health care reform since 2009 has brought with it increasing scrutiny of its public hospitals with regard to improving their quality and efficiency. Reform measures have included an emphasis on improving hospital governance with clearer regulations and transparency regarding overall performance [5]. Although these measures show promising signs, questions remain about their overall impact and sustainability [6], as well as those concerning the information asymmetries that exist for patients and providers that limit the market conditions of competition and choice deemed necessary to rate hospital performance [7].

An enduring feature of China's health care provision is the dominance of the hospital sector. Within these contexts, patients are offered different forms of provision ranging from grade I community hospitals, grade II secondary or county hospitals serving several communities, and grade III tertiary hospitals serving districts or cities. This classification [8] remains a powerful driving force for decision-making, with tertiary hospitals often deemed the preferred option for better clinical quality. Pan et al [7] explain how such trends are driven by a culture where patient volume often represents the primary measure of hospital performance used by government administrators. Patients often equate hospital size as a signal of quality, thus preferring to self-refer to larger tertiary hospitals. Large patient volume is also deemed essential for hospitals in developing a good reputation and acquiring high-quality research and training programs.

U.S. News & World Report's Best Hospitals ranking is one of the well-known hospitals ranking systems that aims to help patients find professional medical centers and doctors across the United States. The relative success of the Best Hospitals ranking demonstrates that the objectivity of measures such as mortality and morbidity can provide an important contribution for accurate evaluation of health care quality [9]. However, influential rankings in developed countries, such as Best Hospitals ranking and Vizient Award [10], are based on solid medical information supporting mechanisms and are challenging to be applied to low- and middle-income countries or regions with relatively underdeveloped medical information supporting facilities.

In order to try and disentangle these trends, China is increasingly seeing the development and use of hospital performance rankings. The annual publication of the Hospital Management Institute of Fudan University Hospital Ranking list [11] ranks hospitals according to a social reputation score that is determined based on survey responses from physicians combined with a review of scientific research outputs from their affiliated institutions. The Science and Technology Evaluation Metrics (STEM) of hospitals developed by the Chinese Academy of Medical Sciences [12] ranks tertiary hospital performance based on their science and technology investment and any associated outputs. Other influential rankings include the top-100 China Hospitals Competitiveness by Alibi Hospital Management Research Center, Hong Kong [13], and China's best clinical discipline rankings released by Peking University [14].

These indicators provide a valuable contribution to debates and decision-making about hospital performance in China. Nevertheless, given the current situation in China, and the asymmetries of information that exist, important limitations of the current ranking systems have been highlighted, including a reliance on reputation scores [11], a limited menu of performance measures, and a lack of consideration and engagement with measures of quality and safety [8].

Current ranking systems undoubtedly have merit in signifying attempts to better understand hospital performance; however, further research is needed to better understand and triangulate publicly available hospital performance information. Thus far, there has yet to be a comprehensive analysis of what performance information is actually available in China [15]. This study aims to review the publicly available performance information with the view to assess different ways in which hospital performance can be ranked. In doing so, in this paper, we present a new hospital ranking system, termed the "China Hospital Development Index" (CHDI). Although this ranking system faces notable limitations, we argue that our review of measures and development of a ranking system break new ground that can inform both current and future policy and practice for hospital performance in China.

Methods

Limitations of Major Hospital Ranking Systems in China

Current hospital performance rankings in China [11-13] classify hospital performance across a range of indictors, including the availability of hospital facilities, services, and personnel; the calculation of social reputation scores; and the publication of scientific research inputs and outputs. These indicators provide valuable contributions for understanding hospital performance; however, a notable limitation in the rankings produced so far has been the emphasis on the quality and safety of health care provision. Quality and safety represent core domains of medical services; therefore, any assessment of hospital performance should aim to incorporate any available measures [16].

It is worth pointing out that for the clinical disciplines ranking reported in Table 1, more than 48 million clinical data records were collected from nearly 400 hospitals across China from 2006 to 2014. The main characteristic of this ranking is that the focus has been shifted to the clinical specialties rather than the number of funds and articles published; it is also the first application of effective medical clinical data for evaluation of hospitals. It should be mentioned that its methodology has not been made public. However, this ranking was unsuccessful (published only once in 2015). The main reason is the standardization of clinical data, such as inconsistent disease codes, which directly affects the quality of medical record information used. Although hospitals in China are vigorously promoting medical informatization at this stage, there is still a long way to use medical data to rank hospitals even if such data are available.

Table 1. Overview of China's hospital ranking systems.

Characteristic	Best Hospitals ranking [11]	STEM[a] [12]	Hospital competitiveness ranking [13]	Best Clinical Disciplines ranking [14]
Primary objective	To provide guidelines for patients seeking treatments	To measure a hospital's value in scientific research	To identify the top hospitals with the best competitiveness	To provide a tool to help patients find skilled specialty care
Domains of measure	• Social reputation • The ability of sustainable development (scientific research outcomes)	• Scientific research inputs, outputs, and impacts	• Medical service • Academic impacts • Resource management • Hospital operation	Unclear
Indicators	• Social reputation scores • SCI[b] papers • National awards	• Key laboratories and projects • Researchers • Clinical trials • SCI papers • Medical standards • Medical association leaders • National awards	• Inpatients and outpatients • Beds • Health workers • Medical facilities • Personnel • Medical fee • Length of stay • Academic leaders • Key laboratories and projects • National awards	• Perioperative mortalities • Readmissions • Postoperative complications • Timely care • Finance
Data sources	National surveys	SCI database and official documents	Reporting data voluntarily	Medical records
Publication frequency	Annually	Annually	Annually	Only in 2015
Transparency of methodology	Provided	Provided	Provided	Not provided

[b] SCI: Science Citation Index.

Exploring Available Performance Measures

Based on the assessment of current measures and the identification of areas for improvement, a group of 6 experts with physician and methodological expertise in performance measurement was established within the China Hospital Development Institution (HDI) to assess the available options and provide feedback at each step of the process (see Multimedia Appendix 1). To begin the analysis, we mapped publicly available measures and identified different information sources that reflected our interest in better understanding *hospital performance*. Through iterative discussions among the study group, a review of the available literature, and discussions with experts, we established three performance domains for the purpose of ranking hospitals in China. These domains were categorized as research and development, academic reputation, and quality and safety (described below and summarized in Table 2).

Table 2. Summary of measures and clustering of performance indicators into three domains: research and development, academic reputation, and quality and safety.

Domains and measures	Indicators	Data sources
Research and development		
Publication outputs	Number of SCI[a] papers by authors, by first author, and by corresponding author	Web of Science [17]
Number of citations	Number of citations by authors, by first author, and by corresponding author	Web of Science [17]
Number of high-impact outputs	Number of SCI papers with journal IF[b] ≥10 by authors, by first author, and by corresponding author; number of papers published in top-6 journals by authors, by first author, and by corresponding author	Web of Science [17]
Clinical trial activity	Number of registered clinical trials	ChiCTR[c] [18]
Academic reputation		
Academician	Number of academicians of CAS[d] and CAE[e]	CAS [19], CAE [20]
Chief editor	Number of staff as chief editors of core medical journals included in CSCD[f]	CSCD, Science China [21]
Association chairperson or member	Number of staff as National Association chairperson and National Association members	CMA[g] [22], CMDA[h] [23]
Award	SPSTA[i], SNSA[j], STTPA[k], CMSTA[l], CDA[m]	CMA [22], CMDA [23], NOSTA[n] [24]
Quality and Safety		
Quality of specialty care	Number of national key clinical specialties, diagnosis and treatment, Improvement of Rare Diseases Program	Official websites of each hospital; NHC[o], People's Republic of China [25]
Medical malpractice claims	Ratio of compensation cases, ratio of liability	Laws and Regulations – Peking University [26]

To begin our analysis of available measures, we used the Health Statistics Yearbook issued by the National Health Committee to gather baseline information regarding outpatient, inpatient, and emergency admissions to hospitals in China [27]. Second, given the importance placed on research and development in China as a measure of performance, we also sought to identify research and development indicators for hospitals gathered from research databases in order to gauge the research activity and outputs being produced by each hospital. This would include any hospital affiliation of authorship to published Science Citation Index (SCI) papers, the number of citations obtained, and the number of SCI papers for which an impact factor (IF) ≥10 per hospital. Information regarding clinical trial activity was also collected as an indicator for research activity.

As a follow-up to the research and development activity, we were able to obtain measures demonstrating clinical academic reputation of hospital staff engaged in high-impact research outputs demonstrating wide scholarly impact in their clinical area of expertise. This included measuring the number of academic affiliations with the Chinese Academy of Science (CAS) and the Chinese Academy of Engineering (CAE); the number of staff as chief editors of core medical journals included in the China Science Citation Database (CSCD); membership of national associations, including the Chinese Medical Association (CMA) and the Chinese Medical Doctor Association (CMDA); and the number of national awards received per hospital, including the State Preeminent Science and Technology Award (SPSTA), the State Natural Science Award (SNSA), the State Scientific and Technological Progress Award (STTPA), the Chinese Medical Science and Technology Award (CMSTA), and the Chinese Doctor Award (CDA).

Finally, our analysis of the quality and safety performance measures was able to draw on medical malpractice litigation records [28,29] adjusted for complexity and risk of patient disease as two useful indicators for patient safety. Based on the experience the team had in analyzing litigation data as a measure of quality, the selection of such measures resonates with others such as Wang et al [28], who argued that in the absence of more robust indicators, records of medical malpractice litigation in China warranted further exploration as an indicator of health care quality. Additional measures of clinical quality were accessed by reviewing hospital standards and accreditation of treatment excellence performance against the National Health Commission's Diagnosis and Treatment Improvement of Rare Diseases Program and National Key Clinical Specialty Program.

Developing a Hospital Ranking System

Several rounds of expert consultation identified publicly available indicators, deliberated their utility, and assessed how best to triangulate and weight these measures into comparative performance information. Following the identification and clustering of the available performance measures, we set out to translate these into a practical performance ranking table to assess variation in hospital performance.

Our analysis of operational size and scale highlighted practical limitations to the sample of hospitals included in our ranking. As a result, we focused on the tertiary hospital sector based on the availability of current data as well as to provide an option for comparison with other available measures. By the end of 2017, according to the China Health Statistics Yearbook, there were 1360 grade III, level A hospitals nationwide [27]. The inclusion of these hospitals over others was on the basis that these organizations continue to be the focus of attention in China given their prominence and popularity. These hospitals have also been the focus on other performance rankings in China; hence, the development of any new ranking system would be comparable with other respective performance measures. Our inclusion criteria, therefore, required hospitals to be a grade III, level A hospital, featuring on one of the lists of the four Chinese Hospital rankings in any previous year, and have at least 500 beds. A total of 310 hospitals were thus deemed eligible for ranking under the full criteria.

To develop our ranking system, we relied on statistical procedures such as principal component analysis (PCA) and categorical principal component analysis (CATPCA) [30,31]. PCA is defined as a variable reduction technique that can be used when variables are highly interrelated, providing a way to reduce the number of observed variables into a smaller number of linear, uncorrelated summary variables called principal components (PCs) that account for variation in observed variables. Here, we hypothesized that the various candidate indicators for a given hospital can be represented by several underlying, or latent PCs that reflect the overall strength of this hospital. Thus, for each PC, the model can estimate the extent to which the values are the result of a relationship with the composite score. The remaining variance in the indicators is attributed to measurement error. The degree to which an indicator is correlated with other indicators helps to determine its weight in the equation for the composite scores.

We developed PCA/CATPCA models for each of the three domains of ranking, by evaluating model statistics for all possible combinations of indicators that included at least one indicator. From the resulting list of candidate models showing acceptable fit statistics, we selected a final model for each domain, providing a combination of the number of indicators (models with more indicators produce more accurate component scores), number of outcomes, and model fit.

The PCA/CATPCA replaces the original n features with a smaller number of m features, which are linear combinations of the old features, making these linear combinations as irrelevant as possible. To adjust for linear distribution, before incorporating the values of PCs into the scoring, we implemented a logit transformation for each domain. Equation (1) presents the formula for logit transformation:

Score(i): final score for PC_i; i: PC_i; G(m): accumulation of variance; C_i: variance for PC_i; and F_i: original score for PC_i.

Entropy Weight Method

For each domain, we incorporated the values of PCs into the scoring by using entropy weight method, in which weights are systematically calculated based on the level of the difference between the original values. Simply put, if the value difference between the objects, when evaluated using an indicator, is higher than the difference using other indicators, that indicator has more weight than other indicators [32].

Matrix after logical transformation:

where n: number of hospitals; m: number of variables.

Weighting

Deliberations between the expert panel of HDI stakeholders determined the appropriate weights for each domain based on their importance in defining the overall attributes of strength within hospitals.

For presentation purposes, we created what we define as CHDI to measure the development level of the hospitals evaluated. Raw scores were transformed to a scale that assigns a CHDI score of 100 to the top hospital. The formula for the transformation is shown in Equation (7):

CHDI score = (raw score – minimum) / range (7)

Before applying PCA, we also measured the correlation of each variable using Kaiser–Meyer–Olkin (KMO) analysis. If the KMO value is >.7, there is a relatively high level of correlation among variables, and it is thus suitable to use PCA. Similarly, we calculated Cronbach α coefficient before applying CATPCA. CATPCA is an alternative to standard PCA that is particularly useful for data sets consisting of categorical variables (nominal or ordinal) that might be nonlinearly related to each other. CATPCA quantifies categorical variables using optimal scaling, resulting in optimal PCs for the transformed variables. The correlations, shown in Table 3, provide strong evidence of construct validity.

Table 3. Kaiser–Meyer–Olkin (KMO) analysis (Cronbach alpha values) of the three domains of the China Hospital Development Index.

Domain	KMO/Cronbach α
Research and development	.850
Academic reputation	.802
Quality and safety	.936

Results

PCA Results

Table 4 shows the results of the analysis, including the number of original indicators, number of selected indicators, number of PCs retained, and accumulation of variance for each domain. The PCA resulted in two PCs, which explained no less than 81% of the variance in the original matrix for each domain.

For research and development, the first principal component (PC1) is highly correlated with the amount of SCI papers and citations, whereas the second principal component (PC2) is highly correlated with high-quality paper measures such as “number of IF≥10 SCI papers by authors” and “number of IF≥10 SCI papers by first author” with correlation coefficients of 0.489 and 0.575, respectively, between the original variables and PCs identified. For quality and safety, PC1 is highly correlated with the medical malpractice claims measures, whereas PC2 is highly correlated with the quality of specialty care measures.

Table 4. Principal component analysis and categorical principal component analysis results of the three domains of the China Hospital Development Index.

Domain	Original indicators	Selected indicators	Principal component	Accumulation of variance
Research and development	13	11	2	0.936
Academic reputation	9	6	2	0.818
Quality and safety	3	3	2	0.887

Results of Entropy Weight Method

Table 5 shows PC1 has a higher entropy weight than PC2 for each domain, suggesting that this component has a bigger difference.

The results of our CHDI rankings by score for the top 10 hospitals are shown in Table 6.

Table 5. Results of the entropy weight method for the three domains of the China Hospital Development Index.

Domain	PC1[a] (%)	PC2[b] (%)
Research and development	85.4	14.6
Academic reputation	70.2	29.8
Quality and safety	85.1	14.9

[a] PC1: first principal component.

[b] PC2: second principal component.

Table 6. An example of the China Hospital Development Index (CHDI) ranking results.

Rank	Hospital	CHDI
1	XH Hospital, Beijing	0.9739
2	HX Hospital, Chengdu	0.9635
3	JZ Hospital, Beijing	0.9634
4	RJ Hospital, Shanghai	0.9632
5	ZS Hospital, Shanghai	0.9527
6	HS Hospital, Shanghai	0.9400
7	ZY Hospital, Hangzhou	0.9284
8	CH Hospital, Shanghai	0.9206
9	RM Hospital, Beijing	0.9171
10	BY Hospital, Beijing	0.9137

Validation

Table 7 shows the correlation between scores of domains for 310 hospitals. All of the correlation coefficients between the total score and the score of each domain are above 0.57. The scores of different domains also correlate well among themselves with correlation coefficients higher than 0.50, indicating that the set of indicators is compact and coherent.

Table 7. Correlation coefficients (*r*) between scores of the three domains for all hospitals evaluated (N=310).

Domain	Research and development	Academic reputation	Quality and safety	Total score
Research and development				
r	1	0.788	0.577	0.959
P value	—[a]	<.001	<.001	<.001
Academic reputation				
r	0.788	1	0.597	0.857
P value	<.001	—	<.001	<.001
Quality and safety				
r	0.577	0.597	1	0.773
P value	<.001	<.001	—	<.001
Total score				
r	0.959	0.857	0.773	1
P value	<.001	<.001	<.001	—

Discussion

Principal Findings

The ability to assess the performance of hospitals in supporting the delivery of high-quality patient care represents a priority for all health care systems [33]. In China, such interest and scrutiny are growing; however, gaining access to relevant performance information remains challenging [34]. Through our analysis of available performance measures, our study aims to contribute to these discussions and debates with a review of hospital performance measures in China. Compared to other health care systems, most notably those in the United States and Europe, what these various measures show are clear limitations in what is currently available to understand hospital performance. For example, our use of research and development indicators and academic reputation as proxy measures for managerial and clinical leadership are exposed to criticisms for their limited connections to day-to-day hospital practice. Our use of litigation data and accreditation standards as proxy measures for hospital quality and safety again have limitations in terms of how far these reflect the clinical quality of hospital care [35]. There is further work to be done regarding how China can develop more clinically focused performance measures that are comparable across hospitals.

Nevertheless, we would argue that our review and subsequent development of a new ranking system breaks new ground in understanding hospital performance in China. Where current hospital rankings in China often rely on reputation scores and investment (input) measures [8,11,12], our review of publicly available measures and their development into a ranking system appears to be the first in opening up the debate for more rigorous and transparent performance information. This is particularly the case for quality and safety performance. Our review and inclusion of litigation data [28,29,36,37] provides a valuable opportunity to assess the comparative performance of quality and safety across hospitals in China.

Thus, this paper contributes to what appears to be a growing body of knowledge that is using innovative and feasible methodologies in data collection and modeling to better understand the performance of public hospitals in China [38].

Based on our analysis, we suggest that further research and policy development is needed to build on these results. Given the practical limitations of securing comparative data and the interest in benchmarking our analysis with existing hospital rankings in China, our sample has focused exclusively on a number of tertiary hospitals. Our rankings reflect the high performance of these organizations compared to that of other hospital and primary care providers; however, we are also mindful of the possible further imbalance this can create in China's health care system by virtue of acute medical care over primary and community care. The fact that the majority of our highest ranked hospitals are located in Shanghai and Beijing also illustrates important challenges facing access to high-quality hospital care in other parts of China. Such findings support those of Yu et al [38] who have documented how the unevenness of health care resources in China is closely related to a city's administrative rank and power: the higher the level, the better the resources. Such arrangements are reinforcing investment in high-ranked hospitals at the expense of primary care services. The correlation between the quality and safety domain and the overall hospital performance in our ranking system is slightly lower than that with the other two domains; therefore, more clinical objective measures should be included to increase the influence of this domain.

Therefore, we call on further research and development to access and compare performance measures from within each hospital, including private hospitals, as well as other parts of the health care system, including primary and community care. For this purpose, China could build on the cross-sectional research it has undertaken into mortality trends [39] and nurse staffing levels [40]. Such research has the potential to be scaled up and developed into performance measures translatable across all hospitals and incorporated into our methodology.

We also support further research and development that draws on the views of a range of different stakeholders in terms of what performance measures would be meaningful for patients, public, and health care staff. Given the well-documented challenges facing the doctor-patient relationship in China [41,42], we encourage deliberative events involving a range of stakeholders to discuss what constitutes good performance with the view to developing shared understanding of performance measurement from different perspectives. The Delphi method [43] is one way to do this, and such an approach has been used in other parts of China to good effect. This includes further development of comparative measures for health outcomes and the development of experiential data about how different stakeholders experience the health care received and how they can improve hospital performance as well as other aspects of China's health care system.

The year 2019 marks the tenth year for China's goal to deepen the reform of its medical and health system. In 2019, the Chinese government formulated the National Tertiary Public Hospital Performance evaluation index system and unified the collection of performance information across hospitals [44]. The implications of such changes remain to be seen, with the results of these assessments not yet fully disclosed. However, we anticipate this is an important step in developing greater understanding of hospital performance in China. We believe that our review and the newly developed ranking index (CHDI) has an important role to play in shaping such discussions and assessments, particularly in relation to the improvement of quality and patient safety, as well as raising public awareness regarding the information that is available to inform their decision-making.

Conclusions

The reform of China's health care system has brought with it increasing scrutiny regarding the quality of care delivered to patients. Our analysis presents what appears to be the first review of publicly available performance measures for hospitals in China. In collaboration with an expert panel, in the review, the available measures have been clustered into three performance domains, namely research and development, academic reputation, and quality and safety of hospital care. Furthermore, based our analysis, we have applied these performance measures to a selection of tertiary hospitals in China with the view to better understand their comparative performance. There remain some notable limitations and challenges regarding this performance information; nevertheless, we believe that our review and ranking system break new ground in assessing hospital performance in China. Although further research and development is clearly needed to enhance and refine this performance information, we argue that the proposed hospital development index sets a new and important research agenda for understanding and improving hospital care in China.

Acknowledgments

The authors acknowledge the research institution, university, and the data collectors for their participation and support in this study. This study was supported by Major Key Research Projects in Philosophy and Social Sciences of the Ministry of Education of the People's Republic of China (grant 18JZD044) and National Natural Science Foundation of China (grant 72074147).

Authors' Contributions

SJD participated in the acquisition of data, design and analysis of the study, and drafted the manuscript. RM was involved in drafting the final manuscript. CSS contributed to the conception and design of the study. MYD and YYX assisted with data collection and statistical analysis of the data. GHL, JS, and XQF prompted discussion on the implications of the study and its results and critically revised the manuscript for important intellectual content. All authors have read and approved the final version of the manuscript and are accountable for all aspects of the work.

Conflicts of Interest

None declared.

Abstract

Background: Engagement is positively associated with the effectiveness of digital health interventions. It is unclear whether tracking devices that automatically synchronize data (eg, Fitbit) produce different engagement levels compared with manually entering data.

Objective: This study examines how different step logging methods in the freely available 10,000 Steps physical activity program differ according to age and gender and are associated with program engagement.

Methods: A subsample of users (n=22,142) of the free 10,000 Steps physical activity program were classified into one of the following user groups based on the step-logging method: Website Only (14,617/22,142, 66.01%), App Only (2100/22,142, 9.48%), Fitbit Only (1705/22,142, 7.7%), Web and App (2057/22,142, 9.29%), and Fitbit Combination (combination of web, app, and Fitbit; 1663/22,142, 7.51%). Generalized linear regression and binary logistic regression were used to examine differences between user groups' engagement and participation parameters. The time to nonusage attrition was assessed using Cox proportional hazards regression.

Results: App Only users were significantly younger and Fitbit user groups had higher proportions of women compared with other groups. The following outcomes were significant and relative to the Website Only group. The App Only group had fewer website sessions (odds ratio [OR] −6.9, 95% CI −7.6 to −6.2), whereas the Fitbit Only (OR 10.6, 95% CI 8.8-12.3), Web and App (OR 1.5, 95% CI 0.4-2.6), and Fitbit Combination (OR 8.0; 95% CI 6.2-9.7) groups had more sessions. The App Only (OR −0.7, 95% CI −0.9 to −0.4) and Fitbit Only (OR −0.5, 95% CI −0.7 to −0.2) groups spent fewer minutes on the website per session, whereas the Fitbit Combination group (OR 0.2, 95% CI 0.0-0.5) spent more minutes. All groups, except the Fitbit Combination group, viewed fewer website pages per session. The mean daily step count was lower for the App Only (OR −201.9, 95% CI −387.7 to −116.0) and Fitbit Only (OR −492.9, 95% CI −679.9 to −305.8) groups but higher for the Web and App group (OR 258.0, 95% CI 76.9-439.2). The Fitbit Only (OR 5.0, 95% CI 3.4-6.6), Web and App (OR 7.2, 95% CI 5.9-8.6), and Fitbit Combination (OR 15.6, 95% CI 13.7-17.5) groups logged a greater number of step entries. The App Only group was less likely (OR 0.65, 95% CI 0.46-0.94) and other groups were more likely to participate in Challenges. The mean time to nonusage attrition was 35 (SD 26) days and was lower than average in the Website Only and App Only groups and higher than average in the Web and App and Fitbit Combination groups.

Conclusions: Using a Fitbit in combination with the 10,000 Steps app or website enhanced engagement with a real-world physical activity program. Integrating tracking devices that synchronize data automatically into real-world physical activity interventions is one strategy for improving engagement.

KEYWORDS

physical activity intervention; activity trackers; engagement; Fitbit; pedometer; eHealth; mobile phone

Introduction

Background

Meeting or exceeding recommended physical activity levels is key for the prevention and management of noncommunicable diseases [1,2]. However, large proportions of the population do not meet these recommendations [3,4]. In response, web- and app-based programs to promote physical activity among adults have been developed [5]. Few of these interventions have been evaluated in real-world settings [6]. Relative to randomized controlled trials whose participants are rigorously screened, have repeated contact with trial staff, and may include participants who are motivated to change behaviors, interventions conducted in less controlled and real-world settings may have significantly different levels of usage, engagement, nonusage attrition (users stop interacting entirely), and behavior change [6]. However, the greater accessibility of real-world programs makes them valuable avenues to reach larger populations at a relatively low cost [7]. Furthermore, the way users engage with web- and app-based programs in ecologically valid circumstances may potentially impact the effectiveness of these programs [6].

Web- and app-based programs that promote physical activity frequently include self-monitoring as an effective behavior change technique [8]. Although pedometers are commonly and successfully used in activity promotion efforts [9], the emergence of wrist-worn activity trackers such as Fitbit has provided a convenient, reliable, and accurate alternative to pedometers for tracking step counts. Worldwide sales of health and fitness trackers have more than tripled from 2014 (26 million units) to 2017 (87 million units) [10]. The use of technology to track health is widespread, with 33% of the worldwide population across all age groups using a mobile app or a fitness tracking device in 2016 [11]. Australia had the second highest wearable fitness device adoption rate in the world in 2016, with 14% of the population owning at least 1 device [12]. Therefore, it is logical to integrate advanced activity trackers that can automatically synchronize activity behavior into web- and app-based programs [13].

A randomized controlled trial, the *TaylorActive* intervention, delivered the same web-based computer-tailored physical activity intervention to a Fitbit group and a non-Fitbit group [14]. Compared with the non-Fitbit group (which self-reported frequency of, and time spent in, mild, moderate, and strenuous physical activity on the website or app), the group using Fitbit activity trackers significantly increased in total weekly physical activity (mean total physical activity increase of 163.2 min/week; 95% CI 52.0-274.0) and weekly moderate-to-vigorous physical activity (mean moderate-to-vigorous physical activity increase of 78.6 min/week; 95% CI 24.4-131.9) after 3 months [14]. However, it is unclear how the addition of a physical activity tracking device impacts the use of free real-world physical activity promotion programs. Previous research has questioned whether there is a difference in the effectiveness of active (eg, manual entry of step count into a database) versus passive (eg, automatic entry of step count into a database by an activity tracking device requiring no cognitive attention) self-monitoring of behaviors. However, there is a paucity of research on this subject [15]. The lack of effort required to log in to a website or app to manually enter recorded physical activity may limit both the cognitive effort and subsequent focus on improving or maintaining an activity goal. It may also preclude opportunities to engage with other program features found on websites and apps, such as goal setting and social support features, which may consolidate behavior change [16,17]. Alternatively, the reduced burden of having to manually log steps may remove perceived barriers, such as time constraints, and subsequently provide more time to engage with program features and result in longer engagement before nonusage attrition occurs. Furthermore, having multiple options on how to self-monitor physical activity could overwhelm some users, but it may increase interest and better engagement in other users through enhanced accessibility of their preferred self-monitoring method. In addition, fitness trackers are used more commonly by women and younger adults, which may influence engagement with web-based health interventions [10,11,18].

The 10,000 Steps program is a free, publicly available program that aims to promote physical activity through the use of pedometers, activity trackers, a website, and an app [19]. The website and app have been available for public use since 2004 and 2012, respectively. A previous study examining user engagement with 10,000 Steps program found that program engagement was higher and nonusage attrition was lower among those who used the app or a combination of app and website compared with those using only the website [18]. However, the effect on engagement since the capacity to automatically record and sync step counts with the 10,000 Steps website and app using a Fitbit activity tracking device was introduced in January 2017 has not been assessed.

Objectives

This study aims to examine whether users' logging methods (Website Only, App Only, Fitbit Only, Web and App, and Fitbit Combination) differ according to age and gender as well as how different methods of logging steps in the 10,000 Steps physical activity program are associated with engagement with the program.

Methods

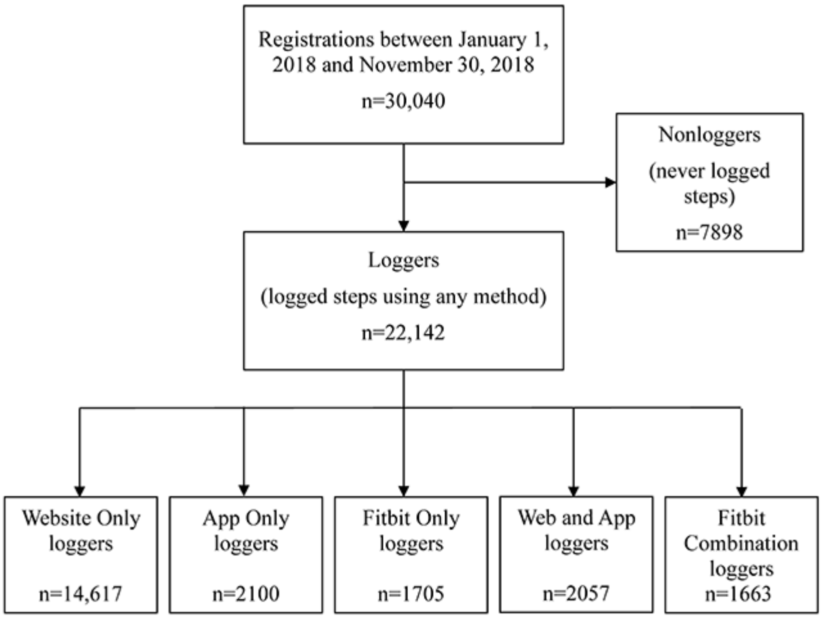
Participants and Procedures

The 10,000 Steps program was designed as a free, publicly available, whole-of-community program to increase physical activity among adults. The program, which is based on a socioecological framework, began in Rockhampton, Australia, and utilizes multiple strategies to promote physical activity [20].

Further details on the program design and development are available elsewhere [21,22]. In general, the program encourages users to accumulate physical activity each day and monitor their daily physical activity levels (actively or passively) by recording their pedometer, activity tracker–counted steps and/or time spent in physical activity using a web-based step log. The web-based step log is available to users on both the 10,000 Steps website and a smartphone app. Activity and/or steps logged using the app are automatically synchronized with the user's account on the website [18]. Steps recorded via a Fitbit activity tracking device were also synchronized with the app and website. Users can also access additional program features, including monthly Challenges for individuals (users may choose from a selection of virtual journeys with predefined monthly step goals and receive feedback in relation to progress), team Tournaments (created by 10,000 Steps coordinators from workplaces, community organizations, or groups of friends that involve team-based virtual walking Challenges based on a set amount of time or a predefined journey), and virtual *friends* (which allow users to track one another's progress and motivate each other) [18].

In this study, participants were users of the 10,000 Steps program who registered between January 1, 2018, and November 30, 2018 (N=30,040). When registering with the 10,000 Steps program, users provided informed consent for the usage of their data for research purposes. Of these new registrations, 7898 never logged steps (referred to as *Nonloggers*) and were not included in the analyzed sample. The remaining 22,142 new users were classified into one of five user groups based on the method they used to log steps. Participants captured their daily step counts using either a Fitbit or some other device (eg, pedometers, phone apps, or non-Fitbit activity monitors). Then, they recorded their step counts on the 10,000 Steps platform by manually entering data via the website or app or via automatic syncing of their Fitbit with the platform. The methods used to log step entries were recorded on a website database. The user groups were as follows: Website Only (14,617/22,142, 66.01%; step count data entered *only via* the website), App Only (2100/22,142, 9.48%; step count data entered *only* via the app), Fitbit Only (1705/22,142, 7.7%; step count data entered *only* via the Fitbit), Web and App (2057/22,142, 9.29%; entered step count data using the website and the app), and Fitbit Combination (1663/22,142, 7.51%; step count data entered using a combination of Fitbit and website and/or app). The Fitbit Only group logged steps passively (although may have actively engaged with the website content otherwise) while the Fitbit Combination group logged steps passively and actively. All other groups actively logged the steps. Regardless of how users logged steps, they were all able to interact with the website content (Figure 1).

Figure 1. Classification of logging methods of new registrations to the 10,000 Steps program between January 1, 2018, and November 30, 2018.



Data Collection and Extraction

Data were extracted from the 10,000 Steps website database and Google Analytics to assess user characteristics, engagement, and platform usage. Data for new users were tracked from the time of registration (between January 1 and November 30, 2018) until December 31, 2018, which allowed a minimum of 31 days opportunity to observe all participants' self-monitoring of physical activity.

Measures

User Characteristics

The date of birth, gender, and registration date were recorded and stored in the website database. The date of birth was used to determine the age at the time of registration. Gender was categorized as male, female, or other.

User Engagement With Website and Program

User engagement data were extracted for the entire study period from January 1 to December 31, 2018. User groups were mutually exclusive and were defined based on the method of logging steps. However, irrespective of a user's logging method, all users had the potential to access the website (eg, Fitbit Only users only logged steps via a Fitbit and had the opportunity to view the 10,000 Steps website and/or app). The website includes a variety of information, including library articles (eg, benefits of physical activity and strategies for increasing activity) with information on workplace and individual Challenges [22]. Users' engagement with the 10,000 Steps website was assessed based on all pages or sections of the website by using the average number of sessions (using the website to interact with content; eg, viewing step statistics and joining a Challenge), average time per session, number of pages viewed, average number of pages viewed per session, average number of step log entries, and average daily step count on days when steps were logged. Participating in individual Challenges and team Tournaments and receiving or sending friend requests were all dichotomized as *yes* or *no* (yes=participated in ≥1 Challenge or Tournament; yes=received or sent ≥1 friend request). Any average daily step count of more than 20,000 steps was truncated to 20,000 steps (n=1147) [18]. Nonusage attrition was classified as having no data entries for ≥14 consecutive days. The time to nonusage attrition was calculated using data exported from the website [23].

Statistical Analysis

Results were expressed as differences in least square group means (odds ratios [ORs]) or hazard ratios (HRs) with 95% CIs. α was set at .05 for all analyses, which were conducted using Stata V15.1 (StataCorp LLC). in August 2019 [24]. Summary statistics were used to describe user characteristics. Group comparisons regarding age were assessed using 1-way analysis of variance with Bonferroni correction. Group comparisons regarding gender and how users found the program were assessed using chi-square tests.

Generalized linear models were used to examine differences between user groups in website sessions, minutes per session, page views, pages per session, daily step count, and total step log entries. Negative binomial family and identity link functions were used for all analyses except step count, which used a Poisson family and identity link model. The specification of the family and link functions was informed by residual diagnostics. All models were adjusted for participation in Challenges and Tournaments, as these features have been shown to be associated with usage in previous studies of 10,000 Steps users [18,25].

Associations between user groups in participation in Challenges and Tournaments and receiving and sending friend requests were assessed using binary logistic regression. These models were adjusted for Challenges and/or Tournaments depending on the outcome examined (eg, when Challenges were the outcome, model adjusted for participation in Tournament; when Tournaments were the outcome, model adjusted for participation in Challenges).

Usage and engagement with the 10,000 Steps program have been shown to be affected by participation in Challenges and Tournaments [18,25]. Consequently, 2 Cox proportional hazards regressions were conducted to assess between-group differences in time to nonusage attrition, first using an unadjusted model and then using a model adjusting for participation in Challenges and Tournaments. User group time to nonusage attrition was plotted using Kaplan-Meier survival estimates and adjusted survival curves. No obvious violations were observed upon examination of Schoenfeld residuals.

Results

Overview

Of the 30,040 participants', whose mean age was 40 years, 20,992 (69.88%) were women and 7898 never logged steps (Table 1).

Table 1. Descriptive summary of new users—by user group—of the 10,000 Steps program registered between January 1 and November 30, 2018 (N=30,040).

Characteristics	Website Only (n=14,617)	App Only (n=2100)	Fitbit Only (n=1705)	Web and App (n=2057)	Fitbit Combination (n=1663)	Nonlogger[a] (n=7898)
Age (years)[b,c], mean (SD)	40.45 (12.5)	37.7 (11.8)	39.9 (11.3)	38.9 (11.6)	40.5 (12.0)	41.0 (14.0)
Gender[d], n (%)						
Female	9837 (67.3)	1363 (65)	1279 (75)	1391 (67.6)	1285 (77.3)	5837 (73.9)
Male	4620 (31.6)	725 (34.5)	409 (24)	653 (31.8)	367 (22.1)	2015 (25.5)

Participated in at least 1 Tournament, n (%)	10,740 (73.5)	1635 (77.9)	1323 (77.6)	1691 (82.2)	1370 (82.4)	12 (0.15)
Sent or received in at least one friend request, n (%)	1956 (13.4)	247 (11.8)	363 (21.3)	374 (18.2)	334 (20.1)	1 (0.01)

[a] Some users engaged with program content but never logged steps.

[b] For the *Age* row, n=29,961 because of missing values.

[c] Indicates a significant difference (F_5=26.84; *P*<.001) between usage groups with respect to age.

[d] Indicates a significant difference (X^2_{10}=216.7; *P*<.001) between usage groups with respect to gender.

[e] The mean daily steps include steps allocated as a result of additionally recorded moderate or vigorous activity and/or distance.

User Characteristics

Table 1 shows a descriptive summary of user groups related to age and gender. App Only users were significantly younger than all other groups (Website Only: *P*<.001; Fitbit Only: *P*<.001; Fitbit Combination: *P*<.001; Nonloggers: *P*<.001; Web and App users: *P*=.05). Web and App users were significantly younger than Website Only users (*P*<.001), Fitbit Combination users (*P*=.001), and Nonloggers (*P*<.001). Nonloggers were significantly older than all other groups except Fitbit Combination users (Website Only: *P*=.01; App Only: *P*<.001; Fitbit Only: *P*=.01; Web and App: *P*<.001). Although statistically significant differences in age were found, they are unlikely to be meaningful because the difference in years was small. Gender was significantly different between user groups with the highest proportions of women in the 2 groups that used Fitbits (Fitbit Only: 1279/1705, 75.01%; Fitbit Combination: 1285/1663, 77.27%).

Between-Group Differences in Engagement With the 10,000 Steps Program

The between-group differences in program engagement metrics from January 1 to December 31, 2018, are shown in Table 2. On average, the App Only group had significantly fewer website sessions (mean difference [MD] −6.9; 95% CI −7.6 to −6.2), whereas the Fitbit Only (MD 10.6; 95% CI 8.8-12.3), Web and App (MD 1.5; 95% CI 0.4- 2.6), and Fitbit Combination (MD 8.0; 95% CI 6.2- 9.7) groups had significantly more website sessions, relative to the Website Only group. The App Only and Fitbit Only groups spent significantly fewer minutes (MD −0.7;

95% CI −0.9 to −0.4; MD −0.5; 95% CI −0.7 to −0.2, respectively), whereas the Fitbit Combination group spent significantly more minutes (MD 0.2; 95% CI 0.0-0.5) on the website for each session, relative to the Website Only group. These differences, although statistically significant, were small in magnitude (<1 min per session).

Table 2. Marginalized means and between–user group differences for website usage and mean daily step count and logging between January 1 and December 31, 2018.

Website usage parameters, step counts, and step log entries[a,b] by group	Value, mean (95% CI)	Between-group coefficient (95% CI)	*P* value[c]
Total number of sessions[d,e]			
Website Only	18.8 (18.4 to 19.1)	Reference category	N/A[f]
App Only	11.9 (11.2 to 12.6)	−6.9 (−7.6 to −6.2)	<.001
Fitbit Only	29.4 (27.7 to 31.1)	10.6 (8.8 to 12.3)	<.001
Web and App	20.2 (19.2 to 21.3)	1.5 (0.4 to 2.6)	.01
Fitbit Combination	26.8 (25.1 to 28.5)	8.0 (6.2 to 9.7)	<.001
Minutes per session[d,e]			
Website Only	5.9 (5.8 to 6.0)	Reference category	N/A

Fitbit Only	37.3 (35.8 to 38.8)	5.0 (3.4 to 6.6)	<.001
Web and App	39.5 (38.2 to 40.8)	7.2 (5.9 to 8.6)	<.001
Fitbit Combination	47.9 (46.1 to 49.7)	15.6 (13.7 to 17.5)	<.001

[a] Between user groups; Website Only group: n=14,617; App Only group: n=2100; Fitbit Only group: n=1705; Web and App group: n=2057; Fitbit and web and/or app group: n=1663.

[b] Website usage: website usage engagement may not have occurred on consecutive days.

[c] α=.05.

[d] Session: using the website to interact with content. For example, viewing step statistics and joining a Challenge.

[e] Model based on generalized linear regression using negative binomial family and identity link, which was adjusted for Challenge and Tournament counts.

[f] N/A: not applicable.

[g] Model based on generalized linear regression using Poisson family and identity link, which was adjusted for Challenge and Tournament counts.

Significantly fewer website pages were viewed by the App Only (MD −69.5; 95% CI −72.9 to −66.1) and Web and App (MD −8.6; 95% CI −14.2 to −3.1) groups relative to the Website Only group, whereas significantly more pages were viewed by the Fitbit Only (MD 47.6; 95% CI 38.8 to 56.5) and Fitbit Combination (MD 50.8; 95% CI 42.5 to 59.0) groups. All groups, except the Fitbit Combination group, viewed significantly fewer website pages per session than the Website Only group.

The mean daily step count was significantly lower for the App Only (MD −201.9; 95% CI −387.7 to −116.0) and Fitbit Only (MD −492.9; 95% CI −679.9 to −305.8) groups relative to the Website Only group, whereas the mean daily step count of the Web and App group (MD 258.0; 95% CI 76.9- 439.2) was significantly higher. The App Only and Website Only groups did not significantly differ from each other in the number of step log entries, whereas the Fitbit Only, Web and App, and Fitbit Combination groups all logged steps a significantly greater number of times (MD 5.0, 95% CI 3.4-6.6; MD 7.2, 95% CI 5.9-8.6; and MD 15.6, 95% CI 13.7-17.5, respectively) than the Website Only group, with the Fitbit Combination group logging steps the highest number of times.

The App Only group was less likely (Challenges: OR 0.65, 95% CI 0.46-0.94; friend requests: OR 0.86, 95% CI 0.75-0.99) and all other groups were significantly more likely (Challenges: OR 2.38-4.48; *P*<.001; friend requests: OR 1.37-1.67; *P*<.001) than the Website Only group to participate in Challenges as well as send and/or receive friend requests. All groups were more likely than the Website Only group to participate in Tournaments (OR 1.26-1.79; *P*<.001; Table 3).

Table 3. Associations between participating in Challenges and Tournaments and receiving and sending friend requests from January 1 to December 31, 2018 among the 10,000 Step user groups.

User groups[a]	OR[b] (95% CI)	*P* value

Nonusage Attrition

Of the 22,142 new users who logged steps at least once, 21 (0.09%) did not succumb to nonusage attrition between the time of registration and December 31, 2018. The mean time to nonusage attrition was 35 (SD 26) days (Website Only: mean 32 days, SD 22 days; App Only: mean 33 days, SD 23 days; Fitbit Only: mean 40 days, SD 29 days; Web and App: mean 39 days, SD 27 days; Fitbit Combination: mean 50 days, SD 40 days). Among those who logged steps at least once, the estimated median time to nonusage (ie, the time after which 50% of users cease logging steps) was 31 days, with the Fitbit Combination group taking the longest time to reach this point (41 days; Table 4). All groups, except the App Only group, had a significant difference in time to nonusage attrition relative to the Website Only group (HR: range 0.55-0.75), and this association remained, although slightly attenuated, after adjusting for participation in Challenges and Tournaments (HR: range 0.59-0.78; Table 5; Figure 2, Figure 3). The Fitbit Combination group had a >40% lower likelihood of succumbing to nonusage attrition than the Website Only group.

Discussion

Principal Findings

This study examined whether different methods of logging steps in the 10,000 Steps physical activity program are associated with engagement with the program. The results showed that those who used Fitbits (Fitbit Only and Fitbit Combination) were the most engaged with the program. There was also some evidence that those who used the combination of Web and App were also well engaged with the program, but not to the same extent as Fitbit users.

The Fitbit Combination group had an engagement profile that included a high number of website sessions, page views, and step log entries as well as a higher likelihood of participating in both individual Challenges and team Tournaments. This group also had the lowest risk of succumbing to nonusage attrition, which corresponded with the longest time to succumb to nonusage attrition. The Fitbit Only group also had relatively good engagement characteristics and logged steps for the second longest time. These results suggest that the use of a Fitbit may enhance engagement with a real-world physical activity program. This also indicates that using a Fitbit in combination with other step-logging methods may further enhance engagement.

These findings were not expected because Fitbit users had the option to view their step counts either on the Fitbit itself or on the Fitbit website or app. Subsequently, they could have neglected to log in to the 10,000 Steps website to synchronize their Fitbit steps and interact with the other program content on the website. A number of factors may partially explain the superior engagement of the groups using Fitbits. The financial investment involved in purchasing a Fitbit may indicate that these device-owning individuals were more motivated to increase their activity levels compared with the other groups. Previous research has suggested that monetary investment may be associated with behavior change either because of the presence of motivation at the time of purchase or through financial investment stimulating motivation [26]. Advanced activity tracking devices have previously been shown to reduce the burden of self-monitoring activity compared with traditional self-monitoring methods such as pedometers [27]. The increased convenience may lead to improved engagement with other program features (eg, reading website content). In addition, wearing a Fitbit may serve as an activity-related prompt or cue. Another factor may include the nature of the Fitbits themselves. Users of activity tracking devices have cited a number of features that apply to Fitbits as being important characteristics, such as being wrist-worn; being accurate [28]; having the ability to synchronize with other devices; and having the ability to track additional items such as heart rate, distance traveled, and sleep [29,30]. Given that the level of engagement with activity trackers is associated with high user satisfaction [29] these factors may act as motivators for users to maintain program engagement and be active. Other features of Fitbits that may improve engagement within these groups include the associated Fitbit app, which may have increased exposure to additional motivational messaging and the incorporation of behavior change techniques such as goal setting and feedback [8]. Engagement may be active (ie, logging data or completing quizzes) or passive (viewing the intervention without interacting) [31], and it is unclear how Fitbit use may influence this as the data are automatically synchronized to the 10,000 Steps platform. This aspect of engagement with a Fitbit may be passive relative to the manual entry of data. Furthermore, differences in broader indicators of use, such as session duration and page views, were not consistent between the groups that included Fitbit. Consequently, it may be interesting for future studies to examine the mode of self-monitoring in the context of a broader set of engagement indicators.

The Fitbit Combination group was less likely to succumb to nonusage attrition and took longer to succumb to nonusage attrition. This might reflect research showing that behavior change and the sustained use of activity trackers are enhanced when trackers (such as Fitbit) that provide feedback are used in conjunction with other interventions (such as the 10,000 Steps program), which delineate target behaviors and provide a plan of action [32]. In addition, research exploring the relationship between the use of a Fitbit and changes in physical activity suggested that being accountable to someone else had a greater influence on increasing physical activity than simply self-monitoring the data on a Fitbit [27]. A sense of accountability might have been created through registration with the 10,000 Steps program and by the greater participation in individual Challenges and team Tournaments among the Fitbit Combination group. Furthermore, team Tournaments involving social interaction are associated with improved adherence to physical activity interventions [33].

A higher proportion of women were found in the 2 groups that used Fitbits. This is contrary to previous research showing that men were more likely to use advanced activity trackers [29]. Previous research also indicated that women were more likely to use any type of activity tracker [29]; therefore, perhaps the fast-growing adoption of advanced activity trackers is now greater in women. It has been shown that the sustained use of activity trackers is longer among women than in men [32], and this factor might have contributed to the longer time to nonusage among the Fitbit Combination group, which had the highest proportion of women.

The App Only group was significantly younger, with a higher proportion of men than the other groups. This group demonstrated the lowest overall interaction with program content and was among the groups with the lowest mean daily step count and the earliest time to nonusage attrition. These findings suggest that additional strategies may be required to better engage younger male users of the program. Interestingly, 2 previous studies of the 10,000 Steps programs, which also examined app use, found contrasting outcomes [18,34]. The first study found the App Only group to be the youngest but mostly female, with engagement and time to nonusage attrition being better than those in the Website Only group [18]. The second study, which was undertaken when the app was first introduced, examined the app and web users of the 10,000 Steps program and found that app users logged more steps more often than Website Only users [34]. These discrepancies in findings could potentially be explained by those users who tend to be the *early adopters* of innovations [35]: those who were *early adopters* of the app when it was first introduced may have similar characteristics to those who are now the *early adopters* of the Fitbit functionality.

The groups that used a combination of step-logging methods had the best program engagement profile. This is highlighted by the greater number of step log entries. The higher the mean daily step count, the greater the likelihood of participating in individual Challenges and team Tournaments, and the longer the time until nonusage attrition by the Fitbit Combination group compared with the Fitbit Only group and by the Web and App group compared with both the App Only and Website Only groups. This consolidates the findings from a previous study of engagement with the 10,000 Steps program that found the Web and App group to have a better engagement profile than the Website Only and App Only groups [18]. It is difficult to determine whether the act of using multiple methods to log steps maintains a longer interest in the program or whether it is a personality type or level of motivation to be active, which leads them to both use several logging methods and stay engaged.

Nonusage attrition is a common problem among internet-delivered health interventions [36]. The mean time to nonusage attrition in this sample was similar to previous studies of the 10,000 Steps program, and both studies found that groups that logged steps using multiple methods (eg, using a combination of Web and App to log steps) took longer to cease logging steps [18]. The time to nonusage attrition in this study also compared favorably with several other mobile health physical activity studies conducted under both real-world settings (35 days in this study vs 11 days in another study [37]) and tightly controlled conditions (35 days in this study vs 32 [38] and 46 days [39] in other studies).

The mean daily step counts of all the groups was greater than 10,000 Steps, which is above the average of 7400 for Australian adults [40]. Although this is a promising indicator that this real-world physical activity intervention is effective, the magnitude of differences between the groups was <500 per day. Consequently, the broader public health implications of these differences are unclear and may be more relevant and meaningful for less active people, given that they benefit most from small increases in activity [41]. Alternatively, it may reflect that more active individuals are attracted to the program. The mean daily step counts were also the highest for the groups that used more than one method to log steps. However, the Fitbit Only group took the fewest steps, including fewer steps than the Website Only and App Only groups, despite the groups' other engagement parameters being generally better. This might also be indicative of the different impacts on behavior stemming from active versus passive self-monitoring [27]. Those required to manually enter their daily step counts may be more likely to consciously scrutinize their step counts during the process and consequently make a greater effort to take more steps. Meanwhile, the passive nature of the automatic synchronization of step counts by the Fitbit, when not linked to other interactions with program content, may lead to a loss of attention to step counts and subsequently to less stimulus to change behavior. A previous study of Fitbit users found that there were better improvements in physical activity among users who interacted with both the app and the Fitbit device than those who just checked their device [27]. Therefore, it is possible that the groups in this study who used a greater number of methods to monitor their steps might be undertaking active rather than passive self-monitoring (ie, paying attention to the feedback or graphs, etc), which led to better engagement by these groups.

Strengths and Limitations

Among the strengths of this study is the real-world delivery of a web-based physical activity intervention, not in a controlled setting. In addition, the sample was large and examined over a long time frame. The findings of this type of study are likely to provide more accurate information regarding how interventions work when they are delivered in ecologically valid settings [6]. Other strengths include the examination of various combinations of user step-logging methods that allow for a nuanced understanding of user engagement patterns. There are several limitations to consider. The results of this study must be interpreted in the context of the vast majority of users belonging to the Website Only group, and the outcomes may have been different if the groups were more evenly balanced. In addition, the only measure of physical activity was step count, which does not necessarily capture the overall physical activity. Furthermore, the Fitbit groups provided objective step data that were automatically synced with the website, whereas the others provided manually entered pedometer measured step counts that are prone to bias (ie, people may report more than what the pedometer actually measured). This might have created a disparity in the accuracy of step counts between the groups. Only 25% (5536/22,142) of those who actively logged steps were still engaged after 43 days; therefore, it is unknown whether the impressive >10,000 daily mean step counts of all groups was ongoing. It is noteworthy that the engagement metrics used in this study did not include broader indicators of different types of engagement (reflective, altruistic, and gamified), which may be important to behavior change [31].

Conclusions

This study found that multiple methods of logging steps were associated with better program engagement. The use of a Fitbit appears to enhance engagement with a real-world physical activity program, particularly when used in conjunction with other platforms (ie, a combination of Fitbit and website and/or app). Therefore, integrating tracking devices that synchronize data automatically into real-world physical activity interventions is one strategy to improve engagement.

Abstract

Background: When studied in community-based samples, the association of physical activity with blood pressure (BP) remains controversial and is perhaps dependent on the intensity of physical activity. Prior studies have not explored the association of smartwatch-measured physical activity with home BP.

Objective: We aimed to study the association of habitual physical activity with home BP.

Methods: Consenting electronic Framingham Heart Study (eFHS) participants were provided with a study smartwatch (Apple Watch Series 0) and Bluetooth-enabled home BP cuff. Participants were instructed to wear the watch daily and transmit BP values weekly. We measured habitual physical activity as the average daily step count determined by the smartwatch. We estimated the cross-sectional association between physical activity and average home BP using linear mixed effects models adjusting for age, sex, wear time, antihypertensive drug use, and familial structure.

Results: We studied 660 eFHS participants (mean age 53 years, SD 9 years; 387 [58.6%] women; 602 [91.2%] White) who wore the smartwatch 5 or more hours per day for 30 or more days and transmitted three or more BP readings. The mean daily step count was 7595 (SD 2718). The mean home systolic and diastolic BP (mmHg) were 122 (SD 12) and 76 (SD 8). Every 1000 increase in the step count was associated with a 0.49 mmHg lower home systolic BP (*P*=.004) and 0.36 mmHg lower home diastolic BP (*P*=.003). The association, however, was attenuated and became statistically nonsignificant with further adjustment for BMI.

Conclusions: In this community-based sample of adults, higher daily habitual physical activity measured by a smartwatch was associated with a moderate, but statistically significant, reduction in home BP. Differences in BMI among study participants accounted for the majority of the observed association.

Introduction

Understanding the relationship between physical activity and blood pressure (BP) is crucial because promoting physical activity might help address the community burden of hypertension. Several observational and interventional studies have explored the association between physical activity and BP. Data from community-based observational studies suggest that higher self-reported moderate to vigorous physical activity, but not overall physical activity, is associated with lower research center/in-office BP and lower prevalence of incident hypertension [1-6]. Similarly, in interventional studies, promoting moderate to vigorous physical activity leads to a consistent reduction in BP in both normotensive and hypertensive individuals [7,8]. Most individuals, however, spend the majority of their time performing light activities, such as walking, which are suboptimally quantified using physical activity questionnaires [9,10], but can be accurately measured using accelerometers or smartwatches. Understanding the relationship between habitual physical activity and BP might yield fruitful targets to address the community burden of hypertension.

Smartwatches are commercially available devices for monitoring habitual physical activity and can enhance phenotyping of community-dwelling individuals. Daily step count reported by smartwatches could be a useful measure of overall physical activity capturing all intensities of exercise. Home BP, when compared to in-office BP, is a stronger predictor of adverse cardiovascular outcomes and mortality [11]. Merging the vast data continuously being collected using smart gadgets, such as smartwatches and Bluetooth-enabled BP cuffs, not only enriches the phenotypical information for individuals, but also opens up the possibility of studying the relationship of these novel ambulatory phenotypes (eg, daily step count) with cardiovascular risk factors (such as home BP).

We hypothesized that higher habitual physical activity is associated with lower home BP. To that end, we leveraged data from the ongoing electronic Framingham Heart Study (eFHS) cohort [12] to assess the association between home BP and habitual physical activity measured using a smartwatch (daily step count). Additionally, we sought to study the moderators of this association by adjusting for previously known correlates of hypertension and physical activity.

Methods

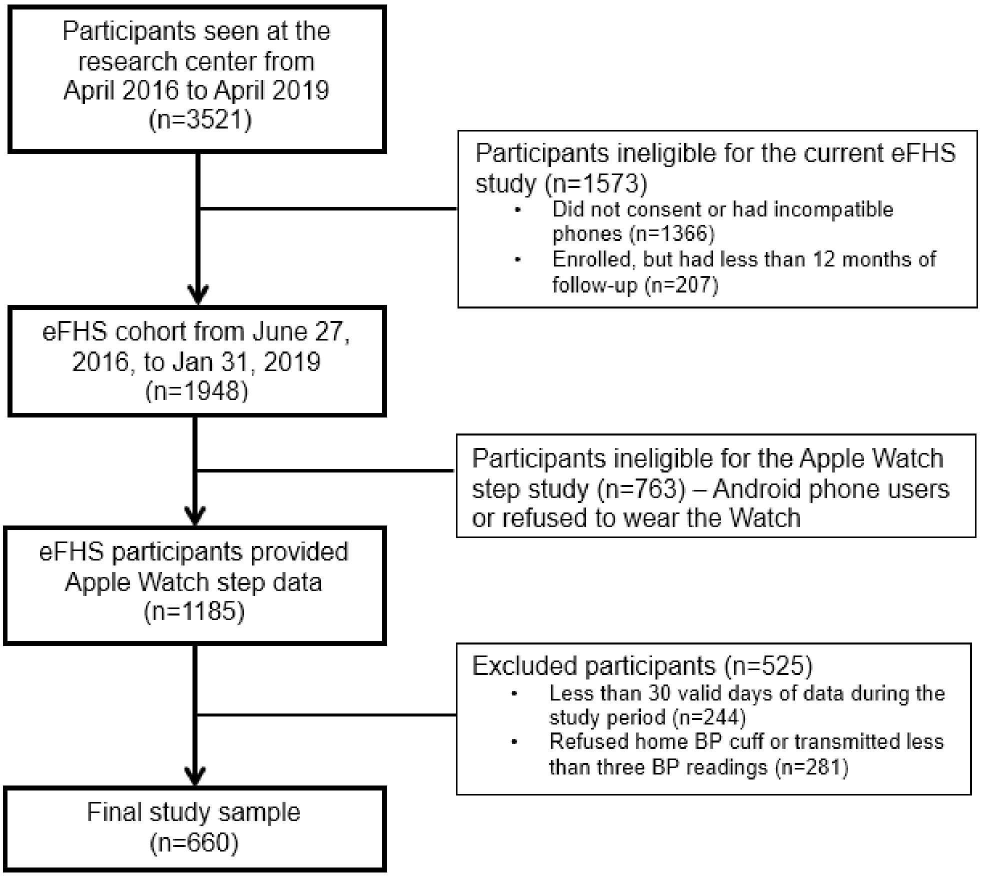
Overview

The Framingham Heart Study (FHS) is a multigenerational cohort study that was originally designed to study the risk factors for cardiovascular disease [13]. The eFHS cohort started enrolling participants from the FHS Third Generation Cohort (Gen 3), multiethnic Omni Group 2 Cohort (Omni 2), and New Offspring Spouse Cohort in June 2016 during regular research center examination [12]. The participants were offered a smartphone app, a Nokia Withings BP cuff for home BP monitoring, and a smartwatch (Apple Watch, Series 0, started November 2016). To be eligible for the BP cuff and Apple Watch, the participants were required to own an iPhone with a compatible iOS version (version 9 or higher). We chose the Withings wireless BP device because it is Food and Drug Administration approved for home BP monitoring and it has been validated (mean differences between the device and mercury readings for systolic and diastolic BP of −0.2 [SD 5.0] mmHg and 0.4 [SD 4.2] mmHg, respectively) [14,15]. The research protocol was approved by the Boston University Medical Center Institutional Review Board. All participants provided written informed consent.

Study Protocol

In this study, eFHS participants enrolled between June 27, 2016, and January 31, 2019, were included, and the median follow-up was 375 days from the date of enrollment (Figure 1). The participants were asked to wear the Apple Watch every day and transmit home BP readings every week. Habitual physical activity was measured as the average daily step count transmitted by the smartwatch. To reduce the bias related to low watch wear time, we only averaged the data from "valid days," which were defined as those days with at least 5 hours of wear time. We, however, also performed sensitivity analyses leveraging an alternate threshold of 10 hours/day to define valid days. Of note, wear time from the Apple Watch was determined based on a combination of the heart rate and step count data transmitted by the watch. At rest, the watch measures the heart rate opportunistically every 5 minutes (heart rate is measured at a higher frequency during workouts) [16]. Therefore, any clock hours with more than one heart rate recording were included in the wear time. For the hours with one or less heart rate recordings, we only included clock hours with 30 or more steps in the wear time. Additionally, participants with less than 30 valid days were excluded (n=244; Figure 1). Several prior studies have measured physical activity by deploying accelerometers over short periods of time (eg, 1 week), which carries the risk of potential bias, as the participants might modify their behavior for the duration of the study [7,17]. In comparison to accelerometer-based studies, we leveraged physical activity measured by the smartwatch over a median follow-up of just over a year and did not include the data from participants with less than 30 valid days. Therefore, we likely captured the "habitual" level of physical activity, that is, the level of physical activity a participant will automatically perform if not being monitored (eg, using accelerometers).

Figure 1. Cohort development diagram for the study. BP: blood pressure; eFHS: electronic Framingham Heart Study.



Home BP Measurement

The participants were advised to measure home BP once a week, ideally on the same day every week and at the same time during the day. They were advised to sit in a comfortable position with the feet flat on the floor and the left arm resting on a table with the palm up, rest for 5 minutes without talking, and then take the BP measurement. Participants were advised against BP measurement after exercise, after consuming caffeinated beverages, or after a high excitement activity. All BP recordings were date and time stamped. The BP recordings taken by the participants during the study period were averaged to calculate average home systolic and diastolic BP for each participant. We only included participants who transmitted three or more home BP recordings. We chose a threshold of three readings because prior studies have reported that home BP readings averaged over 3 days versus 7 or 10 days yield similar results [18,19]. We, however, did perform sensitivity analyses leveraging an alternate threshold of nine or more home BP readings (as described below). The variability in home BP readings was measured using the coefficient of variation (standard deviation/mean).

Other Variables

Clinical and laboratory variables were measured during the examination at the research center [13]. Hypertension was defined as systolic BP ≥140 mmHg, diastolic BP ≥90 mmHg, and/or self-reported use of antihypertensive medications. Diabetes was defined as fasting plasma glucose ≥126 mg/dL and/or self-reported use of medications for diabetes. BMI was calculated by dividing body weight (in kg) by height (in meters) square.

Statistical Methods

Baseline variables (from research center examination) were presented as mean (SD) or median (IQR) for continuous variables and as frequency (proportion) for categorical variables. The correlation between average daily step count and home systolic and diastolic BP was determined using the Spearman correlation coefficient and depicted using a correlation matrix. The association between average daily step count and home BP was measured using separate linear mixed effect regression models for systolic and diastolic BP. Primary models were adjusted for age, sex, familial structure/relatedness in the FHS, antihypertensive drug use, and watch wear time. The secondary model was further adjusted for BMI. We checked for interaction with wear time using the interaction term step count×wear time. For each model, we also performed sex-stratified analyses and tested assumption of linearity by inspecting the residual plots. As the FHS is a multigenerational study, to account for relatedness between the participants, we included the familial relatedness variable. This variable was derived from the self-reported pedigree structure by R package kinship and was treated as a random effect in our regression models. Additionally, sensitivity analyses were performed leveraging alternate inclusion thresholds for valid days (60 days or 90 days instead of 30 days), wear time (10 hours per valid day vs 5 hours per valid day), and home BP recordings (minimum nine home BP recordings vs three recordings). Similarly, we studied the association between home BP variability and average daily step count in primary and secondary models. Additionally, BMI-stratified exploratory analyses were performed to study the association between home BP and daily step count across various BMI strata (normal BMI <25 kg/m^2, overweight BMI 25-29.9 kg/m^2, and obese BMI ≥30 kg/m^2). These stratified models were adjusted for age, sex, familial structure, antihypertensive drug use, and watch wear time (similar to the primary models). We also performed exploratory analyses using regression models 1 and 2 in a subsample of participants with a history of hypertension. To account for multiple comparisons in these exploratory post-hoc stratified analyses, Bonferroni correction for the *P* value was used to determine statistical significance (*P*<.05/3=.017). For other a priori models, the significant association was defined by a two-sided *P* value <.05. Box plots were used to show the distribution of average daily step count and home BP across BMI strata. All statistical analyses were performed using R software package version 3.5.0 (The R Project for Statistical Computing).

Results

Our study sample consisted of 660 adults (mean age 53 years, SD 9 years; 387 [58.6%] women; 602 [91.2%] White; Table 1). Approximately one in five participants reported taking antihypertensive medications. The mean BMI was 27.8 kg/m^2 (SD 5 kg/m^2), and over two-thirds of participants were overweight (n=277) or obese (n=183). The baseline prevalence of smoking, diabetes, and cardiovascular disease was low. In Multimedia Appendix 1, we have presented the baseline characteristics of the study participants including all research center exam attendees and eFHS cohort participants. The eFHS participants were younger and more likely to be female, compared to all research center examinees. Other baseline characteristics were comparable between all eFHS participants and the study participants.

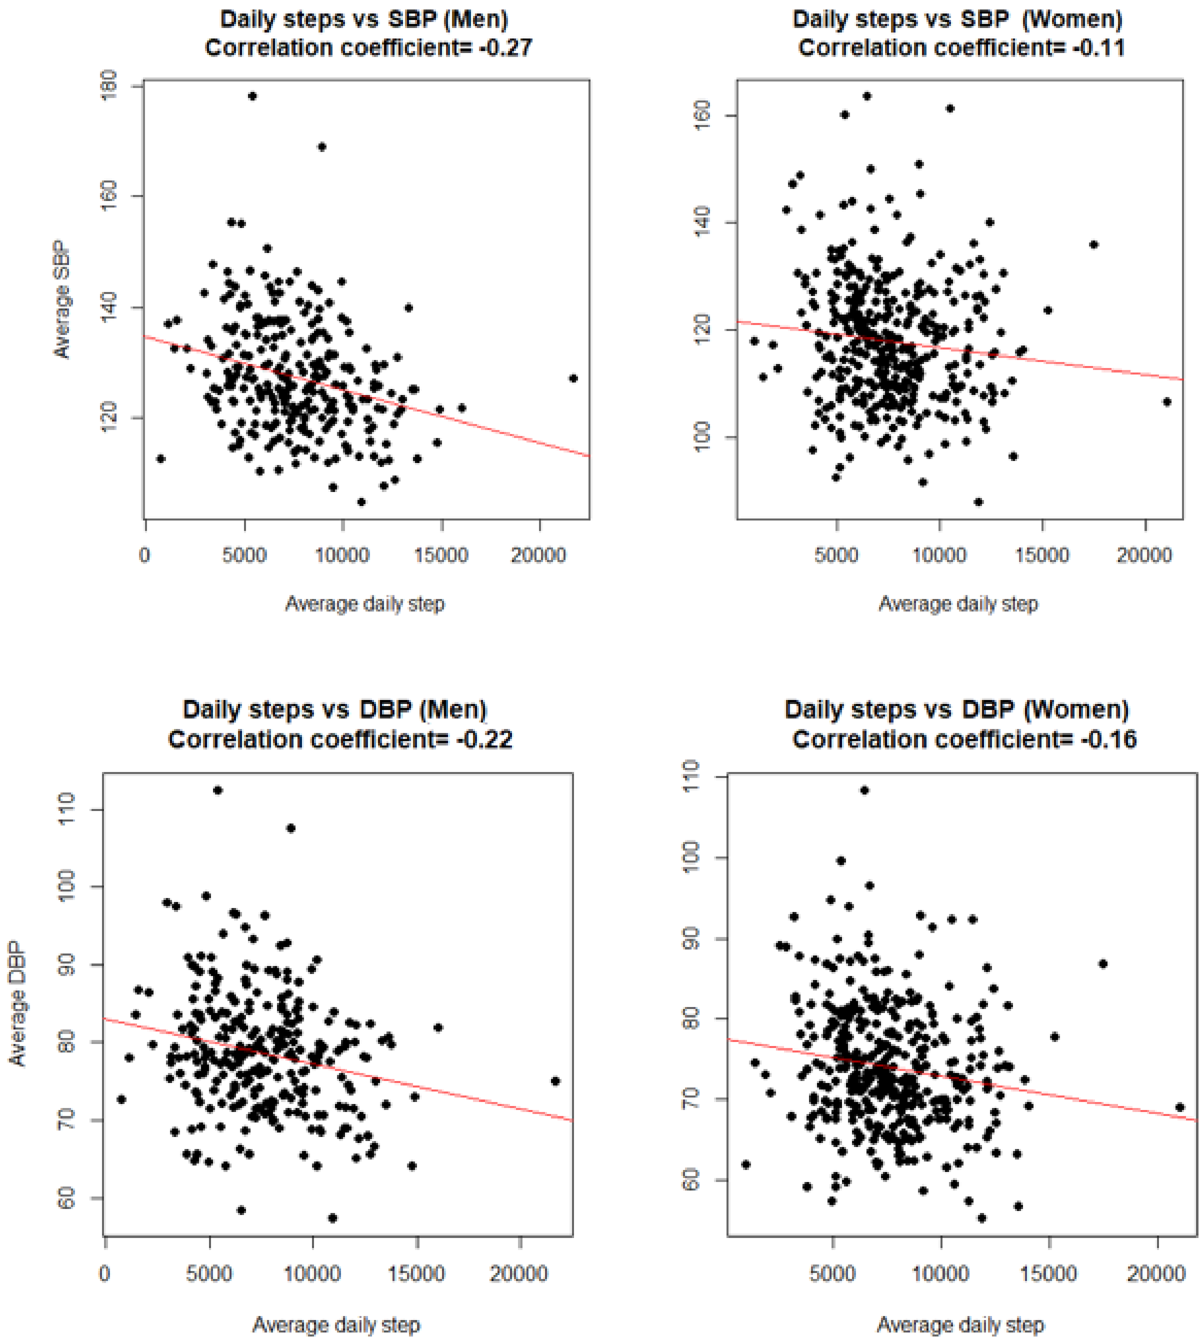
Table 1. Baseline characteristics of the study participants (N=660).

Variable	Value, mean (SD) or n (%)
Age (years), mean (SD)	53 (9)
Female sex, n (%)	387 (58.6%)
BMI (kg/m^2), mean (SD)	27.8 (5.0)
Systolic BP[a] (research center) (mmHg), mean (SD)	119 (14)
Diastolic BP (research center) (mmHg), mean (SD)	76 (9)
Antihypertensive drug use, n (%)	145 (22.0%)
Current smoking, n (%)	28 (4.2%)
Diabetes mellitus, n (%)	41 (6.2%)
Race, n (%)	
White	602 (91.2%)
Black	14 (2.1%)
Hispanic	17 (2.6%)
Asian	13 (2.0%)
Other	14 (2.1%)
Cardiovascular disease, n (%)	26 (3.9%)
Systolic BP (home) (mmHg), mean (SD)	122 (12)
Diastolic BP (home) (mmHg), mean (SD)	76 (8)
Daily step count, mean (SD)	7595 (2718)

[a] BP: blood pressure.

Over a median of 375 (25%-75%: 180-581) follow-up days, participants wore the Apple Watch for a median of 13.7 (IQR 12.4-14.8) hours per day and sent BP readings for 28 (IQR 11-63) weeks. The mean daily step count was 7595 (SD 2718). The mean home systolic and diastolic BP (mmHg) values were 122 (SD 12) and 76 (SD 8), respectively. In sex-stratified analyses, average daily step count was inversely correlated with home systolic and diastolic BP (in both men and women; Figure 2), that is, participants with a higher daily step count had lower home systolic and diastolic BP.

Figure 2. Scatter plots depicting the correlation of average daily step count with average home systolic and diastolic blood pressure. DBP: diastolic blood pressure; SBP: systolic blood pressure.



In the regression models adjusted for age, sex, watch wear time, family structure, and antihypertensive drug use (model 1), each 1000-step increment was associated with a 0.49 mmHg lower home systolic BP and 0.36 mmHg lower home diastolic BP (Table 2, Figure 3). No significant interaction with wear time was noted (*P*=.82 for systolic BP analyses and *P*=.35 for diastolic BP analyses). In sex-stratified analyses, the findings were overall similar in men and women, although the *P* value did not reach the statistical significance threshold in men for diastolic BP. Given the same directionality of the association in men as the overall sample and subsample with women and a relatively weak correlation between diastolic BP and daily steps (correlation coefficient −0.22), we suspected that we were underpowered in our sex-stratified analyses. We have included the power calculation in Multimedia Appendix 2. With further adjustment for BMI (model 2), the strength of the association between daily step count and home BP attenuated and became statistically nonsignificant. When we studied the association of log-transformed daily step count with home BP, the results remained unchanged (Multimedia Appendix 3).

Table 2. Association of daily step count with home blood pressure using separate mixed linear effect models for systolic and diastolic blood pressure.

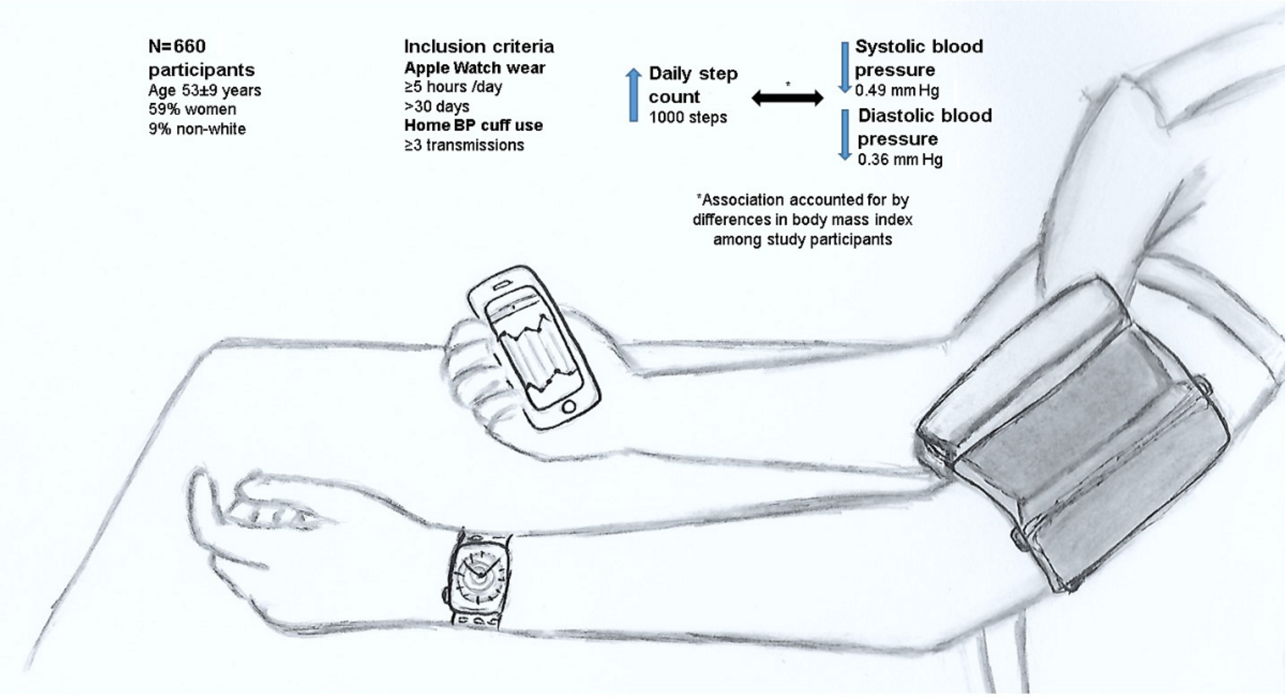
[b] Model 1 was adjusted for age, sex, family structure, reported antihypertensive drug use, and watch wear time.

[c] Model 2 was adjusted for model 1 covariates and BMI.

[d] β represents the change in BP (mmHg) for every 1000 increase in daily steps.

Figure 3. Association of daily step count with home blood pressure. BP: blood pressure.



Of note, our primary analyses were restricted to the participants who had at least 30 active days and transmitted three or more home BP readings. We performed four sensitivity analyses to test the generalizability of our findings and increase the validity of our results as follows: (1) participants with 60 or more active days (n=611; Multimedia Appendix 4), (2) participants with 90 or more active days (n=578; Multimedia Appendix 5), (3) participants with nine or more home BP readings (n=540; Multimedia Appendix 6), and (4) using a 10 hours per valid day threshold (n=634; Multimedia Appendix 7). The results in sensitivity analyses were similar to the primary analyses, that is, there was an inverse association between daily step count and home BP in model 1, but the association became nonsignificant in model 2.

We also studied the association of home BP variability (coefficient of variation) with the daily step count using separate mixed linear effect models for systolic BP and diastolic BP in models analogous to the primary analyses (model 1 adjusted for age, sex, watch wear time, antihypertensive drug use, and family structure, and model 2 further adjusted for BMI). In these models, a higher daily step count was associated with significantly lower diastolic BP variability (but not systolic BP variability; Table 3). In sex-stratified analyses, the findings were overall similar in men and women, although the *P* value did not reach the statistical significance threshold in women for diastolic BP variability. Given the same directionality of the association in women as the overall sample and subsample with men, we suspected that we were underpowered in our sex-stratified analyses.

To further explore the association of BMI with home BP and daily step count, we performed BMI-stratified analyses. In these models adjusted for age, sex, familial structure, antihypertensive drug use, and watch wear time, we did not observe any statistically significant association of home BP (separate models for systolic and diastolic BP) with daily step count (Table 4). In Multimedia Appendix 8 and Multimedia Appendix 9, we depict the distribution of average daily step count and home BP across different BMI strata (normal weight, overweight, and obese). There was a significant trend toward a lower step count and higher systolic and diastolic BP with a higher BMI stratum (*P*<.001). In Multimedia Appendix 10, we have shown scatter plots depicting the correlation of average daily step count and home BP stratified by different BMI categories. We also performed exploratory analyses among participants with a history of hypertension (n=183). Compared to participants without a history of hypertension, participants with a history of hypertension had a lower daily step count, were older, were more likely to be men, and had a higher BMI (Multimedia Appendix 11). In these analyses, we did not observe a significant association between step count and systolic or diastolic BP in models 1 and 2 (Multimedia Appendix 12). Although the findings might be because of underpowering, they suggest that the relationship of step count with home BP is not stronger among participants with a history of hypertension. When we treated home BP as a tertile variable, we observed results similar to those in our primary analyses (Multimedia Appendix 13).

Table 3. Association of daily step count with home blood pressure variability (coefficient of variation).

Discussion

Principal Findings

In this study of community-dwelling participants, we measured habitual physical activity using a study smartwatch and home BP device. We observed an inverse association of higher habitual physical activity with lower home BP, even after adjusting for age, sex, watch wear time, antihypertensive drug use, and family structure. The association between physical activity and home BP, however, was rendered statistically nonsignificant after further adjusting for BMI, suggesting the mediating role of BMI.

When studied in community-based samples, the association of physical activity and BP remained controversial [3,20] and is perhaps dependent on the intensity of activity. For example, in a community-dwelling sample from the Dutch Lifelines cohort (n=125,402), higher self-reported commuting and leisure time moderate to vigorous physical activity was associated with lower BP in a dose-dependent manner (cross-sectional analysis) [1]. Similarly, in a sample of African American participants derived from the Jackson Heart Study (n=1311), lower baseline moderate to vigorous physical activity, but not overall physical activity, was associated with an increased risk of incident hypertension over a median follow-up of 8 years [2]. On the contrary, in 1717 participants of the Framingham Offspring study, the self-reported physical activity index (a composite score of daily physical activity and sedentary behavior) did not emerge as an independent predictor of incident hypertension in multivariable-adjusted models [6]. A similar lack of an independent association of physical activity with incident hypertension was observed in the participants of the National Health and Nutrition Examination Survey [5] and Coronary Artery Risk Development in (Young) Adults Study [4]. Since 2016, eFHS participants have undergone digital phenotyping using research smartwatches and BP cuffs, thereby enriching the existing information about these FHS participants [12]. With the goal of better understanding the relationship between physical activity and BP, in our current investigation, we studied the association of a common measure of physical activity (daily step count) [21] and home BP (a powerful predictor of adverse cardiovascular outcomes) [11]. The demographic-adjusted regression model (primary model) revealed an inverse association of habitual physical activity with home BP. However, with further adjustment for BMI (secondary model), the association became attenuated and nonsignificant, suggesting that BMI accounted for most or all of the association between habitual physical activity and home BP. The results of our exploratory BMI-stratified models further confirmed this observation as no significant association of habitual physical activity with home BP was observed in any BMI subgroups (normal weight, overweight, or obese).

Our findings, when taken together with prior observations, suggest that the effect of overall physical activity on BP in community-based settings is likely mediated via correlates of physical activity such as obesity. While several prior studies have reported an association of moderate to vigorous physical activity with BP and incident hypertension [1,2], we were unable to study the relationship of exercise intensity with home BP as the current wearables (including the Apple Watch used in our study) do not accurately discriminate between the intensity of exercise [22-24]. Nevertheless, community-dwelling individuals spend the majority of their time performing light physical activity (such as walking), and over the last decade, several studies have reported the beneficial effects of light physical activity on overall metabolic profile [25-27] and mortality [28]. It is plausible that light physical activity modulates BP via improvement in the metabolic profile (eg, BMI in our study) [29,30], whereas moderate to vigorous physical activity lowers BP more directly by reducing the vascular tone [3]. In fact, interventions aimed at increasing moderate to vigorous physical activity consistently lead to a reduction in BP in both normotensive and hypertensive individuals [7,8]. Of note, we observed an inverse association of home diastolic BP variability, an independent predictor of adverse cardiovascular outcomes [31], with higher step count independent of BMI. The association of habitual physical activity with reduced diastolic BP variability might be attributable to its effect on autonomic modulation [32]. Our findings suggest that overall habitual physical activity could lead to reduced cardiovascular risk despite the lack of an independent association with absolute home BP.

Another major implication of our study is that smartwatches provide scalable instruments to measure habitual physical activity in community-based settings. Prior studies have reported a significant reduction in BP-leveraging pedometer and smartphone-based physical activity promotion interventions [7]. Home BP is a stronger predictor of adverse cardiovascular outcomes compared with in-office BP [11], and self-monitoring of postexercise hypotension can improve exercise adherence [33]. Nearly one in five Americans currently own a smartwatch [34]. With the burgeoning field of wearable smart devices, our findings raise the possibility of leveraging smartwatches and home BP monitoring to promote physical activity to address the community burden of hypertension and associated comorbidities such as obesity [35].

Limitations

Our study has several limitations. First, the participants in our study were predominantly White and of European ancestry, and had a higher average daily step count (7595 steps/day) than the US average (4774 steps/day) [36]. Further, we acknowledge that our study sample (n=660) represents a subset of younger participants who attended the research center examination (n=3521). Although the baseline characteristics of the eFHS cohort and our study sample were similarly distributed, the possibility of selection bias exists. Our findings should be validated in samples with older participants and in racially diverse samples as there is evidence supporting the differential association of physical activity with incident hypertension, based on race [37]. Second, the analyses performed in our observational study are cross-sectional in nature. Therefore, our findings do not imply a causal association between lower PA and higher BP. However, our eFHS cohort is embedded in the overall FHS, and as these participants are systematically followed over the next few years, we would be able to study the pattern of habitual physical activity that relates to a higher risk of incident hypertension. Third, although the association between habitual physical activity and home BP was statistically significant, whether a 0.49 mmHg lower systolic BP and 0.36 mmHg lower diastolic BP per 1000 daily steps translates to a clinically meaningful impact in the community should be assessed in future studies. Even a 2 mmHg reduction in the average diastolic BP, however, would lead to a 17% decrease in hypertension prevalence [38]. From the clinical standpoint, considering the large number of daily steps required to achieve a modest reduction in BP, our findings might not translate to significant benefits at the individual level. Fourth, we relied on outputs from the Apple Watch proprietary algorithms to measure physical activity in our study. Although validated for measuring physical activity, these algorithms are not available publicly [22,39].

Conclusions

In this community-based sample of middle-aged adults who were enrolled in an electronic cohort at the time of their routine research center examination, we observed that higher habitual physical activity measured by a smartwatch was associated with a moderate, but statistically significant, reduction in home BP. Differences in BMI among study participants accounted for the majority of the observed association. The results of our study lay the ground work for leveraging smart devices to promote physical activity and improve the cardiometabolic phenotype in the community.

Acknowledgments

The Apple Watches were provided to Boston University by Apple, Inc at no cost to the study. This study was supported by an award from the Robert Wood Johnson Foundation (number 74624) and a grant from the National Heart Lung and Blood Institute (R01HL141434, HHSN268201500001I). Investigator time was supported from the following grants: R01HL126911 (EJB), 2R01 HL092577 (EJB), 2U54HL120163 (EJB), R01HL126911 (DDM), R01HL137734 (DDM), R01HL137794 (DDM), and R01HL13660 (DDM).

Conflicts of Interest

DDM discloses equity stakes or consulting relationships with Flexcon, Bristol-Myers Squibb, Boston Biomedical Associates, Pfizer, and Samsung, and research support from Sanofi Aventis, Otsuka Pharmaceuticals, Philips Healthcare, Biotronik, Bristol Myers Squibb, Boeringher Ingelheim, and Pfizer. DDM has an inventor stake in Mobile Sense Technologies, LLC. VK is a principal, and CN is an employee of CareEvolution, Inc, a health care technology company (https://careevolution.com). Apple was not involved in the study design, analysis, interpretation, or reporting of the study results. Starting 2020, EJB has been an uncompensated member for MyHeartLab Steering Committee, a primary investigator-initiated study from Samsung in the University of California San Francisco (PI: Jeffrey Olgin, MD). NS received funding from Novo Nordisk for an investigator-initiated research grant unrelated to the current paper. Other authors have no relevant disclosures.

Abstract

Background: Clinical decision support systems are designed to utilize medical data, knowledge, and analysis engines and to generate patient-specific assessments or recommendations to health professionals in order to assist decision making. Artificial intelligence–enabled clinical decision support systems aid the decision-making process through an intelligent component. Well-defined evaluation methods are essential to ensure the seamless integration and contribution of these systems to clinical practice.

Objective: The purpose of this study was to develop and validate a measurement instrument and test the interrelationships of evaluation variables for an artificial intelligence–enabled clinical decision support system evaluation framework.

Methods: An artificial intelligence–enabled clinical decision support system evaluation framework consisting of 6 variables was developed. A Delphi process was conducted to develop the measurement instrument items. Cognitive interviews and pretesting were performed to refine the questions. Web-based survey response data were analyzed to remove irrelevant questions from the measurement instrument, to test dimensional structure, and to assess reliability and validity. The interrelationships of relevant variables were tested and verified using path analysis, and a 28-item measurement instrument was developed. Measurement instrument survey responses were collected from 156 respondents.

Results: The Cronbach α of the measurement instrument was 0.963, and its content validity was 0.943. Values of average variance extracted ranged from 0.582 to 0.756, and values of the heterotrait-monotrait ratio ranged from 0.376 to 0.896. The final model had a good fit (χ_{26}^2=36.984; *P*=.08; comparative fit index 0.991; goodness-of-fit index 0.957; root mean square error of approximation 0.052; standardized root mean square residual 0.028). Variables in the final model accounted for 89% of the variance in the user acceptance dimension.

Conclusions: User acceptance is the central dimension of artificial intelligence–enabled clinical decision support system success. Acceptance was directly influenced by perceived ease of use, information quality, service quality, and perceived benefit. Acceptance was also indirectly influenced by system quality and information quality through perceived ease of use. User acceptance and perceived benefit were interrelated.

artificial intelligence; AI; clinical decision support systems; evaluation framework

Introduction

Clinical Decision Support Systems

Clinical decision support systems are computer-based enterprise systems designed to utilize massive data, medical knowledge, and analysis engines as well as to generate patient-specific assessments or recommendations to health professionals in order to assist clinical decision making through human–computer interaction [1,2]. These systems provide services ranging from simple reminders to complex risk prediction [3] and support health care providers in diagnosis, treatment decisions, and population health management. Clinical decision support systems assist one or more levels of decision making: alerting, interpreting, critiquing, assisting, diagnosing, and managing [4]. Diagnostic support systems are a subset of clinical decision support systems that are specifically designed to support clinician in diagnosing patients [5]. Artificial intelligence (AI)–enabled clinical decision support systems combine the knowledge reasoning techniques of AI and the functional models of clinical decision support systems [6].

AI-Enabled Clinical Decision Support Systems: Characteristics, Usage, and Benefits

AI-enabled clinical decision support systems include an intelligent component [6], and in comparison to traditional clinical decision support systems, represent a paradigm shift. They are designed to aid clinicians by converting raw medical-related data, documents, and expert practice into a set of sophisticated algorithms, applying techniques such as machine learning, knowledge graphs, natural language processing, and computer vision so that users find suitable solutions to their medical problems and make clinical decisions [7]. AI-enabled clinical decision support systems have the potential to improve clinicians' performance, quality of health care, and patient safety [8].

Diagnostics are a primary use case of AI-enabled clinical decision support systems, and these systems have been applied in the field of rare disease diagnosis [9], sepsis detection or prediction [10], fracture detection [11], and cancer detection or diagnosis [12,13]. In addition, current AI-enabled clinical decision support systems are also used in medication therapy [14,15] and health care management [16,17].

The greatest benefits of AI-enabled clinical decision support systems reside in their ability to learn from real-world use and experience (ie, training) and their capabilities for improving their performance (ie, adaptation) [18]. By using techniques such as knowledge graphs and natural language processing, AI can deal with large amounts of text classification, information retrieval, and information extraction from the corpora that is provided by hospital electronic health records. Based on structured data, AI can support more comprehensive and more personalized decision-making suggestions for clinicians through techniques such as machine learning. Another benefit is that the functionality and utility from combining clinical decision support systems with AI techniques surpass those of traditional clinical decision support systems, and the system improves and supports the decision-making process by providing intelligent behavioral patterns, with the ability to learn new clinical knowledge [7].

Need for AI-Enabled Clinical Decision Support System Evaluation

A comprehensive evaluation framework with common elements and interoperability is necessary to serve as a reference for AI-enabled clinical decision support system design and evaluation, with focuses on cross-disciplinary communication and collaboration, and there is a pressing need to develop robust methodologies and empirically based tools for such evaluation. The factors driving this need are the uncertain added value of AI-enabled clinical decision support system implementation, lack of attention, and the possible benefits of comprehensive evaluation implementations.

First, the added value of AI-enabled clinical decision support system implementations in a clinical setting is not firmly established, though evidence exists that such implementations offer potential benefit to patients, clinicians, and health care in general [19]. Introducing this type of system in clinical settings is not without risk [8]. Similar to any other newly introduced technology, AI-enabled clinical decision support systems may disrupt clinical service, threaten patient safety [20], and cause more negative than positive impacts [19]. As a result, there are concerns that AI-enabled clinical decision support system implementation can introduce new errors and have unintended consequences [21]. Additionally, the effect of these systems on clinical, social, and economic outcomes is still controversial which highlights the need to evaluate recognized value parameters [22]. Second, attention to evaluation of clinical decision support systems, in general, and AI-enabled clinical decision support systems, in particular, remains weak [23], which has resulted in a paucity of data on safety, effectiveness, cost benefits, and impacts of AI-enabled clinical decision support systems on patients and health systems [24,25]. Finally, the evaluation of AI-enabled clinical decision support systems is a learning and knowledge-gaining process, and it also helps to identify the gaps to be filled [26]. Findings of comprehensive evaluations could be used to help improve implementations [27].

AI-Enabled Clinical Decision Support System Evaluation Methodologies

The approach to AI-enabled clinical decision support system evaluation is influenced by a sociotechnical regime, which informs and guides the development of the robust and focused evaluation method of this study. It has increasingly been acknowledged that evaluations of such systems are based on a sociological understanding of the complex practices in which the information technologies are to function [28]. A careful balance between social and technical value is required in order to ensure that unwanted consequences do not pose a threat to patients [26] and clinical practices.

A well-defined success measure, based on users' perspectives, that specifies aspects of AI-enabled clinical decision support systems that determine their success [29] is critical for a robust performance and usefulness evaluation framework. Due to the user-centric nature of information system development and evaluation [30,31], evaluation of AI-enabled clinical decision support system success aims to recognize factors relevant to user acceptance and utility, thus analysis of articulated users' opinions is necessary [32]. Clinicians are the direct users of AI-enabled clinical decision support systems; the adoption of the product depends on the individual physicians who decide to use it [5]. In many scenarios, clinicians make decisions for patients, and clinicians are responsible for the medical decisions they make. Predicting and managing users' attitudes toward AI-enabled clinical decision support systems lead to an in-depth understanding of these systems via situated practice [33] and help developers and medical managers maximize user acceptance. Lack of a well-defined success measure is likely to lead to inappropriate evaluation that does not reflect the clinical impact of AI-enabled clinical decision support systems and may hamper technology advancement[19].

A comprehensive evaluation methodology involves a multidisciplinary process and diverse stakeholder involvement, which, when applied to AI-enabled clinical decision support system evaluation, refers to a mixed methodology not only based on tenets in medicine and information technology but also social and cognitive psychology [30]. Using both qualitative and quantitative methods within a single research project has been shown to provide a richer understanding of a given topic than using solely either a qualitative or quantitative approach, facilitate better and more accurate inferences, and provide an integrated perspective [34]. A similar benefit would likely apply when employing mixed methods in designing an AI-enabled clinical decision support system evaluation scheme.

AI-enabled clinical decision support system interface with a diverse set of clinical and nonclinical users and stakeholders whose inputs are integral to the evaluation process. Health care enterprises are multiprofessional organizations that often include dual hierarchical structures involving clinical practitioners and managers [35], and in such settings, AI-enabled clinical decision support systems are not only tools for clinical practitioners who interact directly with the system (eg, physicians, nurses, pharmacists) but also for nonclinical workers (eg, medical administrators). Additionally, there is still an important group of invisible stakeholders, namely patients, who can be affected by these systems use even without direct interaction. The relationships of such diverse groups of stakeholders can prove to be complex, with competing interests and values; therefore, the views, beliefs, and assumptions of stakeholders must be exposed and considered within the AI-enabled clinical decision support system evaluation process [33,36].

Objective

We aimed to address the gap in evaluation knowledge and methodologies by identifying which variables influence AI-enabled clinical decision support system success and using these variables to develop a parsimonious evaluation framework. Specifically, we (1) proposed an evaluation framework with 6 variables and hypotheses about interrelationships between the 6 variables based on the literature review, (2) developed and validated an instrument using the 6 variables for assessing the success of diagnostic AI-enabled clinical decision support systems, and (3) tested the hypotheses using path analysis with latent variables in a structural equation model.

Methods

Ethics Approval

This study was approved by the Ethics Review Committee, Children's Hospital of Shanghai/Shanghai Children's Hospital, Shanghai Jiao Tong University (file number 2020R050-E01).

Overview

Our study combined qualitative and quantitative methodologies to validate a proposed evaluation framework, which consisted of a model with hypotheses and containing 6 variables.. A Chinese-language measurement instrument was developed with the goal to measure and quantify the 6 variables, following established instrument development paradigm. A literature review and a Delphi process were conducted to develop the measurement instrument items, cognitive interviews, pretest, and web-based survey. Exploratory factor analysis was used to construct the constituent questions of the measurement instrument, reliability and validity tests were performed, and the interrelations of the variables were tested and verified.

Theory

Evaluation methodologies are informed by a rich corpus of theory, which provides a robust foundation for designing an AI-enabled clinical decision support system evaluation framework. In this study and in previous review work [37], three classic theories were used, namely, the DeLone and McLean Model of Information Systems Success [38], the Information Systems Continuance Model [39,40], and the Information Value Chain Theory [29].

An updated model of information systems success that captures multidimensionality and interdependency was proposed by DeLone and McLean in 2003 [38]; the model is a basic and flexible framework of information system evaluation that can adapt to the complexity of the clinical environment [41-44]. In considering the importance of user acceptance and retention to an information system's success, the information systems continuance model describes the path from expectation confirmation to the formation of users' intention to continuance [39]. The information value chain theory underlines decision improvement as the main purpose of technology and provides a mechanism to separate process outcomes from clinical outcomes [45].

Evaluation Framework Model Variable and Measurement Instrument Item Selection

Literature Search

A set of evaluation model variables and a candidate set of medical AI and clinical decision support system evaluation items were collected through a literature review [35]. A broad search strategy was employed, using multiple databases including Cochrane, MEDLINE, EMBASE, Web of Science, PubMed, CINAHL, PsycINFO, and INSPEC. Studies published from January 2009 to May 2020 were utilized to inform the clinical decision support system evaluation items selection and studies published January 2009 to April 2020 for the AI evaluation items discovery. A candidate set of 6 model variables (Multimedia Appendix 1) and a candidate set of 45 evaluation items were identified.

Delphi Process

The candidate set of evaluation items was examined and finalized using a Delphi process. Delphi is a structured group communication process, designed to obtain a consensus of opinion from a group of experts [46].

Snowball sampling was used to identify a group of experts. Expert selection criteria were (1) clinical practitioners who worked in a medical specialty at least 10 years, preferably had a PhD (minimum postgraduate qualification), had a professional title at the advanced level or above, had an appointment or affiliation with a professional organization, and had more than 1 year of practical experience (with respect to AI-enabled clinical decision support systems); (2) hospital chief information officers who worked in an information system specialty at least 10 years, had a postgraduate qualification, had a midlevel professional title or above, and had an appointment or affiliation with a professional information system organization; or (3) information technology engineers working in medical information system enterprises who worked in AI or clinical decision support systems at least 5 years, had a postgraduate qualification, and had a midlevel position title or above.

In addition to these selection criteria, a measure of degree of expert authority was introduced to add or remove experts from each round of the Delphi process. The degree of expert authority C_r was defined $C_r = (C_a + C_s) / 2$, using 2 self-evaluated scores—C_a is their familiarity with the problem, and C_s is their knowledge base to judge the program. C_s and C_a ranged between 1 and 5, with a higher value indicating more reliable judgment and more familiarity with the problem. If the self-rated degree of expert authority was >3, the expert was retained, otherwise the expert was removed from group. As a result, a total of 11 experts were selected from diverse areas of expertise and professional focus: clinical practitioners, hospital chief information officers, and information technology engineers working in medical information system enterprises.

The experts were invited to participate in the modified Delphi process via email. Those who accepted were sent an email with a link to the round 1 consultation. Experts were required to provide a relevance score for each item in the candidate set using a 4-point Likert scale (1=not relevant, 2=relevant but requires major revision, 3=relevant but requires minor revision, 4=very relevant and requires no revision). Experts were given 2 weeks to complete each round. A reminder was sent 2 days before the deadline to those who had not completed the survey. The 2-round Delphi process was carried out from May to July 2020.

The content validity was assessed in the last round of the Delphi process. Item-content validity was calculated as the percentage of expert ratings ≥3; if item-content validity was ≥0.8 (ie, expert endorsement), the item was retained. The mean item-content validity, representing the content validity of the measurement instrument of all retained items from the last round was computed. At the end of this step, the set of evaluation items for the measurement instrument were finalized. The final set consisted of 29 evaluation items.

Measurement Instrument Refinement

The measurement instrument consisted of the set of evaluation items measured by a web-based survey. A draft set of survey questions was refined by employing cognitive interviews and a pretest. Interviewees (n=5) who were postgraduates majoring in health informatics or end-users of AI-enabled clinical decision support systems (ie, clinicians) were asked to verbalize the mental process entailed in providing answers. The pretest included 20 end-users. The interviews and pretest were conducted in July 2020 and aimed to assess the extent to which the survey questions reflected the domain of interest and that answers produced valid measurements. Responses used a Likert scale from 1 (strongly disagree) to 7 (strongly agree). The wording of the questions was subsequently modified based on the feedback from the respondents. The web-based survey was initiated in July and was closed in September 2020.

Study Population

The evaluation entities chosen in this study were AI-enabled clinical decision support systems designed to support the risk assessment of venous thromboembolism among inpatients: AI-enabled clinical decision support systems that automatically capture electronic medical records based on natural language processing supporting assessment based on individual risk of thrombosis (eg, Caprini scale or Wells scoring), with monitoring of users and reminders sent to users to provide additional data were targeted.

Survey Participants and Sample Size

Users of target AI-enabled clinical decision support systems who had at least 1 month of user experience were included. The convenience sample participants were based in 3 hospitals in Shanghai that implemented venous thromboembolism risk assessment AI-enabled clinical decision support systems in clinical settings. We appointed an investigator at each hospital site who was responsible for stating the objective of the study, for identifying target respondents, and for monitoring the length of time it took the participants to complete the survey. This was a voluntary survey. The investigators transmitted the electronic questionnaire link to the respondents through the WeChat communication app.

To ensure usability for exploratory factor analysis [47] and to obtain parameter estimates with standard errors small enough to be of practical use in structural equation modeling [48,49], the required sample size was calculated using to participant-to-item ratio (ranging from 5:1 to 10:1), yielding n=150. A response rate ≥70% was targeted to support external validity [50].

Quality Control Measures

Quality control measures were implemented to ensure logical consistency, with completeness checks before the questionnaire was submitted by the responders. Before submitting, respondents could review or change their answers. In order to avoid duplicates caused by repeat submissions, respondents accessed the survey via a WeChat account. Submitted questionnaires meeting the following criteria were deleted: (1) filling time <100 seconds, or (2) the answer of following 2 questions were contradictory: “How often do you use the AI-enabled clinical decision support systems?” versus “You use the AI-enabled clinical decision support systems frequently.” Finally, we asked the point-of-contact individuals in each hospital to send online notifications to survey respondents at least 3 times at regular intervals in order to improve the response rate.

Statistical Analysis

Overview

Statistical analyses were performed (SPSS Amos, version 21, IBM Corp) to (1) identify items of measurement instrument that were not related to AI-enabled clinical decision support system success for deletion, (2) explore the latent constructs of the measurement instrument, and (3) evaluate reliability and validity of the measurement instrument.

Measurement Instrument Item Reduction

Critical ratio and significance were calculated using independent *t* tests between high- (upper 27%) and low- (lower 27%) score groups. Item-scale correlation was calculated using Pearson correlation. Corrected item-to-total correlations and the effect on Cronbach α if an item was deleted were calculated using reliability analysis. Item-scale correlation and corrected item-to-total correlations were indications of the degree to which each item was correlated with the total score. Criteria for potential elimination were (1) nonsignificant critical ratio (*P*>.05), (2) item-scale correlation <0.40, (3) corrected item-to-total correlation <0.40, (4) an increased α if the item was deleted [51,52], that is, if α increased with an item removed, we considered removal of the item from the measurement instrument [49].

Latent Construct of Measurement Instrument

Construct of the measurement tool was tested using exploratory factor analysis. Principal component analysis was applied for factor extraction, and the Promax with Kaiser normalization rotation strategy was used to redefine the factors to improve their interpretability. The cutoff strategy was based on verify if the data set was suitable for exploratory factor analysis—the Bartlett test of sphericity should be statistically significant (*P*<.05) and a Kaiser-Meyer-Olkin value ≥.60 is considered mediocre [49], a value ≥.90 is marvelous [53]. Only factors with an eigenvalue ≥0.50 were retained.

Reliability and Validity of Measurement Instrument

Cronbach α coefficients were calculated to assess internal consistencies of the scale and each subscale; values >.80 are preferred [49,50]. Convergent validity and discriminant validity were tested using maximum likelihood estimation confirmatory factor analysis in structural equation modeling. Average variance extracted was used as an indicator of convergent validity, and values >.50 were considered acceptable. The heterotrait-monotrait ratio of correlations was used to test discriminant validity. A heterotrait-monotrait ratio value <0.90 provided sufficient evidence of the discriminant validity of constructs [54].

Path Analysis

Interrelationships between variables selected for the evaluation framework were hypothesized in a model (Figure 1). The model was tested using path analysis with latent variables in structural equation modeling. We used the following indicators to assess competence of the model fit: chi-square (significant if *P*>.05), ratio of chi-square to degrees of freedom <2.00), comparative fit index >0.95, goodness-of-fit index >0.95, root mean square error of approximation <0.06, and standardized root mean square residual ≤0.08 [52,55].

Measurement Instrument

Delphi Process and Evaluation Item Selection

Of the 11 experts invited to participate (Multimedia Appendix 2), all accepted in round 1 (100% response rate) and 10 accepted in round 2 (91% response rate). Most respondents in round 2 (9/10, 90%) identified themselves as expert or very expert ($C_r \geq 4.0$) with respect to AI-enabled clinical decision support systems. Consensus was reached in round 2: 29 items obtained at least 80% endorsement (Table 1).

Table 1. Accepted items in the Delphi process.

Variables and items	Item-content validity	Critical ratio[a] (*t* value)	Item-scale correlation[a]	Corrected item-to-total correlation	Cronbach α if item was deleted
Perceived ease of use					
Learnability	1.00	6.419	0.643	0.615	.961

[a] For all values in this column, $P<.001$.

[b] Based on this value, the item meets the standard for potential deletion.

Measurement Instrument Formatting

Based on the feedback from the cognitive interviews and pretesting, we made modifications to the wording of 4 items and added explanations to 2 items in order to make them easier to understand. This self-administered measurement instrument with 29 items was used to collected survey data.

Results of Survey

Characteristics of Survey Respondents

Survey responses were collected from a total of 201 respondents (Multimedia Appendix 3) from 3 hospitals in Shanghai, China, of which 156 responses (77.6%) were valid. No data were missing. The ratio of participants to items was 5.4 to 1.

Reduction of Items for the Measurement Instrument

One item—usage behavior—was deleted based on item-scale correlation, corrected item-to-total correlation, and effect on Cronbach-α-if-the-item-was-deleted criteria (Table 1).

Latent Construct of the Measurement Instrument

Exploratory factor analysis was deemed to be appropriate (Kaiser-Meyer-Olkin .923; χ_{378}^2=3859.495; and significant Bartlett test of sphericity, P<.001). Eight components, which explained 80.6% of the variance, were extracted (Table 2; Multimedia Appendix 4; Multimedia Appendix 5). For interpretability, we classified decision change, process change and outcome change as one factor—*Perceived benefit*—thereby, the constructs of measurement instrument reflected the 6 variables in the hypothesis model.

Table 2. Principal component analysis results.

Component	Extraction			Rotation
	Sums of squared loadings	Variance (%)	Cumulative variance (%)	Sums of squared loadings
Perceived ease of use	14.447	51.596	51.596	11.354
System quality	2.504	8.941	60.537	9.824
Information quality	1.423	5.082	65.620	11.299
Service quality	1.212	4.328	69.948	5.687
Decision change	0.841	3.005	72.953	6.449
Process change	0.779	2.780	75.733	7.736
Outcome change	0.715	2.555	78.288	6.588
Acceptance	0.658	2.350	80.638	5.997

Reliability and Validity of Measurement Instrument

The 28-item scale appeared to be internally consistent (Cronbach α=.963). The Cronbach α for the 6 subscales ranged from .760 to .949. Content validity of the overall scale was 0.943. Values of average variance extracted ranged from .582 to .756 and met the >.50 restrictive criterion, which indicated acceptable convergent validity. The values of heterotrait-monotrait ratio ranged from 0.376 to 0.896 and met the <0.90 restrictive criterion, which indicated acceptable discriminant validity of constructs (Table 3, Multimedia Appendix 6).

Table 3. Internal consistency, convergent validity, and discriminant validity of constructs.

Variables	Heterotrait-monotrait ratio						Average variance extracted	Composite reliability
	Perceived ease of use	System quality	Information quality	Service quality	Perceived benefit	Acceptance		
Perceived ease of use	1	0.753	0.765	0.412	0.657	0.736	.582	.892
System quality	0.753	1	0.637	0.376	0.455	0.636	.674	.803
Information quality	0.765	0.637	1	0.721	0.729	0.767	.620	.760
Service quality	0.412	0.376	0.721	1	0.654	0.673	.752	.858
Perceived benefit	0.657	0.455	0.729	0.654	1	0.896	.595	.935
Acceptance	0.736	0.636	0.767	0.673	0.896	1	.756	.949

Model Validation

Hypothesized Model Modification

The chi-square of the hypothesized model was significant (χ_{30}^2=126.962, P<.001; ratio of chi-square over degrees of freedom 4.232). Model fit indices (comparative fit index 0.921; goodness-of-fit index 0.874; root mean square error of approximation 0.144; standardized root mean square residual 0.131) suggested the hypothesized model needed to be modified in order to have a better fitting model: 2 paths, predicting *Acceptance* from *Information quality* and *Service quality*, were added, and one path, predicting *Perceived ease of use* from *Service quality*, was moved, which significantly improved the model and lowered the chi-square values. This meant that in addition to the relationship between *Perceived ease of use* and *Information quality* or *Acceptance*, there was also a direct relationship between *Information quality* and *Acceptance*.

Revised Model Fit and Pathway Coefficients

The chi-square of the revised model was not significant (χ_{26}^2=36.984, P=.08; ratio of chi-square over degrees of freedom 1.422). Model fit indices (comparative fit index 0.991; goodness-of-fit index 0.957; root mean square error of approximation 0.052; standardized root mean square residual 0.028) indicated a good-fitting model (Figure 2). All of the path coefficients between measured variables and factors in the final model were significant (2-tailed, P<.05). Better *System quality* (P<.001) and better *Information quality* (P<.001) significantly increased *Perceived ease of use*. Better *Information quality* (P=.04), better *Service quality* (P<.001), and *Perceived ease of use* (P<.001) significantly increased *Acceptance*. *Acceptance* and *Perceived benefit* were interrelated (Figure 2, Table 4). Variables in the final model accounted for 89% of the variance in *Acceptance* (Table 5). Parameter estimation of error in measurement, standardized total effects, direct effects, and indirect effects are shown in Multimedia Appendix 7-10.

Figure 2. Final evaluation model (comparative fit index 0.991; goodness-of-fit index 0.957; root mean square error of approximation 0.052; standardized root mean square residual 0.028).

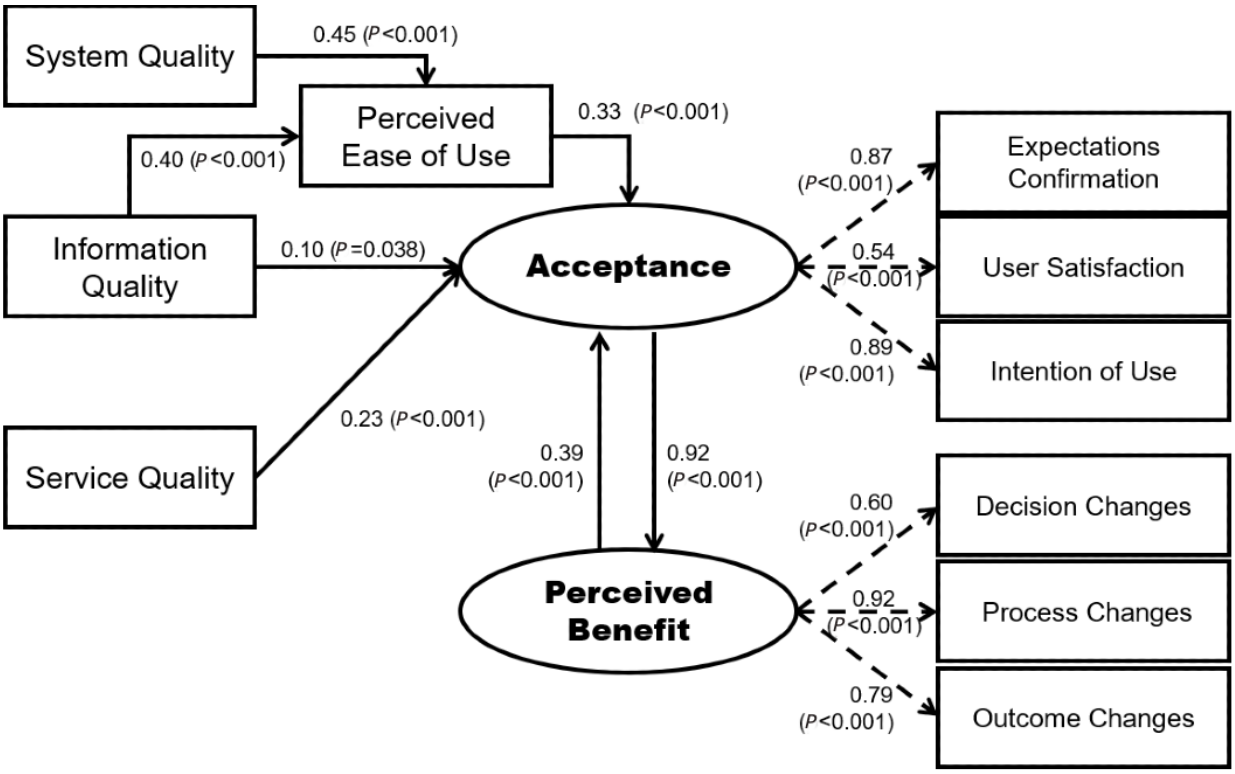

Table 4. Parameter estimation for path coefficients.

Pathway		Regression weights	Standardized regression weights	Standard error	Critical ratio	*P* value
Perceived ease of use	System quality	0.292	0.446	0.041	7.139	<.001

User satisfaction	0.853

Discussion

Main Findings

User acceptance was established as central to AI-enabled clinical decision support system success in the evaluation framework. A 28-item measurement instrument was evaluated, yielding an instrument that quantifies 6 variables: *System quality*, *Information quality*, *Service quality*, *Perceived ease of use*, *User acceptance*, and *Perceived benefit*.

User Acceptance is the Central Dimension

User acceptance is the traditional focus of evaluation in determining the success of an information system [15,17,32]. User acceptance is a synthesized concept—we used expectation confirmation, user satisfaction, and intention of use as secondary indicators. The item *system usage* was removed; DeLone and McLean [38] suggested that “intention to use,” that is, *intention of use* in our study, may be a worthwhile alternative measure in some contexts. Our work demonstrated that the use or nonuse of AI-enabled clinical decision support systems is not a universal success criterion. Therefore, the item was removed from the measurement instrument. The nature of health care settings, wherein diverse perspectives, power asymmetry, and politically led changes co-exist, supports this approach [26]. The use of an AI-enabled clinical decision support system tends to be mandatory, thus it is difficult to interpret users’ evaluations with respect to system usage. Our model demonstrated that User *Acceptance* of AI-enabled clinical decision support systems was directly determined by *Perceived ease of use*, *Information quality*, *Service quality*, and *Perceived benefit*.

Perceived Ease of Use

In this study, perceived ease of use encompassed human–computer interaction (eg, user interface, data entry, information display, legibility, response time), ease of learning, and workflow integration [17,56,57]. *Perceived ease of use* was a mediation variable between *System quality*, *Information quality*, and *Acceptance*. *System quality* did not directly affect user *Acceptance*, but indirectly exerted influence through

Perceived ease of use, principally because clinicians' intuitive feelings of ease of use are fixed on external, tangible, and accessible features. Engineering-oriented performance characteristics of an AI-enabled clinical decision support system and necessary supporting functionalities are not their main concerns.

Information Quality

Information quality refers to reliable and valid suggestions, provided by an AI-enabled clinical decision support systems, and directly and indirectly affected user *Acceptance*. Suggestions without reliability or validity not only reflects low diagnostic performance of AI-enabled clinical decision support systems but also may excessively interrupt daily work [36,58], negatively affecting ease of use and further lowering user acceptance.

Service Quality

Service quality required by clinicians emphasizes knowledge updating for timeliness and system improvement [9,56].

Perceived Benefit

Perceived benefit and user *Acceptance* were interrelated; and clinicians are always concerned with the usefulness of AI-enabled clinical decision support system adoption for themselves, groups, and patients [19]. AI-enabled clinical decision support system products with anticipated benefits are more likely to be accepted by clinicians. As demonstrated in our study, *Perceived benefit* was not the conclusive criterion of AI-enabled clinical decision support system success even if it could be measured with precision [59]. There will be a comparison between assumptions and expectations of personal preference with perceived benefit [36]. When clinicians are not willing to accept a new AI-enabled clinical decision support systems, the system will face adoption difficulties in clinical practice even if the system is considered to be a benefit to quality of care and patients' outcomes in general.

Recommendations of Benefit Measures for AI-Enabled Clinical Decision Support Systems

Decision Changes

We recommend using *Decision change* as an outcome measure rather than appropriate decisions. Decision change for AI-enabled clinical decision support system usage underlines decision inconsistency between system and human. These decision-making suggestions might correct users' clinical orders, particularly for those who have insufficient practical experience [21]. Consequently, measuring user decision change (eg, tests cancel, order optimization) is more straightforward than measuring appropriate decisions.

Process Changes

Process change, which is similar to perceived usefulness [39], mainly covers individual, group, or organization levels of performance improvement. This study used knowledge, skills, confidence [17,25,60-62], and work efficiency [17,61] as indicators of individual performance and used quality of health care and documentation [57,62-66] as indicators of group or organization performance.

Outcome Changes

Outcome measures tended to be complicated indicators of AI-enabled clinical decision support system success, which often failed to be objective in clinical settings [15,58]. Beneficial patient outcomes from AI-enabled clinical decision support system implementations are the concern of all stakeholders. But there remains a paucity of high-quality evidence for outcome measures [19]. Consequently, although both subjective and objective measures of AI-enabled clinical decision support system success should compensate for the shortcomings of each other, our work showed that it is valuable to evaluate clinicians' attitude toward perceived benefit for patients that can be obtained from specific AI-enabled clinical decision support system implementation under the health care contexts when objective measures are difficult to qualify.

Limitations

This study is an innovative attempt and pilot examination of an evaluation framework in relation to AI-enabled clinical decision support system success. This evaluation framework is widely applicable, with a broad scope in clinically common and multidisciplinary interoperable scenarios. In order to test the validity of the variables and the hypotheses about their relationships, an empirical methodology was needed. Specifically, the items of the measurement instrument were developed targeting diagnostic AI-enabled clinical decision support systems, and AI-enabled clinical decision support systems designed to support the risk assessment of the venous thromboembolism among inpatients was the focus. Thus, one potential limitation may arise due to this narrow focus. A future expanded evaluation framework would require validation among diverse populations and encompassing AI-enabled clinical decision support systems with diverse functions.

Implications and Conclusion

This study offers unique insight into AI-enabled clinical decision support system evaluation from a user-centric perspective, and the evaluation framework can support stakeholders to understand user acceptance of AI-enabled clinical decision support system products with various functionalities. Given the commonality and interoperability of this evaluation framework, it is widely applicable in different implementations, that is, this framework can be used to evaluate success of various AI-enabled clinical decision support systems.

From a theoretical point of view, this framework can be an evaluation approach to help in describing and understanding AI-enabled clinical decision support system success with a user acceptance–centric evaluation process. There are also practical implications in terms of how this evaluation framework is applied in clinical settings. The 28-item diagnostic AI-enabled clinical decision support system success measurement instrument, divided into 6 model variables, showed good psychometric qualities. The measurement instrument can be a useful resource for health care organizations or academic institutions designing and conducting evaluation projects on specific AI-enabled clinical decision support systems. At the same time, if the measurement instrument is to be used for AI-enabled clinical decision support system products with different functionalities in a specific scenario, item modifications, cross-cultural adaptation, and tests of reliability and validity testing (in accordance with scale development guidelines [52]) is needed.

Abstract

Background: Patient portals offer the possibility to assess patient-reported outcome measures (PROMs) remotely, and first evidence has demonstrated their potential benefits.

Objective: In this study, we evaluated patient use of a web-based patient portal that provides patient information and allows online completion of PROMs. A particular focus was on patient motivation for (not) using the portal. The portal was developed to supplement routine monitoring at the Department of Internal Medicine V in Innsbruck.
